RADIOBES AND BIOGEN.

The Origin of Life: Its Physical Basis and Definition. By John Butler Burke. Pp. xiv+350; with illustrations. (London: Chapman and Hall, Ltd., 1906.) Price 16*s*. net.

MR. J. B. BURKE describes, under the name of "radiobes," minute bodies which appeared in sterilised bouillon when small quantities of radium chloride or bromide were brought into contact therewith.

"A minute quantity of the salt contained in a small glass tube, one end of which was drawn out to a fine point, was introduced into an ordinary test-tube containing bouillon. The test-tube was plugged with cotton-wool in the usual way with such experiments, and then sterilised at a temperature of 130° C. for about thirty minutes at a time. On cooling, as soon as the liquid had coagulated, the fine end of the inner tube containing the radium was broken by means of a wire hook in a side tube. The salt was thus allowed to drop on the surface of the gelatin. After twenty-four hours signs of growth were already visible."

The radiobes had appeared! They were at first like diplococci, and varied considerably in size from mere specks as seen with a $\frac{1}{12}$-inch lens. There is a lack of precise measurements.

"The growth is from the minutest visible specks, which develop into two dots, then into a dumb-bell shaped appearance, later a biscuit-shape, and later still more like frog's spawn, through various stages, as in the figures, until a shape is reached different from its previous forms, when it divides and loses its individuality, and ultimately becomes resolved into minute crystals."

Some of them show a nucleated structure, which may exhibit subdivision "as in karyokinesis"; they are stainable; they are credited with "assimilation"; there is a "stoppage of growth at a certain stage of development"; there is a peculiar segmentation, like that in yeast-cells, said to be quite different from any cleavage due to surface tension; and, finally, there is a disintegration. The author speaks of them as intermediate between crystals and bacteria, and as possessing $n-1$ of the n properties of living bacilli.

The author is somewhat vacillating in his description of his "radiobes," but he does not regard them as living things in the ordinary sense. They "obviously lie altogether outside the beaten track of living things" (p. 109), but they may bridge over the apparently insuperable gap between the organic and inorganic world (p. 110).

"Forms we have obtained are analogous to living types and may be called artificial forms of life, but they are not the same as life as we know it to-day: they may help, however, to fill in some of the gaps between living and dead matter" (p. 187).

"These bodies are neither crystalline nor colloid in disguise, though colloids, as aggregates, but something more: and crystals in their constituent parts. The point which distinguishes them from both of these is perhaps the fundamental principle which marks them out at once as possessing the elements of vitality in a primitive and most undeveloped state" (p. 112).

The author started with proteid material, which we know to be an essential constituent of organisms, which has not as yet been artificially synthesised, and he brought into contact with this a stimulus provocative of molecular change, namely, a radium salt; he thus obtained radiobes, and the interesting point is whether these do in any way approximate in their behaviour to simple organisms. As we have not studied radiobes we can only judge from the evidence the author adduces, and it seems to us entirely inconclusive. We find no convincing evidence of assimilation, cyclic development, or reproduction in the ordinary sense of these terms; and we do not think the author succeeds in showing that radiobes are essentially different from the minute aggregates or mimic cells produced by many other experimenters. We cannot bring ourselves to believe that little bodies which are soluble in water will throw light on the nature or origin of living organisms. The evidence of anything approaching the behaviour of an organism seems to us so flimsy that we cannot but wonder at such a paragraph as this :—

"The structure and composition of such artificial cells is sufficient to enable them to perform the functions of organic life, as distinct from such simpler forms of vitality which we at first supposed inorganic matter to possess. Thus they can assimilate, grow, pass into higher types, subdivide, multiply, and finally, having gone through the whole cyclic process, disintegrate and lose their structure in the course of time, being sensitive all the while to external stimulation, both electrical and chemical, in various degrees" (p. 133).

The explanation of the author's apparent oscillation between scientific caution and imaginative hope is to be found in the fact that he has re-defined the ordinary biological terms. Life, for instance, is

"the specialised mode of motion of a complex system of molecules in a dynamically unstable state, so that there is a continuous or continual change, or flux of its substance, between the individual aggregates of molecules and their surroundings" (p. 49).

"An organism has a structure, a nucleus, and an external boundary or cell-wall, and its vitality may be described as being a continuous process of adjustment between its internal and its external relations" (p. 102).

There is metabolism in the phenomena of flames, fluorescence, and phosphorescence—"a physical process which is not merely analogous to, but essentially of the same kind as, even if incomparably simpler than, organic metabolism" (p. 179). It is this re-editing of the biological dictionary that enables the author to write regarding his radiobes :—

"We can say perhaps that we are witnesses at last to the first beginnings of life in its higher sense; but though apparently a case of abiogenesis, to our mind it seems to be a case of biogenesis, from the view of matter which we take, of biogenesis indeed carried to its logical extreme."

We sympathise with the author's vigorous protest against the libel implied in the phrase "dead matter," but we do not think the apartness of vital sequences is diminished by giving a more elastic definition to "life" and "metabolism." As to the bearing of radiobes on the problem of the origin of living creatures upon the earth, we do not think that it amounts to much, not only because Mr. Burke started with proteid material (the natural synthesis of which it is at least difficult to imagine), but also because it seems to us too short and easy a disposal of problems simply to suppose that the coordination and regulation of organic metabolism, the power of effective response, and other insignia of living creatures are secondary acquisitions gradually wrought out in the course of selection. Our business is to try to make the hypothesis of primitive abiogenesis more plausible, and we can only do this by condescending to discuss the detailed difficulties in a concrete fashion.

Mr. Burke's method is different; he elaborates a new theory of vitality which seems to us quite in the air.

"For anything we know there is no such thing as really dead matter, and there may be in all matter a certain amount of energy stored up which would entitle it to be regarded as possessing a certain amount of potential life" (p. 186).

He postulates original units of life, bio-elements. biogens, or ultimate nuclei, possibly consisting of cyanogen (as suggested by Pflüger's well-known hypothesis), more probably of something with a larger store of energy—"an element possessing many of the chemical properties of carbon and the radio-active properties of the more unstable elements."

"Life-activity is a phenomenon of matter as much as radio-activity, although really of a more complex kind, and the manner in which the energy is stored up in the ultimate nucleus is probably pretty much the same. Such nuclei may have existed, like the chemical elements themselves, throughout the universe for an almost indefinite time. To account for their formation would be the same as to account for the formation of the elements" (p. 166).

They may have existed in the nebula which formed the earth or they may have been borne to the earth by meteors, as has been previously suggested.

"The formation of cellular life as we see it to-day was the result of the subsequent interaction of this radio- or bio-element with organic compounds," and of course there was an elimination of failures when nature was trying her prentice hand at organism-making. One of these failures Mr. Burke may have been on the track of when he made his radiobes. In ordinary cell-life the bio-element persists as the vital spark, the nucleus within the nucleus, the *n*th or ultimate nucleus, the real source of vital energy. It is also the hereditary substance, and it "may be all of us that survives when we have shuffled off this mortal coil."

The author tells us much more about biogens than about radiobes, soaring in a region where verification and contradiction are alike impossible. He supports his theory by arguments from analogy, mainly drawn from his studies on the "physical metabolism" seen in the phenomena of fluorescence and phosphorescence, and he shows that the theory is the natural outcome of his discovery of radiobes, to which the bouillon supplies the soil or constituents, but the radium the seed or vital spark. It is difficult for a biologist to follow the details of this physicist's theory of vitality, *e.g.* when we read of two kinds of biogens —the "characterless nebulous biogen" which corresponds to an ovum, and the concentrated biogen which corresponds to a spermatozoon. But Mr. Burke's general view may be indicated by quoting a few more sentences.

"Life is as much a phenomenon of matter as electricity is. More clearly, life and matter are merely different phenomena of electricity, matter being merely the fossilised state of biogen, and life of the phenomena which take place in biogen in that stage through which electronic aggregations have to pass before they are converted into the crystalline forms of electrons which we call the chemical atoms of matter" (p. 192).

If this is what the author calls "more clearly," his standard of lucidity must be very divergent from that of the mean of the biological race. Biogen is "nothing more or less than *matter in the process of becoming*."

"Biogen may be regarded as the intermediate state between free electricity and condensed electricity which we call matter—the hiatus between electricity as we know it and matter as we know it; the missing link that bears

'The heavy and the dreary weight
Of all this unintelligible world.'"

We cannot follow the author further with his new "Naturphilosophie," but it is interesting to point out that, although he says life-activity is a phenomenon of matter, he is far from being a materialist. For matter, he tells us, is really *mind-stuff*, and "atoms are nothing more than ideas." We have always suspected that this would turn out to be the case.

As an interesting book on a perennially interesting theme "The Origin of Life" will probably soon pass into a second edition, and we therefore note a few errata. "Wiesmann" (p. 56), "Debois" (p. 175), "Luduc" (p. 208), "nucleosus" (p. 136), "mytosis" (p. 137), are obvious misprints. We suppose that the "chlorophyll" referred to thrice on p. 135 is a misprint for chromatin, but the author seems confused in his picture of a typical cell. Mitosis is not "the multiplication of the chromosome"; the centrosome is not "the inner portions of the nucleus, or nucleolus"; and we cannot speak of "the karyokinesis of the centrosome." There are several such errors indicative of haste, and there is a disconcerting lack of correspondence between some of the figures and the references to them in the text.

The author is so enthusiastic over his radiobes and *n*th nuclei that we almost wish we could believe more in the importance of either of them. The former seem to us very far from possessing $n-1$ of the n properties of the simplest living creature we know; the latter seem to us ingenious fictions too remote from everyday physiology to have even suggestive value. But these are merely our opinions, and it may be that Mr. Burke will, by more precise observations and more restrained theorising, justify the views of those who have hailed him as a pioneer and a prophet.

J. A. T.

PRINCIPLES AND PRACTICE OF POTTERY.

La Ceramique industrielle. Chimie-Technologie. By A. Granger. Pp. x+644. (Paris: Gauthier-Villars, 1905.) Price 7 francs.

THIS is an excellent example of the technological handbooks which the young Frenchman and German find ready to their hands when they proceed from school or college to take up industrial work, and which, in so many businesses, the young Englishman just as conspicuously lacks. At the present moment there is no English book on pottery manufacture, other than indifferent translations of a French and a German book, to which a student of the principles of pottery manufacture can turn, and these deal most accurately with processes unknown or unused in England.

The volume in question is, as is perhaps inevitable, stronger on the theoretical than on the practical side. The first nine chapters, comprising about half the book, give a clear and logical account of the physical and chemical properties of the materials used in the preparation of pottery paste and glazes of all descriptions, together with laboratory methods of chemical analysis and such methods as have been devised for testing the degree of fineness, plasticity, and tensile strength of the various natural clays and clay mixtures, as well as a theoretical discussion of the behaviour of complex mixtures of silicates (clays and glazes) when fired at varying temperatures up to their fusion point. All this is put forward with that clearness of expression and logical precision of arrangement that seem to come so naturally to the French teacher.

The feeling cannot be resisted that the author, with the very best intentions, has covered too much ground. It would seem as if he had attempted to describe every known process, apart from its merits or demerits, with the result that the student is overwhelmed with methods, and at the same time left without a clue as to the suitability of particular methods in special circumstances. In the section on silicate analysis, for example, the ordinary methods of treatment are given for silicates soluble in strong acids, and the methods of attack with carbonate of soda, lime, baryta, oxide of lead, boracic acid, and hydrofluoric acid for the insoluble silicates, yet not one of the processes is described in such detail as would enable the student to conduct an analysis, and the refinements and corrections introduced into the ordinary methods of silicate analysis by Hillebrand, without which it is impossible to guarantee one's results, are never mentioned. In the same way, in the sections dealing with the various methods used by potters for determining the temperature of their kilns, a long account is given of Wedgwood's pyrometer, Seger cones, and all the later forms of electrical pyrometers, including the Féry radiation pyrometer, but there is no adequate discussion of the relative value of these different methods in the actual working of a pottery, the observations on the employment of pyrometers (pp. 257–261) being simply a one-sided account of the merits and demerits of Seger cones.

The second half of the book contains a reasonably detailed account of the processes of manufacture, firing, glazing, and decoration of bricks, tiles, terracotta, refractory pottery, stoneware, earthenware, and porcelain. Again the method is excellent, but, of course, too much has been attempted, and it seems obvious that the student would have been better trained or assisted by a more complete treatment of one or two sections only. From the English point of view, the greatest failure of the book is the ignorance shown of actual English methods in those branches of pottery manufacture where this country is supreme. Thus the account given of the manufacture of English earthenware is not merely incomplete, but is full of misapprehensions—even of mistakes. The mixtures said to be used for English bodies and glazes are such as no first-rate potter would dream of using; the description of our ovens and kilns is singularly incomplete, and the statement is made that, owing to the nature of the English earthenware bodies, the firing of on-glaze decorations in the continuous kiln has been a failure, when, as a matter of fact, many of these kilns are in successful operation. The treatment accorded to our English bone-china is just as incomplete.

The accounts of French and German processes are naturally much better, not only because the author is better acquainted with them, but no doubt because so much more has already been published about them.

The author had the excellent idea of adding to his volume a vocabulary of technical terms in German, English, and French, and tables showing the relative importance of the industry in various countries. Unfortunately, the idea has been very imperfectly executed. In the vocabulary many of the English terms are such as no potter would use, while some few of them are nonsense; and the figures given as to the extent of the industry in various countries are so incomplete and incomparable as to be positively misleading. On the whole, however, the book must be described as excellent for its purpose; and the English potter might well wish that he had such a book to put into the hands of the young men who are likely to occupy responsible positions on his works.

William Burton.

THE SOIL AND ITS TILLAGE.

Agriculture Générale. Le Sol et les Labours. By Paul Diffloth. Pp. xii+490. (Paris: J. B. Baillière et Fils, 1906.) Price 5 francs.

THIS is the first book of a new French agricultural encyclopædia, which is being published in forty volumes, under the direction of M. G. Wéry, assistant director of the Institut National Agronomique. It is written by Prof. Paul Diffloth. The aim of the encyclopædia is expressed in an introduction by Dr. Paul Regnard, successor to the late M. Eugène Risler as director of the institute. It is to extract from the present teaching of agricultural science all that is available for immediate application by the practical farmer, making him acquainted at the same time with the scientific facts upon which actual practice is based.

Dr. Regnard pays a compliment to English agriculturists by stating that they have never accepted the notion which he attributes to his own countrymen that agricultural science is antagonistic to practical experience. We fear the compliment is not altogether deserved, and that French and English farmers have much in common in this respect; yet the remarkable progress in the direction of higher agricultural education during the past ten years in this country may be regarded as both cause and effect of the gradual disappearance of the idea that the practice of agriculture can derive no advantage from the labours and teachings of science.

With the love of logical analysis which characterises French scientific literature, M. Diffloth's work is divided and subdivided almost *ad infinitum*. An idea of its completeness may be gathered from a summary of these divisions. The book comprises two main branches, viz. "Agrologie" and "The Preparation of the Soil," the former being defined as the study of land in relation to agriculture and of the relationship which subsists between the nature of a soil and its produce. The first branch treats of the soil, the subsoil, their physical and chemical properties; water in relation to fertility, its distribution, rainfall, permeability, impermeability, water levels, wells, watercourses, &c.; the analysis of soils by processes physical, mechanical, geological, chemical, &c.; the relations of the soil with the plant, comprising the subjects of nitrification, denitrification, humus, fertility, and the nature of the soil suited to different plants. The second branch of the book, "The Preparation of the Soil," treats of cultivation, the clearing of land, peaty and brackish soils, and the improvement of soils by warping, tree planting, levelling, removal of rocks, stones; tillage operations, including digging, drainage, and the various systems of ploughing; semi-tillage, so called, consisting of scarifying, cultivating (in its technical sense), extirpation of weeds, &c.; harrowing, rolling; and, lastly, of manures and artificial fertilisers.

We do not remember ever before to have read any precise definition of what agriculture is. The author defines it as the art of obtaining from the soil the maximum of substances useful to man at the minimum cost. We do not quarrel with such a definition, though it represents the ideal rather than the actual.

Full justice is done to the part played by the soil in the sustenance of plants, and in particular to the nitrogen problem, which has been the subject of so much scientific investigation and discussion during the past twenty years. The author indicates briefly the discoveries made by de Saussure, Dumas, Boussingault, and others as to the action of carbonic acid of the air and of nitrogen in the soil in the nourishment of plants; the work of mineral salts as demonstrated by Berthier, Sprengel, and Liebig; the experiments of Schlœsing and Müntz showing the action of ferments in transforming organic nitrogen into nitric acid and of micro-organisms in nitrification; and, lastly, the experiments of Hellriegel and Wilfarth revealing the existence of bacteria in the nodules found on the roots of leguminous plants and the absorption by their agency of nitrogen from the free and unlimited supplies present in the air.

M. Diffloth refers to the great developments in France and other Continental countries of the principle of agricultural cooperation. Its successful application to Ireland is well known, and in Great Britain, too, it is now making some headway. The future of agriculture, writes the author, may be summed up in two words as living symbols of its progress and prosperity, "Science et Association." We agree that if "Practice with Science" have been the agricultural watchwords of the nineteenth century signs are not wanting that "Science with Cooperation" may be those of the twentieth.

The practical operations of French husbandry are carefully described, with their scientific significance;

but as they differ in many respects from the English, the chief interest of the book for English readers of French agricultural literature will lie in its admirable exposition of the scientific principles underlying practice. The book is well illustrated on the whole, but in some cases the photographic reproductions can hardly be regarded as truly illustrative. Otherwise we have nothing but admiration for the manner in which Prof. Diffloth in this first volume has given effect to the aim of the new French agricultural encyclopædia.

INORGANIC CHEMISTRY FOR STUDENTS.

Outlines of Inorganic Chemistry. By Frank Austin Gooch and Claude Frederic Walker. Pp. xxiv+514. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1905.) Price 7*s.* 6*d.* net.

THE authors say in the preface that their aim is "to introduce the student to chemistry by consideration of the simplest and fewest things." Their intention is laudable enough, but it may be questioned whether their plan of entering into a long discussion of "the consecutive development of the principles upon which systematic chemistry rests," before taking up the descriptive part of the subject, is one which can be commended.

The first 233 pages of the book are entirely devoted to theoretical matters, and a wide range of subjects is included. Beginning with an exposition of the outward characteristics and quantitative laws of chemical combination, the authors pass on to discuss balanced actions, chemical equilibrium, and the phase rule. Then follows a short chapter on specific heats and thermochemistry, after which the student is "introduced" to atoms, molecules, ions, and electrons. Finally an attempt is made to teach him something about the kinetic theory of gases, the properties of solutions, the theory of valency, constitutional formulæ, physical isomerism, and stereochemical relationships. Whatever fault the reader may have to find with the mode of presentment in this part of the book, he will have no reason to complain of lack of variety. The authors have attempted too much, and have sacrificed clearness to the exigencies of space. The beginner will, we fear, be confused, and the more advanced student will find the treatment of the subject inadequate and superficial.

Without attempting any detailed criticism of these theoretical chapters, which would indeed serve no useful purpose, we may give one or two examples of what we think an unsatisfactory way of presenting ideas to the beginner. In speaking of chemical changes, the authors make use of the term "*factor*" to denote "substances which enter into reactions"; thus we read of "the change of the factor mercuric oxide into the elementary products mercury and oxygen by heat," and so on. Nor do we think their invention of the clumsy expression "*mass-unit weight*" of an element will at all help the student to grasp the idea of "*atomic weight.*" The beginner will probably be at a loss to understand why the compound NO is called "nitrogen dioxide," whilst CO is called "carbon monoxide."

The descriptive part of the book (493 pages), which is arranged in accordance with the periodic system, calls for little comment. Much valuable space is wasted on elaborate constitutional formulæ, the majority of which are advanced without the slightest attempt at proof or criticism. When, however, the authors do discuss such matters they are not always convincing, as the following example will show:

"The possible constitution of phosphorus pentoxide may be made a matter of discussion. If we assign to phosphorus the symbol

suggested by the specific gravity of phosphorus in vapour condition, we might conceive phosphorus pentoxide, formed by the complete oxidation of phosphorus, to have a similar constitution.

Of the molecular weight of phosphorus in solid condition, or of phosphorus pentoxide, we have no knowledge, so we find it convenient to represent both substances by the simplest possible equivalent symbols, P and P_2O_5."

We thought that the once prevalent idea of the preferential combustion of hydrogen in hydrocarbon flames had long since been discarded; the authors however, still believe in it, for in discussing the luminosity of the acetylene flame they tell us that the gas "burns from an ordinary gas jet with a flame which is luminous, but very sooty from finely divided free carbon, the hydrogen burning first

$$2C_2H_2 + O_2 = 2C_2 + 2H_2O."$$

In short, we find much in this book which would deter us from recommending it as a clear and trustworthy exposition of chemical facts and theories.

W. A. B.

OUR BOOK SHELF.

Collodion Emulsion. By Henry Oscar Klein. Pp. 95. (London: Penrose and Co., 1905.) Price 5*s.* net.

THE advent of gelatin plates has almost driven collodion out of the photographic world. The wet collodion process has all along retained its position in some kinds of photo-mechanical work, but collodion emulsions seemed to have no place left for them until a few years ago their advantages for certain technical purposes were insisted on, and the publishers and author of this volume did a good deal towards reintroducing them into this country on a commercial basis. As collodion emulsion can now be purchased the author has very little to say about the preparation of it; he only quotes two or three formulæ from other workers. The volume must be regarded as a guide to the practical user of commercial emulsions. Their applications in the making of ferrotypes, lantern slides, opals, and transparencies, and for photographing on wood are concisely described; but the principal part of the work, and by far the most important, deals with the colour sensitising of emulsions, and the applications of such sensitised emulsions to the production of negatives in the many methods of dealing with and reproducing colour that are now in vogue.

The applications of the newer sensitisers are described in many scattered communications, and often with very little discrimination between the practically useful and the merely theoretically interesting. Mr. Klein states that he has included only those that have passed the test of time and been found to be thoroughly practical. It is in this that the value of the work lies, and we think that it would have been better to have restricted the volume to this aspect of the subject. The occasional references to the underlying scientific facts will not help the practical man, nor would they if they were free from the errors that now disfigure them. A volume of practical instructions is not the place for a page or two of chemical equations or the expression of theoretical views that have often been called in question. However, these occupy but little space, and scarcely interfere with the use of the book as a strictly practical manual.

Der Gegensatz zwischen geographischer und nicht-geographischer Variation. By Karl Jordan. Pp. 59; with 73 figures in the Text. (Leipzig: W. Engelmann, 1905.)

THE present treatise affords an excellent example of the light that may be thrown on questions of biological interest by the scientific use of entomological data. Dr. Jordan here presents a valuable *résumé* of some of the most important results of the elaborate investigation of the chitinous sex-organs of insects, more particularly the Papilios and Sphingidæ, carried on by him for many years past at the zoological museum at Tring. These researches, the detailed results of which have already appeared in the pages of "Novitates Zoologicæ," are of high interest, not only to entomologists, but also to all students of the methods of evolution.

It must, however, be confessed that the author's interpretations are less acceptable than his facts. Starting from the position that "species" have a real objective existence, he endeavours to show that new species could only have arisen from geographically isolated variations, not from variations occurring side by side with the parent form. The main fact on which he relies is that while "individual" or "seasonal" variation of forms inhabiting the same locality is never accompanied by a variation in the sex-organs (with the single known exception of *Papilio xuthus*), the diverse geographical forms of a species are in very many cases found to be distinct from one another in sex-organs as well as in aspect. There is thus a correlation in the latter case which does not exist in the former, and which seems to the author to warrant the conclusion that these geographical forms only can occupy the position of incipient species. Some of the obvious objections to this view are dealt with by Dr. Jordan, others are left unnoticed.

A slight inaccuracy occurs on p. 177, where a figure of *Byblia goetzius* is said to represent *B. ilithyia*, while the true *B. ilithyia* bears the legend *B. anvatara*; both mistakes being repeated in the text. A more serious matter is the absence of any detailed reference to Mr. G. A. K. Marshall's work on this genus and his remarkable discoveries in the genus Precis. Some special recognition of these should have found a place, even in a treatise of general nature like the present. It will be gathered from what has been said that Dr. Jordan's conclusions are open to criticism. There can, however, be no doubt as to the value of the researches so ably carried on by himself and others in connection with the ample material of Mr. Rothschild's museum at Tring.

F. A. D.

Butter-making on the Farm and at the Creamery. By C. W. Walker-Tisdale and T. R. Robinson. Sixth edition, revised and enlarged. Pp. 162. (London: Office of the *Dairy World*, 1906.) Price 2*s*. 6*d*. net.

WE import into the United Kingdom perhaps twice as much butter as we make, and pay twenty millions yearly for it. Some, at least, of these millions would have been saved to the agricultural industry if our farmers and dairymen had given as much intelligent study to the principles of butter-making as, for instance, the Danes have done. Unfortunately, however, in such matters as the use of centrifugal cream-separators, the employment of pure bacterial cultures for "starters," and the general organisation of the industry, we did not lead the way; we were content to follow, and that, too, with somewhat halting footsteps. Even now the small butter-maker is often a sad empiricist. If cleanliness, for example, is an article of faith with him—and frequently it is not—he holds it as a dogma, not as reasoned knowledge.

The little book under notice may help in the recovery of some of those lost millions. It gives an outline of approved present-day practice in butter-making, though it does not purport to offer much in the way of theoretical explanation and discussion. Mainly it is an account of how best to conduct the operations of a small modern dairy. It is practical and simple; well suited for the elementary dairy-student, for the farmer's son who wishes to know something more than mere rule-of-thumb work, and for the private maker who supplies his own household from his own cows. The first few pages deal with the design, construction, and equipment of the dairy. Then cream is considered, and its separation and "ripening" are described, after which we pass to the churning and subsequent operations. A number of simple arithmetical examples are worked out to illustrate various points that arise. The last thirty pages deal, briefly and in a more technical manner, with the operations of a fully-equipped creamery, including "pasteurisation" and refrigerating.

The book does not profess to be much more than a useful note-book and practical guide, but as far as it goes it is excellent.

C. SIMMONDS.

The Deinhardt-Schlomann Series of Technical Dictionaries in Six Languages: English, German, French, Italian, Spanish, Russian. By Kurt Deinhardt and Alfred Schlomann. Vol. i. The Machine-Elements and Tools for Working in Metal and Wood. Together with an Appendix, edited by P. Stülpnagel. Pp. 403; 823 illustrations. (London: Archibald Constable and Co., Ltd., 1906.) Price 5*s*. net.

THIS volume is the first of a series intended to aid engineers and others in reading technical works in any of the principal modern languages. Terms of general importance only are included; they are classified into subjects and many are accompanied by an explanatory sketch. Formulæ and symbols, serving as they do the purpose of an international language, are introduced wherever possible. The translations have been tested in workshops and offices in the various countries represented; so the work ought to prove of service in reading technical literature. The convenient pocket size of the dictionary, the systematic arrangement of its matter, and the full alphabetical index of words in each of the six languages should gain for it a sphere of usefulness among technical students.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Osmotic Pressure.

THE publication of a paper by Mr. Spens in vol. lxxvii. Proc. Roy. Soc., p. 234, in which he criticises a relation between the vapour and osmotic pressures of a solution which Mr. Hartley and I had deduced (see same volume), seems to be an opportune moment for directing the attention of physical chemists to the necessity for an agreement as to what is meant by the term osmotic pressure.

Mr. Spens, following Duhem, points out that the osmotic pressure, defined as the difference between the pressure on the solvent and the pressure applied to a solution to keep it in equilibrium with the solvent, when the two are separated by a semi-permeable membrane, varies according to the pressure on the solvent. He suggests using a definite pressure on the solvent, say its vapour pressure, as the standard.

I would point out that, by accepting this definition, one is necessarily bound to compare two solutions when they are under different conditions—not only on account of the different vapour pressures of different solvents, but also on account of the different pressures on the solutions themselves.

The following consideration will, I think, make this clear, and at the same time will suggest a more scientific standard.

There seem to be two methods of examining directly the osmotic phenomena of a solution.

(1) One, which I may call the osmotic "force" method, depends essentially on the determination of the rate at which the solvent will flow through a semi-permeable membrane into an infinite mass of solution when there is no pressure on the latter.

It is evident that if one knew the frictional resistance to the flow, the heat developed, &c., one could calculate the osmotic "force" in absolute units.

I would mention, in parenthesis, that Mr. Hartley and I have made some comparative experiments in this direction with results which were not entirely unsatisfactory.

(2) All other direct methods give what may be called equilibrium pressures; they depend on the measurement of the pressure necessary to bring about a balance between the solution and the solvent. These equilibrium pressures cannot, on account of the compression of the solution, be measured under the same conditions.

An example will show this plainly. The equilibrium pressure between a solution of 540 grams of cane-sugar in the litre of solution and the solvent (water) under atmospheric pressure is, in round numbers, 70 atmospheres. The equilibrium pressure for 750 grams in the litre is 134 atmospheres. In the actual measurements each solution had been compressed, in one case by 71 atmospheres and in the other by 135 atmospheres. The conditions were therefore not comparable.

If we could measure the osmotic "force" of these two solutions as in (1) then comparable results would be obtained, for in both cases the solution and the solvent would be under the same pressure (gravitational).

Up to the present, so far as I am aware, no serious attempts to measure the osmotic "force" have been made, but I would suggest that, pending these, the relation between the vapour and osmotic pressures of a solution as deduced by Mr. Hartley and myself may be useful for the purpose of comparing *the* osmotic pressures of different solutions.

This relation gives the osmotic pressure of a solution when it is under no pressure but its own vapour pressure. A knowledge of the vapour pressure, together with the density of the solvent, is all that is required for calculating that pressure; while to apply the standard that Mr. Spens proposes, it is necessary to determine the increment in volume of the solution when unit mass of solvent enters it, and in some cases it may be necessary to obtain the coefficient of compression of the solution.

The experimental work saved by the adoption of the standard here proposed is apparent when it is remembered that, owing to the want of suitable semi-permeable membranes, the measurement of equilibrium pressures is confined to but a few substances dissolved in water.

The Eruption of Vesuvius.

YESTERDAY I ascended the cone of Vesuvius up to the crater, being, I suppose, one of the first climbers after the eruption. The ascent was made from Torre Annunziata without any difficulties, but care had to be taken to avoid the courses of the avalanches of stones and ashes rushing from the cone and spreading over the slopes more than half a mile from the foot of the cone.

I estimated the new crater to have a diameter of about 3000 feet; the bottom was not visible, but the walls could be seen to a depth of about 1000 feet. The inner walls are nearly perpendicular, partly overhanging, and I saw pieces of the very narrow crater edge breaking down, in this way still enlarging the crater. The very regular stratified construction of the crater walls was visible. The height of the crater edge is very different from what it was before the eruption, being greatest on the west side, and diminishing in irregular steps to the north and east. At the point to which I ascended the aneroid showed an elevation of 3760 feet. From this point, which was on the southern side, the Somma was clearly visible over the lower northern edge of the crater. This shape of the crater may account for the fact that the showers of lapilli and other fragmentary products which destroyed the villages of Ottajano and San Giuseppe were given a direction to the north and east over the Somma.

The crater now closely corresponds to the descriptions of the great crater formed in 1822, and described by Forbes and Scrope. From the throat of the crater I heard a constant roaring, and saw that white clouds of vapour filled the huge hollow, but I did not see any ejections of stones or dust.

On descending I visited the points where the lava streams started from the foot of the cone. The first lava reached the surface on the morning of April 4 a little west of the Casa Firenze, but it soon stopped. Another stream started from Casa Firenze, destroying the buildings, and flowed half the way toward Bosco-Trecase. The lava which damaged a part of Bosco-Trecase started on April 6 a little lower on the slope, and divided into two parallel branches. The quantity of lava during this eruption was on the whole comparatively small. No lava came from the crater. The general characteristics of the eruption are the immense amount of volcanic ash, lapilli, and other fragmentary material ejected, and this makes the eruption of April, 1906, very similar to that of the year 79 A.D.

Visiting the destroyed village Ottajano on April 19, I made the following curious observation. A great number of the window glasses are broken, but among the others there are many regularly penetrated or pierced by circular holes one or two inches in size. These holes are as common on the northern and eastern sides of the houses as on the other sides, and they can therefore not have been caused by the showers of lapilli, which only came from the south-west. Some people ascribed these holes to the very heavy lightning which accompanied the fall of the lapilli, but I am not aware that electrical discharges may produce such effects.

It may be of interest to note that when visiting the volcanic vents of the Phlegræan Plain to investigate if any kind of volcanic activity was shown in connection with the eruption of Vesuvius I heard that the emanation of steam from the Solfatara diminished greatly during the days of the strongest eruption of Vesuvius: normal conditions set in later. Naples, April 23.

Lightning Flashes.

In your issue of January 14, 1886 (vol. xxxiii., p. 245), Mr. T. Mackenzie reported lightning from a bank of cloud to the clear sky, but, as it was quite dark, one cannot be certain that there were no indistinct outliers. In Hann's "Lehrbuch der Meteorologie" (ed. 1, p. 632) other cases of lightning from a cloud to the clear sky are referred to.

On the evening of March 26, at 6.30 p.m., before dusk had set in, there was a large thunder cumulo-nimbus cloud about eight miles north of Johannesburg. The summit of this cloud was very sharp against a clear dark blue sky. There was no false cirrus. Six flashes of lightning darted from near the summit of the cloud into the clear sky. The longest path was about ten degrees. One flash returned to the cloud, the others finished in the clear sky. Before dusk set in this phenomenon ceased to occur. All the flashes were directed to that part of the sky from which the cloud moved.

In a well-known book on meteorology we read "it is impossible to say whether a flash of lightning moves from a cloud to the earth or in an opposite direction," and further that the lightning is instantaneous. Hann does not confirm these statements, and it is time that they were modified in English text-books. Quite frequently I have observed lightning flashes leaving a cloud for the earth, but fading away before reaching it; the opposite phenomenon has not been observed. The paths of lightning shown by photographs taken in the Transvaal all indicate discharges from cloud to cloud, and from cloud to earth. The enclosed photograph, taken by Mr. T. N. Leslie at Vereeniging, is typical. Some flashes of lightning are instantaneous, the majority are not, but I do not think any exceeds a duration of a third of a second. The revolving wheel has been used, and shows that the duration is often certainly much longer than 1/40th of a second.

Johannesburg, April 2. R. T. A. I.

Diurnal Variation of Ionisation in Closed Vessels.

Until Messrs. Campbell and Wood give us some more definite information as to the magnitude of the daily variation which they have found in the natural ionisation of air in closed vessels (Nature, April 19, vol. lxxiii., p. 583), it is somewhat premature to go into a detailed discussion as to how this discovery will affect theories of atmospheric electricity. Still, the letter in Nature of April 26 (vol. lxxiii., p. 607) on this question from Dr. O. W. Richardson calls for some remarks.

The facts are shortly:—(1) Messrs. Campbell and Wood discover that the natural ionisation of air in a closed vessel has a double daily period, the maxima being between 8 a.m. and 10 a.m. and between 10 p.m. and 1 a.m., the corresponding minima being at 2 p.m. and 4 a.m.; (2) the potential gradient in the lower atmosphere has, at most places, also a double period, the maxima being at about 8 a.m. and 8 p.m., and the minima at about 4 a.m. and midday. Thus, allowing for a certain amount of uncertainty in the exact determination of the times of the maxima and minima, we may say that the daily variations of the natural ionisation and the potential gradient are similar.

In order to discuss a possible dependency of these two factors, Dr. Richardson assumes that "the distribution of the earth's field reduces itself to a case very similar to that between two plane electrodes immersed in a gas and maintained at a constant difference of potential." It is more than questionable as to whether this assumption is justifiable or not, for in atmospheric electricity we are dealing with constant quantities of electricity, and not with constant potentials. But, rather than follow up this objection, I would prefer to look at the problem from a different point of view, and show that the exact contrary conclusions can be deduced.

In discussing this problem, it is usual to accept that there is a negative charge on the earth's surface, and that the corresponding positive charge is a volume charge distributed in the atmosphere. Now all the measurements which we have of the daily variation of potential gradient have been made within a few metres of the surface. Within these few metres there can be, relative to the charge on the earth, very little volume charge, so what our measurements actually refer to is the charge on the surface, the relation being $dv/dh = -4\pi\sigma$. The point to notice in this is that, with a given charge on the surface and the corresponding charge in the atmosphere above, the vertical distribution of the charge and the conducting state of the upper atmosphere do not in the slightest affect the potential gradient within a few metres of the surface. If the potential gradient changes there it can only be by a change in the surface charge on the earth.

If there is a penetrating radiation which, besides ionising the air in closed vessels, also ionises the air in the atmosphere, we should expect from Messrs. Campbell and Wood's experiments the ionisation of the air in *all parts* of the atmosphere to have a daily variation. Thus the air quite near the surface would twice a day be exceptionally conducting; one would expect that at these times there would be a greater loss of the surface charge, and so the remaining charge to be diminished, and with it the potential gradient. The consequence would be a daily variation of the potential gradient corresponding to the variation of ionisation, but the maxima of one corresponding to the minima of the other.

That such a relation does exist between the ionisation of the lower atmosphere and potential gradient has been shown by many observers situated in most parts of the globe. Thus from Messrs. Campbell and Wood's results one would expect minima of the potential gradient to occur at about 8 a.m. and 10 p.m.; this is the exact reverse of what really occurs.

Thus it would appear as if Messrs. Campbell and Wood have added one more to the many puzzling factors connected with atmospheric electricity.

Manchester University. George C. Simpson.

August Rainfall.

According to Greenwich experience, August has been a very dry month considerably oftener about sun-spot *maxima* than about *minima*. This fact may be of some practical interest.

Using Mr. Nash's table (from 1815), let us confine our attention to the three years about the eight maxima and the three about the eight minima, *i.e.* twenty-four years in each division.

The driest August in the *minima* division was in '55, with 1·40 inches. But in the *maxima* division there are ten cases of lower values, ranging from 1·25 inches down to 0·45 inch, viz. '38, '49, '50, '61, '69, '71, '82, '83, '84, '93. Since 1837 no three-year group of this division has been without at least one such very dry August, two have had two, and one three.

The total August rainfall in those twenty-four-year groups is, in the sun-spot *maxima* division, 50·25 inches, in the *minima* division 66·50 inches, the higher value thus showing an excess of 16·25 inches (nearly one-third of the lower).

The sun-spot maximum we are now near (1905?) has not been here considered, but I may remark that in 1904 we had one of those low August values (1·24 inches).

Alex. B. MacDowall.

AT THE HEAD OF LOCH FYNE.[1]

A LARGER number of contributors even than those mentioned on the title-page have conspired to make this memoir authoritative and complete. It is descriptive of Sheet 37 of the 1-inch geological map of Scotland, an attractive work published in 1903, in which the north-east and south-west lines of the Caledonian earth-folding predominate, and are followed out in the trend of the intrusive masses. The memoir is illustrated by excellent plates, one of which is here reproduced; and the fact that part of the ground is familiar to the tourist gives it an additional interest.

The region described is cut, from corner to corner, by the noble inlet of Loch Fyne. The parallel reach of Loch Awe lies in the north-west, and Loch Eck, banked out by gravel terraces from the sea, comes in near Loch Long in the south-east. The traveller by land usually enters the region by the steep and rugged fastnesses of Glencroe, and leaves it by Glen Aray, if he is willing to face the rain-swept moorland above which Cruachan towers in the north. The geological surveyors, however, have become familiar with a wide area practically untrodden by any visitor. Mr. Hill's appreciative introduction should be read with the aid of the hill-shaded Ordnance map, Sheet 37, one of the most beautiful products of a draughtsman who surely possessed a sentiment for landscape. The fundamental rocks of the district are metamorphic, and formed a part of the Caledonian continent, on which the Old Red Sandstone gathered; and Mr. Hill points out how denudation is removing the Devonian lavas and lake-deposits in the north-west, and is revealing, in the sculpture of the old continent, a highland much like that of modern days. The ice-flows of the Glacial epoch, however, have moulded the present surface in many of its details, have left erratic blocks in quaint positions on the hills, and have deposited moraines and banks of gravel across the edges of the ancient schists.

The metamorphosed series is mainly of sedimentary origin, with many bands of limestone. The albite-schists (p. 15), which are "highly micaceous or chloritic rocks with grains or crystals of clear secondary albite," are of special interest. Dr. Teall supplies an analysis, showing 3·2 per cent. of soda and an equal amount of potash. This allows 28 per cent. of the rock to be formed of albite. "Green beds," which are hornblendic, and yet are not the intrusive epidiorites so familiar in Dalradian areas, occur in a band south-east of Loch Fyne, and may have been derived clastically from some preexisting basic igneous series (p. 18). True sills of epidiorite occur, however, plentifully among the metamorphic rocks between Loch Awe and Loch Fyne. In the same region there are numerous later intrusions of quartz-porphyry and other igneous rocks, probably post-Silurian in age. "Kentallenite," described in detail by Mr. Hill in 1900 (Quart. Journ. Geol. Soc., vol. lvi., p. 531), and first known from the Appin promontory, occurs here and there, as a link between

FIG. 1.—The summit of the Pass of Glencroe, with Loch Restil. The rugged hill scenery is formed by the Ben Bheula schists. From "The Geology of Mid-Argyll."

[1] "The Geology of Mid-Argyll." By J. B. Hill, with the collaboration of B. N. Peach, C. T. Clough, and H. Kynaston, with petrographical notes by J. J. H. Teall and J. S. Flett. Pp. vi+166. Memoirs of the Geological Survey, Scotland. (Glasgow, for H.M. Stationery Office: J. Hedderwick and Sons, Ltd., 1905.) Price 8s.

the masses rich in alkalies and the biotite-peridotites. Mr. Kynaston (p. 102) regards this rock, with the granites and diorites of the north-west area, as contemporaneous with the Ben Cruachan granite, that is, as later than the Lower Old Red Sandstone lava-flows. The regional metamorphism of the older rocks of mid-Argyll is not due to these numerous intrusive masses, nor to any concealed dome of granite. It increases in intensity from north-west to south-east, and also along the strike of the ancient sedimentary series in a north-easterly direction, so that comparatively unaltered rocks of the "Loch Awe group" (p. 76) pass, outside the limits of Sheet 37, into schists of a very pronounced degree of crystallisation. Local thermal alteration tends to mask both the original clastic structures and the subsequent foliation (p. 39).

The form of the lake-floors in connection with the passage of ice across them is interestingly discussed in chapter xiii. At the time of maximum glaciation, the upper portion of the Loch Fyne ice moved out westward towards the Sound of Jura, the general south-westerly course being resumed as the ice thinned down again and became guided by the topographic features. It is held that Loch Awe at one time drained southward, when the level of its waters was nearly 200 feet higher than at present.

The economic resources of the district, which are neither conspicuous nor generally accessible, are referred to at the close of the memoir. If petrographic details naturally predominate in such a work, they only testify to the scientific thoroughness with which the Geological Survey is encouraged to explore the Scottish highlands.

THE EGYPTIAN HEAVEN AND HELL.[1]

IN his "Egyptian Heaven and Hell" Dr. Wallis Budge has contributed another work to his already long list of books dealing with the subject of ancient Egyptian religions. It appears in three-volume form in the useful little series of "Books on Egypt and Chaldæa," written by Dr. Budge and Mr. L. W. King, and published by Messrs. Kegan Paul. Those who are interested in the subject are familiar with Dr. Budge's edition of the "Book of the Dead" in the same series. These volumes form a companion work, being an edition of the two subsidiary collections of funerary texts, "The Book of the Am-Tuat (that which is in Hades)" and "The Book of the Gates," which accompanied the great "Chapters of Coming Forth into the Day," the "Book of the Dead" proper. As in the former work, Dr. Budge gives the text, translation, and illustrations from the original papyri.

The two subsidiary books differ somewhat in purpose and scope from the "Book of the Dead" itself. The latter is a collection of spells and "words of magic power" to be learnt by the dead in order to win their way past the dangers of the unseen world into the presence of Osiris. The individual dead man, identified with Osiris, "the Osiris N," is the central figure of every chapter of the "Book of the Dead." "Chapter so-and-so. I, the Osiris so-and-so, say," and so on. But in the Book of That which is in Hades, and in the Book of the Gates, the dead man is not the principal figure. In fact, in the first-named (hereinafter called "The Book of the Tuat") he hardly appears at all; the book is merely a description of the other world as it appears to the beatified spirits who follow the bark of the sun-god in its passage through Hades (the Tuat) from west to east, from his setting to his rising. During the night the dead sun-god, known as Auf ("his limbs," *i.e.* the carcass of the sun), sails through the regions of the underworld to give light to the dwellers therein, and during his voyage the souls of the blessed rise up and join themselves to his boat. It is a weird conception, and the description of these regions of the dark beyond, as given in Dr. Budge's book, is still more weird. The Tuat is divided into several distinct Tuats, each corresponding to one of the great Egyptian necropoles, Abydos, Thebes, Sakkara, and Heliopolis. Each has its peculiar features, and appears to be tenanted by demons and spirits with unpronounceable names and of strange appearance, some of whom are good and help the bark of the god on its way, while others are bad and seek by every means in their power to oppose its progress. These are vanquished in succession as the sun passes their territories. The "Book of the Gates" is so called on account of its chief feature being the successive mention of the gates of the Tuats, each of which has its demon-guardian, who is passed by means of the appropriate spell. In it the

FIG. 1.—The Boat of the Sun towed by Gods of the Tuat. From "The Egyptian Heaven and Hell," vol ii., The Book of Gates.

god Osiris appears, but not to the extent to which he appears in the "Book of the Dead," the chapters of which seem to have originally emanated from the original seat of his worship at Busiris in the Delta. Indeed, the "Book of the Tuat" may be a much later invention of the Theban priests, designed to divert the attention of the faithful from the northern Osiris to the sun-god of Thebes. It is homogeneous in plan, which the "Book of the Dead" is not. Dr. Budge gives a parallel version of both subsidiary books in his third volume, so that they can conveniently be compared. In the same volume are to be found his introduction and a most compendious index.

The pictures of these two books are extremely remarkable. Their general appearance will be well known to those who have visited the tombs of the kings at Thebes, or have seen the wonderful alabaster sarcophagus of King Seti I. in Sir John Soane's museum in Lincoln's Inn Fields. Under the eighteenth and nineteenth dynasties the walls of the royal tombs were decorated with scenes from the "Book of the Tuat" and "Book of the Gates," so that the dead monarchs could see in pictures at least the weird forms which the imagination of the

of the dead in the next world as given in these two books are also well worth the attention of the anthropologist.

ANCIENT ECLIPSES.

THE results of recent discussion of ancient eclipses may for convenience be divided into three sections. The conclusion of each section depends upon the truth of the conclusions of the preceding sections, but not vice versâ, that is to say, the results of the last section may be rejected without in the least impairing the validity of the earlier conclusions. The results are as follows:—

(1) If an astronomer had been asked a year ago by a historian or a chronologist whether the tables of the sun and moon accurately accounted for the recorded phenomena of ancient eclipses, he could only have replied that the tables failed altogether to account for the solar eclipses; that they had been empirically altered so as to account for the observed *times* of certain lunar eclipses; and that the question whether the tables so altered accounted for the *magnitudes* of the same lunar eclipses had not even been examined. There seemed to be no possible modification of the tables that would bring them into harmony with the recorded solar eclipses, and it was therefore the received opinion that the historical accounts of these were untrustworthy. The first result is that two slight modifications of the existing tables will cause them to satisfy the records.

The modifications in question may be stated as follows:—Define the nodical month as the mean period between one passage of the moon from south to north of the ecliptic and the next passage, and define the nodical year as the mean period between one passage of the sun from south to north of the plane of the moon's orbit and the next passage, purely periodic variations being left out of account. Then the eclipses show that the rate of change of length of both the nodical month and nodical year as given in the tables must be altered.

(2) The second section of the results is concerned with the question, "In order to alter the rate of variation of the nodical year, are we to alter the acceleration of the node or of the sun?" Now the motion of the node depends upon theory, and the same theory which accounts for its motion at the present time will suffice to calculate its motion at any time during the last few centuries. The motion of the sun, however, is purely a question of observation. Unknown causes may easily be conceived as altering its motion. The second result is therefore to ascribe an acceleration to the sun's motion to account for the variation in the nodical year inferred from ancient eclipses, or in other words, we may leave out the word "nodical" in our statement and say, "The ancient eclipses indicate certain definite rates of change in the lengths of the month and year."

(3) We lastly require some physical explanation of the sun's acceleration. Here there are many possibilities. The æther may offer a sensible resistance to the passage of the earth; or an electro-magnetic theory of gravitation may compel us to take account of the small, but not infinitesimal, ratio between the velocity of a planet in its orbit and the velocity of light; or again, electrical theories of matter somewhat modify the old conception of mass, and with it the fundamental equations of motion on which planetary theory rests. But the explanation tentatively put forward at the April meeting of the Royal Astronomical Society is as follows:—Let us suppose the acceleration of the sun to be due to a change in the length of the day caused by tidal friction. The tides check the rotation of the earth, lengthen the day, and therefore apparently increase all diurnal movements by the same fraction of their whole amounts. Introducing numbers for greater definiteness, let us suppose that in a century the day increases in length by a two-hundredth part of a second of time. Then in a century the sun's apparent rate of motion will increase by one part in seventeen million, which is exactly the change indicated by the eclipses. If, however, the moon's apparent rate of motion also increased by one part in seventeen million the acceleration would be ten times larger than that indicated by the eclipses.

But if the tides are checking the diurnal rotation of the earth, it follows from the principle of conservation of angular momentum that the moon must be receding from the earth, and absorbing the spin lost by the earth. This implies that the moon is really moving more slowly. It is impossible to make accurate calculations, for the action of the tides on an earth with oceans and continents of irregular shape cannot be computed, and it is impossible to say how the tidal action varies for different positions of the moon in its elliptic orbit. Hence we cannot say how far the action of the tides is distributed between changes in the length of the month and changes in the eccentricity of the moon's orbit. But it seems a plausible hypothesis that the large eccentricity of the moon's orbit was evolved somehow, presumably by tides, and that the eccentricity is therefore increasing, and calculation shows that if the rate of increase assigned to the eccentricity be about one-hundredth of a second of arc a century, the consequent change in the absolute angular velocity of the moon is such as to cancel nine-tenths of the apparent decrease in the length of the month, leaving the remaining one-tenth in agreement with the change inferred from ancient eclipses. This explanation, it should be clearly understood, only shows that certain correlated quantities are of the right order of magnitude: it is unable to prove or disprove an exact numerical relation.

In the remaining part of this article the basis of the conclusion of the first section is examined. That is the foundation, which must be rendered secure before interest can attach to any superstructure.

Let us select a definite eclipse, for instance, the eclipse of Thucydides in the first year of the Peloponnesian War. The record states that stars appeared. It is certain on the other hand that the eclipse, at the most, could only have been annular. There is therefore a strong presumption that Athens was not far from the central line of the eclipse, or in other words, at the time of conjunction in longitude as seen from Athens, the difference of apparent latitudes must have been small. The hypothesis that Athens was the place of observation has been objected to. This however is the natural interpretation of the passage in Thucydides; let us adopt it for the present and see where it leads. For Athens, therefore, let the difference of apparent latitude for the instant of apparent conjunction in longitude be computed from the present tables. The result is so large as absolutely to negative the possibility that stars could have been seen. Reserving the hypothesis that the record is untrustworthy as a last refuge in case of trouble, let us suppose for the present that the tables require alteration.

What kind of alteration is permissible? It has been argued in *Ast. Nach.*, No. 3682, on physical grounds, that only one unknown quantity may be introduced. Now against physical reasoning of this kind, strong objections may be urged. It proceeds necessarily on the assumption that the general nature of the problem of the apparent motions of the sun and moon is fully understood. It absolutely limits the investigation to the numerical determination of quantities connected with a preconceived theory, and it prevents, at the outset, the attainment of results of a new character. Now as the preconceived theory was entirely based upon two centuries of observation, there is no improbability in our knowledge being widened, when the period of observation is largely increased. In the whole of astronomy there is not a single case of a theoretical value of a secular term, that is to say, a term proportional to the square of the time, being confirmed by observation. This is because the series of modern observations is not yet long enough. Is it not possible that one or two centuries hence the observed values of these terms will lay bare a whole series of new phenomena? Physical considerations of the kind alluded to absolutely prevent the achievement of such a result. They may advantageously be replaced in the following manner by considerations of a purely geometrical character.

It being, for a time at least, granted that the eclipse of Thucydides suggests that the existing tables require large modifications, geometrical considerations tell us, that in order to diminish by 200″ or thereabouts the difference of latitude at conjunction, we must alter the mean distances of the sun and moon from the node as given by the tables for the year −430 by quantities of the order of 2000″. The only geometrical alternative is to assume alterations ten times as large in some other quantity such as the position of the perigee, and this alternative may be put aside. Now the mean distances can be expanded in powers of the time, the origin of time being taken near the present day. Then modern observations forbid the correction of the mean motions or of the terms independent of the time. The corrections are therefore necessarily thrown about the coefficients of the square of the time, that is to say, upon what are called the secular terms, in the mean distances of the sun and moon from the node. Geometrical considerations therefore, combined with a becoming modesty as to our powers of applying physical considerations, present us with two unknown quantities for correction, one of which is the quantity admitted in *Ast. Nach.*, No. 3682 to be arbitrary, while the other is a new one.

If the preconceived theory is correct and the records are trustworthy the value of the second variable will on solution turn out to be zero or so nearly zero as to suggest that zero is the true value. If no values satisfy all the equations of condition, then some of the records are untrustworthy or the geometrical considerations have been carelessly thought out. If the equations can be satisfied simultaneously, and the value of the second variable is not zero, a very strong case is established against the physical considerations of the preconceived theory.

If we write down five simultaneous linear equations in two unknown quantities x and y, all satisfied by the same values of the variables, and if we then put y equal to zero, or in other words, rub out the terms in y, we shall of course find the equations in x are inconsistent. If the equations represent historical data, and if, as men of science, we have a proper contempt for literature, we shall no doubt proceed to quarrel with our evidence. This is exactly the way in which astronomers have in the past treated ancient solar eclipses. When, however, equations of condition involving two unknown quantities are formed for all the solar eclipses in which the place of observation appears to have been fairly near the central line, whereas modern tables give residuals of the order of 200″, that is to say, make the apparent differences of latitude at conjunction in longitude of the order of 200″, values can be found for the unknown quantities, which will make all the residuals less than 50″; in other words, whereas the present tables would leave about ten per cent. of the sun's diameter visible, the alterations proposed never leave so much as two per cent. visible.

Let it be here stated that no solar eclipse is an exception to the above statement. The conclusions rest, not upon the evidence of a majority but upon the unanimous evidence of all eclipses used. A list of these is given in Monthly Notices, lxv., p. 861, and a reference is given on p. 867 to the eclipse of Agathocles. The eclipse of Thales has not been worked up as it occurred a hundred years before the birth of Herodotus; its evidence, whether for or against, is held to be inadmissible.

A confirmation of these results is supplied by the lunar eclipses of the Almagest. On working them up, it is found that the residuals are so large as to show that they are entitled to far less weight than the solar eclipses. Their value lies in the fact that the separate determinations from the lunar eclipses group themselves round the values derived from solar eclipses. The lunar eclipses are given in Monthly Notices, lxvi., pp. 6–7; they are nineteen in number, and in only ten cases is a numerical estimate of the magnitude recorded. These ten cases alone therefore test the newly-discovered fact which, in language that becomes appropriate only if the second section of results is admitted, states that the earth's orbital motion is subject to a secular acceleration of $4''$. Now of the ten lunar eclipses available, seven give accelerations lying between $2''$ and $6''$. It is therefore hard to believe that zero and not $4''$ is the correct value. The times of the lunar eclipses are equally striking in their confirmation of the result. Nearly thirty years ago a correction was introduced into Hansen's Tables based upon these eclipses. The main question is one of evidence. It is no use to point out in the third section of this paper how certain changes may be accounted for, if they are not shown to exist. On the other hand, no objections to a particular explanation of the physical reason can weaken the case for the observed fact that these changes are taking place. What is sufficient evidence? Two eclipses would suffice, if they had been described with a wealth of detail that established complete confidence in the records. A hundred eclipses of the actual sort would probably satisfy the most sceptical, even though the place assigned were always "tacitly assumed (to be) the capital where the record was made, or the place where the poet or historian lived." The smaller number of eclipses, which it has alone been possible to produce, should suffice to make a case almost if not completely amounting to certainty.

P. H. COWELL.

VARIATIONS OF DOMESTIC POULTRY.[1]

THE book under notice is one of an original character. It is an attempt to describe all the different races of domestic poultry that exist in various parts of the world, and as such is not without its value, as it gives us a description of the races of fowls as they exist, not only in Asia, but in the various States of Europe and the United States of America. The book treats almost solely of the races of fowls from a fancier's point of view. The plumage and external characters which would be noticed in a show-pen are those that are dwelt upon, and as a scientific treatise the work cannot be regarded as having any special value, and would be unfairly treated if it were regarded from the same standpoint as Darwin's "Variation of Animals under Domestication."

The illustrations, which are very numerous, are not original, but taken from the fancy poultry journals, where the birds are drawn with the usual exaggeration of the points valued by the fancier, and bred for securing prizes. The consequence is that some of them are good and others quite the reverse, but the plumage in many is exaggerated. To scientific ornithologists this history of the location of colour in the different parts of the plumage of birds, and the fixture of the patterns in the races, is one of considerable interest. To those acquainted with the details of poultry breeding it is well known that any variation of the colour or texture of feathers which appears in any particular specimen can, by careful selection of the offspring, for a series of generations, be readily perpetuated, and by crossing with other varieties almost any pattern or disposition of colour can be obtained, and what is called a new breed formed. This is illustrated by the engraving, which we borrow from the work, of a German race at present but little known in this country, called the Lakenfelder. In this the colours are transposed from their general position, and a remarkable looking fowl is produced, which is correctly represented in the engraving.

It is of much scientific interest to trace the extent of the variation which can be induced by careful breeding. In the fowl, these variations have been almost exclusively confined to the plumage, which in some instances has been increased to an enormous extent, as in the production of quill feathers 8 inches long on the feet of the show Cochin, and the general

FIG. 1.—Lakenfelders. From "Races of Domestic Poultry."

increase of the plumage to a great extent, so that the modern show Cochin does not at all resemble the original birds brought from Shanghai. In other cases the plumage has been partially abolished, as in the Nackthälse or Transylvanian naked necks, in which the head and neck are entirely denuded of feathers, and the skin assumes the red colour of the comb. These variations are permanent, and are intensified by long-continued breeding. The production of spangles or dark markings at the end of the feathers, of bordered margins of black on a light ground in the whole of the body feathers, and of regular transverse bars across each feather of the plumage, have all been accomplished and perpetuated by careful selection.

The various breeds of ducks, geese, and turkeys are also treated of.

The work contains in an appendix a very elaborate and useful list of the names of the races in all the European languages, which will prove of great value to all investigating the subject of variation.

W. B. TEGETMEIER.

NOTES.

THE gentlemen's conversazione at the Royal Society will be held on Wednesday next, May 9.

THE summer meeting of the American Chemical Society will this year be held in Ithaca, N.Y., on June 28–30.

IT is announced that the German Government has issued invitations for an International Conference on Wireless Telegraphy to meet on June 28.

THE sixth International Congress of Applied Chemistry was opened at Rome on April 26 by the King and Queen of Italy in the presence of the Diplomatic Body, the members of the Cabinet, high officials of the State, and about two thousand delegates. Speeches were delivered by Prof. E. Paternò, president of the congress, Signor Boselli, Minister of Public Instruction, Prof. O. Witt, and delegates of the chief nations represented at the congress. The British delegates are Prof. W. A. Tilden, F.R.S., Prof. W. N. Hartley, F.R.S., and Dr. J. J. Dobbie, F.R.S.

A REUTER telegram from New York states that the new French liner *La Provence*, when 1800 miles from Poldhu and 1700 miles from Cape Cod, on April 25 at 2 p.m., simultaneously communicated by wireless telegraphy with both stations, and received answers from both.

ACCORDING to the *Chemiker Zeitung* there were 183,532 persons connected with chemistry who were insured against accident in Germany in 1904: of these, 1535 cases received compensation from the insurance companies. This number includes 109 cases of death, 14 completely and 1040 partially incapacitated from following their vocation in life, whilst 372 were only for a time unable to work; the amount paid to the injured or the relatives of the deceased was nearly 2,200,000 marks.

IN honour of the International Medical Congress to be held in Lisbon this year, there has been opened a small exhibition of the products of the Portuguese colonies in the rooms of the Colonial Museum. The exhibits, which are chiefly from Cape Verde, Mozambique, the Portuguese Indies, Angola, Timor, and Guinea, deal almost exclusively with wool, coffee, cocoa, and india-rubber; palm oil, &c., and other raw materials of the fatty and oil industries, although important exports of the Portuguese colonies, are not represented.

ARRANGEMENTS are being made to hold a "Country in Town" exhibition at the Whitechapel Art Gallery in July. The object of the exhibition is to show East Londoners what can be done to bring into the neighbourhood something of the beauty of nature. It is proposed to show living things, pictures and models, materials and appliances, plans for the improvement of certain areas in London, and exhibits explaining city life in Japan and other countries. Contributions towards the necessary expenses are asked for, and these may be sent to the Rev. Canon Barnett at Toynbee Hall, E.

THE ninth annual meeting of the Childhood Society will be held on Tuesday next, May 8, at the residence of the president, Earl Egerton of Tatton. Sir Edward Brabrook, C.B., will deliver an address. The chief object of the society is to promote the study of educational methods and of the environment of children during school life, best suited to ensure satisfactory mental and physical development of children. The society numbers among its members representatives of educational science, teachers, medical experts, and others interested in the investigation of mental and physical conditions of childhood.

EARTHQUAKE shocks have again been common during the past week. Reuter's messages show that on April 25 a disturbance was felt at 3.15 p.m. at San Francisco, and lasted nearly a minute. This shock was also felt at Oakland and Berkeley. On April 26 shocks were felt at Salinas, 100 miles south of San Francisco, at 8 p.m. and 9.50 p.m., and these were followed by a third on April 27 at 2 a.m. Each of these three disturbances lasted about four seconds. A later telegram reports that earthquakes were felt at Salinas every day from April 18 to 27. On April 27, too, four disturbances of increasing intensity were felt at Dresden, and on April 28 in Schönberg, Brambach, and other places in the Vogtland district. Two slight shocks were felt at San Francisco on the morning of April 30.

IT is arranged that the International Association for Testing Materials, which holds its congresses about every three years in industrial centres in various countries, shall this year meet in the Academy of Science at Brussels on September 3–8. The King of Belgium has accorded the congress his patronage, while Prince Albert of Belgium will be one of the honorary presidents, as also will the Ministers of Finance, Railways, War, and Trade, and the Mayor of Brussels. Among the papers to be read will be one on the industries of Belgium, by Baron E. de Laveleye and M. Camerman. It is expected that a considerable number of members and delegates from this country will be present at the congress. Mr. J. E. Stead, F.R.S., Middlesbrough, is the English secretary of the association.

AT the annual general meeting of the Institution of Civil Engineers, held on April 24, Sir Alexander B. W. Kennedy, F.R.S., was elected president of the institution. The council has made the following awards for papers read and discussed before the institution during the past session:—A Telford gold medal to Mr. J. A. Saner, a Watt gold medal to Mr. G. G. Stoney, and a George Stephenson gold medal to Dr. T. E. Stanton; Telford premiums to Mr. Leonard Bairstow, Mr. H. S. Bidwell, Mr. J. J. Webster, Mr. Cathcart, Mr. W. Methven, Mr. H. A. Mavor, Sir Frederick R. Upcott, K.C.V.O., C.S.I., and a Manby premium to Mr. D. E. Lloyd-Davies. The presentation of these awards, together with those for papers which have not been subject to discussion, and will be announced later, will take place at the inaugural meeting of next session.

IN Tennyson's "Palace of Art" occur the lines:—

> "She saw the snowy poles and Moons of Mars,
> That mystic field of drifted light
> In mid Orion, and the married stars."

This at first sight looks like a literary parallel to Swift's well-known fortuitous forecast of the discovery of the Martian satellites, and Mr. J. S. Stevenson, writing from Blairavon, Norwood, Ceylon, points out that Prof. H. H. Turner quotes it in "Modern Astronomy" as having been written in 1835. This, however, appears not to have been the case; for Mr. Stevenson, on reference to the biography of the late poet laureate by the present Lord Tennyson has found the note, "The 'Moons of Mars' is the only modern reading here, all the rest are more than half a century old." Scientific discovery was thus not anticipated by Tennyson in the mention of Martian satellites.

THE Paris correspondent of the *Times* made the following announcement in a message on Monday night:—"The Prince of Monaco formally announced to the French Minister of Education to-day his decision to establish in Paris the Oceanographic Institute that he has founded. He will endow the institute with the magnificent museum now existing at Monaco, including its laboratories, collections, aquaria, &c. The Prince has set apart 4,000,000 francs (160,000*l.*) for the maintenance of the institute. It will be established on grounds recently bought by the University of Paris with the assistance of the Prince in the rue Saint-Jacques and the rue d'Ulm. The scientific direction of the institute is vested in an international committee of specialists in oceanography. The French Government has expressed its formal thanks for this really princely gift."

The first of a series of four lectures on atmospheric circulation and its relation to weather was delivered by Dr. W. N. Shaw at the University of London on Tuesday, May 1. Dr. Shaw referred to the valuable contributions to meteorology in the last fifty years by Dr. Buchan, Abercromby, and Clement Ley, and he pointed out that, so far as the forecasting of the weather is concerned, no great advance has been made in recent years, and that it is necessary to take into consideration the atmosphere in the upper regions and to deal with the general circulation as a whole. Great advance has been made recently in that way by the use of kites and balloons, and the direction of the air currents in the higher regions can be determined from the records of the barometer, thermometer, and hygrometer obtained in those ascents. Some very interesting diagrams were thrown on the screen, showing the circulation at a height of 4000 metres, from charts constructed by M. Teisserenc de Bort, and also showing the results of international upper-cloud observations as deduced by Dr. Hildebrandsson for various parts of the globe.

The contents of Irish Fisheries Scientific Investigations, 1904, No. 6 (1905), includes a paper on "plankton" collected at light-stations, by Dr. L. H. Gough, and hydrographical observations made at the same. In connection with the plankton, it is noticeable that when this comprises a large number of copepod crustaceans, the vegetable organisms are much less numerous than usual, and *vice versâ*.

The four articles in the April issue of the *Zoologist* are equally divided between birds and fishes. In recording the rare birds seen in Norfolk during 1905, Mr. John Gurney again notices the occurrence of quite a number of avocets on Breydon Flats. The birds of Derbyshire, as observed in 1904–5, form the subject of an article by the Rev. Mr. Jourdain. Mr. L. E. Adams describes his own observations on the mode of flight of flying-fishes, while Prof. McIntosh discusses certain Japanese food-fishes.

Six new fishes from Japan, described by Messrs. Jordan and Seale, form the subject of No. 1445 of the Proceedings of the U.S. National Museum; while the succeeding number of the same journal (No. 1446) is devoted to descriptions of new American Palæozoic ostracod crustaceans, by Messrs. Ulrich and Bassler. In No. 1447 of the Proceedings Mr. J. W. Gidley describes the skull of a ruminant allied to the musk-ox from Pleistocene strata in New Mexico. The new generic name Liops is proposed for this ruminant, which is of special interest on account of its southern habitat.

The trustees of the Indian Museum, Calcutta, according to the report for the past financial year, have decided to charge an admission-fee of 8 annas on Sundays between the hours of 3 p.m. and 5 p.m., in order to give the educated classes an opportunity of studying the contents of the galleries under more favourable opportunities than has been hitherto possible. As a rule, the galleries are absolutely crowded with members of the illiterate class throughout the time when they are open to the general public. It is proposed greatly to enlarge the museum, at an estimated cost of 2½ lakhs of rupees a sum apparently already at the disposal of the trustees.

Mr. F. A. Lucas, curator of The Museum, Brooklyn Institute of Arts and Sciences, Brooklyn, N.Y., desires to direct attention to a photograph of Laysan Island, issued several years ago, showing on the beach a large turtle, and, what is more important, a large seal, which appeared to be of the genus Monachus. He points out that if this seal really belongs to the genus Monachus, the fact is of great scientific interest, as it would make the seal circumtropical. Mr. Lucas would be glad to know if anything has been published regarding this seal, specimens of which he believes were taken to Europe.

A pamphlet has reached us containing an address delivered by Dr. Paul Kronthal before the Berlin Psychological Society in October of last year on the idea of the soul (Jena: Gustav Fischer). The lecturer, continuing the investigation of which notice has already been taken in these columns, elaborates his account of the soul as the sum of reflexes. This definition, he claims, does justice to all the facts, *e.g.* of inheritance of physical characteristics, of mental disease, of memory, and the like. He occupies several pages with a discussion of the freedom of the will, a conception which, it appears, is abandoned by all consistent theologians, men of science, historians, and jurists. But it appears also from the later half of the lecture that to define the soul as the sum of reflexes satisfies only natural science; from the standpoint of metaphysics we must speak of the soul as sensation. Apparently, too, the metaphysical view leads directly to solipsism, and the metaphysical world consists of abstractions like love, hate, joy, sorrow, good, bad. The world of the scientific man, on the other hand, is made up of five entities, which at first sight appear very real as compared with these abstractions, but which are ultimately admitted to be five metaphysical ideas—time, space, matter, energy, number. It is further admitted that the fundamental law of causality is for natural science undemonstrable. Dr. Kronthal concludes his somewhat paradoxical lecture with two dicta—that the honourable metaphysician must grant that the conceptions of natural science are the more justifiable, and that no thoughtful man of science can deny that the conceptions of natural science are in the last resort only matters of faith.

A catalogue of microscopical objects and accessories has been received from Mr. R. G. Mason; a special feature is made of geological and stained botanical sections that can be mounted by purchasers. A section of limestone sent as a sample of the mounted objects shows a variety of Foraminifera, and is otherwise a desirable specimen, also a double-stained section of pine stem is a thoroughly satisfactory preparation.

The second number of the *Journal of Economic Biology* contains papers on the effects of metazoan parasites on their hosts, by Messrs. Shipley and Fearnsides; on the bionomics of grain weevils, by Mr. F. J. Cole; on the deposition of eggs and larvæ in *Œstrus ovis*, by Mr. W. E. Collinge; and on the ox-warble flies, by Mr. A. D. Imms. The reviews and current literature, with notes, which complete the number are a valuable feature of the journal.

A SERIES of identifications of Philippine plants is published in Publication No. 35 of the Bureau of Government Laboratories, Manila. Mr. H. N. Ridley has worked out the Scitamineæ, describing three new species of Amomum; Mr. C. B. Clarke has named the Acanthaceæ; Dr. E. Häckel has identified a collection of grasses; and Mr. E. D. Merrill contributes some notes on Cuming's Philippine plants, as well as the fourth series of diagnoses of new or noteworthy plants. Among the latter are two new species of Rhizophoraceæ, a Gynotrochea growing in forest at an altitude of 4000 feet, and a Pellacalyx, also new species of Eugenia and of Saurauia.

THE original habitat of the coconut palm has often been the subject of speculation. In a paper read before the Ceylon branch of the Royal Asiatic Society, Mr. J. Ferguson, tracing the early history of the cultivation of the coconut palm in Ceylon, accepts the general dictum that the plant is not indigenous, and attributes its origin to nuts washed up by the sea. It is recorded that, at the instigation of a Singhalese king, a plantation was formed on the south coast as early as the middle of the first century, and subsequently King Prákrama Báhu the Great also interested himself in extending its cultivation.

IN the Journal of the Royal Horticultural Society (vol. xxix., part iv.) Mr. E. S. Salmon describes a white mildew disease that has been prevalent on shrubs of *Euonymus japonicus* in the south of England. From the mycelium on the surface of the leaf, hyphæ are produced that pierce the cuticle of the epidermis and form haustoria in the epidermal cells, thus enabling the fungus to maintain its parasitic life. The mycelium persists on the leaves through the winter, so that perithecial resting spores are not required and are not formed. The disease can be checked by collecting and burning in the winter all leaves that bear the white patches of hibernating mycelium; also treatment with sulphur or other fungicides is recommended.

THE paper on ramie read by Mrs. E. Hart before the Society of Arts, and printed in the Journal of the Society (April 6), is interesting, not only as it indicates some of the difficulties that had to be overcome in spinning and weaving, but also because it bears out the opinion that, given cooperation between producer and manufacturer, the cultivation, preparation, and weaving of ramie can be profitably undertaken. In the matter of decortication, Mrs. Hart advocates hand-stripping in preference to machines wherever cheap labour can be obtained, and recommends that the degumming process should be carried out under expert supervision in the mills. The fabrics that have been woven of pure ramie, warp and weft, vary from the lightest gossamer to a heavy cloth.

IN Hawaii, root disease of the sugar-cane produced by a species of the basidiomycetous fungus Marasmius—not improbably *Marasmius sacchari*—is so prevalent that a Bulletin (No. 2 of the Division of Pathology and Physiology) has been issued to provide information on the subject. The writer, Mr. L. Lewton-Brain, traces the connection between the fungus that attacks primarily the growing point of the root and the symptoms, similar to those caused by drought, of rolled-up leaves, matted leaf-sheaths, and undeveloped roots; also he indicates how the plant can be strengthened by judicious irrigation and by liming the soil. A variety possessed of a certain power of resistance to the disease has been found in the Yellow Caledonia, but a variety that is perfectly immune has yet to be discovered.

THE *Naturwissenschaftliche Wochenschrift* (vol. v., No. 8) contains a long paper by Dr. W. R. Eckardt on the climatic conditions of past geological times. The author deals specially with the climate of the Carboniferous and Tertiary periods, and concludes that the explanation of all changes of climate is to be sought in variations in the distribution of land and sea.

WE have received a copy of the tide tables for Charlottetown, Picton, and St. Paul Island, C.B., for the year 1906, issued by the Department of Marine and Fisheries of the Dominion of Canada. The tables are based on direct observations made at eleven localities in the south-western portion of the Gulf of St. Lawrence and in Cabot Strait. It has been ascertained that the tides can best be deduced from St. Paul Island, for which continuous records extending over four years are available.

DR. WALTHER VON KNEBEL contributes a paper to the *Naturwissenschaftliche Rundschau* (vol. xxi., No. 12) on the hot-spring areas of Iceland. A careful comparison of the conditions occurring in the regions of geysers and of solfataras leads the author to the conclusion that only a small part of the water ejected by the geysers is "juvenile," the bulk of it coming from the ordinary ground water. Geysers occur, in effect, where ground water is abundant and volcanic action relatively feeble, and solfataras where volcanic action is more vigorous and the amount of ground water deficient.

WE have received a copy of the meteorological records for 1905, published in the second annual report of the Agricultural Department of the British East Africa Protectorate, which extends, roughly speaking, from 5° N. to 5° S. latitude, the sea coast north of the equator forming part of the Italian Somaliland. The report contains rainfall observations at a large number of stations, and general observations at eight stations, several of which exceed 6000 feet in altitude. The work is a valuable contribution to meteorological knowledge, and will be found most useful when arrangements can be made for dealing with the meteorology of all our colonies according to some regular and properly organised plan. A good beginning was made in this direction by the Meteorological Council in a work entitled "Climatological Observations at Colonial and Foreign Stations, I., Tropical Africa," published in 1904, from tables prepared by Mr. E. G. Ravenstein. This work contained results from several of the stations included in the report of the Nairobi Agricultural Department.

IN his last report as secretary of the Smithsonian Institution of Washington, the late Dr. S. P. Langley dealt with the work of the Astrophysical Observatory for the year ending June 30, 1905. The evidence of solar variability is not in the report considered as conclusive. However, two lines of investigation have become very prominent in the work of the observatory, and these will almost certainly lead to a conclusion regarding this important question. The first of these is the almost daily bolometric examination of the large solar image formed by the great horizontal telescope, for the purpose of detecting changes in the transparency of the solar absorbing envelope. This work depends so little on the transparency of the earth's atmosphere that it can be done almost as well in Washington as at a station more favoured as regards atmospheric transparency. The year's work did not give evidence of very marked variations either in the transparency of the sun's envelope or in the supposedly dependent mean temperature of the earth, but, on the contrary, the results of the observations continued most of the time near the mean in both respects. The second line of investigation is the determination of the total solar radiation outside our atmosphere, by observations with the bolometer and pyrheliometer at a station situated in a relatively clear and cloudless region and at a considerable altitude. This work is being done on Mount Wilson, in southern California, and it seems that the estimates it is hoped to obtain there will be so close an approximation to the truth that if a notable variation of solar radiation outside our atmosphere occurs the results will show it.

THE much-debated n-rays form the subject of a short note by Dr. P. Stefanelli in the *Rendiconto* of the Naples Academy, xi., 12. Referring to Meyer's experiments on the decrease of phosphorescence in sulphide of lime when placed in the glass receiver of an air pump, Dr. Stefanelli considers the effects to be attributable to the fall of temperature produced by the expansion of the air, and not to depend on the existence of n-rays for their explanation.

IN NATURE of January 11 (vol. lxxiii., p. 246) Mr. C. E. Benham pointed out that Swedenborg in his "Principia," published in 1733, constantly regarded both heat and light as ethereal undulations. Mr. I. H. H. Gosset, of St. Aubyns, Hove, now informs us that, as a matter of fact, in the year 1719, fourteen years before he published his "Principia," Swedenborg wrote a treatise "On Tremulation," in which he advanced the theory of ethereal undulations as applicable to our vital forces, light, heat, sound, &c.

IN the *Philosophical Magazine* for April, Prof. Alfred W. Porter discusses the inversion points of the Joule-Kelvin effect for a fluid passing through a porous plug. The paper is a simple and straightforward deduction from the laws of thermodynamics. The condition that an infinitesimal difference of pressure on the two sides of the plug should give rise to no "cooling" or "heating effects" is given by the equation $\mathrm{T}dv/d\mathrm{T}-v=0$, and when the pressure-volume-temperature equation is given, this condition determines a curve in the p,T or v,T diagram formed by the inversion points. Prof. Porter's paper is mainly taken up with examining the form of this curve corresponding to various assumed equations of state, such as that of van der Waals or Dieterici. From the form of the curves it is shown that in general two inversion temperatures exist for the same pressure, between certain limits of pressure; in the case of van der Waals's equation, the maximum limit is nine times the critical pressure. Finally, the author points out that the experimental study of these inversion curves affords a very valuable method of testing the relative validity of different equations of state. Theoretically also a knowledge of the inversion curve and the equation of state referred to any given thermometric scale afford sufficient data to determine the relation between that scale and the absolute temperature.

ACCORDING to the annual report of the Badische Anilin- und Soda-Fabrik, the price of artificial indigo is now one-third less than that of the natural product, the yield of which was last year so small that the requirements of the eastern markets could not be satisfied.

IN the *Far Eastern Review* (vol. ii., No. 9), a monthly engineering journal published at Manila, Shanghai, and Yokohama, Mr. A. C. Hobble gives some excellent illustrations of the largest hydroelectric installation in southern Asia, at the Cauvery River Falls, in Mysore. There is a fall of 400 feet. Power is transmitted at a pressure of 35,000 volts over duplicate 3-phase lines a distance of 92 miles to the Kolar gold mines.

IN the *Chemiker Zeitung* we read of a serious laboratory accident to Dr. Franz Wartensberger, a German chemist, who is credited with having discovered a new explosive considerably more violent than dynamite, and to whom it is said that the American Government offered to pay one million dollars for the explosive, provided its discoverer were able to suggest a suitable method of firing it electrically instead of using a fuse. As Dr. Wartensberger was experimenting with this idea in mind an unexpected explosion is supposed to have taken place, and he was so badly hurt that it is doubtful whether he will recover.

THE ash of the Vesuvius eruption contained, according to Prof. Zinno's analysis, various quantities of silica, alumina, lime, magnesia, iron, and manganese; traces of ammonium chloride were frequently found, but these may possibly have been formed after the ash had fallen. No indications of either free sulphur or of free acid were detectable. The deposit of the ash is held to have been beneficial to vegetation rather than the reverse, especially in the growth of vines, grass, and vegetables, a fact that has been observed on other occasions.

IN an interesting note to the *Chemiker Zeitung* for April 21, Dr. M. C. Schuyten, of Antwerp, directs attention to the differences of temperature which are observable in chemical drying cupboards. Dr. Schuyten was led to consider the question experimentally from the fact that mercury phenyldimethylpyrazolone bromide was found to melt in a drying cupboard when the thermometer did not register a temperature so high as its melting point. The temperature of the air in the cupboard was observed in the great majority of cases to be very much less than that of the walls and shelves; a volatile liquid placed in a vessel in direct communication with the case evaporated much more quickly than when suspended by threads. From the numerical data given variations of 20° C. and more are noticeable.

WE learn from the *Chemist and Druggist* that the Committee on Ways and Means, which sat at Washington on March 30, authorised a favourable report on the Free Alcohol Bill, which removes the internal revenue duty from denaturised alcohol for use in the arts and sciences. The Bill has the approval of Commissioner Yerkes, and it is estimated that the annual loss in revenue will not exceed 100,000*l*., and may not be more than 60,000*l*. It is held that the Bill will be of great benefit to manufacturers, and will afford an enlarged market for farm products from which alcohol is made. The sale of denaturised alcohol as a beverage or for liquid medicinal purposes is forbidden by the measure.

THE following particulars of two prizes offered by the French Government may prove of interest to industrial chemists:—(i.) The methylation of alcohol (prize of 20,000 francs). (1) The smell and taste of the proposed methylating addition must be such as to preclude the use of methylated alcohol as a drink; (2) the smell of the methylating addition must, however, not be so objectionable and strong as to prove harmful to those engaged in the manufacture of or in industries using methylated spirits, that is to say, the use of such bodies as acetylene, asafœtida, garlic, &c., is not permitted; (3) the method of methylating adopted may not leave any deposit on the wick or on any part of the lamp, if likely to interfere with the process of burning, as, for example, sea salt, sodium sulphate, alum, tincture of aloes, &c.; (4) the methylating additive may not be separable by fractional distillation; (5) it may not contain any substance which will attack the metallic parts of lamps or motors, *e.g.* ammonia, nitrobenzene, sulphuric acid, carbon bisulphide, &c.; (6) nor may it be poisonous; (7) further, its cost must not be so high as to prejudice the use of methylated spirits for industrial purposes or household use; (8) its presence in methylated alcohol must be easily detectable; (9) it must possess advantages over that now in use in France, and not permit of any swindling of the Excise. It might be remarked that the discovery of a methylating additive which shall fulfil all the foregoing conditions is a matter of great difficulty; indeed, four years ago the Russian Government offered a prize of about 50,000 marks for a similar purpose, without, however, as yet having had a satisfactory entry. (ii.) The use of alcohol for illuminating purposes (prize of 50,000 francs). In this the competitors are allowed full scope as to the proposed system to be followed in order that alcohol may be used for illuminating purposes under the same conditions as petroleum. Suggestions, together with the necessary apparatus and methods of using, are to be sent to the Chef du Service des Laboratoirs du Ministère des Finances, 11 rue de la Douane, Paris.

IT was pointed out recently by a correspondent of the *Times* that though in the manufacture of pig-iron before 1880 England was preeminent, and the product was 50 per cent. more than that of the United States and Germany combined, yet ten years later the former country produced more than England, and the United States and Germany together twice as much. In 1903 Germany produced more than England, while the United States alone produced twice as much as England. In 1880 England produced 45 per cent. of the world's make, Germany 15 per cent., the United States 14 per cent. In 1903 the United States produced 39 per cent., Germany 20 per cent., and England only 19 per cent. With steel the case is even worse. Since 1880 steel has replaced wrought iron in nearly all manufactures, and in 1830 the United States and Germany manufactured about 30 per cent. less than England. In 1888 the United States equalled England. In 1893 Germany nearly equalled, and the United States largely exceeded England. About 1898 Germany's manufacture was much greater than that of England, and America's manufacture three times as great. These figures show that during the last twenty-five years England has receded from a position of great preeminence to the lowest place among the three great steel-producing countries. On the other hand, between 1900 and 1905, the importation of iron and steel into England increased very largely, the importation in 1905 being 1,435,000 tons, as against 741,402 tons in 1900.

MESSRS. E. DENT AND CO. have lately introduced a new astronomical clock which should find its way into many observatories where an accurate instrument is required at a moderate cost. For the sum of 21*l*. they supply a clock with a 10-inch dial, dead-beat escapement, and wooden rod seconds pendulum in a solid mahogany case; and after examining the instrument we have no hesitation in pronouncing it a marvel of cheapness.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES IN MAY:—

May 1–6. Epoch of Aquarid meteoric shower (Radiant 338° – 2°).
2. 17h. Mercury at greatest elongation, 26° 46′ W.
4. 10h. 4m. Minimum of Algol (β Persei).
5. 13h. 33m. to 14h. 3m. Moon occults γ Virginis (mag. 3·0).
6. 2h. Venus in conjunction with Mars. (Venus 0° 5′ S).
May 11. 15h. Venus in conjunction with Jupiter. (Venus 1° 11′ N.).
15. Venus. Illuminated portion of disc = 0·921. Of Mars = 0·990.
18. 0h. Mars in conjunction with Jupiter. (Mars 1° 6′ N).
20. 23h. Ceres in conjunction with Moon. (Ceres 1° 6′ S.).
24. 5h. Mars in conjunction with Moon. (Mars 4° 57′ N.).
,, 11h. 46m. Minimum of Algol (β Persei).
25. 3h. Venus in conjunction with Moon. (Venus 4° 51′ N.).
27. 8h. 35m. Minimum of Algol (β Persei).

COMETS 1906*a* AND 1906*c*.—The results of a number of observations of comets 1906*a* and 1906*c*, made at the Royal Observatory at Arcetri during February and March, are recorded in No. 4083 of the *Astronomische Nachrichten* by Prof. Abetti.

The same journal also contains the following set of elements, and an ephemeris extending to May 8, for comet 1906*c*, computed by Herr E. Strömgren from places determined on March 19 (Nizza), 22 (Glasgow, Mo.), and 29 (Arcetri).

Elements.

$$T = 1906 \text{ Feb. } 20{\cdot}7555 \text{ M.T. Berlin.}$$
$$\left.\begin{array}{l}\omega = 274^\circ\ 46'{\cdot}4 \\ \Omega = 71^\circ\ 47'{\cdot}7 \\ i = 84^\circ\ 36'{\cdot}8\end{array}\right\} 1906{\cdot}0$$
$$\log q = 9{\cdot}84916$$

THE TOTAL SOLAR ECLIPSE OF JANUARY, 1908.—For the information of those astronomers who intend to observe next January's eclipse, Dr. Downing has prepared a number of astronomical details for the observations at two islands in the Pacific which are favourably placed.

These two stations are Hull Island (long. = 172° 13′ W., lat. = 4° 30′ S.) and Flint Island (long. = 151° 48′ W., lat. = 11° 26′ S.), now the properties of Lever's Pacific Plantations Company, Port Sunlight, Cheshire, with whom intending observers should communicate.

As the errors of the moon's tabular places now amount to sensible and apparently increasing quantities, Dr. Downing warns observers that the calculated times of the several phases may differ sensibly from the observed times. To obviate the possible inconvenience arising from this source, he gives the number of seconds before the commencement of totality that the cusps will subtend specified angles (Monthly Notices R.A.S., vol. lxvi., No. 5).

RADIANT POINT OF A BRIGHT METEOR.—In No. 4083 of the *Astronomische Nachrichten* Dr. Jiří Kaván publishes an account of a bright meteor observed at Prague at 6h. 21m. (M.E.T.) on October 1, 1905.

From observations of the altitude and azimuth, Dr. Kaván has deduced the following positions for the beginning and end points of the meteor's path:—

Beginning	$\alpha = 293°{\cdot}1$ ...	$\delta = -\ 2°{\cdot}6$
End	$\alpha = 273°{\cdot}4$ ...	$\delta = -11°{\cdot}1$

The duration of the meteor's flight was 2 to 2·5 seconds, and the colour of the object was green.

LUMINOUS PARTICLES IN THE CHROMOSPHERE.—The details of the equipment employed by Dr. Deslandres, in his experiments to determine whether the chromosphere contains luminous liquid or solid particles, are described in No. 14 (April 2) of the *Comptes rendus*. The results of the experiments were briefly described in these columns on April 19 (vol. lxxiii., p. 592).

NEW CATALOGUE OF DOUBLE STARS.—In No. 93 of the Lick Observatory Bulletins, Prof. R. G. Aitken publishes the detailed measures of 350 new double stars, A 901 to A 1250 inclusive. The stars contained in the present catalogue are similar in character to those published in Prof. Aitken's previous lists; 267 of them, or 76 per cent. of the entire number, have apparent distances less than 2″, 31 of them less than 0″·25, while only 9 approach the limit of 5″. Some of the pairs consist of closer components to Struve and Herschel stars, and most of them were observed with the 36-inch refractor.

EXPLORATIONS IN THE HIMALAYAS.

THE paper read by Mrs. Bullock Workman before the Royal Geographical Society in November last is published in the February number of the *Geographical Journal*. An account is given of the exploring work carried out by Dr. and Mrs. Bullock Workman during 1903 in the region of the Karakoram mountains lying south-west of the Hispar glacier, or between that glacier and the Indus. This region is cut off from the Hispar glacier by a practically continuous ridge, and is crossed by glaciers moving from north and north-west, the chief being the Chogo Lungma, Alchori, Hoh Lumba, and Sosbon glaciers. The work of the expedition consisted chiefly in the examination of the Hoh Lumba and Sosbon glaciers, and in ascents of Mounts Chogo (21,500 feet) and Lungma (22,568 feet), near the head of the Chogo Lungma glacier.

The narrow Hoh ravine runs northward from the junction with the Braldo River, and is ascended along the precipitous cliffs of nude mountains. It is filled by old glacial débris several hundreds of feet deep, the river cutting its way often at a great depth. Some four miles up is Pirnar Tapsa, a small grazing ground, and two miles beyond is Nangma Tapsa, a similar spot at an elevation of 11,595 feet. Immediately above this is a huge terminal moraine, of which we are able to reproduce a photograph. The snout of the glacier is about a mile further up, and the total length from the snout to the source on the "col des Aiguilles" is twelve miles. The expedition found much evidence that the glacier has retreated somewhat rapidly of late years.

FIG. 1.—Nangma Tapsa and the huge terminal moraine of the Hoh Lumba, forming a large hill about 500 feet high; its age is indicated by the tree growth covering its surface.

OSMOSIS AND OSMOTIC PRESSURE.

NO problem is of greater importance in modern physical chemistry than the determination of the true nature of osmosis and of osmotic pressure. Although for some considerable period this problem has to most chemists appeared solved, several recent investigations have thrown doubt upon the validity of van 't Hoff's hypothesis that the osmotic pressure developed in solutions is purely a kinetic phenomenon. The experiments of Battelli and Stephanini in this connection have already been referred to in NATURE (vol. lxxii., p. 541). Some remarkable results which have been obtained by Prof. Louis Kahlenberg are now described in the Transactions of the Wisconsin Academy (March) and the *Journal of Physical Chemistry* (vol. x., pp. 141–209); these, if subsequently verified, will invalidate van 't Hoff's theory, and, what is of even greater importance, destroy the basis of the theory of electrolytic dissociation, developed by Arrhenius, upon which modern physical chemistry so largely depends.

Prof. Kahlenberg's experiments would indicate that the osmotic pressure developed in the case of any solution depends essentially on the nature of the membrane used, even when this is practically semi-permeable, as well as on the nature and concentration of the solution. Strictly speaking, there is no definite osmotic pressure characterising a solution of given concentration at a definite temperature; the pressure depends on the septum employed. It is recalled to mind that van 't Hoff's conception really rests on the measurements of osmotic pressure made by Pfeffer, that these measurements were few in number and were obtained with one membrane only, and that several recent direct measurements of osmotic pressures have given values not in accord with the gas laws. It is stated that in order to obtain a definite value for the osmotic pressure it is absolutely necessary that the solution within the osmometer should be well stirred, a precaution that has hitherto been omitted in all measurements. The measurements obtained by the author, observing this precaution, did not agree in any case with the gas laws.

The magnitude as well as the direction of the osmotic pressure are, according to Prof. Kahlenberg, determined by the power of the membrane to "imbibe" the solvent and solute, and by the mutual solubilities of the substances dealt with. Cases of abnormal dialysis are adduced in support of this theory. Thus a colloid, copper oleate, dissolved in pyridine, will diffuse through a rubber membrane, whilst a crystalloid, cane sugar, remains behind. Again, when a solution of camphor and cane sugar in pyridine is subjected to dialysis through the same membrane, the camphor diffuses through it, and the cane sugar is again left behind. In this case two crystalloids are separated completely by dialysis. Such facts are not reconcilable with the ordinary views of diffusion. Some suggestive remarks by the late Prof. Raoult, contained in a letter to Prof. Bancroft, in criticism of van 't Hoff's theory are now published for the first time.

MARINE BIOLOGY ON THE WEST COAST.[1]

THE report for 1905 on the Lancashire Sea Fisheries Laboratory at the University of Liverpool and the Sea Fish Hatchery at Piel is a somewhat thicker volume than was the report for 1904, and contains some interesting papers.

Besides the introduction and general account of the work by Prof. Herdman, and a report upon the classes, visitors, &c., at Piel by Mr. Andrew Scott, it contains eleven scientific papers, two of which are from Prof. Herdman's pen, while Mr. James Johnstone is responsible for five and Mr. Andrew Scott for four, one of which he contributes jointly with Mr. Thomas Baxter. The papers are upon the same lines of work as have been carried on in previous years, but the one upon mussel transplantation, by Messrs. Scott and Baxter, describes for the first time an experi-

[1] No. xiv. Report for 1905 on the Lancashire Sea Fisheries Laboratory at the University of Liverpool and the Sea Fish Hatchery at Piel. Drawn up by Prof. W. A. Herdman, F.R.S., Hon. Director of the Scientific Work, assisted by Mr. Andrew Scott and Mr. James Johnstone. Illustrated. (Liverpool, 1906.)

ment commenced some years ago, which has given interesting results. The removal of mussels from overcrowded beds and the laying down of new grounds and the restocking of old ones has proved eminently successful, and the increased rate of growth of transplanted individuals is very marked.

From the report on the sea-fish hatching at Piel we learn that more than a million plaice larvæ and nearly twelve million flounder larvæ were liberated during the breeding season, and a similar report upon the sea-fish hatching at Port Erin shows that five million plaice larvæ were liberated off the Isle of Man, but we look in vain for any word which will show us that the liberation of these fry during several years has produced any effect upon the fisheries of the district.

An interesting paper upon trawling observations, by Mr. James Johnstone, contains a section upon the food of plaice, dabs, and other fishes, and we gather that the results so far obtained tend to show that the plaice and the dab are not competitors for food, although living upon the same ground; that whereas the former feed chiefly upon molluscs, the latter prefer Ophiurids and Crustacea, although they are less particular as to the nature of their food than are the plaice. Mr. Todd's observations as to the food of these species in the North Sea seem to bear out the omnivorous tendency of the dab, but they also seem to show that the chief food of both species in that region consists of molluscs.

Mr. Johnstone also contributes a paper on the marked fish experiments, in which he sets out the migrations of the plaice in the district, as shown by the re-capture of marked specimens. He finds that the fish tend to move along the shore lines during the winter months, and to migrate off-shore during the summer months, which facts appear to agree with the results so far determined as to the migrations of this species in the North Sea.

Mr. Andrew Scott's report on the tow-nettings for the year contains a large amount of material, but the author has not drawn conclusions therefrom, so that the paper is somewhat heavy reading.

Prof. Herdman's paper upon the oligodynamic action of copper, dealing with the possibilities of purifying infected shell-fish by immersion in distilled water which has been in contact with copper-foil, is extremely interesting, but is in the nature of a preliminary statement, as he is about to investigate the whole question in conjunction with Prof. B. Moore.

The volume is illustrated, including a useful series of plates of copepods, trematodes, &c., in connection with Mr. Andrew Scott's "Faunistic Notes."

FRANK BALFOUR BROWNE.

PHYSIOLOGICAL EFFECTS OF MENTAL ACTIONS.

THE most recent number of the *Beiträge zur Psychologie und Philosophie* (Band i., Heft 4) contains two articles, one by the editor, Prof. Martius, on the theory of the influence exerted on pulse and respiration by mental stimuli, while the other, by Mr. C. Minnemann, discusses pulse and respiration as studied in the subjects of genuine, first-hand emotion. Prof. Martius starts with pointing out the contradictory opinions held by other investigators regarding the effect of attention, of joyful or painful emotions on pulse and respiration. This diversity he regards as partly due to the neglect of several precautions, and he proceeds to study, amongst other points, those fluctuations of the pulse which are in direct correspondence with respiration periods. He then examines the plethysmographic method, and comes to the conclusion that variations of volume registered by it are partly due to movements of the limb under investigation, and that the method cannot be used at present to secure any definite results regarding the circulation of the blood.

Elaborate details and analyses are next given of his experiments on five human subjects; they are classed thus:—(1) effects on the pulse of artificial alterations in respiration (*e.g.* deepening, acceleration, retardation of breathing); (2) effects of bodily activity on pulse and respiration; (3) effects of mental activity; (4) effects of bodily pain; (5) effects of taste and smell (whether pleasant or unpleasant; (6) effects of moods (of joy and depression) artificially induced, *e.g.* by hearing witty stories, recalling the contents of certain poems, or the like.

With regard to many points Prof. Martius thinks that definite conclusions are at present impossible; all that he regards as established is the presence of a series of types of general emotional or "affective" states, and especially the distinction of the two types of activity and rest. But the methods described are insufficient to characterise definitely for us special emotions like those of fear or sympathy. It seems established, too, that joy and sorrow do not possess definite complexes of symptoms by which they can be separated from one another, and further, bodily and mental activity produce the same appearances. Hence while the will and the intellect are not to be regarded as one, they cannot be separated, and we can never analyse the products of intellect merely into sensations and feelings. The other article follows the same lines and reaches a similarly safe conclusion, that we can read out of the experiment curves nothing but the most general characteristics of emotional states, viz. excitement or repression.

DISCOVERY OF SEVEN THOUSAND ROMAN COINS.

A COARSE earthenware jar containing upwards of seven thousand "third brass" Roman coins was recently unearthed by the ploughshare on the farm of Mrs. Wheatley, Stanley, near Wakefield. In very early times the bed of the river Calder, which has a remarkable sweep at this point, was deepened by the ancient Britons or Romans, and an embankment made with the sand; in this the jar, with its contents, was deposited 1500 years ago.

The coins all belong to the Constantinian group; to Constantine the Great, to his mother Helena, his stepmother Theodora, his four sons, Crispus, Constantine, Constantius, and Constans, Licinius his brother-in-law, with his wife Constantina and their son Licinius, and to Delmatius. The reverses are chiefly of the "Gloria Exercitus" type.

One-half, of nearly five thousand coins, which I have carefully examined is, in about equal quantities, of the "Urbs Roma" type, with wolf and twins on the reverse, and "Constantinopolis," with a Victory on the reverse with spear and shield, standing on the prow of a vessel; these latter were struck to commemorate the founding of Constantinople A.D. 330. There are twelve represented of the twenty-four mints of issue known to us, among which are Carthage, Alexandria, Antioch, Rome; but most are from Treves in Germany, the residence of the governor of the west, Lyons, and Constantina, now Arles in France.

Very few of them, if any, have ever been in circulation. They are most likely a portion of a military chest concealed during a threatened raid or invasion. It is remarkable that ten or twelve years ago a find of seventeen thousand was made in the Forest of Dean, covering the same period, of exactly the same types, with a similar redundancy of certain coins and a scarcity of others. A series of the Stanley coins has been presented to the museum of the Leeds Philosophical and Literary Society, and are now on exhibition.

AQUILA DODGSON.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The date of the fellowship examination in chemistry at Merton College has been altered from September 25 to September 18. Candidates are asked to send their names to the Warden on or before September 1, and to call on him on September 17, by which date they should submit to him any dissertations or papers, or evidence of research they have done.

During the vacancy of the Linacre chair of comparative anatomy, Mr. Edwin S. Goodrich, fellow of Merton College, has been appointed to act as deputy-professor.

New College has resolved to raise the college contribution to the stipend of the Wykeham professor of physics to 650*l.* a year, thereby increasing the total income of the professorship to 800*l.* a year.

H. W. Normanton, of Batley Grammar School, has been elected to a natural science postmastership at Merton College. A. H. Simpson, of Rugby School, has been elected to a natural science scholarship at Corpus Christi College.

CAMBRIDGE.—The striking success of the Appointments Board in procuring appointments for young graduates at Cambridge is shown by the following figures:—in 1902 the number of appointments obtained was 67; in 1903, 93; in 1904, 102; in 1905, 134. These appointments fall mainly into the following classes:—appointments under various public authorities at home and abroad, industrial and technical appointments, administrative appointments on railways, appointments for scientific work of various kinds, and lectureships in university colleges.

Major E. H. Hills, C.M.G., R.E., late head of the Topographical Department of the War Office, will deliver a public lecture on the geography of international frontiers, at the Sedgwick Museum, on Saturday, May 5.

The governing body of Gonville and Caius College, Cambridge, proposes in the summer, if suitable candidates apply, to make an election to the Wollaston research studentship in physics. The value of the studentship will be 120*l*. a year. It will be tenable in the first instance for one year, but may be prolonged for a second year. Candidates for the studentship must be more than twenty-one and under twenty-five years of age on the first day of October, 1906. The studentship is open to students of all British, colonial, and American universities. Applications should be made before July 21 to the Master (the Rev. E. S. Roberts).

The Gilbey lecturer on the history and economics of agriculture gives notice that he will lecture on "The Relations of Rent, Profits and Wages in Agriculture, and the bearing on Rural Depopulation," on Tuesday, May 15, and the three following days.

By the bequest of Dr. E. H. Perowne, the late Master of Corpus, a fine collection of specimens of amber has been acquired by the Sedgwick Museum.

ON Commemoration Day, Wednesday, May 9, after the presentation of graduates at the University of London, there will be a reception at Bedford College for Women from four to seven o'clock.

PROF. T. W. RICHARDS, professor of chemistry at Harvard University, has been designated by the German Government as Harvard visiting professor at the University of Berlin for the academic year 1906–7.

THE fiftieth anniversary of the foundation of the University of Melbourne was celebrated last week. Congratulatory addresses were presented by representatives of British and other universities.

IT is proposed to form an association of past students of the Technical College, Finsbury. With this end in view a meeting of old students will be held at the college on May 8. Sir Owen Roberts will preside. Any old student who has not received a notice of this meeting is requested to communicate with Mr. J. W. G. Brooker, Durlstone, Brockley Park, Forest Hill, S.E.

PROF. WALTER NERNST, director of the chemical physics institute, Berlin, is to deliver a course of lectures on experimental and theoretical applications of thermodynamics in Yale University, Connecticut. He will also give the Silliman lectures, founded in memory of Benjamin Silliman, father and son, the former of whom was connected with Yale so far back as 1805, and is best known to European people as the founder of *Silliman's American Journal of Science and Arts*.

UNDER the doubtfully appropriate title of "Technical Overtraining in Germany," attention is directed in the Journal of the Society of Arts for March 30 to what is undoubtedly a real danger. It is not a question of overtraining in the sense that the courses of the technical colleges are of too high a scientific standard, but the danger lies in the great increase in the number of technically trained students, an increase which makes the supply greatly in excess of the demand. A survey of the figures given, which are largely based on the report of the American Consul at Mannheim, shows that in such branches of technical instruction as building, for example, there has been an increase of, say, 200 per cent. in ten years in the output of the technical colleges, whereas in such subjects as medicine and theology there has been a considerable falling off in the number of students. As the writer of the note points out, "The consequence of this over-production in technical resources is a constantly diminishing rate of wages."

THE Government of India has decided, says the *Pioneer Mail*, to make to the Punjab University for the next four years an annual grant of 20,000 rupees. The main purpose of the grant is to assist in the improvement and efficiency of the constituent colleges in those respects in which an inspection by the University showed them to be defective. The Government of India has decided that no part of the grant shall be devoted to the improvement of the Government colleges. In addition to this grant, another of 10,000 rupees a year for four years has been assigned to the Punjab University by the Government of India. This sum is to be regarded as a consolidated grant to be applied primarily to the inspection of colleges and to strengthening the administration of the University. The Government of India has made a further grant of 30,000 rupees a year for four years for building purposes and for the equipment of the new Senate hall and the University library.

SPEAKING on Saturday last at the opening of a new grammar school at Farnham, the Archbishop of Canterbury remarked that secondary education in England has not made progress during the last fifty years commensurate with that made by those forms of education that are both above and below it. He believes that the explanation lies in a certain unwillingness to bring this kind of education under central government and organisation. He does not believe that either the German or French people are more anxious as a whole for higher education than we are in England, but they will consent to what English people will not consent to, viz. a kind of drilling on the subject which will bring about a uniformity that can better promote progress than the more lax, scattered, and independent efforts which the people of this country in their national nature prefer to the more hide-bound and red-tape systems. The Education Bill recently introduced in Parliament, if it passes into law, will give English people an opportunity which they have never had before of taxing themselves ten times as much for secondary education. No one will be forced to do it, but everyone will be able to do it, and those who have been pining to be able to give more largely to the cause of secondary education will, if the Bill becomes law, have an opportunity of doing so.

THE paramount importance of secondary education in any national system designed to educate the children of all social grades becomes more recognised every year by those in authority. The presence of the President of the Board of Education at the opening of the new county school at Acton on April 28, and of Sir William Anson, late Parliamentary Secretary to the Board of Education, at Sutton Coldfield on April 27, on a similar occasion, are indications of this recognition. Speaking at Acton, Mr. Birrell said the only difference of a philosophical character between elementary and secondary education turns upon the lengths of time available for each. There is naturally a distinction between children who remain at school only to the age of fourteen and those who stay until sixteen or seventeen years of age. The great thing for the nation to accomplish is the wise selection of those children who are fitted to benefit from a prolonged educational course, and to see that they get it, irrespective of their rank or position in life. Sir William Anson, dealing with the question of the curriculum in secondary schools, said he does not think it is possible ever to revert to the old type of classical school. He went on to say that the claims of science are nowadays never likely to be disregarded, but the study of languages should not be neglected. He remarked, in conclusion, that the overloading of the curriculum of secondary schools with subjects which might be postponed to a later stage is a mistake.

IT appears from an article by the special correspondent of the *Times* at Palo Alto, published in Tuesday's issue, that the Leland Stanford Junior University at Palo Alto suffered great damage by the earthquake on April 18. A massive gateway of stone at the main entrance to the University grounds is now a ruin, and the great dragons which surmounted it lie broken to pieces on the ground. An immense memorial arch has been wrecked, and a fine marble memorial to Henry Lathrop, Mrs. Stanford's brother, has been demolished. The museum has been seriously damaged, the whole roof of the art gallery having fallen in, and part of the roof of the other wing. The entire centre of the building devoted to the department of chemistry is a wreck. The gymnasium, just completed and never used, is an absolute ruin, and another large new building, the library, also just completed and about to be dedicated, is in the same condition. The building devoted to zoology and physiology is not much damaged. The president of the University, Dr. D. S. Jordan, who was at home at the time of the earthquake, believes that the shock of April 18 was not only one of the severest, but also one of the longest duration on record. The *Times* correspondent learns also that the narrow-gauge railway to Santa Cruz has been so badly damaged that it will be months before trains can again be run. There are many tunnels on this line, and in various instances these tunnels, which formerly were straight lines, are now corkscrew-shaped. At San Jose a flower garden was turned into a lake of mud from which a dozen geysers burst into activity after the earthquake.

THE current number of the *University Review* contains an inspiring article on "Science and the Public" by Major Ronald Ross, F.R.S., professor of tropical medicine in the University of Liverpool. Insistence is laid on the fact that science is almost exclusively the work of individuals, and that, though willing enough to benefit by the discoveries and inventions of men of science, the public is in no sense imbued with the scientific spirit. Instead of cultivating the absolutely impartial judgment demanded by science, the public encourages the habit of mind eulogised by Tennyson, "believing where we cannot prove," and forgets there is nothing meritorious in such conduct, but much that is the reverse. The essay proceeds to show that to this willingness to ignore science and scientific methods may be traced the credulity of the public which leads it to subsidise quack medicine, to ignore beneficent discoveries like that of Jenner, to hamper scientific research by unintelligent anti-vivisection societies, and generally to proclaim its adherence to the policy of "muddling through." An instance is given by Major Ross from his own experience which shows how slightly as yet the mass of mankind has been influenced by scientific methods. More than seven years ago it was demonstrated that malaria is conveyed from man to man by a group of gnats, and several obvious and practicable modes of prevention were suggested in consequence of the discovery. But when these measures were urged upon the public and governments of our tropical colonies, the so-called educated white people scoffed at the whole discovery, without troubling to ascertain the facts, and the governments, with the exception of a few, took no action which could for a moment be called adequate. The magnitude of the offence may be gathered when it is remembered that half the people in the tropics suffer from the disease every year; but in view of recent events it is easy to see that the world will be dominated eventually more and more by the disciplined and scientific peoples, and those nations which reject science will be set aside.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, January 25.—"An Electrical Measuring Machine." By Dr. P. E. **Shaw.** Communicated by Prof. J. H. Poynting, F.R.S.

The principle of the measuring machines in general use is that one face of the gauge rests against one jaw, fixed, of the machine, whilst the other jaw is moved forward by a screw until it touches the other face. These machines may be called mechanical-touch machines in contradistinction to the new machine called the electric-touch machine. This depends on the same general principle as the electric micrometer used by the author in several researches.

Objections to the mechanical-touch methods are:—(1) they involve strain in the machine of a much larger order than in the electric method; (2) they are less sensitive; (3) it is impossible to measure between point and point. To measure between points or rounded points is essential in accurate metrology, especially for gauges with flat ends; for when each jaw has a flat face and each end of the gauge has also a flat face, each of these four faces having errors in planeness and parallelism, the resulting measurements must be erroneous. If, however, measurement be taken between small spheres on the screw ends, no assumptions as to planeness and parallelism are made, and such errors vanish from the results.

The electric measuring machine consists of (*a*) two head-stocks containing micrometer screws; (*b*) a table to carry the gauge; (*c*) a massive slide bed, on which run the head-stocks and table. The gauge to be measured is clamped on the table, and is set true with respect to the micrometer screws by two rotations and two translations provided in the table. This adjustment is made by special electric-touch methods devised for the purpose. To make a measurement of the gauge the left screw is brought into electric contact (indicated by a telephone) with the gauge; then the right screw is brought into electric touch with it, and when current passes through from one measuring point to the other the two divided heads on the micrometer screws are read. To turn the graduated head the screw system is not actually touched by the hand, but is worked by an outside hand-pulley and string.

Special care is taken in the design of the machine to avoid periodical screw error and backlash.

A careful calibration by wave-lengths of several millimetres of the screws shows where they are specially uniform, and therefore fit for use.

Results are obtained for all kinds of gauges. For bar gauges with flat ends, measurements taken at many places reveal considerable variation in thickness, so that irregular contour curves, roughly centred in the centre of the gauge faces, can be drawn showing that the ends are far from being plane or parallel. These errors in bar gauges have not been previously pointed out or measured. The author contends that all bar gauges should be measured by this method and the errors registered, so that, even if the errors are not corrected, by re-scraping or otherwise, they will be known and allowed for.

Cylindrical and spherical gauges are also tested; these are shown to be much more nearly perfect than bar gauges.

A further use of the machine is in the measurement of non-conducting bodies, such as glass plates, the thickness of which can be measured with great accuracy.

Readings are taken with ease and certainty to 1/250,000th of an inch, and one-quarter of this can be obtained if specially desired.

March 1.—"An Experimental Inquiry into the Factors which determine the Growth and Activity of the Mammary Glands." By Miss J. E. **Lane-Claypon**, D.Sc., and Prof. E. H. **Starling**, F.R.S.

So far as the authors' experiments go, they show that the growth of the mammary glands during pregnancy is due to the action of a specific chemical stimulus produced in the fertilised ovum. The amount of this substance increases with the growth of the fœtus, and is therefore largest during the latter half of pregnancy. Lactation is due to the removal of this substance, which must therefore be regarded as exerting an inhibitory influence on the gland cells, hindering their secretory activity and furthering their growth. It is probable that the specific substance is diffusible, and will withstand the boiling temperature.

The authors do not, however, claim that these conclusions are firmly established. A final decision can only be given by a research carried on under more favourable conditions. In fact, a farm is required where the authors could have at their disposal 500 rabbits, and could arrange for a plentiful supply each day of rabbits about the middle of pregnancy.

Zoological Society, April 10.—Mr. H. Druce, vice-president, in the chair.—The fresh-water fishes of the island of Trinidad: C. Tate **Regan**. The author's remarks were chiefly based on a collection made by Mr. Lechmere Guppy, jun., and presented by him to the British Museum.

The collection was accompanied by natural history notes and by a series of beautifully executed water-colour drawings. Forty species of fresh-water fishes were now known from the island; these were enumerated in the paper, and four of them described as new to science.—The collection of Alcyonarians made by Mr. Cyril Crossland at Zanzibar in 1901–2: Prof. J. A. **Thomson** and W. D. **Henderson.** Specimens of sixty-five species or varieties were contained in the collection, of which twenty-seven were described as new.—Cyclopia in osseous fishes, as observed in several advanced trout embryos: Dr. J. F. **Gemmill.** A detailed account of the anatomy of the specimens was given, and a comparison made with Cyclopia in mammals. The author's views were also put forward regarding the mode of origin of this condition in fishes.—Cases of supernumerary eyes, and local deficiency and re-duplication of the notochord, in trout embryos: Dr. **Gemmill.**—Descriptions of three new varieties of butterflies of the genus Heliconius: P. J. **Lathy.**

Faraday Society, April 10.—Prof. A. K. Huntington in the chair.—Electrothermics of iron and steel: C. A. **Keller.** The author deals with the present position of his processes; he describes the electrical steel plant which Messrs. J. Holtzer and Co. have just installed in their works at Unieux (Loire). This is a 1500 h.p. plant, and will utilise in a single furnace the current from a 20,000-ampere Westinghouse alternator. The furnace, which rests on a steel cradle and can be tilted, weighs about 50,000 kilos.; the various mechanical and electrical controls are obtained by hydraulic motors. The steel obtained from a Siemens-Martin furnace will be run into the electric furnace immediately after the oxidising melt, and for the remaining operations of deoxidising and refining the current exclusively will be used.—Note on the rotating electric steel furnace in the Artillery Construction Works, Turin: Ernesto **Stassano.** The furnace described and illustrated in the paper is being installed by the "Forni Termoelettrici Stassano" Company for the Italian War Office. It is of the author's well-known arc type, and absorbs 140 kilowatts, yielding 2400 kilos. of steel in twenty-four hours. The current is a rotary one with 80 volts between each phase. The consumption of electrodes is less than 5 kilos. per ton of steel, and the cost of renewing the refractory covering of the furnace 10 francs per ton of metal made. The furnace is principally used for refining pig-iron and smelting scrap. The product ordinarily made is used for artillery projectiles.—Note on recent developments in the Gin electric steel furnace: Gustave **Gin.** The author's canal-type of furnace is now installed at the Plettenberg Works, Westphalia, of which illustrations are given in the paper, but it is not stated which particular type of furnace has there been experimented with. The following types are described:—(1) furnace with canals and chambers; (2) combination furnace; (3) induction furnace.—Notes on the cleaning of work by means of the electric current: H. S. **Coleman.** The work to be cleaned (usually preparatory to electro-plating) is suspended in a hot solution of equal quantities of brown Montreal potash and sodium hydrate contained in a wrought-iron tank. The work and the tank are connected to a dynamo, and the tank used as the anode for five to ten minutes, the voltage being about 2·5. The current is then reversed for a short time, until the surface of the work is clear and bright. The operation is repeated as many times as may be necessary.

Royal Meteorological Society, April 18.—Mr. R. Bentley, president, in the chair.—Some so-called vagaries of lightning reproduced experimentally: A. **Hands.** The author, in the course of an extended investigation into the effects of lightning, has come across many cases that have been called vagaries, but which on a close inspection have proved to be extraordinary only in the erroneous way in which they were described, and, had they been correctly reported, would have appeared perfectly consistent with preconceived ideas—in fact, could have been foretold in every case if the conditions that led to those effects had been known before the events occurred. The author reproduced experimentally several so-called vagaries of lightning, showing by means of rough models the conditions under which they occurred.—The value of a projected image of the sun for meteorological study: Miss C. O. **Stevens.** By this method it has been ascertained that where the direction of movement of the atmosphere is tangential to the limb of the sun, the phenomenon of "boiling" displays a coursing or rippling character, and that where it is perpendicular to the limb of the sun, the character of the movements of distortion is that of springing in and out of the area of the sun's image. Both these elements of movement are continuous even in the absence of all visible cloud, and it is possible, not only to detect, but also to distinguish between overlying invisible atmospheric strata.

Mathematical Society, April 26.—Prof. A. R. Forsyth, president, and subsequently Prof. W. Burnside, vice-president, in the chair.—Perpetuants and contra-perpetuants: Prof. E. B. **Elliott.** It is proposed to apply a method, based on the use of symmetric functions and of certain differential operators, to the discovery of complete systems of perpetuants of given partial degrees in assigned sets of coefficients, which shall be equivalent in their aggregate to those which have been arrived at by the systematic examination of symbolic products. Contra-perpetuants are introduced in connection with Hermite's doctrine of reciprocity between degree and extent in systems of seminvariants when this doctrine is correlated with the theory of perpetuants.—A set of intervals about the rational numbers: A. R. **Richardson.** A definite construction is given for associating a set of intervals with the rational numbers, in such a way that all the rational numbers are included in the intervals, and certain definite sets of irrational numbers are excluded from all the intervals.—Some theorems connected with Abel's theorem on the continuity of power series: G. H. **Hardy.** The paper deals with the generalisation, for series of which the terms are continuous functions of a variable, of certain well-known theorems relating to power series. The convergence of Σa_n is sufficient to secure the uniform convergence of $\Sigma a_n f_n(x)$ in an interval in which all the functions $f_n(x)$ are continuous, and these functions diminish in value as n increases; a similar theorem holds also if Σa_n diverges, but is of the type which can be summed by averages.—The canonical forms of the ternary sextic and quaternary quartic: Prof. A. C. **Dixon.** The forms are the sums of ten sixth, or fourth, powers, as the case may be. Processes are given for carrying out the reductions to these forms, and it is shown that in each case there are two solutions.—The accuracy of interpolation by finite differences: W. F. **Sheppard.** The paper deals with the relative accuracy of the ordinary advancing-difference formula and the central-difference formulæ in regard to the two sources of error which arise (1) from omitting the remainder in the series by which the values of a function are calculated, (2) from the fact that tabulated values of a function are only approximate.—The geometrical interpretation of apolar binary forms: C. F. **Russell.** The paper is concerned with geometrical constructions which may be regarded as generalisations of the construction of the fourth harmonic point of three given points in a definite order. For two apolar forms of the same order, analogous to two quadratic forms harmonically related, the construction is linear.—Two cubic curves in triangular relation: Prof. F. **Morley.**—The question of the existence of transfinite numbers: P. E. B. **Jourdain.**—A question in the theory of aggregates: Prof. A. C. **Dixon.**

Paris.

Academy of Sciences, April 17.—M. H. Poincaré in the chair.—The president announced the death of Prof. Langley, correspondant of the academy.—The evaluation of the foco-facial distances of microscopic objectives: L. **Malassez.** A comparison of two experimental methods with the results of a formula developed by the author in previous papers.—Pure ferro-molybdenums: contribution to the study of their constituents: Em. **Vigouroux.** Alloys of iron and molybdenum containing varying proportions of the two constituents were submitted to treatment either with dilute hydrochloric acid or an acid solution of cuprous chloride. The insoluble residues from fourteen separate alloys were analysed, and the following four compounds of iron and molybdenum isolated in a pure state:—Fe_2Mo, Fe_3Mo_2, FeMo, $FeMo_2$. The physical and chemical properties of each of these are given.—A characteristic reaction of ethyl glyoxylate: the action of ammonia on this ether and its derivatives: L. J. **Simon** and G. **Chavanne.** By the action of ammonia on ethyl glyoxylate a substance $C_4H_9N_3O_4$ is formed. This is blue-black in colour, and possesses very powerful tinctorial properties, and hence may form a useful test for this ester. The composition of this substance has not yet been established.—The acid properties of starch: E. **Demoussy.** Starch possesses all the characters of a feeble acid, comparable with carbonic acid, and resembling in this respect the other carbohydrates. It forms compounds with metallic hydroxides which are dissociable by water, and can absorb small quantities of neutral salts. These properties probably play a part in the absorption of mineral matters by plants.—The state of colouring matters in crystals coloured artificially: P. **Gaubert.** It has been shown in previous papers that there are two cases in the artificial colouring of crystals; in the first case the crystal is only coloured when the solution from which the crystal is depositing is nearly saturated with the colouring material; in the other case the crystal is coloured, whatever the dilution of the colouring material. The present paper gives details of measurements made on crystals of the latter class, phthalic acid, with methylene blue in solution. It was found that the ratio of the concentrations of the methylene blue in the liquid and crystals was practically constant, although the absolute concentration of the methylene blue was made to vary within wide limits. Similar results were found with methylene blue and crystals of urea nitrate.—The Vesuvian origin of the dry storm observed at Paris on the morning of April 11: Stanislas **Meunier.** A microscopical examination of the dust deposited during this storm showed it to be identical in nature with the dust from Vesuvius in 1822.

DIARY OF SOCIETIES.

THURSDAY, MAY 3.

ROYAL SOCIETY, at 4.—Election of Fellows.—At 4.30.—On a Static Method of Comparing the Densities of Gases: R. Threlfall, F.R.S.—The Stability of Submarines: Sir William H. White, K.C.B., F.R.S.—The Action on Bacteria of Electrical Discharges of High Potential and Rapid Frequency: A. G. R. Foulerton and A. M. Kellas.—The Action of Pituitary Extracts upon the Kidney: Prof. E. A. Schäfer, F.R.S., and P. T. Herring.

ROYAL INSTITUTION, at 5.—The Digestive Tract in Birds and Mammals: Dr. P. Chalmers Mitchell.

CHEMICAL SOCIETY, at 8.30.—The Relation between Absorption-Spectra and Chemical Constitution, part v.: The *iso*Nitroso-compounds: E. C. C. Baly, E. G. Marsden, and A. W. Stewart.—The Action of Tribromopropane on the Sodium Derivative of Ethyl Malonate, part ii.: W. H. Perkin, jun., and J. L. Simonsen.—Brazilin and Hæmatoxylin, part vii., Some Derivatives of Brazilein: P. Engels, and W. H. Perkin, jun.—Pipitzahoic Acid: J. M. Sanders.—The Constitution of the Hydroxides and Cyanides obtained from Acridine, Methyl-acridine and Phenanthridine Methiodides: C. K. Tinkler.—The Constitution of Ammonium Amalgam: E. M. Rich and M. W. Travers.—Action of Light on Potassium Ferrocyanide: G. W. A. Foster.

LINNEAN SOCIETY, at 8.—Origin of Gymnosperms (*Continuation of Discussion*): Dr. D. H. Scott, F.R.S.

CIVIL AND MECHANICAL ENGINEERS' SOCIETY, at 8.—Some Observations on Bacterial Tank Operations: Dr. W. O. Travis.

FRIDAY, MAY 4.

ROYAL INSTITUTION, at 9.—The Steam Turbine on Land and at Sea: Hon. Charles A. Parsons, C.B., F.R.S.

GEOLOGISTS' ASSOCIATION, at 8.—The Erosion of the Batoka Gorge of the Zambesi: G. W. Lamplugh, F.R.S.

MONDAY, MAY 7.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—From the Victoria Nyanza to Kilimanjaro: Col. G. E. Smith, R.E.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Some Notes on the Gutzeit Test for Arsenic: J. Goode and Dr. F. Mollwo Perkin.—The Separation of Brucine and Strychnine. Influence of Nitrous Acid in Oxidation by Nitric Acid: W. C. Reynolds and R. Sutcliffe.—Absorption of Gallic Acid by Organic Colloids: W. P. Dreaper and A. Wilson.

VICTORIA INSTITUTE, at 4.30.—The Zodiac: its History and Biblical References: Rev. A. B. Grimaldi.

TUESDAY, MAY 8.

SOCIETY OF ARTS, at 8.—Damascening, and the Inlaying and Ornamenting of Metallic Surfaces: Sherard Cowper-Coles.

UNIVERSITY OF LONDON, at 5.—The Atmospheric Circulation and its Relation to Weather: Dr. W. N. Shaw, F.R.S.

ROYAL INSTITUTION, at 5.—Glands and their Products: Prof. W. Stirling.

WEDNESDAY, MAY 9.

SOCIETY OF ARTS, at 8.—Bridge Building by Means of Caissons, including Remarks upon Compressed Air Illness: Prof. Thomas Oliver.

GEOLOGICAL SOCIETY, at 8.—The Eruption of Vesuvius in April, 1906: Prof. Giuseppe de Lorenzo.—The Ordovician Rocks of Western Caermarthenshire: D. C. Evans.

THURSDAY, MAY 10.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: "Adsorption" and "Occlusion": the Law of Distribution in the Case in which one of the Phases possesses Rigidity: Prof. M. W. Travers, F.R.S.—Cyanogenesis in Plants, part iv., Phaseolunatin in Common Flax (*Linum usitatissimum*); part v., The Occurrence of Phaseolunatin in Cassava (*Manihot Aipi* and *Manihot Utilissima*): Prof. W. R. Dunstan, F.R.S., Drs. T. A. Henry, and S. J. M. Auld.—A Variety of Thorianite from Galle, Ceylon: Prof. W. R. Dunstan, F.R.S., and B. Mouat Jones.—The Mechanism of Carbon Assimilation in Green Plants: the Photolytic Decomposition of Carbon Dioxide *in vitro*: F. L. Usher and J. H. Priestley.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Long Flame Arc Lamps: L. Andrews (Adjourned Discussion).

FRIDAY, MAY 11.

ROYAL INSTITUTION, at 9.—Some Astronomical Consequences of the Pressure of Light: Prof. J. H. Poynting, F.R.S.

PHYSICAL SOCIETY, at 8.—The Effect of a Rapid Discharge on the Throw of a Galvanometer: A. Russell.—Exhibition of Lippmann Capillary Dynamo and Electromotor: Prof. H. A. Wilson.—Exhibition of an Apparatus for demonstrating the Movements of the Diaphragms of Telephonic Transmitters and Receivers and the Current flowing into and out of the Cable during Speech: W. Duddell.

ROYAL ASTRONOMICAL SOCIETY, at 5.

MALACOLOGICAL SOCIETY, at 8.—Notes on the Subgenus Malluvium: E. A. Smith, I.S.O.—Notes on some Species of the Genus Mitra, with the Description of *M. Brettinghami*, n.sp: E. A. Smith, I.S.O.—On some Land- and Fresh-water Mollusca from Sumatra, part ii.: Rev. R. Ashington Bullen.—Notes on a Collection of Nudibranchs from the Cape Verde Islands: C. Crossland and Sir Charles Eliot, K.C.M.G.—Notes on Indian and Ceylonese Species of Glessula: Col. R. H. Beddome.

THE CELL IN MODERN BIOLOGY.

Algemeine Biologie. Die Zelle und die Gewebe. Second edition. By Oscar Hertwig. Pp. xvi+648; 371 illustrations. (Jena: Gustav Fischer, 1906.) Price 15 marks.

THE volume before us appears as the second edition of the author's well known treatise on the cell, the first part of which was published so long ago as 1892.

Cytology has advanced a good deal since that time, and one finds a significant recognition of its wider scope in the new title—"General Biology" given by Prof. Hertwig to his book. Experience is showing that the larger problems connected with living things, such as organisation, heredity, function, as well as those abnormal reactions constituting what we call pathology, are all reducible to cell problems.

For the most complex living creature is resolvable into groups of more or less modified cells, and the latter are not merely bound together like faggots in a bundle, but each group, each cell it may be, in so far as it is the seat of chemical or physical change, is able in greater or less degree to exert an influence on other individuals of the cell community. In this way there arise those adjusted relationships that exist between different organs, tissues, and cells which we designate as correlations, and it is just because of the existence of these inter-dependent cellular reactivities that complex organisation has come to be a possibility.

One of the chief aims of Prof. Hertwig's book is to trace the cell in its manifold variety of form and its diverse conditions of activity, especially with reference to the part it plays as a corporate unit of the organism. It is perhaps inevitable that such a task should prove too great for any single writer to accomplish satisfactorily throughout, and, indeed, the present work is by no means free from the faults of its ambition. Some aspects of the subject are exceedingly well treated, others are left comparatively untouched, while in the case of yet others the standpoint taken up perhaps hardly represents that of contemporary thought. The last criticism especially applies to the discussion of some of the physiological attributes of cell life. Again, the more recently studied phenomena of apospory, apogamy, and parthenogenesis, with their general bearings on the processes of maiosis and fertilisation, are very scantily dealt with. The work is decidedly strongest on the morphological side, although even here the treatment seems to suffer from want of the physiological relationships involved.

A considerable portion of the book is occupied with discussions as to the connection that may subsist between the facts of cell structure and the phenomena of ontogeny and heredity. Brief accounts are given of the standpoints adopted and the theories advocated by other writers, and Hertwig adds another of his own, which he terms biogenesis.

It is not very easy to extract the author's exact position with regard to biogenesis, and nowhere in the volume does the theory appear to be summarised and presented in a succinct and complete form. But the doctrine it seems to embody is that development and specialisation of function, with the corresponding segregation of structure, are due to the correlative action of the parts on one another coupled with the influence of agencies operating from without—*i.e.* of the environmental conditions. It is this speculative part of the treatise, suggestive and interesting as it is, that will probably provoke the greatest antagonism. Hertwig is a thorough believer in the inheritance of acquired characters, though it seems not improbable that many will dissent from the interpretations he puts on cases that he apparently regards as critical ones.

The example of the supposed inheritance of immunity against the poisonous action of ricin, shown by Ehrlich to occur in the case of the offspring of mice under certain conditions, can hardly be accepted as satisfactory evidence of the "inheritance of acquired characters" as the phrase is critically understood. Indeed, it seems to break down altogether when the conditions under which it may be observed are examined and analysed. Mice are excessively sensitive to the effects of ricin, very minute doses being sufficient to bring about the death of the animal. But by repeated inoculation of sublethal doses of the poison a mouse may reach a state of immunity against the action of a quantity far greater than that which normally proves fatal. The offspring of *female* immunised mice are themselves also immune, at least during early life, whereas the young resulting from a cross between an immune male and an ordinary female do not exhibit the transmission of the "acquired character." In other words, the transmission is confined to the female side. It is evident, however, that such a case is really of no value whatever as evidence of transmission of acquired characters in the proper acceptation of the term. For it is manifest that the young animal during the whole of its existence *in utero* has been directly exposed to influences that ought to confer immunity upon it, apart altogether from any question of "transmission." Furthermore, it might well be that the bulky protoplasm of the egg, irrespective of the maternal influence after conception, may have been affected without any disturbance of the hereditary mechanism, and, indeed, Hertwig himself admits as much.

The case of certain Lepidoptera is more difficult of satisfactory explanation, although the evidence would probably be insufficient to convince an opponent. Some of these insects respond to different climatal conditions by the production of different colour-patterns on their wings. Now if the pupæ of some species (*e.g. Arctia caja*) be subjected to cold, the "cold" form of imago will appear, and if the fertile eggs of such "cold" forms be raised under warmer conditions, a small percentage of the perfect insects thus produced will retain the characters of the "cold" form. Hertwig dissents from the explanation, suggested by Weismann, that the eggs themselves may have been affected whilst still in the body of the parent insect in the pupal condition, but his argument does not amount to much; and it may well be borne in mind that an example of somewhat analogous character is afforded by the alternative characters exhibited by the leaves and other structures of many amphibious plants. Many of these can assume one of two different forms, the production of either depending on the stimulus given by the environment to the embryonic tissues at the growing points. Thus the form of, say, a leaf of such a plant is determined at a very early stage in its development, and long before it is sufficiently advanced for any functionally direct adaptation to a terrestrial or to an aquatic environment. But when once the stimulus has operated, subsequent removal to opposite conditions does not result in a corresponding alteration in the future development of such a leaf—it belongs definitely to the aquatic or to the terrestrial type, whichever line of ontogeny it embarked on from the first. It would seem, at any rate for the present, and in the absence of sufficient experimental evidence to the contrary, more natural to regard these di- or polymorphic species as "balanced" forms; the actual course of their ontogeny, whilst restricted to certain directions, and confined within definite limits, depending on the alternative character of some metabolic activity. This is, however, very different from an admission of the "inheritance of acquired characters." For if anything at all is meant by the expression, it can only imply that the hereditary mechanism has itself undergone a definite and corresponding change; and at present a direct influence of the environment in this sense is negatived by the results of the most critically conducted experiments on breeding.

Hertwig takes up a definite position as to the relation of the "somatic" to the "germ" cells. He regards all the cells of the body as fundamentally equivalent, though differentiation may mask and finally render impossible the return of a particular cell to the embryonic state. The definite tissue cell has become specialised rather as the result of an impulse from without than by a segregative process of analysis; and herein he is diametrically opposed to Weismann and his followers, in regarding cellular differentiation as a secondary rather than as a primary matter. In this he will find many who are at one with him, for the "erbungleich" division postulated by Weismann, which would result in development consisting of a sorting out or analysis of the characters of the germ, conflicts with many facts of experience, and it is only by numerous "Hilfshypothese" that it can be sustained for the plant and vegetable kingdoms.

In a notice of a book like this one of Hertwig's, it is natural that the points on which diversity of opinion prevails should occupy a relatively prominent place. But such treatment is in no way intended to detract from or to minimise the great value of the work, coming as it does from one who has himself done so much to advance the subject of which he writes, and whose lucid and suggestive treatment of his theme will always command attention. It is a book that should be read by all who are interested in the questions of modern biology. J. B. Farmer.

APPRECIATIONS OF HAECKEL.

(1) *Ernst Haeckel: Der Mann und sein Werk.* By Carl W. Neumann. Pp. 80. (Berlin: Gose and Tetzlaff, n.d.) Price 1.50 marks.

(2) *Haeckel: His Life and Work.* By Wilhelm Bölsche, with introduction and supplementary chapter by the translator, Joseph McCabe. Pp. 336; illustrated. (London: T. Fisher Unwin, 1906.) Price 15*s*. net.

(3) *Last Words on Evolution: a Popular Retrospect and Summary.* By Ernst Haeckel. Translated from the second edition by Joseph McCabe. Pp. 127; with portrait and three plates. (London: A. Owen and Co., 1906.) Price 6*s*.

(1) MANY who know Prof. Haeckel only as the author of zoological memoirs, evolutionist essays, and monistic propaganda, will be glad of the opportunity which this brightly written booklet affords of becoming more closely acquainted with the man himself and with the story of his life. We read with interest of the eager boy-naturalist wandering on the Siebengebirge, of the apprenticeship under Johannes Müller, of the year of medical practice (if a man can practise on three patients!), of the eventful year in Italy during which Haeckel nearly became a landscape painter, of the growing fascination which the plankton exerted, satisfying at once his artistic and scientific interests, of the influence that the "Origin of Species" had on him, and of his early settlement in Jena—that "feste Burg freien Denkens"—which nothing could ever induce him to leave. At the Stettin Versammlung in 1863 Haeckel entered the lists as a champion of the evolutionist "Weltanschauung," contending almost single-handed against contempt and prejudice. His cause, which eventually prevailed, as the truth must, had to be fought for, and those who are offended by the impetuous expressions of Haeckel's "Stürmernatur" are profitably reminded by this little book of the courage and indefatigability of perhaps the most virile protagonist of a thesis which has been one of the greatest contributions made by science to human progress. The author has told the story of Haeckel's life and work with vividness and enthusiasm. He concludes his effective sketch by indicating, somewhat too tersely and vaguely, how it has been possible for him to use the truth that is in Haeckel in developing a monistic philosophy more satisfying to the human spirit.

(2) Prof. W. Bölsche's study of Ernst Haeckel is, like the frontispiece to the book, a picture in warm colours. The author is nothing if not enthusiastic, and indeed no one can think over the achievements of Haeckel's life without sharing the author's admiration for his hero. If it be true, as the translator says, that "a hundred Haeckels, grotesque in their unlikeness to each other, circulate in our midst to-day," this "plain study of his personality and the growth of his ideas" should go far to replace them by giving us an appreciation approximately true. We should not ourselves have called Bölsche's book, as Mr. McCabe does, a "plain study," for its characteristic features are exuberant enthusiasm and a brilliantly

picturesque style which sometimes startles the reader with its daring.

We cannot do more than refer to a few of the interesting facts regarding Haeckel to which the author gives prominence. "Haeckel's genealogical tree spreads into the legal profession in a curiously complex way." This inheritance was expressed in Haeckel's imperious craving for clear lines and systematic arrangement, and in his fondness for formulating "laws." Apart from the influence of his teachers, such as Johannes Müller and Virchow, and of his friends, such as Gegenbaur, it was the sea—at Helgoland, at Nice, at Messina—that really won Haeckel for zoology. Regarding his pupillary period, the curious fact is mentioned that one of the theses he defended when taking his doctorate at Berlin was the impossibility of spontaneous generation. In 1860 Haeckel was "profoundly moved" by a first reading of "The Origin of Species," and conversations with Gegenbaur finally confirmed his conviction of the truth of Darwinism—a conviction which found its first, though not prominent, expression in his monograph on Radiolaria (1862). In 1863, at the Stettin congress, when Haeckel made his first open confession of the faith that was now in him, he won a laurel crown at the Leipzig athletic festival for the long jump (20 feet), and the translator justly remarks that we have here "the note of much in his character." What many zoologists, who neither misunderstand Haeckel nor fail to do him homage, feel, is that the impetuous, daring, pioneering evolutionist of Jena has taken many long jumps which scientific caution makes them refuse.

A fine chapter of the book is devoted to what is perhaps Haeckel's best and most lasting work, the "Generelle Morphologie" (1866). It was written, partly as a relief from sorrow, in less than a year, during which the author lived the life of a hermit, sleeping barely three or four hours a day, with habits so ascetic that he wondered at his survival. But the great work was too difficult for the general reader, too philosophical for the biologists, too biological for the philosophers, and thus with a clearly defined mission Haeckel set himself to the task, which he has so successfully accomplished, of making monistic evolutionism "understanded of the people."

One of the many interesting incidents related in Bölsche's appreciation may be quoted.

"A stern theologian presented himself in person at the chateau of Karl Alexander, Grand Duke of Weimar, and begged him to put an end to this scandal of the professorship of Haeckel, the arch-heretic. The Grand Duke, educated in the Weimar tradition of Goethe, asked, 'Do you think he really believes these things that he publishes?' 'Most certainly he does,' was the prompt reply. 'Very good,' said the Grand Duke, 'then the man simply does the same as you do.'"

As Prof. Bölsche closed his charming biographical sketch in 1900, the translator, who has done his work admirably, has added a chapter on the crowning years, dealing with the controversies over the "Riddle of the Universe," and other events. The whole work, helped by the excellent portraits, leaves one with a grateful impression of a remarkable personality who has all his life been a good fighter yet most lovable withal, who has done much for pure science and yet has never ceased to say "Das Leben ist schön."

(3) In these three lectures, delivered last year in Berlin, Prof. Haeckel reiterated with wonted frankness and fearlessness his evolutionist and monistic convictions. He trounced the theologians and metaphysicians for ignoring or combating or misrepresenting the secure results of science, and he did not refrain from reproving some of his own craft—even his revered master, Virchow—for trying to sit on both sides of the fence. He is himself so well satisfied with the naturalistic formulation of what goes on, and has gone on, in the wide world, that he has no patience with those who seek for explanations that science *ex hypothesi* can never give.

The law of evolution and the law of substance (the conservation of matter and energy) "are irreconcilable with the three central dogmas of metaphysics, which so many educated people still regard as the most precious treasures of their spiritual life—the belief in a personal God, the personal immortality of the soul and the liberty of the human will." Not that these are to be driven out of the world. "They merely cease to pose as truths in the realm of pure science. As imaginative creations, they retain a certain value in the world of poetry."

To many this will seem a false antithesis, an opposition of incommensurables. It can hardly be pathologically that the human spirit has so persistently attempted to get beyond common sense and empirical science to a formulation of the efficient causes, the significance, the purpose of all becoming. As a matter of fact, Haeckel himself is a worshipper of "a Monistic god, the all-embracing essence of the world, the Nature-god of Spinoza and Goethe, identical with the eternal, all-inspiring energy, one, in eternal and infinite substance, with space-filling matter," whose "will is at work in every falling drop of rain and every growing crystal, in the scent of the rose and in the spirit of man."

The lectures have been very successfully translated by Mr. McCabe. We may note that the date given for Weismann's theory of germ-plasm is 1844, which seems rather early, while that of Lamarck's "Philosophie Zoologique" (1899) is rather late.

PRACTICAL GEOGRAPHY.

An Introduction to Practical Geography. By A. T. Simmons and Hugh Richardson. Pp. xi+380. (London: Macmillan and Co., Ltd., 1905.) Price 3*s*. 6*d*.

THIS book is based on an excellent idea, which has in many ways been excellently carried out. Its design is to show how to cultivate in the teaching of geography the methods of scientific training, the methods by which boys and girls are guided to reach sound conclusions from their own observations and experiments.

Unfortunately, the execution of this design is marred by the apparent absence from the minds of the authors of a clear idea of what geography is. Geography, it must be admitted, is a subject which is sadly in want of a generally accepted definition fitted to give a clear idea of its scope. But though this definition is lacking, the handling of the subject is coming to be more and more in accordance with the idea that the governing function of geography is to indicate the nature and relative importance of the influences exercised on the life of the globe, especially human life, by local conditions and place relations. It is evident that this idea has been implicitly in the minds of the authors in the preparation of some parts of the book, but it is equally evident that the idea has never been expressly recognised by them, and accordingly it has not been consistently acted on. One result is that a good deal is admitted into the book which has no place in geography, but a still more serious result is that again and again the practical guidance stops short of the goal to which the learners should have been led.

Some examples may be given. Inevitably the work lays stress on map-making and the observations on which maps are based. Maps being necessary in the study of geography, boys and girls must be got to understand as clearly as possible how far those records of the facts which have to be studied serve in place of the actual facts, and in what points they are apt to mislead. Now, while there is much that is admirable in what is said, shown, and hinted on pp. 51–72 on hachures and contours, there is no hint of what hachures and contours respectively fail to represent. The subject of projections is rightly dealt with, for within due limits it is not beyond the reach of school children. But here the failure is more striking. The only reason for taking up this subject is to get the learners to understand how inevitably any projection must fail to represent the truth in some points, to perceive in each case the chief failures, and to discern the reasons for using certain projections in spite of their defects. But on these points no hint is given. The principle of the construction of what is called Mercator's projection is described, but, strangely enough, no question is put with the view of getting those who use the book to recognise its obvious faults, and no indication is furnished of its compensating utilities. This, indeed, would have been impossible, at least in the case of its utility for marine charts, inasmuch as the projection described is not Mercator's, but the useless central cylindrical. So, too, the projection described as the conical is not the conical, and is, in fact, no used projection whatever.

To take another subject, under the heading of isotherms and parallels of latitude we have on pp. 227 and 228 a large number of average mean temperatures for the months of January and July, but for different places, thus failing to afford an opportunity for comparing ranges of temperature. Then again, under the heading of aspect and temperature, pp. 241–3, the important subject of the difference of temperature between the east and west of the northern oceans and land-masses is dealt with, but is illustrated only by certain figures from Hann presenting this difference in the least instructive light, in the manner which fails to bring out the difference which is of most practical importance to the inhabitants of the earth. The figures show only the difference in the mean annual range of temperature, and do not indicate that this difference is brought about in every case in a greatly preponderant degree by the varying range of the winter temperatures.

Such defects are worth pointing out, chiefly because the book is on the whole so good that one cannot help earnestly wishing that it were better, and because it may be hoped that they will be removed in a future edition. Even as it is, it must be recognised that the immense pains taken by the authors have resulted in the preparation of a work which is full of suggestiveness, and ought to supply a countless number of useful hints to capable teachers of geography.

Geo. G. Chisholm.

FOLKLORE AND MEDICINE OF THE ZULU-KAFIR.

Bantu Folklore (Medical and General). By Dr. Matthew L. Hewat. Pp. 112. (Cape Town: T. M. Miller; London: J. and A. Churchill, n.d.)

THIS is an interesting little work. It will be of value to students of primitive races. It deals chiefly with the ideas of the South African Kafir tribes on the subject of magic, medicine, diseases, and initiation ceremonies. Incidentally it gives a great insight into the extraordinary mixture of superstition, quackery, and practical research in native medicine. The Kafirs are nearly always at fault in their guesses as to the origin of diseases. Some maladies are thought to be caused by the supernatural influence of snakes or of water monsters, half man and half animal, or by the strange bird called impundulu, which by some is thought to be the origin of lightning. Other diseases are attributed to direct poisoning—the word for poison, *ubuti*, being a very old Bantu root that means the "essence of the tree." This is a word that in many Bantu languages means medicine quite as much as poison, all the medicines of primitive man having been derived from the bark, sap, fruit, or leaves of trees. Some of the "snakes" alluded to by the author as the cause of intestinal diseases (in the native mind) are evidently distorted accounts of guinea-worm or tape-worm.

The king or chief of the tribe is theoretically regarded as the first amongst the local medicine men. Professional doctors, however, may be of either sex. They are often divided into the following classes: (1) Witch doctors—diviners, mesmerists, prophets, or secret service agents, "faith-healers," and masseurs. The last-named type of witch doctor is the only one that performs any good service. Like most negro races, the Kafirs believe greatly in the efficacy of massage. (2) The surgeon or bone-setter, who also practises cupping. (3) The physician or herb doctor. In addition there are two special classes of medicine men, who attend to the bringing of rain or the prediction and direction of warlike operations. Very great misery and loss of life were caused until quite recently by the witch-hunting practices of the medicine men. These priests often became petty tyrants, introducing a tyranny as hateful as that of the Holy Inquisition by their witch-smelling practices.

As regards the use of herbs, it is pointed out that the natives are in the possession of many valuable drugs. Amongst these they have been for generations in the habit of using a decoction of the leaves of the Cape willow for the cure of rheumatic pains, thus preceding Europe in an appreciation of the curative properties of salicin. A list of all the diseases to which Kafir man, woman, and child are liable is given, together with their native names, and the remedies which the natives so successfully apply. There is a chapter on midwifery and the rearing of infants, which leaves one surprised that the Kafir race has not long since come to an end by indirect infanticide. The extraordinary treatment of newly-born children may act as a kind of spur to the survival of the fittest; it most certainly kills out weakly children. The newly-born baby is "bled at the point of the fingers for luck; then held in the smoke of a slow fire till it sneezes or coughs, to show that it is not bewitched. It is then thoroughly rubbed all over with a solution of cow-dung," and so forth. Instead of being allowed to suck at the breast, it is fed at first on sour cow's milk, which is "forced down the throat of the poor little mortal by blowing into its mouth and compelling it to swallow."

Notes are given as to the operations performed on girls in the initiation schools (the elongation of the *labia minora*), and also in regard to the circumcision of the males.

The introduction to the book contains a useful summary of Kafir history, but is marked, like nearly all the writing that comes from South Africa, by a curious ignorance of Bantu history north of the Zambezi.

H. H. JOHNSTON.

OUR BOOK SHELF.

Sociological Papers. Vol. ii., 1905. Pp. xiii+312. Published for the Sociological Society. (London: Macmillan and Co., Ltd., 1906.) Price 10s. 6d.

THOUGH hardly equal in interest to its precursor, the present volume contains some valuable contributions to sociology. First, and foremost in interest and importance, comes a paper on eugenics by Mr. Francis Galton. He argues that man, whether civilised or barbarian, has submitted to restrictions in marriage, and, therefore, that a new restriction in accordance with eugenics may be imposed. Mankind has borne the yoke of monogamy, endogamy, exogamy. He has recognised prohibited degrees of kinship. Why cannot a new taboo be started? Dr. Haddon adduces an argument that is much to the point: the world is becoming self-conscious and modern civilisation has at command great resources for bringing about a revolution in men's views and practice. Dr. Max Nordau thinks the proposals unpractical. Modern restrictions would have no religious sanction, and would therefore fail. He would trust more to an improvement of the environment than to eugenics. There are many medical men who, like Dr Max Nordau, think that environment is everything. Prof. Tönnies fears that *mariages de convenance* and *mariages de passion* will continue in spite of eugenics. Lady Welby sees the difficulty of considering the interests of the race and at the same time making the most of the individual. Mr. Galton, whose enthusiasm compels admiration, answers the main objections forcibly.

Among the other papers are the following:—Civics, by Prof. Geddes (he argues for evolutionary sociology and for a civics exhibition); The school in some of its relations to social organisation and to national life, by Prof. M. E. Sadler (he urges that scope be left for "group effort and private enterprise in education"); The influence of magic on social relationships, by Dr. E. Westermarck; On the relation between sociology and ethics, by Prof. Höffding; Some guiding principles in the philosophy of history, by Dr. J. H. Bridges; Sociological studies, by Mr. J. S. Stuart-Glennie.

F. W. H.

The Heart of a Garden. By Rosamund Marriott Watson. Pp. 162. (London: Alexander Moring, Ltd., The De La More Press, 1906.) Price 7s. 6d. net.

THE title of this book is significant. The reader is not led to expect cultural details or botanical technicalities. To use a vulgarism, "science is not in it." What we have is a record of musings, such as would suggest themselves at each successive season, to one more concerned with the poetry and beauty of nature than with its philosophy. Notwithstanding this, the author shows herself a careful observer and a skilful delineator. Take, for instance, this account of the winter aconite (Eranthis). The writer is descanting on the promise of early spring, and goes on to say:—

"And even flowers are not wanting; multitudes of small, gold heads have shyly thrust themselves up through the dark earth, wrapped closely about in their green hoods which, as the sun grows warmer, they will fling back to do service as jaunty fringed capes."

This is not a botanical description; nevertheless, there is no mistaking what flower the writer had in view. The lady, with most other people, has her likes and her dislikes, and her ideals are not those of her gardener. Still, that functionary is paid to do certain work, and it is difficult to see how he can fulfil his duties properly if "milk-white pigeons with the roseate feet" are allowed to gratify their proclivities among the sweet peas and the gooseberries, and other culprits are permitted to make havoc with the strawberries.

Be this as it may, the author contrives to get a continuous feast of pleasure from the garden of which she writes, and by her cheery optimism and the elegance of her narrative affords the reader a share of the gratification she herself experiences. Dainty lyrics enliven the text. Even the pug-dog "Momotaro" is immortalised, though the invocation to him, "Hued like the full moon of the apricot," strikes us as peculiar. What sort of apricots can they be that possess full moons? In a work of this kind, however, allowance must be made for poetic imaginings. The illustrations are numerous and well executed. The book throughout is pleasantly written, and attractive to the eye.

Methods in Microscopical Research—Vegetable Histology. By Abraham Flatters. Pp. x+116. (Manchester and London: Sherratt and Hughes.) Price 21s. net.

THIS work is designed to give a course of instruction in the practical working out of the internal structure of a number of higher types belonging to the vegetable kingdom, and should admirably fulfil this purpose. The earlier portion deals with the general preparation of specimens, collection, fixation, and preservation; instruments and section cutting; staining and mounting, and is fully illustrated. Formulæ for reagents, stains, &c., then follow, after which certain types are selected and full directions given for demonstrating root, stem, floral, cell, and other structures. This section is illustrated with twenty-three coloured plates of the specimens, beautifully executed and with ample descriptions. The author is to be congratulated on the success which he has attained in the production of this work. R. T. Hewlett.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The San Francisco Earthquake of April 18.

This disastrous earthquake was remarkable for its long duration and the rotatory character of the movement. As observed at Mare Island the first sign was a very faint, gentle rustling, the waves being the merest tremors; but after about a minute's duration they had grown to such proportions as to be felt by everyone. The violent phase lasted about forty seconds, and then the shocks died out, the last feeble tremors vanishing about three and a half minutes from the time of the first perception. The writer was favourably situated for noting the slightest disturbance, and had been awake some time before the first tremors were felt, and he could see the clock face at the beginning and end of the disturbance, which read about 5h. 11m. and 5h. 14m. 30s. Two of the four astronomical clocks at the Mare Island Observatory were stopped by having their pendulums thrown upon the ledge which carries the scale for measuring the amplitude of the swing. The time of the violent oscillation thus automatically recorded was 5h. 12m. 37s., Pacific Standard Time, eight hours slow of Greenwich. The waves were mainly from the south and south-south-west, and they seemed to turn to the west, giving the movement an elliptical, clockwise rotation. The pendulums of the two clocks which kept moving had their points rubbed against the swing index of the ledge so violently that the metal of the index was brightened by the friction of the pendulum points, and the time thereby deranged more than twenty seconds. Except for the disturbance of objects on the ground, the earthquake seemed to be essentially noiseless. Other slight shocks have continued at irregular intervals for the past five days. T. J. J. See.

U.S. Naval Observatory, Mare Island, California, April 23.

Interpretation of Meteorological Records.

I regret that, owing to absence from home, I have only now seen Mr. Lander's letter in Nature of April 19; I have to apologise for my inexcusable carelessness in writing of the storm as being accompanied by rain in place of snow and hail. However, accepting Mr. Lander's correction, it does not appear that the change will produce any alteration in the interpretation of the records, as it does not matter whether the water fell in the liquid or the solid state; its presence in either form would check any rise of temperature due to compression in the downward moving air. Any difference in the effect of snow compared with rain in producing a downward movement of the air would be to make the current stronger, because the air offers greater resistance to the fall of snow than to rain.

It is very interesting to know that at the place where Mr. Lander made his observations the barometer began to rise before the first hail arrived. But if the interpretation offered of the records be correct, this would only seem to indicate that his place of observation was not directly under the area where the storm began, and that the compression produced by the falling hail and snow travelled outwards and caused a rise in his barometer before the storm cloud brought the hail to him.

Baveno, Italy, May 7. John Aitken.

RECENT PUBLICATIONS OF THE BUREAU OF AMERICAN ETHNOLOGY.[1]

We welcome the long-looked-for monograph on the Hako ceremony of the Pawnee by Miss Alice C. Fletcher, the Thaw Fellow of Harvard University, as upon her, so to speak, has fallen the mantle of Cushing. Not only has she a long and intimate acquaintance with certain tribes of the Plains Indians, but her affection for and sympathy with the Indians is so marked that the old and prominent natives have confided to her their sacred lore; and she was even able to induce Tahirussawichi to come to Washington, he being the keeper of the old and sacred objects, whose life has been devoted to the acquisition and maintenance of certain sacred rites. In 1898 he was taken to the Capitol and the Library of Congress. While the vastness and beauty of these structures gave him pleasure, they did not appeal to him, for such buildings, he said, were unfitted to contain sacred symbols of the religion of his ancestors, in the service of which he had spent his long life. He admired at a distance the Washington Monument, and when he visited it he measured the base by pacing, but he would not go up, saying, "I will not go up. The white man likes to pile up stones, and he may go to the top of them; I will not. I have ascended the mountains made by Tira'wa."

The purpose of the ceremony was twofold: (1) to benefit particular individuals by bringing to them the promise of children, long life, and plenty; (2) to establish a bond of friendship and peace between two distinct groups of people. It is intertribal, and not only serves as a means for the interchange of ideas through contact and through gifts, but represents one of the many powerful agencies which, by spreading tolerance and friendly feeling, tend to weld scattered warlike bands of men into great, peaceful nations. A desire for offspring was probably the original idea. The ceremony is very old, and has been modified in the process of time to adapt it to changed conditions of environment. For example, the substitution of the buffalo for the deer, and the transference of songs; thus one formerly sung while on a journey to the mesa is now sung within the lodge.

"Each ritual contains one general thought, which is elaborated by songs and attendant acts. These songs and acts are so closely related to the central thought that one helps to keep the other in mind, and they all form a sequence that, in the mind of the Pawnee, can not logically be broken. The compact structure of the Hako ceremony bears testimony to the mental grasp of the people who formulated it. As we note the balancing of the various parts, and the steady progression from the opening song of the first ritual to the closing prayer in the twentieth, and recall the fact that the ceremony was constructed without the steadying force of the written record, we

are impressed, on the one hand, by the intellectual power displayed in the construction, and, on the other, by the sharply defined belief fundamental to the ceremony."

Miss Fletcher gives the music and exact translation of the songs, with a native explanation of their meaning. The ritual objects are illustrated by several coloured plates. This sympathetic interpretation of an ancient ritual deserves the careful study of those interested in comparative religion or in the beginnings of literary expression.

Mr. J. N. B. Hewitt gives the first part of a careful study of Iroquoian cosmology; three texts, with literal and free translations, are given of Onondaga, Mohawk, and Seneca variants. A fact of great importance in these texts is that man-beings were in Iroquoian thought the primal beings; they belonged to a rather vague class of which man was the characteristic type. Beast gods appear later. In the development of

FIG. 1.—The Kurahus in ceremonial dress. A Kurahus is the director of the Hako Ceremony; the name means an old man who is venerated for his knowledge and experience.

Iroquoian thought animals, plants, rocks, and streams, having human or other effective attributes or properties in a paramount measure, were regarded as the controllers of those attributes or properties, which could be made available by *orenda* or magic power. Thus began the reign of beast gods, tree gods, and their kind, but the native term usually translated into English as "god" really signifies "disposer" or "controller," and each received worship and prayers.

In a profusely and beautifully illustrated memoir of over six hundred pages Mrs. Matilda Coxe Stevenson has given us an elaborate account of the mythology, esoteric fraternities, and the ceremonies of the Zuñis, as well as brief sketches describing the everyday life, arts, and customs of the people. It is obvious that it would be very difficult to give anything like an adequate account of this storehouse of data. The ceremonies are described with that commendable wealth of detail which characterises the work done by the best American students, and the book is a worthy extension of earlier studies of the Zuñi by the lamented Cushing and by Dr. J. W. Fewkes. The Pueblo Indians are the most interesting of North American aborigines, owing to the effects the wonderful desert-land has upon the social condition of the people, and to the intricate and symbolic ritual they have evolved, which also may in a real sense be said to be a direct result of their environment. It is therefore with great satisfaction that we welcome additions to the already voluminous literature concerning these charming people. Mrs. Stevenson says:—

"The philosophy of the Indian, as of man wher-

FIG. 2.—Hopi Katcinas drawn by native artists. Pañwû is represented by the two top figures. The figure Tiwenu carries a tablet on the head and a pine branch in each hand. The Kwewû picture has a well-drawn wolf's head with projecting mouth. The kilt is made of horse-hair stained red.

ever found, is the result of his desire and his efforts to understand the mysteries of nature. These children of the human family are highly imaginative. The soul of the Zuñi expands with adoration toward the supreme mysterious power that controls all things, and toward the gods, whose forms are visible in the heavens above, in the earth beneath, and in the waters under the earth, who are only less mighty than the supreme power, and who bless the good and punish the wicked."

She admits it is yet to be determined what part clanship played in the dawn of the ritualistic life of the Zuñi.

"It is certain that for a long time past membership at large in the fundamental religious bodies of the Zuñi has not been dependent on the ties of clanship, though in certain cases succession to office in fraternities does depend on clanship. Before any exposition of the origin of the fundamental religious organisations and of the ritual can be offered, a comparative study of the Pueblos must be made. In this work the passing hours are golden, for not only are the villages losing their old-time landmarks, but the people themselves are changing, are adapting themselves to a suddenly and profoundly altered environment, and the Zuñi at least, whose religion teaches them to speak with one tongue, to be gentle to all, and to subdue the passions, thereby winning the favour of their gods, are, under the influence of modern conditions, losing the restraining power of this religion, and, as a result, are changing for the worse."

It is to be hoped that competent students will make a thorough study of the sociology of these people without delay, and at the same time make a serious effort to trace the transition of the old clan system into the later religious fraternities.

FIG. 3.—Sword Swallowers of Ma'ke Hlan nakwe (Great Fire Fraternity of the Zuñis).

The memoir by Dr. J. W. Fewkes on Hopi Katcinas drawn by native artists cannot fail to be of considerable interest to students of various departments of ethnology. The practice of illustrating ethnological researches by native drawings is much to be recommended, as the drawings throw considerable sidelight upon the ideas and skill of the artists, and help us in the study of their psychology; in the present instance they have additional value in the suggestive similarities they present to pictographs in the codices of more southerly regions. The term katcina was originally limited to the spirits of the ancients of the Hopi or personified medicine power, and personifications of a similar power in other objects have likewise come to be called katcinas. Thus the magic power or medicine of the sun or earth may be called katcina. The term is also applied to personations of these spirits or medicine potencies by men, or their representation by pictures or images. In the Hopi ritual there are dramatic celebrations of the arrival and departure of the katcinas, and during the whole year there are ceremonies in which katcinas take part. The annual ceremonies vary considerably each year, so the katcinas are correspondingly numerous, and not only have clans introduced new katcinas from time to time, but individuals have done the same even by men still alive. Some of these ceremonies have developed into a regular dramatic performance; the motive of one of these dramas is the growth of corn, with representations of the maleficent and beneficent agencies that affect the crop. The performance is designed primarily to invoke the favour of the mysteries by appropriate symbols combined with the edification of the community at large. Thus a portion of the chamber is set apart as a stage, while the greater portion is reserved as an auditorium. A screen on the stage is painted with appropriate symbols, and is perforated to permit the passage of the masked effigies representing the mystical potencies, which are operated by shamans hidden behind the screen, something after the fashion of marionettes. The front of the stage is occupied by a symbolic field of corn, and the figures which represent the storm and drought emerge from their respective apertures in the screen and destroy the cornfield; but they are opposed partly by musical and other incantations of a group of shamans occupying one side of the stage, and partly by human actors who wrestle with and finally overcome the evil marionettes. The entire dramatisation stands on a higher plane than any prevalent among other tribes of the territory of the United States, though lower than that reached among the Nahuatlan and Mayan peoples of Mexico.

Under the title of "Two Summers' Work in Pueblo Ruins," Dr. Fewkes describes his survey of certain ruins mainly in the Province of Tusayan. Dr. Fewkes's excavations confirmed some statements made by the Hopis concerning their former history, and his intimate knowledge of the ritual and ceremonies of the existing Pueblo Indians has enabled him to explain the use or significance of objects dug up by him. The report is illustrated by photographs of ruins, plans of buildings, and a large number of beautifully executed coloured plates of decorated pottery, besides numerous figures in the text. The author inclines to the belief that the Zuñis never advanced to the same perfection in the ceramic art as did the Hopis. The author says, "In the evolution of Pueblo decoration the development of ornamentation advances from geometrical patterns to rude picture writing, and, as a rule, the pottery on which the former predominate is inferior to that on which the latter is most prominent"; but this hardly seems consistent with the subsequent remark that "the more ancient the ruin is, the better is the pottery."

Dr. Cyrus Thomas gives the second portion of his study of Mayan calendar systems, in which he deals with Maudslay's investigation of the ruins at Quirigua and discusses Goodman's results. The paper includes an account of the Maya method of calculation.

Serious English-speaking students of Central American archaeology must know the writings of the distinguished German scholars whose names appear in Bulletin 28 under review; but even they will be glad to have these scattered papers translated for more convenient reference and collected in one volume. Other students who like to know what is being discovered in this region will be very thankful to Mr. Bowditch for his enterprise and labour in translating these papers, and to the Smithsonian Institution for placing all this material at their disposal in so convenient a form. On the whole, these papers will be of most value to those who concern themselves with the chronology and history of the Central American peoples; but there is a great deal to interest the general ethnologist, though he will have to search for his material, as most of it is scattered all over the volume in diverse papers. Particularly interesting in this respect are the papers on "Zapotec Priesthood and Ceremonials," "Deities and Religious Conceptions of the Zapotecs," and "Comparative Studies in the Field of Maya Antiquities"; the last paper deals with the clothing, personal decoration, and utensils of the Mayas as illustrated in the manuscripts, or on the monuments or other remains. According to a widespread tradition, the Toltecs were the originators of all arts and sciences; and the invention of the calendar is ascribed to them, and we are informed they carried their book with them on their migrations. The calendar is the fount of the Central American sacerdotal wisdom, and the great mass of Mexican and Maya manuscripts is nothing more than an elaboration of this calendric system in respect to its numerical theory, its chronology, and its system of divination. The book is copiously illustrated, and altogether it will form a most welcome addition to the working library of various kinds of students of archaeology and ethnology.

Mr. Swanton gives literal translations of a number of Haida folk-tales obtained on the Queen Charlotte Islands, British Columbia; this careful piece of work will be much appreciated by folklorists.

When one looks at the bulk of ethnological matter published by the United States Government, and realises the enormous value to students of these full, accurate, and well-illustrated memoirs, one cannot but feel ashamed of our Government, which, possessing every opportunity and inducement to study and report upon our own native races, does absolutely nothing.

A. C. HADDON.

THE EDUCATION AND TRAINING OF THE ENGINEER.

ENGINEERING in its various branches takes so large and important a part in the industrial activities of modern nations that no pains are too great which will secure for our engineers a suitable and adequate school and college training, supplemented by a judiciously organised scheme of practical work in the shops and drawing office. More especially is this the case in this country, where, owing to the satisfaction which has followed previous success, manufacturers have been insufficiently alive to the fact that for many years other nations have been steadily building up efficient schemes of technical and professional education at the cost of much enterprise and greater self-sacrifice, with the natural result that our supremacy, long undisputed in these spheres of industry, has been undermined, and in some degree wrested from us.

It is for reasons such as these that the investigations inaugurated and carried out under the auspices of the Institution of Civil Engineers, the results of which are embodied in a recent report on the education and training of engineers, are to be welcomed. In November, 1903, the council of the Institution appointed a committee to consider and report as to the best methods of training for all classes of engineers, including both scholastic and subsequent technical education, it being an instruction of the council that the principle was to be maintained that the education of an engineer must include both practical experience and scientific training. The constitution of the committee was completed in February, 1904, and owing to the wisdom and breadth of outlook of the council of the Institution of Civil Engineers, accredited representatives of the various institutions of mechanical, electrical, gas, and mining engineers, naval architects, shipbuilders, and others were added to the committee, which under the able chairmanship of Sir William White, K.C.B., F.R.S., was soon actively at work.

The inquiry, which has extended over more than two years, proceeded under the following sections: (1) Preparatory education in secondary schools; (2) training in offices, workshops, factories, or on works; (3) training in universities and higher technical institutions; (4) post-graduate work. The investigations under the first heading were entrusted to a subcommitee, while the committee as a whole undertook the consideration of the questions arising under the remaining three sections. The inquiries of the committee have been prosecuted by obtaining, sometimes orally though generally by correspondence, the opinions of teachers and professors with experience in engineering education, and of eminent engineers practising in various branches of the profession. The ultimate result is that, though diversities of opinion have been disclosed in regard to some details, yet, in all the main features of its recommendations, the committee has support from the great majority of professional engineers as well as of the professors of engineering subjects in our universities and higher technical institutions.

PREPARATORY EDUCATION.

The subcommittee, entrusted with the work of ascertaining the views of authorities competent to speak concerning the most suitable form of secondary education for boys destined to become engineers, issued a schedule of questions to 120 representative teachers in engineering colleges, headmasters of secondary schools devoting special attention to scientific training, and engineers not engaged in teaching. The queries raised in the schedule dealt with such points as the proper age for leaving school, the desirability of a leaving examination for secondary schools, the extent and methods of the teaching—suitable for future engineers—in English subjects, languages, mathematics, science, drawing, and surveying. The schedule of questions raised, in addition, the important subject as to how far schoolboys should have, as a school exercise, practice in ordinary handicraft work, such as carpentry or turning; and to what extent it has been found better to make all "practical" work into laboratory exercises in science. Replies were received from 80 per cent. of the gentlemen whose opinions were invited, and from these definite conclusions were deduced as to the prevailing opinion on the points raised in the schedule of questions. These conclusions were embodied in a report of the subcommittee, which was eventually approved and adopted by the main committee. The following recommendations are the outcome of the exhaustive inquiry.

A boy intended for the engineering profession should, before leaving school and commencing to specialise, have attained a standard of education equivalent to that recognised by universities for matriculation purposes. His special training should not commence until he is about seventeen years of age. To ensure such a standard of efficiency a leaving examination for secondary schools is desirable throughout the United Kingdom, so that there may be no room for doubt as to whether a boy has received a satisfactory preliminary education.

Advanced teaching of history and geography, with instruction and practice in essay-writing and in précis-writing, should be included in the ordinary school curriculum; and the instruction in English subjects should include at least an introduction to English literature.

Greek should not be required, but an elementary knowledge of Latin is desirable. The study of Latin should, however, be discontinued during the last two years of attendance at school, or after the standard required for the leaving certificate has been attained. Modern languages, especially French and German, should be studied, and should be taught colloquially or in such a way as to give the pupils a practical knowledge of each language, sufficient to enable them to study its literature and to converse in it with some degree of facility.

Instruction in mathematics should be given by methods differing considerably from those usually adopted in the teaching of this subject merely as an intellectual exercise. The geometrical side of mathematics should be fostered, and before they leave school boys should be conversant with the use of logarithms, and with at least the elements of trigonometry. Instruction in practical arithmetic should be carried further than has been generally the case hitherto, with the object especially of encouraging the use of contracted methods and of encouraging also the expression of results with only such a degree of accuracy as is consistent with the known degree of certainty of the data on which the calculations are based.

It is preferable that boys should attain at school a general knowledge of physics and chemistry rather than that they should pursue in detail some particular branch of science. Special attention should be given to drawing. Work in the nature of handicraft, such as carpentry or turning, may be encouraged as a recreation, but should not be required as a school exercise.

The committee very properly recommends that the scheme of education outlined in its report should be communicated officially to the Board of Education and be circulated widely amongst those responsible for the work in secondary schools and engineering colleges. The importance of the committee's recommendations, indeed, cannot be overestimated. Educational experts have long foreseen the impossibility of securing a rational system of secondary education in the absence of a carefully planned investigation to determine precisely what secondary education has to accomplish and how the desired end may best be reached. The Institution of Civil Engineers has by its public-spirited action shown schoolmasters the way so far as the education of future engineers is concerned. Here is the opportunity for which earnest educators have been looking. The ground to be covered has been carefully mapped out by experts, and we at last know precisely what is required of the secondary school so far as training engineers is concerned. It is earnestly to be hoped that the opportunity will not be lost. If for the next ten years these judicious recommendations could be made the basis of the secondary education provided for all boys intended for engineering, and if the results of following the scheme could be accurately recorded during this period, we should in 1916 be in possession of data which would bring us within easy distance of formulating with confidence a course of school study which would provide engineers with boys trained in such a way as to make their future rational development easy and straightforward.

ENGINEERING TRAINING.

It was eventually decided by the committee to deal together with the sections of its inquiry concerned with training in offices, workshops, factories, or on works; training in universities and higher technical institutions; and post-graduate work. As in the case of the investigation dealing with the school career of the future engineer, so in this case a schedule of questions was framed and circulated widely. But a modification was introduced; the committee embodied in the schedule certain conclusions on important subjects on which it was unanimous. At the same time a free expression of divergent opinions was invited.

In the schedule of opinions and questions the committee expressed its opinion that the age for leaving school of the future engineer should be seventeen years, and seventy per cent. of the 267 engineers and others who sent replies expressed agreement with this proposal. The opinion of the committee that it is desirable that the course of training for all branches of engineering should include at least one year's training in mechanical engineering workshops, where, ordinarily, information would be gained of the practical applications of electricity, was endorsed by 72 per cent. of those who responded to the invitation of the committee to express their views, and 21 per cent. considered this period too short. There was, however, far less unanimity as to when this introductory workshop course should be taken. The committee laid it down that the course should be taken at an early period—either previously to the commencement of college training, or after that portion of the college training which is common to all branches of engineering has been completed. Thirty-three per cent. of the responding referees merely expressed agreement with the committee, while 47 per cent. were definite that it should be before the college training began.

Four-fifths of the replies received agreed with the committee that during the introductory workshop course, and indeed in subsequent similar courses, boys should keep the regular working hours, be treated like ordinary apprentices, and be paid wages. Rather more than half the referees replying thought boys should be expected to attend evening classes during this workshop course, and 35 per cent. thought educational work should be suspended during this time. A large majority of the replies showed that it is generally considered desirable that this workshop course should be followed by a period of study in a technical college or university before specialisation in particular branches of engineering is undertaken, and that the period of college study should be arranged so as to alternate with the practical training.

There was great diversity of opinion as to what constitutes a reasonable total period of practical training on works, in factories, workshops, mines, and so on—apart from the introductory workshop course. Thirty per cent. of the replies mention three years, twenty per cent. give two years, and the remaining opinions vary from one to five years. The committee recommends a total period of four years inclusive of the introductory workshop course. On the other hand, it seemed to be generally agreed that the scale on which appliances and equipment for instructing engineering students should be provided in technical colleges should be limited only by the funds at the disposal of the college authorities.

The three concluding opinions formulated by the committee on the schedule distributed met with general approval. It is considered desirable, in connection with the grant of degrees, diplomas, and certificates to engineering students, that great importance should be attached to laboratory and experimental work performed by individual students, as well as to their progress in mathematical and scientific studies, rather than that degrees and so on should be granted on the results of terminal or final examinations. It is urged that facilities for post-graduate work by engineering students in higher technical institutions should be much increased; and it is admitted by almost all authorities that the improvements of engineering education depend greatly on the attitude of employers towards the recommendations made by the committee, and employers are urged to extend the facilities to engineering students for post-graduate study and research.

The recommendations of the committee in respect of engineering training embody the conclusions arrived at by an examination of the replies just summarised, and it is unnecessary to do more than point out the respects in which the recommendations amplify the opinions set forth in the schedule prepared for distribution. The recommendation respecting the introductory workshop course explained above recognises that at present there are practical difficulties in arranging for this workshop year being interposed between the school and college work, and that employers may consider the arrangement detrimental to their interests. The committee suggests, however, that these difficulties should not be insurmountable, and the general agreement as to its advantageous effect on training leads it to hope that practical trial may be given to the plan.

Concerning attendance at evening classes during the introductory workshop course, the committee thinks it is most important that all boys should at least maintain their scholastic acquirements, and it is considered that this result might be secured, by private tuition or otherwise, without undue physical strain. So, too, the general recommendation that the introductory workshop course should be followed immediately by attendance at college is modified. It is stated that in some cases—as, for example, when boys are intended to become mechanical engineers—it may be advantageous to complete the practical training before entering college; but, if this is done, private tuition or evening classes must be the rule during the years of practical work.

The longest of the recommendations urges the need for a sound and extensive knowledge of mathematics in all branches of engineering. The committee endorses the practically universal opinion that a sufficient time should be allotted to the study of pure mathematics during the common college course, and that the extent to which individual students can be carried in mathematics must be decided by the teachers.

Such are, in brief, the more important of the committee's recommendations, and it is interesting to compare these with some aspects of American practice. The rule in the engineering courses of the colleges of the United States, which it must be remembered always follow a prolonged secondary education, is that in the first two years of the course—which generally lasts four years—a fair amount of time is given to mathematics, English, modern languages, and experimental science, and it is chiefly in the workshop and drawing office that the specialisation towards engineering is apparent during these years. Specialisation begins to show itself prominently during the third year, and mechanical technology and electrotechnics are more or less taken up in the mechanical and electrical engineering courses. In the fourth year a crowd of engineering subjects is frequently introduced. But as Prof. Ripper remarks in his Mosely Commission report, "From the English standpoint too much importance may be attached to prolonged literary training, and not enough importance to the practical training of students during the earlier years of their career, nor to the cultural value of a scientific and professional education." But in no respect are American conditions more different from those at home than in the attitude of the employers of labour toward higher education. As Dr. Walmsley has testified in a recent report (see NATURE, vol. lxx., p. 231), "Without exception the officials interviewed asserted that, far from having any difficulty in placing the graduates turned out year by year from the engineering courses, for the last few years the graduate class has had every one of its individual members engaged for remunerative work before the completion of the course at college."

Such are the importance of the report of the Institution of Civil Engineers and the care which has been expended upon its preparation, that it is to be hoped it will be read alike by all responsible for the education of our future engineers, and by those who are in a position to employ the young men when their training is complete. In face of the severe competition between nations for industrial supremacy, it becomes a national duty for each and all, who can assist and forward the means of preparing the men in whose care our manufactures and general mercantile welfare will rest, to do their best; and a debt of gratitude is due to the Institution of Civil Engineers for the work it has accomplished. A. T. S.

BALLOONS AND KITES IN THE SERVICE OF METEOROLOGY.

DURING recent years a considerable amount of information has been accumulated about the conditions which prevail in the higher strata of the atmosphere. Although observations of temperature and humidity were made by Glaisher from a free balloon more than fifty years ago, and later Mr. Archibald used kites to determine the change of wind velocity with elevation, it is only in the last ten years that a systematic attempt has been inaugurated to obtain information. There is now a fair amount of observational material awaiting someone with the necessary skill and leisure to work it up, and it is much to be hoped that the task may be taken in hand shortly, so that the results obtained in various countries and by various organisations or individuals may be arranged and coordinated, in order that further inquiry may be pushed along the most promising lines.

The means of observation available are practically kites and small unmanned balloons carrying self-recording instruments, aided to some extent by direct observations made from manned balloons; and the only obstacle to continuous daily or even hourly readings at moderate heights is that of expense.

The free balloons possess the advantages of reaching heights unattainable by any other means, and of being independent of weather conditions. Either paper or rubber balloons are used of about six to ten feet diameter. These balloons are filled with hydrogen, and carry up with them a self-recording meteorograph made as light as possible; they frequently reach heights exceeding ten miles, and it is seldom, at least on the more thickly inhabited parts of the Continent, such as France and Germany, that they are lost. Each balloon carries an attached label offering a small reward to the finder, and the address to which information is to be sent, and in general the meteorograph is recovered with its record in a decipherable condition within a few weeks or a month. It is desirable that the balloon should fall as near as possible to its starting point, and with a rubber balloon this is effected in the following manner. The balloon is only partially filled with gas, and is then securely tied up. As it rises the external pressure is lessened and the gas inside expands, until finally the rubber is no longer able to stand the strain and the balloon bursts. A small parachute is used to prevent a too rapid fall of the meteorograph, and sometimes a second smaller balloon, filled to a less extent, so that it does not burst, is also attached; the second balloon takes the place of the parachute, but is employed that it may float over the position of the fallen meteorograph, and direct attention to it. With paper balloons an automatic arrangement is used by which the balloon is freed when it reaches a certain height. The general result is that the meteorograph returns to the earth within a time of about an hour, and within a distance of a hundred miles from the starting point.

Observations obtained by the help of kites have the advantage of being less costly, but they are dependent on the weather conditions, and it is not often that heights exceeding two miles are reached. At Lindenberg in Germany, the best equipped station for the purpose in existence, last year a height of just on four miles was reached by a train of kites. Given sufficient wind it is a perfectly simple process to send a kite up to the height of a few thousand feet, although if the wind be very strong it is not so simple to draw it back again. The chief obstacle to attaining great altitudes is the wind resistance upon the cord or wire which holds the kite, and it is on this account that the strongest and thinnest obtainable steel wire is used. The wire introduces many technical difficulties; it is difficult and to some extent dangerous to handle, and although capable of withstanding a great strain if fairly used, if a kink is once formed the piece of wire in which it is, is utterly useless. Usually steel music wire, the kind of wire used in a piano in fact, of about 1-32in. in diameter is used; this will bear a weight of 250lbs., and weighs 16lbs. to the mile. With a good kite presenting 77 square feet of surface to the wind and 8000 feet of this wire, a vertical height of one mile is easily reached under favourable conditions of wind, and one kite of this size has carried a meteorograph to 8000 feet of height. The conditions are not always favourable; instead of a steady wind of twenty-five to thirty miles per hour, increasing somewhat with altitude, which affords the best conditions, it not infrequently happens that quite different velocities are found in different strata. It is impossible to get through a stratum in which the velocity is under fifteen miles per hour, and if a velocity of much over forty miles per hour is encountered in the lower strata, the kite is very likely to be damaged or the wire broken. At greater heights a higher velocity is not so likely to cause damage, since the air is less dense, and (a point of perhaps far greater importance) the wind is far steadier.

Hence it is easily seen that to reach very great heights with a train of kites, in addition to having apparatus of the best design and quality, exceptional weather conditions must hold, and the observer must succeed in straining his wire just short, but only just short, of its breaking point. The attempt very often ends in the breaking of the wire near the winch, and the departure of five or six miles of wire and six or eight kites.

Very interesting results have been given by the unmanned balloons. It has been found that when they have reached a great height they fall in some locality lying to the east of their starting point, not necessarily due east, but on a more easterly meridian. Since they pass far beyond the upper limit of the cirrus cloud, this fact confirms the statement that in the temperate latitudes the upper currents are always from some westerly point. M. Teisserenc de Bort also finds that balloons sent up in a cyclone tend to move away from the centre at great heights, thus showing that the cyclonic circulation is not a mere surface phenomenon. He also states that at ten miles height the air is warmer over the cyclone, and colder over the anticyclone.

When observations by means of kites were first started by Mr. Rotch, at Blue Hill, Boston, U.S., it was hoped that the long disputed point as to the origin of cyclones would be elucidated; so far this has not been the case.

Ferrel, the well-known American meteorologist, held that cyclones were convectional effects, and that they were maintained chiefly by the latent heat of condensation of the vapour in the central and rainy part. Dr. Hann on the other hand considers that cyclones are what may be described as driven eddies in the general circulation of the atmosphere. Opinion on the Continent, based on the results of observations obtained by balloons and kites, seems to be in favour of Dr. Hann's hypothesis, but Mr. Clayton, of Blue Hill, U.S., considers that the ascents there made favour the convectional theory. The results of some two hundred kite ascents which I have obtained in England and Scotland, with an average height of about one mile, seem to me to give no evidence one way or the other. I think, however, that a fundamental error has generally been assumed in the discussion. We know that in a gas in equilibrium under a conservative system of forces the isothermal and isobaric surfaces must be identical; this point at least is not open to question. It is not, therefore, the proper test to consider whether the temperature in a cyclone is greater or less than in an anticyclone at the same height, but the test is whether it be greater or less at points on the same isobaric surfaces; and the isobaric surfaces in temperate latitudes may well differ from surfaces of equal height above mean sea level by a thousand feet or more.

W. H. Dines.

THE BICENTENARY CELEBRATION OF THE BIRTH OF BENJAMIN FRANKLIN.

The oldest scientific society in the new world is, I believe, the American Philosophical Society of Philadelphia. The Society was founded by Benjamin Franklin, son of an English father and born at Boston, Massachusetts, in January, 1706. It was natural that the bicentenary of the birth of a man of such extraordinary and diverse genius as Franklin should be commemorated in his native land, and accordingly during the past winter the Society issued invitations to leading universities and societies throughout the world to be present, through their delegates, at a festival to be held at Philadelphia from April 17 to 20. The date of the meeting was no doubt chosen because Philadelphia is liable to be intolerably hot in the summer, and would certainly be deserted at that season by many of the leading members of the Society, yet the chosen time was not a good one for European delegates, since academic duties would certainly preclude any large attendance from across the seas. Although, then, there were actually present only some half-dozen delegates from Europe, yet many European societies were represented by honorary members of American nationality, and sent addresses of congratulation to the Philosophical Society. The United States and Canada were naturally in great force, and the hundred and fifty or two hundred delegates who attended formed an imposing body of men of scientific repute.

The proceedings began on the evening of April 17, when the President of the Society, Prof. Edgar Smith, presided over a meeting of delegates for the reception of addresses. The President began by a speech in which he set forth the share taken by Franklin in the foundation of the Philosophical Society, and the bearers of addresses then handed to him successively, in the chronological order of the several foundations, the documents with which they had been entrusted. I myself had the honour of presenting addresses from Cambridge, the Royal Society, the Royal Institution, the British Association, and the Royal Meteorological Society. I do not know the whole number of addresses, but 126 bodies were represented in one way or another. The evening ended with an interesting ceremony, when Mr. Carnegie, in his robes as Lord Rector of the University of St. Andrews, conferred the degree of doctor on Miss Irwin, a great-granddaughter of Franklin; she is principal of Radcliffe Hall, which bears nearly the same relation to Harvard University that Newnham and Girton do to Cambridge.

Wednesday, April 18, was devoted to the reading of scientific papers, as in a sectional meeting of the British Association. The session was continued on the afternoon of Friday, and twenty-three papers in all were read. Amongst the papers which appeared to excite the greatest interest were those by Chamberlin, de Vries, Pickering, Hall, and Lorentz. I myself gave an account of a paper recently presented to the Royal Society, but as yet unpublished; but before doing so I had the pleasure of presenting to the Philosophical Society two Wedgwood medallions of Benjamin Franklin and of Erasmus Darwin. The archives of the Society show (what I was not aware of) that both Erasmus Darwin and my father had been honorary fellows—an honour which I share myself.

On Thursday morning, April 19, the University of Pennsylvania (of which Franklin was the initiator) conferred, at the hands of its Provost, Mr. Harrison, a number of honorary degrees in the fine theatre called the Academy of Music. The whole pit was occupied by students, and a national flavour was conferred on the ceremonies by their staccato college yell, and by their singing college songs.

An altogether exceptional feature of the ceremony was that a degree was conferred on the King, who was represented by Sir Mortimer Durand, H.M. Ambassador at Washington. In announcing this degree the Provost read with great effect the celebrated speech on England from Henry V. It is pleasant to record the enthusiastic cheers which the whole audience gave, standing, as the Ambassador was hooded. Some fifteen or twenty degrees were afterwards conferred, and the recipients—amongst whom I may name de Vries, Lorentz, Marconi, and Rutherford—were greeted with hearty cheers by the students. Afterwards the Attorney-General of Pennsylvania, Mr. Carson, gave an address on the shares borne by Franklin and by subsequent benefactors in the foundation of the University. In the afternoon there was a public procession to the grave of Franklin, but as I was not present I am unable to give any account of the proceedings.

On Friday morning, April 19, we heard some interesting speeches in the theatre by Mr. Furness, President Elliot, and Mr. Choate, formerly ambassador in London, on the various sides of Franklin's character and activity. On the stage in full view of the audience was the portrait of Franklin which had been removed from America by General Grey at the time of the revolutionary war. It has just been presented to the President of the United States by Lord Grey, Governor-General of Canada, and its ultimate destination will, I believe, be the White House at Washington. This graceful act of international courtesy is highly appreciated in America, and the fact that it coincides with the bicentenary of Franklin's birth can hardly be merely accidental.

After the addresses of which I have spoken came the presentation to the Republic of France, through the French Ambassador, M. Jusserand, of a gold medal commemorative of Franklin. All who have studied the history of the revolutionary war know the importance of Franklin's residence in Paris as a determining factor in the outcome of the war. It may easily be imagined how great was the enthusiasm created by this ceremony.

The festival closed with a banquet in the evening at which there were many striking speeches. An American dinner is managed somewhat differently from our own, for the toast-master is not, as with us, a servant with a stentorian voice, but is the most highly honoured of the hosts of the occasion. Dr. Weir Mitchell, the illustrious physician, performed this arduous task, and gave us a number of appropriate little speeches to the admiration of all.

To describe the other speeches would be simply tedious, but I may mention the excellent speech of M. Jusserand, who referred with the most exquisite tact to the appalling disaster of San Francisco, then at its full height. M. Jusserand is the most accomplished living student of England of the Plantagenet times, and his speech, although clothed in English, retained all the grace of its French origin.

It was natural that the ruin and misery at San Francisco should exercise a certain depressing influence on all, but those responsible for the proceedings determined, rightly, as I think, to carry them through as planned.

Those who have taken part in such festivals in America need not be told that the organisation was admirable and the hospitality unbounded.

G. H. DARWIN.

NOTES.

THE seventy-eighth annual meeting of the German Association of Naturalists and Physicians will be held at Stuttgart on September 16–22.

A REUTER message from Rome on May 5 reports that the volcano of Stromboli is in active eruption. Advices received from Tacna, Chile, state that a violent earthquake shock was felt in that city on May 6, the vibrations lasting thirty-five seconds. The shock was also felt at Arica.

THE death is announced of Prof. Eugène Renevier, professor of geology and palæontology at the University of Lausanne. Prof. Renevier was president of the Swiss Geological Society and president of the Simplon Geological Society.

ON Saturday week, May 19, Sir James Dewar will deliver the first of a course of two lectures at the Royal Institution on "The Old and the New Chemistry." The Friday evening discourse on May 18 will be delivered by Prof. Arthur Schuster, on "International Science."

THE second annual dinner of the London section of the Society of Dyers and Colourists will be held on Wednesday, May 23. Persons interested in dyeing and the allied industries who are not members of the society are specially invited. Particulars may be obtained from the hon. secretary, Mr. Wallace Burton, 219 Shooters Hill Road, Blackheath, S.E.

AT the final meeting of the sixth International Congress of Applied Chemistry on Saturday, it was resolved that the seventh congress shall be held in London, with Sir

William Ramsay, K.C.B., as the president, and Sir Henry Roscoe as honorary president. We hope to give in an early issue an account of matters of interest and importance brought before the recent congress at Rome.

THE astronomical observatory of La Plata has been affiliated with the new National University of La Plata, recently inaugurated by the Minister of Public Instruction of the Argentine Republic. The director of the observatory, Mr. Francisco Porro, invites observers in similar institutions to exchange publications with him, at the Observatorio Astronómico, Universidad Nacional, La Plata.

WE learn from *Science* of April 27 that the University of California and the Lick Observatory were not damaged by the disastrous earthquake of April 18. The buildings of Leland Stanford Junior University suffered severely, the loss being estimated at 800,000*l*. The building of the California Academy of Sciences and its valuable collections were destroyed.

THE engineering journals publish lengthy obituary memoirs of one of the most prominent figures in the industrial life of the north of England—Sir David Dale, Bart., of Darlington, who died suddenly on April 28. He was an eminent authority on economic questions, and probably did more than anyone to promote industrial peace. He was one of the founders of the Iron and Steel Institute, and served as treasurer until his election as president in 1898.

THE Harben lectures of the Royal Institute of Public Health will be delivered by Prof. Elie Metchnikoff, of the Pasteur Institute, Paris, on May 25, 28, and 30. A course of three lectures on "The Bacteriology of Water, Milk, and Tuberculosis," by Dr. Carl Prausnitz, commenced at the institute on Wednesday, May 9, and a course of three lectures on "The Manufacture and Sophistication of Potable Spirits," by Dr. C. E. Harris, will begin on June 12.

WE regret to see the announcement that Mrs. Brightwen, the popular writer on natural history, died on May 5 at seventy-five years of age. In 1890, at the age of sixty, Mrs. Brightwen published her first book, "Wild Nature won by Kindness." This book was very successful. In 1895 "Inmates of My House and Garden" appeared; then followed, in 1897, "Glimpses of Plant Life"; in 1899, "Rambles with Nature Students"; and in 1904, "Quiet Hours with Nature." Mrs. Brightwen was vice-president of the Selborne Society, a Fellow of the Zoological and Entomological Societies, and an active member of various local associations connected with the encouragement of natural history.

THE eighty-ninth annual meeting of the Société helvétique des Sciences naturelles will be held at St. Gall on July 21 to August 1. This will be the fifth time since the foundation of the society that the town of St. Gall has been the place of meeting. On Tuesday, July 31, there will be a discussion on variations among plants and animals and their phylogenetic and physiological importance, with reports upon the subject by Profs. Goebel and Ernst. During the meeting there will also be papers on the following subjects:—modern views on the tectonic synthesis and genesis of the Alps, Prof. Schardt; measurements of base lines in general, with particular reference to the geodetic work connected with the Simplon Tunnel, Prof. Rosenmund; results of the latest explorations made in the Wildkirchli grotto, and their importance to zoology and prehistoric science, Mr. E. Bächler; fossil remains at Kesslerloch and from palæolithic grottos in general, Prof. C. Hescheler; studies of the plankton of the Lake of Constance. The president of the society is Dr. G. Ambühl, and the two secretaries are Dr. H. Rehsteiner and Dr. A. Dreyer.

AFTER being closed for a very considerable time, the fish gallery of the British Museum (Natural History)—or, to be accurate, the southern half of it—has just been re-opened to the public in what may be termed a metamorphosed condition. In place of a dismal crowd of ill-mounted specimens, faded, for the most part, to one dull uniformity, the public has now a small but well-assorted selection of specimens, coloured artificially to imitate, so far as practicable, their appearance in life, and arranged in such a manner that they can be seen to the very best advantage. Descriptive labels—of which only a portion are yet printed—will render the exhibit about as perfect as is at present possible, and the gallery as a whole will enable the public to gain the greatest possible amount of information about fishes with the least possible trouble. As regards the advisability of colouring exhibited specimens of this nature there can scarcely be two opinions, for, although with our present methods and our present lack of knowledge of the appearance of many fishes in life it is impossible to imitate nature closely, yet such an approximation to natural colouring as it is practicable to make is infinitely better than no colour at all.

THE annual dinner of the Institution of Mining and Metallurgy was held on May 4, when a distinguished company of engineers and others assembled. Sir Julius Wernher, in proposing the toast of the institution, insisted that the mining industry has been conducted in the past as seriously and honourably as any other industry in the world. In replying to the toast, the chairman, Mr. William Frecheville, read a letter from Mr. Birrell, the President of the Board of Education, stating that the Government is keenly interested in the proposal to establish an institution at South Kensington for the advancement of the highest technical education, and that a scheme is in course of preparation designed to give effect to the recommendations of the recent departmental committee. The letter went on to express satisfaction that various bodies and persons associated with mining and metallurgy are showing sympathy with the proposed college by contributing to the Bessemer fund, which has for its object the furtherance of mining and metallurgical science by means of advanced education. Mr. Birrell's letter concluded by expressing the hope that this excellent example may be followed by other great industries, all of which must depend for success in no small degree upon the promotion of the study of the higher branches of science. The chairman announced that the subscriptions to the Bessemer memorial amounted to 11,000*l*.

DR. W. N. SHAW, F.R.S., delivered the second of his instructive lectures on "Atmospheric Circulation and its relation to Weather" at the University of London on May 8. The subjects specially dealt with related to persistent and periodical winds, tropical revolving storms and cyclonic depressions of middle latitudes. The lecturer referred more particularly to the rainfall in the various wind-systems, especially in the monsoons, and also quoted some remarkable instances of increase of rain with height above sea-level, for example, at Ascension and St. Helena. Among the many interesting diagrams thrown on the screen we may mention one showing a remarkable fall of the barometer from 755 mm. to 728 mm. during a typhoon at Manila in October, 1882, with an equally sudden rise in the course of a few hours. A wind velocity of 120 miles in the hour (old factor 3) was recorded in this storm. Diagrams of depressions moving across the British Isles were also shown, and an ingenious explanation was given of the usually heavy rainfall in the central portion of the storms.

The contents of the April number of the *American Naturalist*, which include three articles, are chiefly interesting to specialists. The first, by Mr. A. S. Pearse, is devoted to the fresh-water copepod crustaceans of Massachusetts, of which several new species are described. In the second Dr. J. B. Pollock discusses variations in the pollen-grain of *Picea excelsa*, while in the third Mr. A. M. Reese describes in considerable detail the anatomy of the American salamander, *Cryptobranchus allegheniensis*, comparing and contrasting it with that of its larger relative of Japan and China.

The *Journal of Anatomy and Physiology* for April is mainly devoted to anatomical subjects. Dr. Bertram Windle contributes a valuable report (the sixteenth) on recent teratological literature.

The new catalogue (thirty-third edition) of microscopes and appliances issued by Messrs. Carl Zeiss, of Jena, gives a complete list of apparatus manufactured by this eminent firm. Some new and improved microscope stands are included, and the majority of achromatic objectives are reduced in price.

In the *Révue Scientifique* (March 31) Dr. Remlinger discusses the *rôle* of the rat and mouse in the propagation of rabies. These animals are very susceptible to rabies, and Dr. Remlinger adduces evidence which suggests that certain cases of hydrophobia in man, apparently spontaneous, may be due to this source of infection.

According to the *Pioneer Mail* (Allahabad, March 23), the Plague Research Commission has established beyond question the validity of the theory of plague transmission by rat-fleas. A room was selected in which had been found the dead body of a rat suffering from plague. Animals were placed in this room, some protected by fine metallic wire screens against the attacks of rat-fleas, others unprotected. It was soon found that the unprotected animals were attacked by plague, while the protected animals enjoyed a complete immunity.

We learn from the *Pioneer Mail* that snakes and other wild animals accounted for the death of 2195 persons in the Madras Presidency last year, or twenty-six more than in 1904; and they caused the death of 14,899 cattle in 1905 as compared with 14,146 in the previous year. Of the fatalities among human beings, no fewer than 1896, or more than 80 per cent., were caused by snakes; while of those caused by other wild animals 155 were due to tigers, eighty to panthers, ten to wild pigs, nine to bears, eight to wolves, and five to wild dogs. The elephant only accounted for four deaths and the bison for only one, while the hyæna caused the death of two—presumably children. The total number of wild beasts destroyed, for which rewards were paid during the year, was 809, or four more than in the previous year. Included in this total are ninety-two tigers, 666 leopards and panthers, and fifty bears. The only method of reducing danger to life by snakes is apparently, according to our contemporary, the removal of prickly pear and noxious undergrowth.

Bryologists who have had experience of Jameson's "Guide to Mosses" will be glad to know of a similar work, wherein Mr. Symes M. Macvicar provides a revised key to the liverworts of the British Isles. It differs considerably from the key that was originally published in the *Journal of Botany* five years ago, although drawn up on the same lines. It contains merely the tables for determining the genera and keys to the species, without any further details. It is not apparent why the specific names are not given for the monotypic genera, as was done in the earlier issue.

In a contribution to the *Annales Mycologici*, vol. iii., No. 6, 1905, Mr. E. S. Salmon describes three well-marked varieties of the fungus *Phyllactinia corylea*, two of them distinguished by the characters of the conidiophore and the third by the special shape of the conidia. To a certain extent the characteristic features of the varieties appear to be associated with certain hosts, and Mr. Salmon hopes to discover further new varieties in the examination of the conidial stages of the fungus on other host plants; for this purpose he requests the cooperation of mycologists to supply him with material. Should such new varieties be found, it is probable that Phyllactinia, like other genera of the Erysiphaceæ, will prove to have developed special biologic forms on different hosts.

At the meeting of the scientific society of the Kaiserliche Akademie der Wissenschaften, in Vienna (February 1), Prof. F. Krasser and Mr. Kubart contributed a paper on the fossil flora of Moletein, in Moravia; the list of fossils includes *Gleichenia Kurriana, Sequoia Reichenbachi, Aralia formosa*, and *Eucalyptus Geinitzi*. Prof. O. Richter has confirmed the observation recorded by Molisch and others that seedlings, notably vetches and peas, respond more readily to the stimuli of light and gravity in the impure air of the laboratory than in the purer air of a greenhouse. An account of the nature of the mucilage in the fruit of the mistletoe and *Loranthus Europaeus* was presented by Prof. J. Wiesner at the subsequent meeting on February 8.

The occurrence in the United States of three fungi belonging to the Hypocreales or Perisporiales forms the subject of two papers by Prof. G. F. Atkinson. In the *Botanical Gazette*, December, 1905, he discusses the species *velutacea*, formerly referred to the genus Hypocrea, but now assigned to Podocrea or Podostroma. Tulasne and Winter stated that it was parasitic on Clavaria, but Prof. Atkinson agrees with Schröter that it is an autonomous plant, and adduces the evidence that he has obtained specimens in pure cultures from ascospores. In the *Journal of Mycology*, November, 1905, Prof. Atkinson describes a species of Balansia, a genus differing from Claviceps in the formation of a stroma without a sclerotium, found growing parasitically on *Danthonia spicata*, and another fungus, parasitic on Andropogon, for which he proposes a new genus, Dothichloë, allied to Hypocrea and Hypocrella.

Within the last five years much has been written on the subject of the disposal of towns' refuse by fire. The more technical points have, however, received slight attention, and in this direction a paper contributed to the Transactions of the Institution of Engineers and Shipbuilders in Scotland (vol. xlix., part vi.) by Mr. H. Norman Leask throws much light. The forms of furnace in use and their accessories are described, and the results obtained in various parts of the world are considered. The results of careful tests show that, with a destructor of modern type, a high efficiency, both as regards evaporation and burning, is not more costly to work than a destructor burning at a lower rate and giving lower evaporative efficiencies.

THE general report of the Geological Survey of India for the year 1905, published by Mr. T. H. Holland, F.R.S., in the Records of the Geological Survey of India (vol. xxxiii., part ii.), is a document of permanent value. An enormous amount of valuable information on palæontology, petrology, physical geology, seismology, and economic geology has been got together, and the programme of work arranged for the current season indicates that results of more than ordinary interest are likely to be obtained. The investigation of the manganese ore deposits has now been completed, the deposits of chief importance consisting of braunite, psilomelane, and pyrolusite associated with and derived from manganese-bearing silicates occurring as bands and lenticles in the Archæan schists and gneisses. In the same issue of the Records, Mr. T. D. La Touche and Mr. R. R. Simpson describe the Lashio coalfield in the northern Shan States, and Mr. R. R. Simpson describes the Namma, Man-sang, and Man-se-le coalfields, also in the northern Shan States. In the case of Lashio the results are not encouraging. The coal is lignitic with a large proportion of moisture and more than 9 per cent. of ash. The Namma coal, or rather lignite, is distinctly superior to that of any other field in the northern Shan States; but in its raw state it would be a distinctly poor fuel, unfit for locomotive use, and would be mined under the usual difficulties due to soft including rocks.

THE Meteorological Service of the Netherlands, the central office of which is at De Bilt, a suburb of Utrecht, was recently re-organised, and has commenced the issue of a neat octavo publication entitled *Mededeelingen en Verhandelingen*, containing memoirs on meteorological and allied subjects. The articles will be written in Dutch and French, or in French, English, or German according to the nature of the contributions or the wish of the authors. There are separate branches at Amsterdam and Rotterdam; these act as agencies for maritime purposes, and issue local weather forecasts, while the branch at Amsterdam deals exclusively with storm warnings. Among the various useful publications of the Netherlands Institute we may specially mention (1) the daily weather report; (2) the monthly weather review, containing the results of twelve representative stations; and (3) the annals, which have been issued in various forms for fifty-five years; they now contain (1) the results of the observations made in Holland, and at Paramaribo (Surinam), and (2) observations of terrestrial magnetism. The institute has from time to time published valuable works on marine meteorology, and is at present engaged on a meteorological atlas of the Indian seas and other useful investigations.

IN vol. i., part iv., of "Beiträge zur Physik der freien Atmosphäre," Prof. H. Hergesell gives an interesting account of the exploration of the upper air over the Atlantic Ocean north of the Tropic of Cancer, from the Prince of Monaco's yacht in the year 1905. The observations were made under Prof. Hergesell's superintendence by means of tandem sounding-balloons, between 26° and 38° N. lat., and 10° and 42° W. long., and therefore partly in the true region of the trade winds; the chief object was to determine whether the results obtained in the previous year by means of kite experiments between Gibraltar and the Canaries, along the African coast, would be found in the open ocean, beyond the influence of the continent and islands, and at much greater altitudes. The observations of temperature and humidity completely confirmed those obtained in 1904, and further showed that up to altitudes of 12,000 metres and more, winds with northerly components prevailed, and that the anti-trade wind supposed to exist in the adopted theory of atmospheric circulation was not found in those latitudes over the free ocean. Southerly winds were only observed on one day at altitudes of 2000 metres and upwards in lat. 25° 58′ N., the most southerly point reached, but the next day, in lat. 26° 41′ N., the northerly current had again set in. These results differ somewhat from those given by Clayton and Maurice, acting for Mr. Rotch and M. Teisserenc de Bort respectively, in the same latitudes, as they found southerly winds in the upper strata of air. It will be interesting to determine by further experiments whether this difference really exists, and whether in the observations near the Canaries especially it was possibly due to the proximity of the African coast.

A NEW apparatus for determining the mechanical equivalent of heat or thermal capacity of water is described by Prof. H. Rubens in the *Verhandlungen der deutschen physikalischen Gesellschaft*, viii., 5 (1906). In it the work is supplied by turning a cylinder 60 cm. long through 180° and allowing a weight to descend in oil, and the arrangements for the calorimetric determinations obviate the disadvantages of Grimsehl's apparatus.

REFORM of higher education in France forms the subject of a paper in the *Revue générale des Sciences* (xvii., 4) by Prof. A. Turpain. It would appear that the French statutes relating to the appointment of university professors are unsuited to the present times and operate to the detriment of the provincial universities, and, moreover, the new programme of the École Normale tends to draw students from the provinces to Paris.

A NOTE in the *Revue générale des Sciences* (xvii., 4) directs attention to a method of exploding mines by means of acoustic waves. The method is based on the property that when a disc, free to turn about its diameter, is placed in the interior of a cylindrical resonator and the fundamental note sounded, the disc will place itself in a plane perpendicular to the cylinder. By causing the turning disc to complete an electric circuit a mine can be exploded by means of a signal given by a syren on a warship, tuned to the same note as the resonator. The description is taken from the *Technische Rundschau*.

IN a note contributed to the *Atti dei Lincei*, xv., 6, Dr. G. A. Blanc communicates some further results regarding the radio-active substance discovered by him in the thermal springs of Echaillon and Salins Moutiers, in Savoy, and of which an account was given at the congress of radiology at Liége last year. The experiments show the presence of hydrates in which the radio-activity at first increases instead of continually decreasing, thus reproducing the phenomena associated with thorium hydrate rather than those attributed to the element thorium X; but the radio-activity of the present element is far greater than that of ordinary thorium hydrate. In the same journal Messrs. R. Nasini and M. G. Levi give a preliminary note on the radio-activity of the spring at Fiuggi, near Anticoli.

THE α rays emitted by Prof. Marckwald's radio-tellurium are shown by Mr. H. Greinacher in No. 7 of the *Physikalische Zeitschrift* to be capable of causing a marked fluorescence in glass, and a similar but smaller effect in mica and quartz. The observation is of interest inasmuch as the α rays of radio-tellurium have also been shown to possess the property of causing air to fluoresce.

PROF. NERNST and Mr. H. von Wartenberg describe in the *Verhandlungen* of the German Physical Society a new determination of the melting points of platinum and palladium. The method used was an optical one employing a Wanner pyrometer which was specially calibrated for the purpose; the melting point of gold (1064° C.) was taken as the standard of reference. Pure palladium was found to melt at 1541° C. and pure platinum at 1745° C. Dr. Harker's recent determination of the melting point of platinum gave a value of 1710° C.

In spite of its importance as a fundamental physical constant, the latent heat of fusion of ice is known only very approximately. The value obtained by Bunsen was 80·03 cal., whilst Regnault found it to be 79·25 cal. In the *Journal de Physique* (vol. v., p. 157) M. A. Leduc points out that Bunsen's result is subject to an error due to an incorrect determination of the density of ice at 0°. A re-determination of this constant gave a value of 0·9170, and a re-calculation of the latent heat of fusion from Bunsen's data, using this value, gave a result of 79·2 cal. This is in close agreement with Regnault's determination. The principal difficulty experienced in determining the density of ice is in eliminating gas bubbles completely. M. A. Leduc describes an arrangement by which he was enabled to minimise this source of error.

Some remarkable specimens of phosphorescent calcite from Joplin, Missouri, are described by Mr. W. P. Headden in the April number of the *American Journal of Science*. Some of the crystals, after being exposed to sunlight, were found to become highly phosphorescent, and to retain this property for a period of thirteen hours. The specimens of calcite which showed prolonged phosphorescence were always yellow in colour, and contained 0·007 per cent. of ceria, 0·012 per cent. of the didymium earths, and 0·013 per cent. of yttrium and erbium; the spectrum of the latter was very distinct. Purple-coloured specimens of calcite found in the same neighbourhood were shown to owe their colour to the presence of didymium, and to differ from the yellow calcite in being non-phosphorescent. So far as the analytical evidence goes, the phosphorescence of the yellow calcite seems to be associated with the presence of earths of the yttrium group.

A number of foliaceous and fruticose lichens collected by Mr. A. W. C. Herre on the Santa Cruz peninsula, in proximity to San Francisco, are described by him in vol. vii. of the Proceedings of the Washington Academy of Sciences. Parmelia is an important genus, as the species are both numerous and conspicuous; *Parmelia enteromorpha* is a characteristic lichen of the red-wood forest, and *Parmelia Herrei* provides a new species. The new species *Gyrophora diabolica* forms in its locality, the Devil's Cañon, the dominant feature of the lichen rock-flora; another interesting species is the lace lichen, *Ramalina reticulata*, that festoons the oaks. The writer has drawn up a useful key for the determination of genera, and keys to the species.

A publication just received from the Harvard College Observatory describes in detail, and with examples, a telegraphic cipher code devised by Mr. W. P. Gerrish, of that observatory. Numerous advantages are claimed for this system over other systems now in use, its chief characteristic being the ready transmission of groups of figures in a form at once simple to dispatch and readily translatable. A test of the system between the Harvard and Lick observatories gave great satisfaction.

Messrs. Archibald Constable and Co., Ltd., will publish shortly a new book by Prof. H. C. Jones, of the Johns Hopkins University, entitled "The Electrical Theory of Matter and Radio-activity."

Messrs. Dawbarn and Ward, Ltd., are preparing a new issue of their "Directory of Photographic Dark Rooms," and will be glad to receive from photographers information as to any public dark room not included in their directory.

Some of the natural attractions of Norway are described in an illustrated booklet just received from the Albion Steamship Co., Ltd., Newcastle-on-Tyne, containing the itinerary of fortnightly pleasure cruises to the Norwegian fiords by the steam yacht *Midnight Sun*. The cruises are arranged so that passengers may see the most interesting scenery on or near the fiords from the Ryfylke to the Romsdal, and ample time is allowed for excursions away from the ship.

Mr. C. L. Muller has published a pamphlet giving an illustrated description of Dr. Looser's double thermoscope and some of the experiments possible with it. The instrument is an ingenious form of differential thermometer in which great sensitiveness is secured, and so arranged that it is possible to use it in making quantitative determinations. The booklet contains instructions for the performance of fifty-seven experiments in which the thermoscope can be employed.

OUR ASTRONOMICAL COLUMN.

The Expected Return of Holmes's Comet.—From the observations of Holmes's comet in 1899–1900, Dr. H. J. Zwiers has computed a set of elements of the comet's path and an ephemeris for the probable reappearance of the object during the present year.

Having computed the elements for the epoch 1899, Dr. Zwiers applied the Jupiter perturbations for the period January, 1899, to April, 1906, and for January 16·0 (G.M.T.), 1906, found the following elements:—

$$\begin{array}{ll} M = 351^\circ\ 46'\ 52''.14 & \\ \pi = 346\ \ 2\ 31.63 & \\ \Omega = 331\ 45\ 40.75 & 1906\cdot0 \\ i = \ 20\ 48\ 53.30 & \end{array} \qquad \begin{array}{l} \phi = 24^\circ\ 20'\ 25''.55 \\ \mu = 517''.447665 \\ \log a = 0.5574268 \end{array}$$

The ephemeris computed from these elements extends from May 1 to December 31, 1906, and is given, for every alternate day, in No. 4085 of the *Astronomische Nachrichten*.

According to the above elements, the perihelion passage should have taken place at March 14·1804 (G.M.T.), 1906, but, in a supplementary table, Dr. Zwiers gives the ephemeris corrections which will become necessary should it occur either four days earlier or later.

The Luminosity of the Brighter Stars.—An interesting discussion of the luminosity of the brighter stars is published by Mr. George C. Comstock in No. 3, vol. xxiii., of the *Astrophysical Journal*.

Of twenty-five stars discussed, the brightest in the heavens, Mr. Comstock finds that twenty-two have luminosities less than 1000, whilst three, β Crucis, Rigel, and Canopus, have luminosities *greatly* exceeding this value, the luminosity of the sun being taken as unity.

In Mr. Comstock's opinion, this irregular distribution of values and the enormous excess of the three exceptions above the mean value render it unlikely that the parallaxes hitherto accepted for these three stars are entirely trustworthy, for it is on them that the values obtained for the luminosities are based.

Surveying the whole discussion, Mr. Comstock arrives at the conclusion that there is no adequate evidence that the maximum of stellar luminosity exceeds 1000, and, further, he opines that the mean luminosity of first-magnitude stars is not less than 100.

The Variable Radial Velocity of ϵ Aurigæ.—In No. 4084 of the *Astronomische Nachrichten* Dr. H. Ludendorff discusses the variable radial velocity of the star ϵ Aurigæ.

The variability of this object was discovered by Fritsch in 1821, and its variable velocity by Vogel and Eberhard in 1902.

The present discussion is based on the measurements of twenty-six plates obtained between November 9, 1901, and March 23, 1905, with the No. iv. spectrograph and the 32·5 cm. refractor of the Potsdam Observatory.

The values obtained for the velocity, referred to the sun, vary between +5·3 km. (on November 9, 1901) and −16·9 km. (on December 11, 1902).

Early Observations of Eros.—No. 10, vol. liii., of the Harvard College Observatory Annals contains the details of a number of observations of Eros made at Harvard from twenty-one photographs obtained during the period 1893 (October) to 1896 (June).

The measurements of these plates were published in Circular No. 51 of the observatory, but in the present publication the whole of the data relating to the plates, the original measurements of the photographs, the positions of the standard stars employed, reproductions of the photographs, and many other important matters are dealt with in great detail.

As this number forms the concluding part of vol. liii. of the Annals, several reproductions previously given in the text are now reproduced on plates in a much more satisfactory manner, and published as an appendix.

Observations of Satellites in 1904 and 1905.—In No. 94 of the Lick Observatory Bulletins Prof. R. G. Aitken publishes the results of the observations of satellites made at Lick during 1904 and 1905.

Forty-seven observations of the satellites of Uranus were made, the position angle and distance of each object being referred to those of another satellite.

The second part of the publication refers to the observations of Saturn's satellites during 1905, which were, in some measure, a continuation of Prof. Hussey's work in previous years. Only those combinations most likely to improve our knowledge of the orbits of the inner satellites, *i.e.* Rhea with Dione, Tethys with Enceladus, and, as a check, Tethys with Rhea, were, however, measured. Four eclipses of Saturn's satellites were also observed.

Observations of Jupiter's fifth satellite, made during 1904 and 1905, referring this object to the three inner satellites, form the subject of the concluding section of the Bulletin.

New Variable Stars in Orion.—From a study of the Heidelberg 6-inch plates, Prof. Max Wolf has discovered seven new variables in Orion.

Photomicrographic reproductions, through a microscope, of the regions containing the stars on the 6-inch plates are given, together with the positions and observed variations of the seven objects, in No. 4085 of the *Astronomische Nachrichten*.

RECENT ADVANCES IN SEISMOLOGY.[1]

THE most remarkable development in modern seismology is not the seismic survey of a city, or even of a country, but of the whole world. This branch of inquiry is now in active progress. Since the time of the great earthquake of Lisbon in 1755 it has been known that disturbances of the magnitude of that event, although not directly recognisable as earthquakes in regions distant from the origin, have nevertheless given evidence of commotion by causing the water in lakes and ponds to oscillate. By observing and timing the movements of the bubbles of sensitive levels, astronomers have recorded unfelt pulsatory movements of the ground which they showed to be the result of seismic disturbances in far distant countries. In Japan these unfelt movements have been automatically recorded since 1884 (Seis. Soc. Trans., vol. x., p. 6). They were recognised to have originated at a great distance, but the centres from which they sprang were not determined. Some years later, while seeking for a gravitational influence of the moon, the late Dr. E. von Rebeur-Paschwitz found on his records abnormal movements, several of which he traced to definite but very distant seismic centres. Before this, indeed, it had been predicted that a large earthquake occurring in any one part of the world would produce movements which, with proper instruments, would be recorded in any other part,[2] but it was not until after von Rebeur's announcement that serious attention was directed to what has proved to be a line of research open to workers in all countries. Many instruments have been designed to record these unfelt breathings of our earth, but there is still much uncertainty in the interpretation of all their records.

Observations also show that large earth-waves are from time to time propagated over the whole surface of the globe. These far-reaching commotions lead to the inference that their originating impulse must have been delivered over a large region. Harboe has shown that within a meizoseismic area blows of varying intensity have been struck in quick succession at points long distances apart. A district appears to have given way, not simply along the line of one large fault, but along many minor faults. Oldham estimated that the Assam earthquake of 1897 had been accompanied by the bodily displacement of 10,000 square miles of country along a thrust plane. If we interpret the time observations made in connection with this disturbance in the light of the suggestion made by Harboe, then this relief of seismic strain originated over an area of 500,000 square miles.

Although a large block of the earth's crust may thus be fractured, our knowledge of the depth to which the effects of fracturing descend is largely one of inference. From the observations hitherto published, which are now in progress at Przibram, it would seem that a seismogram obtained at a depth of 1150 metres differs but little from one obtained on the surface. This is contrary to observations on small earthquakes, which, although they may alarm the inhabitants of a town and shatter chimneys, may pass unnoticed in shallow mines.

The fact that the large earth-waves have what is practically a constant arcual velocity of approximately 3 km. per second, whether the path be across continents, over ocean floors, or over districts which vary greatly in their geological structure, suggests the idea that the crust of the earth is moved as a whole, and that under the influence of its own elasticity and gravity it behaves in a manner similar to a sheet of ice upon an ocean swell. An alternative view is to assume that the wave motion is due to energy retained within the crust itself, the heterogeneity of which is superficial. Whichever be the case, we may picture a crust yielding irregularly, and possibly through its total thickness, until it gives up its energy to a medium which transmits undulatory movements with uniform velocity.

Many hypotheses have been adduced which suggest thicknesses for the superficial covering of our globe. To these as an outcome of recent seismological research we may add one more. Preceding the large waves of a teleseismic disturbance we find preliminary tremors. These are apparently propagated through the body of the globe with an average speed along paths which are assumed to be chords at about 10 km. per second. This high and nearly constant rate of transmission, however, only obtains for paths which represent arcs greater than 30°. For chords which lie within a depth of thirty miles the recorded speeds do not exceed those which we should expect for waves of compression in rocky material. This, therefore, is a maximum depth at which we should look for materials having similar physical properties to those we see on the earth's surface. Beneath this limit the materials of the outer part of this planet appear rapidly to merge into a fairly homogeneous nucleus with a high rigidity. Following closely on the heels of the preliminary tremors, but in advance of the large undulations, a second phase of motion appears, the chordal velocity of which up to distances of 120° is approximately 6 km. per second. These are tentatively regarded as the outcrop of distortional waves. When these are better understood it may be expected that they also will play their part in shedding fresh light upon the physics of the earth.

I will now turn to a consideration of the regions in which these sudden accelerations of geological change are in operation. They may be grouped as follows:—

Regions which lie on the western suboceanic frontier of the American and the eastern frontier of the Asiatic continents, and regions which lie on a band passing from the West Indies through the Mediterranean to the Himalayas.

In addition to these there are two minor regions, one following the eastern suboceanic frontier of the African continent, which I have called the Malagasy region, and

[1] Abridged from the Bakerian Lecture delivered by Prof. John Milne, F.R.S., at the Royal Society on March 22.

[2] See "Earthquakes," p. 225, International Scientific Series, 1883.

an Antarctic region which lies to the south-west of New Zealand.

Generally it would appear that regions of instability are to be found along the margins of continents or tablelands which rise suddenly to considerable heights above oceanic or other plains.

At the present time we may, therefore, say that megaseismic disturbances do not occur anywhere, but only in districts with similar contours. Are we dealing with primitive troughs and ridges which are simply altering their dimensions under the continued influence of secular contraction, or do these reliefs of seismic strain represent isostatic adjustments which denudation and sedimentation demand?

These and other activities may be looked to as primal causes leading up to displays of pronounced seismic activity. Their frequency, however, may be dominated by influences which at certain seasons or times cause an increase or decrease in seismic strain.

In the wide variations in position and rapidity of flow of ocean currents and in measured oscillations of sea-level which appear to be seasonal in their recurrence, we see influences which may give rise to seismic frequency in districts that possess a high degree of seismic sensibility. Other causes affecting large areas, and also possibly the frequency of small or after-shocks in different seismic districts, have by Knott and others been sought for in the loads due to the accumulation of snow, and in the seasonal fluctuations in the direction of barometric gradients. It does not seem likely, however, that stresses due to such influences have any marked effect upon the frequency of those reliefs of seismic strain which shake the world.

The data which we possess bearing upon this question are as yet far too meagre to admit of satisfactory analysis. It is, nevertheless, interesting to note the direction in which they point. In the six years ending in 1904 we find that off the west coast of North America fifty-one large earthquakes originated during the winter months (October to May) and thirty-five during the summer months. Off the east coast of Asia, north of the equator, the numbers for these seasons were forty-nine and forty-three. These numbers added together show that for the North Pacific, as a whole, 100 disturbances took place in winter and seventy-eight in summer, while in the Central Asian or Himalayan region the corresponding numbers are twenty-five and twenty-seven. Beneath an ocean, therefore, some indication has been obtained of seasonal seismic frequency, while on a continental surface no such frequency has yet been indicated.

If we take a chart showing the varying position of our earth's North Pole in relation to its mean position, we see that the secular movement of the pole is by no means always uniform. Although it may at times follow a path about its mean position which is approximately circular, at other times there are comparatively sharp changes in direction of motion which may even become retrograde. If now on a chart of this description we mark the time-positions of very large earthquakes, we find that they cluster round the sharper bends of the pole path.

In a period of nearly thirteen years (1892 to 1904) I find records for at least 750 world-shaking earthquakes, which may be referred to three periods continuous with each other, and each two-tenths of a year or seventy-three days' duration. The first period occurs when the pole movement followed an approximately straight line or curve of large radius, the second equal period when it was undergoing deflection or following a path of short radius, and the third when the movement was similar to that of the first period. The numbers of earthquakes in each of these periods taken in the order named were 211, 307, and 232, that is to say, during the period when the change in direction of motion has been comparatively rapid, the relief of seismic strain has not only been marked, but it has been localised along the junctions of land blocks and land plains where we should expect to find that the stress due to change in direction of motion was at a maximum. Until the magnitude of these induced stresses has been estimated, it would be premature to assume that the frequency under consideration is directly due to change in direction of pole movement, it being quite as likely that both phenomena may result from a general cause.

A world-shaking earthquake, wherever its motion is pronounced, gives rise to movements which may extend over three or four hours. They come to a close as a series of pulsations, each lasting a few minutes, and separated from each other by approximately equal intervals of rest. The expiring efforts of an earthquake present something more akin to musical reverberation than to intermittent and irregular settlement of disjointed material.

If instead of studying the life-history of an earthquake as recorded at a given station, we compare the seismograms it has yielded at different distances from its origin, we learn something of the manner in which its energy has been radiated and dissipated. An earthquake which in the vicinity of its origin has a duration of sixty minutes may appear at its antipodes ninety or 100 minutes later as a feeble movement with a duration of only four or five minutes. From the time this movement has taken to travel the half circumference of the globe the inference may be drawn that the surviving phase of such an earthquake is that of the large waves. The compressional and distortional precursors, together with the rhythmical succession of followers, are no longer visible on seismograms. The importance of this knowledge to those who are engaged in the analysis of earthquake registers is apparent.

The paucity of available data renders it premature to

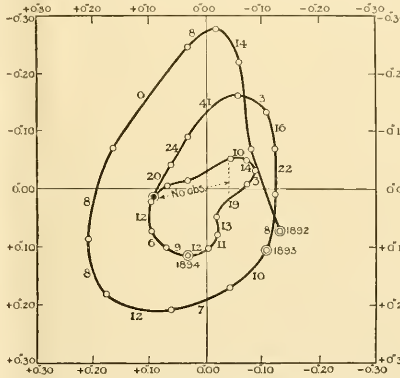

Fig. 1 shows, after Th. Albrecht, the path of the North Pole from 1892 to 1894 inclusive. Each year is divided into tenths or periods of 36·5 days. Numerals indicate the number of large earthquakes which occurred in each of these divisions, commencing with the third tenth of 1892.

make deductions respecting possible alternation in seismic frequency in various localities. But if, instead of confining our attention to a relationship between earthquakes, we consider the question of the relief of volcanic strain, many illustrations may be adduced which indicate a close connection between such activities. For example, all the known volcanic eruptions which have occurred in the Antilles, from the first which took place in 1692, have been heralded or closely accompanied by large earthquakes in that region, but more frequently by like disturbances in neighbouring rock-folds, particularly that of the Cordilleras. This was notably the case in 1902. On April 19 of that year an unusually large earthquake devastated cities in Guatemala. Small local shocks were felt in the West Indies, and on April 25 it was noticed that steam was escaping from the crater of the Mont Pelée, in Martinique. These activities continued to increase until May 8, when they terminated with terrific explosions, submarine disturbances, and the devastation of great portions of the islands of Martinique and St. Vincent.

The last illustration of hypogene relationship between these regions occurred on January 31 of the present year. On that date a heavy earthquake originated off the mouth of the Esmeralda River, in Colombia. Sea-waves inundated the coast, islands sank, and a volcano erupted. The newspapers of February 2 announced that cables between Jamaica and Puerto Rico had been interrupted, and on later dates it was reported that severe shocks had been felt among the West Indian islands, that six or seven submarine cables had been broken, and that Mont Pelée and La Soufrière, in St. Vincent, were again active.

In concluding this short discourse, I wish to direct attention to a class of phenomena from which the working seismologist cannot escape. At certain times horizontal pendulums may be fitfully moving continuously for hours or even days. Similar movements have often been noticed with balances and with other instruments. They are frequently referred to as microseismic disturbances. Inasmuch as they vary with varying meteorological conditions, and

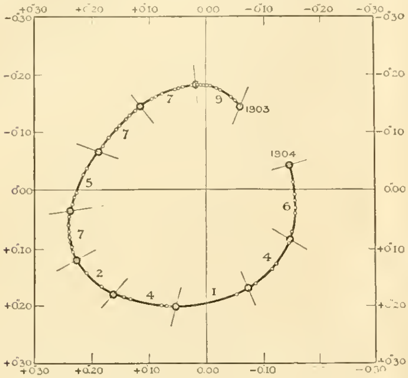

Fig. 2.—This is similar to Fig. 1, but refers to the year 1903, during which period the pole displacement was more uniform than that indicated in Fig. 1.

may be different in neighbouring rooms, I am inclined to think that it would be more accurate to describe these unwelcome visitors, with which not only seismologists, but also astronomers and others, have to contend, as air tremors. When, however, these irregular movements are replaced by movements which have definite periods very different from those of the recording instrument itself, and are at the same time regular in amplitude, it seems possible that they may be connected with actual pulsatory motion of the surface of the ground.

In addition to tremors and pulsations, the records on the films from seismographs show that nearly at all times

with barometric loading. The quantity of water in wells and that flowing in drains and from springs has been observed to vary with fluctuations in atmospheric pressure. Where this takes place, subsurface operations are revealed which may be sufficient to give rise to changes in surface level. Very marked changes of level take place at certain stations during wet weather. In the Isle of Wight, at Shide, which is situated on the side of a valley cut through an anticline of chalk, when heavy rain occurs, levels and horizontal pendulums indicate a tilting towards the bed of the valley. An instrument on the opposite side of the valley behaves in a corresponding manner. In other words, if these observed movements can be regarded as extending to the bed of the valley, it may be said that with rain the steepness of each of its sides is increased. During fine weather the direction of movement is reversed. A more regular movement is, however, found in a tilting known as the diurnal wave. With the same assumption as to the extent of corresponding motion we find, but only during fine weather, that the direction of movement of the sides of the same valley during the night corresponds to that observed during wet weather. During the day it is the same as that which takes place during fine weather. For convenience we may regard the valley as opening and closing. Similar observations have been made on the two sides of a valley which has been cut through alluvium in Tokio.

Probably an important part in the production of these diurnal movements is played by the differential loading and unloading of neighbouring areas by solar influences. During wet weather, in virtue of subsurface percolation and lateral drainage generally, the sides and bottom of a valley where water-level is raised carry a greater load than the bounding ridges. Under these conditions the bottom of a valley may sag and its sides close inwards. During fine weather, in virtue of evaporation and drainage, a movement in the opposite direction may be established. The fine-weather diurnal movement corresponding to the opening of a valley may find a partial explanation in the removal of load by evaporation, but more particularly by plant-transpiration. These activities are more pronounced during the day than at night, and they tend to reduce subsurface percolation and drainage towards the bed of a valley. The comparatively small retrograde nocturnal movement may be partly attributed to an increase of valley load at night, at which time transpiration and evaporation are replaced by surface and subsurface condensation. Transpiration and evaporation being at a minimum at night, it may be assumed that lateral percolation and surface drainage towards the bed of a valley are increased, and, possibly as a consequence of this action, the volume of water in certain wells and that flowing in certain streams and drains has been found to be greater at night than during the day.

Another activity which may result in a nocturnal increase

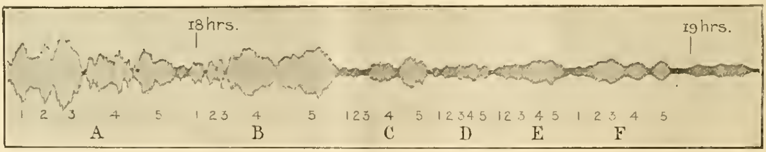

Fig. 3.—Recurrences of Wave Groups A to F in the terminal vibrations of the Colombian Earthquake of January 31, as recorded at Shide, Isle of Wight. Scale 108 mm. = 1 hour.

a slow change of level is taking place. For years a pier may be undergoing a tilt in one direction. Besides this general movement the instruments reveal the existence of waves that indicate a difference in the direction of movement in different seasons. Superimposed upon these again we find records of changes of level which may be associated with variations in the difference in loads on two sides of an observing station. When a horizontal pendulum swings towards the area of greatest atmospheric pressure it apparently indicates a change directly or indirectly connected

in the subsurface flow of water is the expansion of the air in soil by the slowly descending heat of the previous day, this expansion forcing soil-water into passages of easiest escape.

The explanation offered for the phenomena under consideration may be found wanting; but the facts remain that round the face of the globe diurnal superficial distortions can be observed which vary in magnitude and direction, and that rainfall is accompanied by measurable changes in the slopes of certain valleys.

GERMAN CONGRESS OF EXPERIMENTAL PSYCHOLOGY.

THE second congress of the German Society for Experimental Psychology took place on April 18–21 in the picturesque old town of Würzburg, partly at the old university and partly at the well-known psychological laboratory of Prof. Külpe. Two visits were paid to Prof. Rieger's nerve hospital. The attendance amounted to nearly 200, and thus was even more numerous than at the first congress two years previously in Giessen. Prof. G. E. Müller was in the chair. Fewer papers were read than before, but nevertheless they could with difficulty be got through in the three and a half days available, reading eight hours a day.

A new feature in this congress and one that indicates the rapid growth and advancing specialisation of experimental psychology—was that several members of the society had been commissioned to make general reports (Sammelreferate) on particular branches of research with which they were known to have an exhaustive acquaintance. Conspicuous among these reports was that of Külpe (Würzburg), on the general state of experimental æsthetics. The methods of experiment were grouped under three general heads, impression (Eindruck), formation (Herstellung), and expression (Ausdruck); each of these admitted of many further subdivisions. The interesting results communicated were mostly of American and very recent origin. In general, Külpe emphatically maintained that æsthetic values are not wholly of a subjective nature (Einfühlung, zuständlich, &c.), but are to some degree at least objective (gegenständlich). The time was near, he said, when these experimental investigations would claim serious attention from both art critics and artists.[1] Sommer (Giessen) gave a very interesting report on psychiatry and individual psychology, tracing back the modern close union and wonderful development of these two sciences to ideas which arose in the eighteenth century, as the natural sequel to the psychological researches of Descartes and, above all, Locke. The execution of these ideas has only been delayed until now for want of adequate methods. Sommer indicated the essentials of good methods of psycho-pathological investigation, particularly insisting upon the necessity of a uniform system of tests, thoroughly tried in normal, border, and distinctly pathological cases. Weygandt (Würzburg) presented a full report on the psychological examination of weak-minded children. Krueger (Leipzig) reported on the relation between phonetics and psychology. In the course of an exhaustive and lucid exposition of the previous methods and results, he showed that hitherto attention had been almost exclusively confined to the bare morphological elements of speech, as represented by the letters of the alphabet. He himself had chiefly investigated how one and the same syllable can be represented by very varying sounds, according to nationality, emotion, or shade of meaning; his graphic registrations of the modulations of voice as regards speed and pitch excited considerable interest among the audience. On a subsequent day Krueger gave a practical demonstration of his ingenious apparatus for registering the vibrations of the larynx (Kehltonschreiber), designed by himself together with Wirth. Schumann (Zürich) gave a report on the psychology of reading. He described the remarkable success with which reading had been taught by whole words, instead of by single letters. A large portion of the paper dealt with tachistoscopy, and especially with the best means of exposing letters to view for very short periods of time; the difficulty is to prevent a persistent after-image, and the remedy recommended is to let the exposed letters be replaced, not by a blank surface, but by another arrangement of letters.

Turning to the exclusively original papers, a remarkable one was read by Stumpf (Berlin) on the "sensations of feeling" (Gefühlsempfindungen). The feeling (*i.e.* the pleasantness or unpleasantness) that characterises a sensation must be sharply distinguished, he finds, from the feeling characterising intellectual states. The former may be conceived in three ways: first, as a "feeling-tone" or mere quality of the sensation; secondly, as a peculiar element of consciousness, closely associated indeed with the sensation, but just as self-existent as the latter; and thirdly, as only another kind of sensation in addition to, and independent of, those of touch, sight, sound, taste, and smell. He expounded the grounds which had now at last compelled him to adopt the *third* alternative. The paper found warm appreciation, but very little acquiescence. Dürr (Würzburg) had, by means of reaction experiments, investigated voluntary action and association. These two had proved themselves perfectly different from one another; the former was either a making distinct (Verdeutlichung) or else a production (Produktionserfolg); the latter was a *re*production (Reproduktionserfolg). Further, his results were in flat contradiction to the popular theory that the ultimately victorious motive must be the one accompanied by the idea of greatest pleasure or least pain. At the same time, he attributed little causal importance to the consciousness of self (Ichbewusstsein). In harmony with his results was a notable experimental investigation of the will by Ach (Marburg). Here too reaction experiments were used, but cleverly devised so that the force of the will and that of association acted in direct opposition to one another. By this means the manifestations of the two forces could be vividly contrasted, and even subjected to a certain degree of measurement. Ach, like Dürr, finds the pleasure-pain theory to be totally discordant with actual observation. Bühler (Würzburg) discussed the experimental analysis of complicated processes of thought. Each of his observers had had to reply to a series of questions, and at the same time to observe carefully the mental process thereby involved. The result had been to corroborate the statement of Ach and Binet, that the real elements of thought are not faint presentations (verblasste Vorstellungen), but ideas (Bewusstheiten). Messer (Giessen), in his experimental psychological investigation of thought (again by means of reaction experiments), had been able to detect and observe the process of "judgment" as a specific conscious experience. He admitted that this was only possible under certain very favourable conditions, and to this cause he attributed the fact that the experiments of Marbe had resulted in a denial of any such specific experience.

Wirth (Leipzig) dealt with the distribution of attention in different senses (sight, sound, and touch). The allotted three-quarters of an hour barely sufficed for enumerating swiftly the chief features of his wonderfully skilful and complicated mechanical arrangements. Of his rich harvest of psychological results he had only time left to exhibit some numerical tables, showing that all parts of each sensory field presented a regular gradation of sensibility, the maximum of which lay wherever the attention happened to be focused. Fortunately, this research will very soon find more adequate expression in print (*Psycholog. Studien*, ii., 2). Unexpected results had been obtained by Specht (Leipzig) concerning the divergence of the relative and absolute thresholds of sensibility under the influence of alcohol; though the power of discriminating between two sounds of different intensity is much weakened by alcohol, the power of hearing a sound at all is actually increased by it. Rupp (Göttingen) had analysed (by reaction experiments) the localisation of touch stimuli on the fingers into two distinct processes: the localisation of the sensation in space, and its attribution to a particular finger. The former process was the quicker one. By means of certain unusual postures the two processes could be brought to give contradictory indications; thereupon the reaction-time was always lengthened, and sometimes the sensation was even attributed to the wrong finger. Linke (Naumburg) showed by his new stroboscopical experiments that stroboscopical effect is not wholly due to after-images, but also in large measure to causes of a more intellectual nature. The investigation by Veraguth (Zürich) of the galvanic psychophysical reflex had revealed that mental excitement has a marked effect on an electric current passing through any part of the body; but Sommer explained that these electric phenomena were of a secondary character, arising from changes of pressure and sweat-excretion. Marbe (Frankfort) exhibited an ingenious, practical, and comparatively inexpensive experimental arrangement for brief optical stimuli; a ray of light of any desired briefness, intensity, or colour is projected beside another similar but continuant ray. Ebbing-

[1] Külpe's paper will be somewhat amplified in the official account of the proceedings of the Congress. (Published by Barth, Leipzig.)

haus demonstrated his new, but already widely adopted, fall apparatus for the control of chronoscopes and other time-measuring instruments (for full description, see *Zeitschr. f Psychologie*, xxx., 292). Several other apparatus were exhibited, but unfortunately not in such rich variety as at Giessen.

The other papers were those of Jerusalem (Vienna), on remembering and forgetting; Witasek (Gratz), on the methodics of measuring memory; Pfeiffer (Würzburg), on a method of determining qualitative types in school-work; Lipmann (Berlin), on the effect of suggestive questions; Asher (Bern), on the law of the specific energies of the senses; Detlessen (Wismar), on colour-values and colour-measurement; Hughes (Soden), on single affective states; Schultze (Würzburg), on accentual effects (Wirkungsakzente); Decroly (Brussels), on anthropometrical and psychological tests for children; v. Aster (Munich), on the third dimension of the spatial presentation (visual); and Kobylecki (Cracow), on psychological experiment without introspection.

On the whole, the congress showed itself strongly influenced by the universal and increasing reaction against the materialistic atomism of the early days of experimental psychology. The admission is ever gaining ground, that consciousness is something more than a mechanically changing conglomeration of sensations and feelings in varying quality, intensity and complication.

The earnest scientific tone and strict attention to business which had so favourably distinguished the Giessen congress from the international ones was on the present occasion even more marked. The members allowed themselves no relaxation until after the close of the proceedings, when a general picnic was made to the beautiful Veitshöchheim "Pleasure Palace" of the former Prince-Bishops. The next congress will be held at Frankfort (on the Main) on April 22–25, 1908. C. Spearman.

THE MILAN INTERNATIONAL EXHIBITION.

The Milan exhibition, which was opened in state by the King and Queen of Italy on April 28, is still far from complete. The reason for its unfinished condition is to be found in the increased scope of the exhibition. As originally planned, it was intended to commemorate the opening of the Simplon Tunnel by confining the exhibition to a display of progress in transport by land and water. Gradually other branches of industry were added, and support has been accorded by the leading European countries, France predominating with an area of 250,000 square feet. Austria follows with 180,000 square feet, Germany with 160,000 square feet, Belgium with 108,000 square feet, Great Britain with 75,000 square feet, and Hungary with 32,000 square feet. The exhibition covers an area of 400 acres, of which more than half is covered by buildings of a decorative character. Italian exhibitors occupy about one-half of the space, and the exhibits afford striking evidence of the remarkable industrial progress that has been made in Italy of late years. Altogether the exhibition is exceptionally attractive from a popular and a business point of view, whilst from a technical point of view its chief interest is due to the fact that it is the first international exhibition in which electricity has been used for driving the machinery shown in operation.

Of the exhibits of scientific interest, the most interesting are those of the Italian Admiralty. The methods employed in the preparation of charts and the manufacture of torpedoes are well shown. The retrospective exhibition associated with the transportation section is also of great interest. The early history of navigation and of steam transport is illustrated in an admirable manner. Exhibits of historical interest are contributed by the Board of Education, the Corporation of London, Lloyd's Register, the Institutions of Civil and Mechanical Engineers, and the Iron and Steel Institute.

In the various international sections valuable prizes are offered by the King of Italy. They include 400*l.* for the best exhibit of machinery, 400*l.* for the best type of workman's dwelling, 400*l.* for the best flying machine, 400*l.* for the best motor omnibus, 200*l.* for automatic railway couplings, 200*l.* for the best method of testing high-voltage electric currents, 200*l.* for motor-boats, and 200*l.* for the best motor-plough.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The University Alembic Club celebrated its hundredth meeting on Saturday, April 28, by holding a dinner in the banqueting room of the Town Hall. The professor of chemistry, the Lee reader, and the Aldrichian demonstrator were present. All the past-presidents of the club and a number of old members attended.

The 283rd meeting of the Junior Scientific Club was held on Friday, May 4, when papers were read on "Bubbles and Emulsions," by Dr. W. Ramsden, and "Who were the Greeks?" by Mr. J. L. Myres.

Cambridge.—The council of the Senate has nominated Prof. Woodhead, Mr. A. Sedgwick, and Mr. A. E. Shipley, and the special board for biology and geology has nominated Prof. Langley, Mr. J. J. Lister, and Mr. F. F. Blackman, to be members of the board of managers of the Quick fund. The election to the Quick professorship of protozoology rests with the board of managers, who will also control the expenditure of the income derived from the bequest of the late Frederick James Quick.

Mr. F. G. Hopkins, of Emmanuel College, and Mr. W. M. Fletcher, of Trinity College, have been elected examiners to the Gedge prize in physiology.

It is arranged that the voting on the proposals of the Studies and Examination Syndicate with reference to the doing away with compulsory Greek for mathematical and natural science students will take place on the afternoons of Friday, May 25, and Saturday, May 26.

Prof. Macalister, Prof. Langley, and Dr. Hill have published a time-table of courses in human anatomy, physiology, and histology to be held during the long vacation, beginning on July 4.

In addition to the ordinary classes in general pathology and pharmacology to be given at the New Medical Schools during the long vacation, the series of shorter courses dealing with more advanced work will be repeated this year. These courses are open to medical men and senior students only.

A course of seven lectures on "The Morphology of the Bryophyta" was commenced by Prof. J. B. Farmer, F.R.S., at the Chelsea Physic Garden on Tuesday, May 8. Admission is free by ticket, obtainable on application to the Academic Registrar of the University of London.

A course of eight lectures on the "Structure and Functions of the Central Nervous System," with special reference to the brain stem, will be commenced in the physiology department of University College, London, by Dr. W. Page May, on Wednesday, May 16. The lectures are open to all students of the University of London, also to qualified medical men on presentation of their cards.

The following benefactions to higher education in the United States are announced in *Science*:—The University of California has received a gift of 20,000*l.* from the widow of the late Judge John H. Boalt. Mr. Andrew Carnegie has offered 8000*l.* to Denison University for a new library building on condition that a like sum is secured elsewhere for the endowment of the library. Through the generosity of Mr. Robert S. Brookings and Mr. Adolphus Busch, the medical department of Washington University (St. Louis) has received a gift of 10,000*l.*

An earnest and well-informed plea for the provision of more adequate funds for the University of Cambridge is made in the current number of the *Quarterly Review*. Though it is a mistake to suppose that the flow of benefactions to the old universities has ceased entirely, the fact remains that Cambridge has twice appealed, once in 1898 and again in 1904, for help to meet her responsibilities. It is alleged that the demands of science have emptied the University chest, and yet there is a popular belief that the university of Newton and Charles Darwin, of Maxwell and Rayleigh, is still shrouded in mediæval shadow. When it is remembered that the expenditure on buildings devoted to science alone since 1862 must have exceeded 300,000*l.*, and that other great expenses have been incurred in the same direction, it is not difficult to understand that it has been done only with external help, and that unless more funds are forthcoming due growth and development in the scientific departments are impossible. There certainly appears to be an absence of extravagance. The average annual income of the forty-four professors is not more than 550*l*., and the average income of university teachers, other than professors, is only 250*l*. a year. The needs of the University, as detailed in the article, are indeed numerous, and the means of satisfying them are at present ludicrously inadequate. As has been done with wearisome iteration in these columns, the article refers to American and German munificence on behalf of higher education, and points out the tempting chance of sensible generosity the needs of Cambridge offer to our men of wealth. The generous provision made for university education in Germany and the United States, the part played by such education in the progress of a modern State, and the need that exists to strengthen our intellectual defences if we are to take a leading position in the struggle toward efficiency, were described by Sir Norman Lockyer in his presidential address to the British Association at Southport in 1903. The warning uttered on that occasion, and the position taken as to the significance of higher education to national progress, have been the means of directing attention to our educational deficiencies, and a beginning has been made to remedy them by increased grants to university colleges. A capital sum of a million and a half sterling would solve all difficulties at Cambridge, but wealthy benefactors tarry, probably because the State has not in the past shown its belief in the value of university education; meanwhile the work of a great university languishes.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 15.—"Reciprocal Innervation of Antagonistic Muscles. Ninth Note. Successive Induction." By Prof. C. S. **Sherrington**, F.R.S.

In various reflex reactions inhibition is succeeded by marked exaltation of activity in the arcs inhibited. This after-effect may be figured as a rebound from inhibition.

An example is the following. When a dog in which the spinal cord has been transected in the thoracic region is, the period of shock having passed, supported so that its spine is vertical and its hind limbs hang freely, these latter begin to perform a rhythmic stepping movement.

Suppose this reflex is in regular progress and is being recorded from one knee, *e.g.* right, by a thread passing thence to a pulley and light lever, if then the other thigh (left) be gently supported from behind the knee the record shows that the stepping reflex at once ceases in the right limb. The reflex, on recommencing after this pause, continues as it ceases, that is, its tempo and amplitude are practically the same as before the interruption.

This result contrasts with the following. The reflex can be cut short by a strong squeeze of the tail.

The application of this stimulus to the tail does not in any way interfere mechanically with the stepping movement. Suppose the reflex to be in regular progress and recorded as before, if then the tail stimulus be applied the stepping reflex is almost immediately arrested, and in both limbs. The reflex remains in abeyance while the tail stimulus is continued. On the cessation of the latter the reflex returns, and on its return soon shows indubitable increase in activity as compared with its activity before the inhibitory arrest. The increase is chiefly seen in the amplitude of the movement, but there is also often marked quickening of the tempo of the rhythm. The author has seen the rhythm on some occasions quickened by 30 per cent. The after-increase of the reflex may persist in evidence for many seconds. Its decline is gradual.

The arrest of the stepping reflex by tail inhibition cannot be prolonged indefinitely. The reflex tends to return in spite of the inhibitory stimulation when the latter is long persisted in. It is different when the stepping reflex is arrested by lifting one knee; the reflex does not then tend to break through the arrest, however long the latter be continued. In this form the arrest seems referable simply to cessation of the stimulus which excites the reflex. In tail inhibition the arrest seems referable to a central inhibition, the peripheral stimulus excitatory of the reflex remaining in action all the time.

The after-increase consequent upon inhibition may be conveniently termed "*successive spinal induction*," the more so as that term directs attention to the likeness between the spinal process and certain visual phenomena commonly designated "induction."

Again, it is easy to evoke reflex extension of the hind limb by stimulation of the skin of the opposite hind limb. With the spinal dog laid on its side (*e.g.* left) and a thread attaching the knee of the slightly flexed right limb to a recording lever, the delivery of a stimulus at a skin-point of the left foot evokes reflex extension at right hip and knee. If this stimulus, at moderate and unchanged intensity, be given at regular intervals, a series of extension reflexes of regular height and duration is obtained. If in the course of such a series the right limb is, during one of the intervals, thrown into strong reflex flexion, the next extension-reflex following on the intercurrent flexion differs from those prior to it in being more ample and more prolonged. Its after-discharge is greatly increased and its latency is sometimes diminished. If the test stimulus for the extension-reflex be adjusted at just subliminal value, the intercurrent flexion-reflex will make it supraliminal. The exaltation of the extension-reflex may remain perceptible for five minutes.

Successive spinal induction seems to be a process qualified to play a part in linking together simpler reflexes so as to form from them reflex cycles of action. It appears especially fitted to combine the successive opposite phases of such cyclic reflexes as have been termed "alternating," and shown to be particularly characteristic of the locomotor activity of the mammalian spinal cord. If a reflex, A, not only temporarily inhibits the action of an antagonistic reflex, B, but also as an immediately subsequent result induces in arc of B a phase of superactivity, the central organ is in that way predisposed for a second reflex opposite to A to occur in immediate succession to A itself. Such an effect seems proved by the observations in this and a preceding communication.

"On the Existence of Cell Communications between Blastomeres." By C. **Shearer**. Communicated by Adam Sedgwick, F.R.S.

In cutting sections of a number of segmentation stages of Eupomatus and Polygordius eggs, delicate protoplasmic strands were frequently observed connecting the blastomeres. Experiments with different fixing reagents demonstrated that they were not of the nature of coagulation artifacts, or the result of disintegration of the protoplasm, for in many of the sections in which they were to be seen all the finer details of histological structure were well preserved. Under favourable conditions they could be observed during the living state, and were similar in all respects to the filose strands described by Andrews in a number of Metazoan eggs. They possibly afford a means of coordinating the various cell activities.

PARIS.

Academy of Sciences, April 23.—M. H. Poincaré in the chair.—The president announced the accidental death of M. Curie, and gave a short account of his work.—The eruption of Vesuvius, and in particular, remarks on the explosive phenomena: A. **Lacroix**. A general account of the recent eruption, with particulars of the lava outflows and the nature of the explosions.—A method allowing of the study of the solar corona at other times than during eclipses: G. **Millochau** and M. **Stefanik**. It is proposed to photograph the regions near the sun's edge by means of the spectroheliograph, isolating the line λ 4303 in the second slit, and eliminating the light from other radiations by means of an appropriate green screen. Preliminary attempts have been made at Meudon with encouraging results, and the authors hope to be able to complete the work at the summit of Mt. Blanc.—Algebraic curves of constant torsion: Eugène **Fabry**.—Reducible groups of linear and homogeneous transformations: Henry **Taber**.—The equation of Laplace with two variables: Georges **Lery**.—The use of an electrical tuning-fork as a generator of alternating currents: M. **Devaux-Charbonnel**. Some anomalous results obtained with the currents generated in the electromagnet of an electrical tuning-fork were examined with a Duddell oscillograph. The effects produced appear to be due to the electrostatic capacity, and cause difficulty when tuning-forks are used in multiplex telegraphy.—Diffusion of solutions and molecular weights: Michel **Yégounow.**—The atomic weight and spark spectrum of terbium: G. **Urbain.** The atomic weight was determined by estimating the amount of water in the carefully purified sulphate $Tb_2(SO_4)_3,8H_2O$, and was found to be 159·2. The spark spectrum of terbium is rich in lines, the wave-lengths of some thirty-seven of the most characteristic being given.—The estimation of cadmium in a volatile or organic salt: H. **Baubigny.** Cadmium sulphide precipitated in the presence of hydrochloric or hydrobromic acids obstinately retains some of the haloid salt, and this, on ignition, owing to the volatility of the chloride and bromide, gives rise to serious losses. The author proposes to convert the impure sulphide into sulphate, and weigh in this form with certain necessary precautions.—Distemper in dogs: H. **Carré.** Dogs which had been kept isolated from birth remained free from distemper, but were always sensitive to inoculation with the disease, whatever mode of inoculation was used. The blood of the animal, collected when the fever is at its height, is sterile, but communicates the disease.—The Tertiary strata at Turritelles and Congeries, Panama: E. **Joukowsky.**—The phenomena of slipping in Sicily: Maurice **Lugeon** and Émile **Argand.**

DIARY OF SOCIETIES.

THURSDAY, MAY 10.

ROYAL SOCIETY, at 4.30.—On Adsorption and Occlusion: the Law of Distribution in the Case in which one of the Phases possesses Rigidity: Prof. M. W. Travers, F.R.S.—Cyanogenesis in Plants, part iv., The Occurrence of Phaseolunatin in Common Flax (*Linum usitatissimum*), part v., The Occurrence of Phaseolunatin in Cassava (*Manihot Aipi* and *Manihot Utilissima*): Prof. W. R. Dunstan, F.R.S., Dr. T. A. Henry, and Dr. S. J. M. Auld.—A Variety of Thorianite from Galle, Ceylon: Prof. W. R. Dunstan, F.R.S., and B. Mouat Jones.—The Mechanism of Carbon Assimilation in Green Plants; the Photolytic Decomposition of Carbon Dioxide *in vitro*: F. L. Usher and J. H. Priestley.—The Action of Anæsthetics on Living Tissues, part ii., The Frog's Skin: Dr. N. H. Alcock.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Long Flame Arc Lamps: L. Andrews (Adjourned Discussion).

MATHEMATICAL SOCIETY, at 5.30.—On the Substitutional Theory of Classes and Relations: Hon. B. Russell.—On Linear Differential Equations of Rank Unity: E. Cunningham.—On the Motion of a Swarm of Particles whose Centre of Gravity describes an Elliptic Orbit of Small Eccentricity about the Sun: Dr. E. J. Routh.—The Theory of Integral Equations: H. Bateman.—Singularities of Power Series in Two Variables: G. H. Hardy.

FRIDAY, MAY 11.

ROYAL INSTITUTION, at 9.—Some Astronomical Consequences of the Pressure of Light: Prof. J. H. Poynting, F.R.S.

PHYSICAL SOCIETY, at 8.—The Dead Points of a Galvanometer Needle for Transient Currents: A. Russell.—Exhibition of Lippmann Capillary Dynamo and Electromotor: Prof. H. A. Wilson.—Exhibition of an Apparatus for demonstrating the Movements of the Diaphragms of Telephonic Transmitters and Receivers and the Current flowing into and out of the Cable during Speech: W. Duddell.

THE MECHANISM OF THE UNIVERSE.

History of the Planetary Systems from Thales to Kepler. By Dr. J. L. E. Dreyer. Pp. xii+432. (Cambridge: University Press, 1906.) Price 10s. 6d. net.

BY the publication of this masterly account of the development of cosmogonic ideas and the history of planetary systems from the early dawn of Greek philosophy to the final establishment of the Copernican system, Dr. Dreyer has rendered a great service to those who take an interest in the fascinating history of astronomical science. Throughout the work we have reason to admire his lucid exposition, based on profound historical studies, of the manifold views formed by the thinking minds of antiquity and of the middle ages on the mechanism of the universe, his definite conclusions on many controversial points, and, above all, his endeavour to trace out, as much as possible, the influences of the philosophic and religious tendencies of the time on the cosmological conceptions under view.

The opening chapters describe the development of astronomical ideas among the Greeks. After a brief review of the cosmogony of the early atomistic school we are introduced to the more distinct teachings of the Pythagoreans. To their conception of the revolution of the earth round the central fire, notwithstanding its crudeness, distinct merit must be attributed, if judged by the favourable influence which the teaching of Philolaus exerted on the propagation of the Copernican system among those "who could only admire philosophers of classical antiquity." Complicated and erroneous as the Pythagorean idea was, it nevertheless paved the way for the true conception of the earth's rotation, but not, as was often believed, for the heliocentric system. The chapter on the primitive geocentric cosmology of Plato may, at first sight, appear somewhat too prominent. Considering, however, the various controversies to which Plato's astronomical system has given rise, a clear statement of his natural philosophy on the basis of an exhaustive analysis of the Dialogues is of importance, even apart from the author's apology that "there is a charm in the poetical conception of the 'soul of the world' which makes the study of the *Timaeus* peculiarly attractive."

With Eudoxus and Kalippus astronomy has started on its career as a science. Eudoxus is the first to go beyond mere speculative reasoning; he distinctly bases his system of the homocentric spheres on the demand of satisfying the observed motions. The possibilities of this mathematically elegant system, recently pointed out by Ideler and Schiaparelli, were, however, not much appreciated by the ancients, although Aristotle had accepted it in the improved version of Kalippus.

Dr. Dreyer's criticism of Aristotelian metaphysics is severe.

"His careful and critical examination of the opinions of previous philosophers makes us regret all the more that his search for the causes of phenomena was often a mere search among words. This tendency, which to us is his great defect, appealed strongly to the medieval mind and helped to retard the development of science in the days of Copernicus and Galileo."

The attempts of finding the physically true system of the world terminated with Herakleides, who taught the rotation of the earth, and Aristarchus, who proposed, as a way of "saving the phenomena," that the earth performed an annual motion round the sun. But the rapid rise of practical astronomy in the Alexandrian school had so enormously increased the knowledge of the complexities of the planetary motions, which none of the proposed systems could explain, that henceforth the idea of grasping the physical truth was altogether abandoned, and attention became concentrated upon a purely geometrical interpretation of the celestial phenomena.

The subsequent exposition of the theory of the epicycles and their utilisation in the Ptolemaic system naturally forms an important part of Dr. Dreyer's work. We cannot enter here upon his valuable account of the work of Apollonius, Hipparchus, Eratosthenes, and Ptolemy; nor can we dwell upon his fascinating picture of the advances in astronomical knowledge during the Alexandrian era, including, as they do, the discovery of the precession by Hipparchus, the mensuration of the earth by Eratosthenes, and general conclusions as to the dimensions of the universe. The chapter closes with a graphic account of the rapid decline of Hellenic culture after the destruction of the Alexandrian library, when "the curtain went down for ever on the great stage where Greek science had played its part so well and so long."

The return to archaic cosmology in Europe under patristic influence and the supreme sway of Aristotelian metaphysics in scholasticism, mark an epoch of scientific decadence in gloomy contrast to the flourishing period of Hellenic culture. But the same epoch is distinguished by the intense cultivation of Greek astronomy among the Arabs, whose labours, devoted to the further development of the Ptolemaic system, are expounded in chapter xi. Although no direct advance in cosmic ideas accrued from their work, they influenced the subsequent advancement of European astronomy in a most important manner by their invention of the trigonometric calculus.

The description of the revival of astronomy in Europe brings us face to face with some interesting philosophers of the pre-Copernican period. The vague and often mystic speculation of Cusa is contrasted with the practical merits of Peurbach and Regiomontanus, who successfully endeavoured to utilise the Ptolemaic system for the purposes of astronomical calculation, while we also find an interesting account of the hopelessly complicated attempts made by Fracastoro and Amici to revive the theory of solid spheres, and thereby to prove the physical truth of the Alexandrian system.

The three closing chapters dealing with Copernicus, Tycho, and Kepler are naturally those which command our special interest. They contain far more than mere statements of the works of these great heroes of astronomical science. They define clearly the specific *rôle* played by each of these actors in the revolution of scientific thought. In following the author through his analysis of "De revolutionibus," we realise not only the great mental power but also the heroism of the "quiet student at the shore of the Baltic," and we feel the importance of the moment when his work is ushered into the world with Osiander's apologetic introduction. We must agree with the author's endeavour to show how little Copernicus could have been influenced by Philolaus and the vague ideas of Aristarchus, whose anticipations detract nothing from the originality of his own thoughts. On the other hand, the exposition of the defects of the system is so lucid that it requires no intimate technical knowledge of astronomy to recognise the necessity of modification, which so immediately urged Tycho to the invention of his ingenious compromise between the geocentric and heliocentric conception.

How far Tycho's all-important work as an observer has paved the way for the final recognition of the true system by Kepler is admirably shown in the last chapter, where the author opens before us the successive paths along which, through a labyrinth of errors and failures, the never tiring genius of Kepler was finally led to the "golden portal of truth." The long and weary road he had to go before he finally broke away from the time-sacred idea of circular motion and the Ptolemaic *punctum aequans*, and proved conclusively the elliptic character of the Martian orbit, is brought before us by an exhaustive analysis of his works, the study of which is so highly instructive, not only from the scientific, but also from the psychological point of view. The reproach, often levelled against the author of the "Mysterium Cosmographicum," of having filled his books with all sorts of mystic fancies, is, in Dr. Dreyer's opinion, founded on a misconception of Kepler's object in making his investigations. "There is the most intimate connection between his speculations and his great achievements; without the former we should never have had the latter."

We cannot attempt to enter upon the author's review of the opinions of science and church on the Copernican system during the time between Kepler and Newton, with which, on the whole, the student of history is familiar, though it is particularly interesting to hear on this matter the verdict of an historian who has derived his knowledge so directly and completely from an exhaustive study of the original prints and manuscripts.

It is difficult to emphasise sufficiently the specific merits of a work of this kind in a brief review. Doubtless not the least of its many meritorious features is the lucidity and conciseness of exposition. In its endeavour to grasp the essence of the cosmogonic ideas the mind is nowhere impeded by an unnecessary accumulation of cumbersome detail. At the same time the non-mathematical reader is supplied with sufficient technical information to secure his acquaintance with the principal geometry of the cosmic systems under discussion. This latter advantage is important in the case of a work which is clearly not written for a limited circulation among the small section of astronomical experts, but may justly claim to appeal to all who are interested in the history of the general development of scientific culture.

PROF. EHLERS'S "FESTSCHRIFT."

Zeitschrift für wissenschaftliche Zoologie. Vols. lxxxii. and lxxxiii. *Festschrift zur Feier seines siebzigsten Geburtstages am* 11 *Nov.* 1905, *Herrn Geheimen Regierungsrat Prof. Ernst Ehlers.* Band i., pp. iv+692; Band ii., pp. 741; and plates. (Leipzig: Engelmann, 1905.) 2 vols., price 5*l.*

THE distinguished zoologist in whose honour these volumes are issued is widely known as an indefatigable worker and one of the most genial of men. Together with the late von Kölliker, Prof. Ehlers has for many years edited the journal which now celebrates his seventieth birthday. As a testimony of the inspiring character of his teaching and of the regard in which he is held this "Festschrift" gives abundant witness. With no less clearness it indicates the diverse activities of modern zoologists and the particular problems upon which they are engaged.

With such a varied content, the volumes are difficult to review. The systematic work, admirable as it is, and coordinating or expanding as it does our knowledge of annelids, starfish, and flat-worms, can only be mentioned; nor can we do more than indicate the purport of a few of the many anatomical and physiological papers.

The place of honour is appropriately given to von Kölliker's paper on the histogenesis of the vertebrate nervous system, the last contribution of the master of histology, whose amazing vitality at eighty-seven years enabled him to conduct research and to discuss difficulties of fact and interpretation with unabated zeal. The month in which this latest defence of the neuron-theory was published brought the tidings that von Kölliker had ceased from work.

A long and exquisitely illustrated memoir by Vejdowsky gives a minute account of the structure and mode of origin of the annelidan vascular system. The nature of this system in the lower animals has been of late the goal of much research. Under the influence of the trophocœl theory, as stated by Lang on the basis of Bergh's work upon annelids, the vascular system has come to be regarded generally as a mesodermic structure, its cavities as a schizocœl, and not, as had often been suggested, a blastocœlic structure. The results of Vejdowsky's work have led him to a very different conclusion. First he proves, what had often been denied, that annelids possess a vascular endothelium. He finds that this "vasothelium" arises in the following way. Blood-vessels are intimately associated with the gut. Their cavities are at first simply a space between the outer ends of the gut-cells and their basal membrane. Into this space cells are budded off from the endoderm. Some of these become differentiated into epithelio-muscle elements that constitute the vasothelium, and others into blood-cells. Thus the study of annelids leads Vejdowsky to conclude that their hæmocœl is a hypoblastic structure *sui generis*, not comparable to that of arthropods or of molluscs, but rather to the cardiac vasothelium in vertebrates. Such a result emphasises that relation of vascular system to the alimentary tract which topography has insisted upon.

In his article on the morphology of the cestode body, Prof. Spengel stoutly supports the monozoic theory. He regards the Bothriocephalidæ as the most primitive tapeworms, and considers that in the highly modified Tæniidæ we have simply a coincidence of somatic and gonidial segmentation areas. Incidentally he suggests the comparison of the scolex with the hinder end of segmented worm, and emphasises the singular nature of the cestodes by pointing out their entire lack of true regenerative power.

The remaining anatomical papers deal with the modifications of clasping organs in arboreal mammals, with the head of collembolous and culicid insects, the nervous system of leeches, and certain abnormal gasteropods.

Of the embryological memoirs, the accurate and laborious research of Wierzejski on the cell-lineage of Physa will be welcomed as a topographical paper of the first rank. Prof. McIntosh contributes a well illustrated account of the life-history of the shanny, and then follow memoirs on the early development of the blind-worm, on the breeding habits of Rhinoderma and of the salamanders.

The physiological papers are of more general interest. Prof. Häcker continues his illuminating work on the skeleton of the Radiolaria by treating the Tripylaria from the same ecological standpoint which he adopted in his paper of last year. Häcker is the most active of a band of workers who are putting new life and new significance into the merely geometric descriptions of earlier students of these skeletal products. Dr. Rhumbler gives a further instalment of his work on the mechanics of streaming movement in Amœbæ, and shows some interesting stream figures produced by dropping chloroform water upon shellac. He fully recognises the inward and autogenous control that dominates those displays in organisms that we cannot parallel in not-living matter, but he holds that in Amœba the phenomena of movement and feeding are capable of mechanical explanation in terms of the aggregation theory which he has formulated elsewhere.

Dr. Jordan contributes an essay on the origin of species in Lepidoptera. His main thesis is to the effect that geographical subspecies, and no other variations, are the material out of which new species have been evolved. Much of the paper is summarised from his earlier work, and represents a line of research to which several naturalists are applying themselves. The work of Petersen on the Fritillaries in particular pursues the method employed by Dr. Jordan, but in a more comprehensive manner, and it is to be hoped that these important results may be rendered more available to the student of evolution than they now are by a new mode of presentation, graphic, tabular, or other than textual description.

Lastly, the memoir of the Baroness von Linden on the influence of heat, cold, and gases upon the coloration of Vanessid butterflies constitutes a further instalment of the author's prolonged investigation. The general conclusion drawn from these experiments is that whatever lowers the rate of pupal metabolism increases amount of black imaginal pigment and diminishes the extent of red colour in the butterfly.

F. W. Gamble.

THE BIRDS OF TUNISIA.

The Birds of Tunisia. Being a history of the birds found in the Regency of Tunis. By J. I. S. Whitaker. 2 vols. Royal 8vo. Pp. xxxii+294 and xviii+410. Plates and maps. (London: R. H. Porter, 1905.) Price £3 3s. net.

THE two handsome and beautifully illustrated volumes containing the history of the birds of the Regency of Tunis form a fitting crown to the years of work in the field, the museum, and the library which their author has devoted to the ornithology of this until recently little known country. They form too a valuable contribution to the avifauna of the western Mediterranean region; for although the present work purports to be merely a history of the birds noticed in Tunisia, and of their lives as observed in that country, the author has thought it advisable, when possible, to allude to the occurrence of the various species also in Algeria and Morocco, as likewise, in some cases, in Tripoli, and in the Mediterranean basin generally.

The articles on various warblers (especially the interesting remarks on their life-history), and other birds which are met with most commonly in that region, will be most welcome, even to those whose interests are restricted to the birds which figure on the British list. Tunisia, a long and somewhat narrow country, stretching from the Mediterranean back in the vagueness of the great desert, presents a great variety of natural features and climate; and the contrast between the well-watered, wooded and mountainous region north of the Atlas Mountains and the rainless, sandy and rocky desert country is very great. To these circumstances, and to the fact, pointed out by the author, that few countries are geographically so favourably situated as the Regency for the observation of the migration of birds, the wealth of the Tunisian avifauna is due. No less than 365 species and subspecies of birds are included in this work; and only about thirty-five of these have to be relegated to the roll of occasional and accidental visitors. Two beautiful photogravures give an excellent and most truthful idea of the character of the scenery and the traveller's mode of life in the south of the country; while other plates introduce the reader to some of those wonderful Roman ruins, so marvellously preserved in that dry, clear air, which so startle the inexperienced wanderer in the central parts of Tunisia.

Each species is fully described, and a careful account of its distribution in Tunis, with some observations on its range in the neighbouring Mediterranean countries, is followed by an interesting and graphic account of its nesting habits, song, and life-history generally.

The four natural divisions into which the Regency may be divided appear to have each certain species peculiar to it, or more abundant in it than in the other regions. Besides this, in the case of some resident species, such as the crested larks, for instance, different forms of the same species are to be found in the different regions, the variation of these forms being in some cases considerable, and not always limited to the coloration of the plumage alone, but occasionally extending to the structural parts of the birds. The crested larks, says the author, afford a striking example of the extent to which local variation may be carried by natural causes, and no country probably affords a better opportunity of observing and studying this subject than Tunisia. The author is naturally in favour of recognising subspecies, and the use of trinomials for them; and his remarks hereon and upon what constitutes a species and a subspecies may be read with great advantage.

Many noteworthy and peculiar birds may be studied in Tunisia, but probably the families of larks and chats are better represented than any other; of the former twenty-one and of the latter eleven species and subspecies are treated, and the fifteen beautifully executed coloured plates which adorn these sumptuous volumes are largely devoted to illustrating these two families. Tunis is indeed especially rich in larks; and years of study, a long series of specimens collected by himself, and an examination of the various types in museums and the literature of the subject, added moreover to his having had the advantage of observing the birds in life, have enabled the author to clear up many puzzling points respecting the specific and subspecific value of the numerous forms of larks. We have here a very clear and lucid exposition of the larks of the western Mediterranean basin; and especially of the crested larks (the most puzzling of them all), of which the author considers that there are two distinct groups, viz., one including the common crested lark of Europe, the other the small-billed crested lark of Southern Spain, each with its allies.

The necessity for protective colouring is undoubtedly great in a country like Southern Tunisia, where the scanty vegetation affords but little shelter to its feathered denizens. Hence it is that the plumage of most of the species resident in the desert and semi-desert region harmonises with the sandy coloration of the soil. This is especially remarkable in the larks. But the author points out that although at first sight it may appear curious that the chats, except in a few instances, are more or less conspicuously coloured, it will, however, be found that the conspicuously attired chats frequent, as a rule, rocky and broken ground full of dark clefts and fissures, where the rocks are sometimes black and in other cases of a glittering white, and in such situations a strongly marked plumage is really far less conspicuous than a uniform light coloured one would be. The ravens also remain as black as ever, but they, too, frequent cliffs and rocks for the most part, and their case seems analogous to that of the rock-haunting chats. Two good maps enable the reader unacquainted with the country to follow the author's remarks on its topography.

O. V. Aplin.

AMŒBÆ AND THEIR ALLIES.

British Fresh-water Rhizopoda. Vol. i. By James Cash, assisted by John Hopkinson. Pp. x + 148 + xvi plates. (Ray Society, 1905.) Price 12*s.* 6*d.* net.

THE important discoveries that have recently been made on the morphology of Protozoa have revived the interest in British fresh-water amœbæ and their allies, and a monograph on the subject has been regarded for some time as a special need of the zoologist.

Mr. James Cash has been known for some years as an ardent microscopist with a special knowledge of the forms and habits of the species of fresh-water rhizopoda in the north of England, and he has given us in this volume the benefit of his experience in this line of work, illustrated by many beautiful original drawings of the living organisms. As a work of reference for the names of species, and in so far as it suggests to the young amateur naturalist exercises for his amusement and instruction, it will be useful; but as references to important details of structure and reproduction are in general meagre, often misleading, and in many instances omitted altogether, it will not supply the need that is felt. The description of the cell (p. 3) as "physiologically, a minute vesicle, or closed sac, the enveloping membrane or cell-wall enclosing the protoplasmic substance in which the functional phenomena reside," appears to us singularly unfortunate in an introduction to the study of the Protozoa.

The description of the nucleus is very short, but long enough to contain considerable extracts from the work of Calkins, whose views the author adopts, but there is no reference to the chromidial network which the recent papers of Hertwig, Schaudinn, and others have shown plays such an important part in reproductive phenomena of many rhizopoda. It is disappointing to find no reference, either in the introduction or in the systematic part, to the evidence of a developmental cycle in the life-history of Amœba, based on the researches of Scheel and Calkins.

In the very brief account of the reproduction of Arcella, again, although Hertwig's important paper published in Kupffer's *Festschrift* is included in the list of references, the statements made are incomplete and misleading. Many other criticisms similar to these could be made, but the critic is disarmed by the confession in the preface that the author has not "investigated very closely the physiological problems associated with the life-history of these organisms." With this confession before them, it seems difficult to account for the action of the council of the Ray Society in undertaking the publication of this monograph without previously enlisting the services of a trained morphologist, with special knowledge of the group, to correct and revise the introduction and the morphological details in the description of the genera.

A monograph written by Mr. Cash, with the co-operation of a good morphologist, might have been one of really first-rate importance. As it now appears, however, useful as it may be in some respects and valuable in others, it is not complete, and does not constitute a serious advance of knowledge.

OUR BOOK SHELF.

Physikalisch-chemisches Centralblatt. Band i. and ii. (in parts). (Berlin: Borntraeger, 1903–1905.)

WE have received the first two volumes of the above serial, the first number of which was issued on December 15, 1903, twenty-four parts and authors' and subject indexes appearing annually. Besides the German title, the cover bears the titles "Physico-Chemical Review" and "Revue physico-chimique," and the abstracts of French and English papers are given in the respective languages, all others being in German.

The periodical is edited by Dr. Max Rudolphi, of Darmstadt, with the collaboration of chemists and physicists in various parts of the world, London being represented by Sir W. Ramsay. Most, if not all, of the papers abstracted would doubtless be found to be noticed in other publications, and although the multiplication of such serials is not to be commended, this one may appeal to physical chemists who prefer to find abstracts on their own subjects separated from those of general physics and of inorganic and organic chemistry. In order that the serial should be useful to workers, it is necessary that the abstracts should be given as soon as possible after the publication of the original papers from which they are taken. It would not be just to criticise a serial in its infancy, but some of the abstracts mght have appeared earlier; possibly their publication has been unavoidably delayed, and as time progresses the cause of this reproach will be removed. The periodical is well printed and contains many tabulated results.

The Philosophy of Martineau in Relation to the Idealism of the Present Day. By Prof. Henry Jones. Pp. 37. (London: Macmillan and Co., Ltd., 1905.) Price 1s. net.

THIS thoughtful and eloquent address, originally delivered at the celebration of the Martineau centenary, contains much more about absolute idealism than about the philosophic system of the great Unitarian preacher. Prof. Jones, after pointing out the close agreement between Martineau and the Idealists in several respects, finds his text in the division made at the beginning of "Types of Ethical Theory" between systems that start with nature or God, and those that start with the spirit of man. Absolute idealism, of course, ranks under the former head, and the idiopsychological ethics of Martineau under the latter. So in the remainder of the paper the doctrines of absolute idealism are re-stated in a form such as might rob Martineau's chief objections of their force—the objections, in particular, that ethical interests are not conserved, and that a refusal to sever man from nature and God means that man is merged into them and lost within them. Whether the reader will think this re-statement absolutely convincing or not will probably depend on his previous sympathies. Prof. Jones takes occasion, in passing, to notice the similarity of Dr. James Ward's "activity" and Martineau's "free will" as philosophic explanations, and takes occasion, too, as in many other recent utterances, to have one or two clever flings at the Pragmatists.

The Romance of the South Seas. By Clement L. Wragge. Pp. xv+312, with 84 illustrations. (London: Chatto and Windus, 1906.) Price 7s. 6d. net.

IN connection with Mr. Wragge's work as Government Meteorologist of Queensland, he paid a visit to New Caledonia, with the view of establishing a weather-observing station there. In this book he gives an account of his visit to the island, and also to Rarotonga and Tahiti. We wish there were more information in the book about the meteorological results of his journey. The volume contains instead simply a chatty account of the islands; and the most interesting matter is the author's visit to the convict prisons in New Caledonia. At Tahiti he paid a pilgrimage to Point Venus, where Cook on June 3, 1769, observed the transit of Venus. The author is enthusiastic over the scenery in both islands, and the only thing that justifies the mention of "romance" in the title is the spell of their scenery. The author's style is very discursive, and the book is full of smoke-room gossip and snatches of sailors' songs. It is illustrated by some good photographs, and in an appendix is a list of some shells and corals which the author collected in the Society Islands.

The Wild Fauna and Flora of the Royal Botanic Gardens, Kew. Kew Bulletin of Miscellaneous Information, additional series v. Pp. vii+223. Edited by Sir William Thiselton-Dyer. (London: H.M. Stationery Office, 1906.) Price 2s.

THIS volume is the combined work of a number of well-known zoologists and botanists, each of whom has made a special section the subject of his own investigation; it ought, therefore, to be exhaustive and trustworthy, as indeed it appears to be. The chief interest attaching to a catalogue of this nature is in relation to the important evidence it will afford in the future as to how a country fauna and flora become gradually modified as their surroundings become altered with the incoming of suburban conditions. Many such changes have already taken place in the animal and vegetable products of Kew; and many more are likely to take place in the near future. One of the most remarkable instances of adaptation to new conditions in the London parks and gardens generally is afforded by the wood-pigeon, which in the country is one of the wildest and shiest of all birds. A conservative spirit—possibly in the case of the mammals a little too conservative—we are glad to see, obtains in the matter of nomenclature. R. L.

Physical Chemistry, and its Applications in Medical and Biological Science. By Dr. Alex. Findlay. Pp. 68. (London: Longmans, Green and Co., 1905.) 2s. net.

THIS little book makes its appearance at an opportune moment, for no one engaged in biological work can now neglect the teachings of physical chemistry, and the great influence which this branch is exercising on the development of the biological sciences. It is just the sort of work the physiologist, pathologist, bacteriologist, and scientific medical practitioner need—brief and at the same time dealing in a simple manner with fundamental facts. The author thus reviews diffusion, osmosis, cryoscopic methods, and the study of osmotic pressures in plants and animals, chemotaxis, the theory of ionisation and its application to the germicidal action of disinfectants, the permeability of membranes and the influence of this on secretion, the velocity of reactions, catalysis, colloidal solutions, and the bearing of physical chemistry on serum therapy, in which connection the work of Ehrlich, Arrhenius, and Madsen is briefly reviewed. Altogether this book supplies a decided want, and can be thoroughly recommended.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Osmotic Pressure.

In the issue of Nature for May 3 (p. 19) appeared an abstract of a recent paper by Prof. Kahlenberg on "Osmosis and Osmotic Pressure." In Prof. Kahlenberg's paper, and also in the abstract, it is claimed that his experiments invalidate van 't Hoff's theory of osmotic pressure, by which the concordance between the pressure of gases and the osmotic pressure of dilute solutions was established. As the basis of that theory seems sometimes to be misunderstood, may I be allowed to recall the principles on which it is founded?

In a paper published in the *Zeitschrift für physikalische Chemie* for 1887, van 't Hoff showed that, from the well-known experimental relation between the solubility of a gas and the pressure, it followed by a simple application of the second law of thermodynamics that the osmotic pressure of a dilute solution must possess the same value as the ordinary pressure of a gas at the same concentration. The solution must be so dilute that the dissolved systems, each made up of a particle of solute as nucleus, and the portion of solvent which it influences, are beyond each others' spheres of action. The proof has been put in a modified form by Lord Rayleigh (Nature, 1897), and Prof. Larmor has obtained the same result by using the fundamental conceptions of the molecular theory as a basis, instead of the experimental solubility relations of a gas (Phil. Trans., A, 1897). In all these proofs no assumption is made as to the nature of osmotic pressure. It may be due to molecular impacts or to chemical affinity, or to some other undiscovered cause. The strength (and weakness) of a thermodynamic proof lies in this very independence of assumptions as to the mechanism by which the effects are produced. Prof. Kahlenberg and his followers seem to consider that the thermodynamic theory of solutions stands or falls with the hypothesis that the pressure is due to molecular bombardment.

If the conditions assumed in the proofs are realised, the whole authority of thermodynamics goes to support the result. The importance of experiments on osmotic pressure, such as those of Prof. Pfeffer, Lord Berkeley and Mr. Hartley, and Prof. Kahlenberg, lies in the question how far the assumptions made in the thermodynamic proofs can be realised experimentally. This is a much humbler *rôle* than that assigned to the experiments by Prof. Kahlenberg, who claims that the application of gas laws to solutions is based on the few observations of Pfeffer and others by which those laws have been verified directly. Nevertheless, the experiments are of great interest. The gas value for the osmotic pressures measured by Pfeffer shows that the conditions laid down in the thermodynamic theory are realised in practice: (1) that for sugar solutions in water an approximately perfect semi-permeable membrane has been obtained; (2) that no selective action such as could be produced by a Maxwellian dæmon is in operation; (3) that the molecules of cane sugar in solution are the simple molecules indicated by the chemical formula, though they may or may not be combined with solvent molecules; (4) that a solution which is dilute in the thermodynamic sense can be realised at possible concentrations; (5) that a theory deduced for volatile solutes may be extended to other cases. When other solutions and different membranes are employed, one or more of these conditions may fail, and the theoretical value be beyond the reach of experimental attainment. Prof. Kahlenberg remarks that because a semi-permeable membrane does not exist, a theory which postulates one cannot be maintained. We might construct a parallel statement by saying that because a frictionless piston is not practically obtainable, in Carnot's engine and the science of reversible thermodynamics physicists and engineers have imagined a vain thing.

But I may point out that at least two perfect semi-permeable surfaces are probably known: (1) when a solution freezes to give the solid of the pure solvent, the solute is compressed into a smaller volume of liquid solution; the surface of the growing crystals is semi-permeable. (2) When a volatile solvent evaporates from the solution of a non-volatile solute, the free surface of the liquid is again a semi-permeable membrane. From these two facts follows the validity of the thermodynamic relations between the osmotic pressure on the one side and the freezing point and vapour pressure on the other. This is important, for it enables us to use measurements of freezing points or vapour pressures when it is not possible to realise the experimental conditions necessary for a satisfactory determination of the true osmotic pressure.

Osmotic pressure is a thermodynamic conception. The pressures observed in practice may or may not represent the same thing. We may define osmotic pressure as the excess of hydrostatic pressure it is necessary to exert on a solution in order that it may be in equilibrium with the solvent through a perfect semi-permeable membrane. With this definition we may use the conception of osmotic pressure as a basis for a Carnot's cycle and a thermodynamic theory of solutions. Prof. Kahlenberg writes that opponents of van 't Hoff's idea have generally held that the so-called osmotic pressure is an ordinary hydrostatic pressure, brought about by the entrance of liquid into the osmotic cell. It is delightful to find one point at least in which the supporters of van 't Hoff, and van 't Hoff himself, are in complete agreement with his opponents.

In the abstract of Prof. Kahlenberg's paper which appeared in Nature we are warned that, among the general ruin of physical theories which is to follow his experiments, the hypothesis of ionic dissociation is involved. I confess that the warning leaves me unmoved. The idea that the ions of electrolytic solutions are dissociated from each other during their movement (though possibly or probably combined with the solvent) is required by the electrical phenomena. The abnormally great osmotic pressures of certain electrolytes dissolved in water indicate some kind of dissociation, but cannot tell us whether or not that dissociation takes place so as to give rise to electrified systems. In simple salts such as potassium chloride, which we know by their electrical properties to be electrically dissociated, it is difficult to see how a second kind of simultaneous dissociation could occur. But that non-electrical separation is sometimes found is indicated by some older experiments of Prof. Kahlenberg himself, who found that solutions of diphenylamine in methyl cyanide show abnormally low molecular weights, but are non-conductors of electricity. The theory of ionic dissociation rests upon electrical evidence, and by such evidence it must be tried. W. C. D. Whetham.

Trinity College, Cambridge, May 12.

Considerable importance seems to be attached to a recent paper by Prof. Kahlenberg on "Osmosis and Osmotic Pressures" (*Jour. Phys. Chem.*, vol. x.), as is evidenced by a separate summary published in Nature (May 3, p. 19). In these circumstances it may not be out of place to point out that the conclusions Prof. Kahlenberg deduces are not warranted.

On p. 142 he says "indirect measurements of osmotic pressures . . . from vapour tensions . . . involves the assumption that the gas laws hold for solutions." This is contrary to fact. We have shown experimentally (see vol. lxxvii. Proc. Roy. Soc.) that aqueous solutions of cane sugar give the same osmotic pressure whether observed directly or deduced indirectly from their vapour pressures, and the relation connecting the osmotic and vapour pressures is quite independent of the "gas laws holding for solutions."

Leaving out of consideration the experiments made before the solutions were stirred—for on Prof. Kahlenberg's own showing these are not good—his conclusion that the gas laws do not hold for dilute solutions in pyridine is based on four experiments. If one may take No. 59 (p. 201) as a type of these, it is easy to show that the experiment is valueless.

The sugar solution used is 0·125 grm. mol. per litre, and a pressure of 98 cm. of mercury is reached, but the theoretical value is some 3 atmos. Now on p. 184 the diameter of his gauge is given as 0·5 mm., and he says that at the end of three days 0·115 grm. sugar has come through the membrane—this quantity represents 2·8 c.c. of solution. If we assume that this volume of solution came through the membrane at a uniform rate, a simple calculation will show that the rate is equivalent to a fall of 20 cm. *per hour* in the gauge. No wonder the theoretical pressure was never reached!

Diurnal Variation of the Ionisation in Closed Vessels.

In his letter on this subject published in Nature of May 3 (p. 8) Mr. G. C. Simpson is, I venture to think, under a misapprehension regarding the conditions which determine the variations of the earth's electric field. His statement of the problem, which I have slightly abbreviated, is as follows:—"It is usual to accept that there is a negative charge on the earth's surface, and the corresponding positive charge is a volume charge distributed in the atmosphere. There is very little volume charge in the air close to the earth's surface, so the relation between potential gradient and charge on the earth's surface is given by $dv/dh = -4\pi\sigma$. Hence it follows that with a given charge on the earth's surface and the corresponding charge in the atmosphere above, the vertical distribution of the charge and the conducting state of the upper atmosphere do not in the slightest affect the potential gradient within a few metres of the earth's surface."

All this is very true, but it is equally true that *with a constant charge on the earth's surface* nothing whatever will affect the potential gradient close to it. Since the potential gradient is a constant multiple of the surface density, it is absurd to consider the variation of the one whilst the other is kept constant. The only assumption that it seems safe to make about the state of the earth's surface is that, owing to the relatively high conductivity of the earth's crust, for purposes of atmospheric electricity it may be treated as an equipotential surface. The charge in any particular region will be determined by the distribution of electrification and ionisation in the atmosphere, and will readjust itself almost instantaneously when any change takes place in the external conditions. It will not, as an incautious reader might gather from Mr. Simpson's letter, behave as if it were glued to the surface of the earth.

In my letter of April 22 I illustrated my point by considering the analogy with the case of ionised air between two parallel plates maintained at a constant difference of potential. As this comparison is inaccurate, I shall take the liberty of putting the case in another way, in the hope that it may prove more convincing. The earth is to be regarded as a conducting sphere which is continuously receiving a negative charge in certain areas—probably those in which rain is falling—and losing it again by conduction through the atmosphere from all the rest of its surface. Since the observations on the earth's field only refer to fine-weather regions, we need only consider what happens over them. There will be an earth-air current which, under specified conditions, will have attained a steady value, the charge on the earth's surface being that required to give the necessary potential gradient to drive the current. Suppose that by some means the ionisation at some distance from the surface suffers a permanent increase locally, whilst the air close to the surface is unaffected. It is clear that, whatever view is taken of the distribution of the charges producing the earth's field, the increase in the ionisation will produce a local increase in the earth-air current; but by hypothesis the conductivity of the air close to the earth is unaltered, so that the increase in the current must be accompanied by an increase in the potential gradient close to the surface. This is, of course, produced by negative electricity flowing from other parts of the earth.

The above, I imagine, is an exaggerated but otherwise trustworthy picture of the effect an ionising radiation from outside would have on the earth's electric field. The conductivity produced by the rays in the upper atmosphere must be enormous compared with the effects close to the earth. Even if the rays were homogeneous, only a mere trace would remain after passing through a layer of air roughly equivalent in absorbing power to 76 cm. of mercury. But it is far from probable that they are homogeneous, and any want of homogeneity would exaggerate the effect. Other factors conspire to this end: the presence of dust near the earth loading the ions and the smaller rate of recombination at low pressures; whilst the increase in the mobility of the ions at low pressures would just compensate for the feebler absorbing power of the upper atmosphere.

It will be observed that the effect on the earth's field of an increase in the ionisation of the atmosphere depends entirely on where that increase takes place. If the conductivity increases in a greater ratio close to the earth's surface than it does further away, the result ought to be a fall in the potential gradient. Mr. Simpson rightly points out that such a relation between the potential gradient and the leakage of electricity near the earth's surface has been shown to exist. From my point of view this indicates that the bulk of the ionisation near the earth's surface is not caused by radiation from an external source.

Defects in Ostrich Feathers in South Africa

The domestication of the ostrich on a practical basis was undertaken in Cape Colony about 1867, and since then ostrich farming has become one of the most important industries in the eastern province. The census of 1904 gave 357,970[1] tame ostriches in the colony, while the export of feathers reached 470,381 pounds, practically the whole of which came from tame birds; the estimated value of the feathers was 1,058,988*l*., giving about 3*l*. 10*s*. per bird of feather-producing age. During the forty years of domestication the instincts of the ostrich have apparently undergone no change, though its habits are much altered. The feathers cut from the tame bird are shorter, weaker, and not so fluffy as those taken from wild birds, but probably these differences are to be correlated with the greater frequency of plucking, and not with any constitutional change resulting from domestication.

Within recent years much concern has arisen from the prevalence of a defect in the growth of the feather, which seriously reduces the value of the plumes to the farmer. The imperfection, technically known as "barring," takes the form of a series of narrow, chevron-shaped bars or malformations across the whole feather. The general appearance of a moderately affected plume is shown in the accompanying photograph (Fig. 1). Examined closely, it is seen that the regularity of the individual barb is much disturbed at the bars, and that the barbules are there defective and only partly differentiated from the barbs. The appearance is such as to suggest that the barbs have been constricted at these particular regions, and that in the development of the feather the barbules have failed to become differentiated and open out, though with a needle their separation can sometimes be effected. Occasionally several barbs will remain joined together at the bars, they also having failed to differentiate. In many cases some of the barbs are shortened, the missing part having broken

[1] The statistics are taken from a paper by the Hon. Arthur Douglass read before the recent meetings of the British Association at Cape Town. Mr. Douglass is the author of a well-known work, "Ostrich Farming in South Africa," and was one of the pioneers in the domestication of the ostrich, and probably the first to hatch the chicks by artificial incubation. His death, shortly after the meetings of the Association, is a great loss to the agricultural and political life of Cape Colony.

off at one or other of the bars, showing these to be places of weakness.

The extent of the barring varies much on different birds and according to locality and season. Sometimes all the wing, tail, and covert feathers are affected, while in others only a few plumes exhibit the imperfection. Again, the number of bars on different feathers varies greatly; frequently they occur at fairly regular intervals along the entire length of the feather, or only a few are present and the rest of the feather is perfect. Where the barring is close, a single barb will be irregular at five or six places along its length. The deficiency can be overcome to a large degree by juxtaposition in the process of "dressing" before the feathers are retailed, but buyers estimate that, as a result of the presence of the bars, the value of the feather to the farmer is frequently diminished from 20 per cent. to 50 per cent., probably an average of about 25 per cent. As the trouble is very general over all the ostrich-farming districts in South Africa, it is manifest that the subject is one which calls for thorough scientific investigation.

The development of the ostrich feather has not yet been

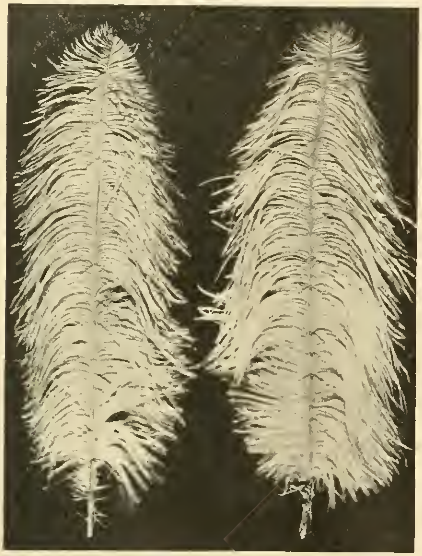

FIG. 1.—Ostrich feathers showing barring.

worked out, but from our knowledge of that of feathers generally there can be no question that the barring represents some interference with the normal growth of the plume at an early stage, an interference which prevents the proper differentiation later of the feather into rachis, barbs, and barbules; moreover, these must recur from time to time during the growth of the feather. As to the cause, the evidence mainly points to impaired nutrition of the feather germ during its early stages. Farmers universally acknowledge that an insufficiency of food during the time the feathers are forming, as from a drought, will result in a plucking full of barrings, breakages, and other malformations. In a general way it is recognised that the better fed the bird the less likely are its feathers to show any defects. Furthermore, from correspondence with Dr. R. M. Strong, of the University of Chicago, who has been engaged upon a study of the development of feathers for years, I learn that experiments have been conducted by Prof. C. O. Whitman and himself upon malformations in other birds exactly similar to those of the ostrich. Ring-doves, after hatching, were alternately starved and fed for some days at a time when the feather was in process of formation, with very remarkable results. On the feathers developing, similar bars were produced in very striking fashion and in great profusion. The results of the experiments were such as to leave no doubt that the barring in this case was due to malnutrition or some disturbance in the metabolism of the bird.

The ostrich farmer, however, is convinced that insufficiency of food is not the only factor involved. Frequently bars appear on the feathers of birds which apparently have been well fed all the time. A general opinion prevails that the ostrich fly, *Hippobosca struthionis*, is often responsible for the trouble, and also the ostrich mite, *Pterolichus bicaudatus*, both of which sometimes infest the birds in large numbers. It is difficult to see how these external parasites can act directly upon the feather germ, but it is undoubted that the progressive farmer who dips or sprays his birds against the pests produces a plumage much less subject to imperfections, and consequently of higher value. Whether the fly or mite can affect the feather directly or only indirectly by lowering the general condition of health of the bird is a subject for investigation, as is also the influence of the tape-worms and thread-worms (*Strongylus douglassi*) which frequently infest the animals. The influence of in-breeding and heredity will also have to be considered. It is significant to find that a similar barring occurs on the ostrich farms in Pasadena, California, among birds which have been ill fed, and the trouble is general on the ostrich farms in Florida, where conditions are not so favourable for birds. A much rarer defect is where the parts of a feather have failed to differentiate along one or more vertical lines extending the whole length of the vane. This irregularity is in all probability the result of some permanent injury to the feather germ or its socket, and occurs independently of the nutritive condition of the bird.

The production of these irregularities in the growth of feathers as epidermal derivatives is of much zoological interest in connection with pathological conditions of epidermal structures generally. As is well known, the enamel of the teeth of children is frequently grooved or pitted in transverse rows, a condition which can usually be traced to some error in feeding, congenital disease, or ailments affecting the general nutrition of the body during the time the teeth were forming; the finger nails are often transversely grooved after an illness or injury, pointing to a response to malnutrition; hair frequently breaks, falls off, or changes in character after an illness from the same cause; the horns of cattle and antelopes occasionally show one or more narrow constrictions representing a diminution in the amount of horny material. All these defects can be correlated with some low condition of health of the animal at the time, and serve to establish that the imperfections in the feathers of ostriches are not an isolated phenomenon, but, *mutatis mutandis*, can be compared with imperfections in the epidermal products of other vertebrates.

While it may be rash to predict before the experiments in hand are completed, yet from the facts already known there seems good reason for expecting that the trouble will be found to rest very largely with the farmer, and that the remedy will be mainly a question of a proper and regular supply of food—not an easy matter in time of droughts. Without question there exists an extremely sensitive relationship between the production of a perfect feather and the proper nutrition of the bird; artificial selection in breeding may also assist towards the production of a strain in which the feathers are less influenced by constitutional changes in the bird. J. E. DUERDEN.

Origin of the Term "Metabatic."

My attention has been directed to the word *metabatic* as relating to the transfer of energy. I should be much obliged if anyone could give me information as to the author of the term, the date of its introduction, or any scientific paper in which it occurs in such form as to betoken its exact meaning. ROBERT E. BAYNES.

Christ Church, Oxford.

THE PEARL FISHERIES OF CEYLON.[1]

THE important series of reports on the pearl-oyster fisheries and on the marine biology of Ceylon, prepared under the direction of Prof. Herdman, which is being published by the Royal Society at the request of the Colonial Government, continues to grow both in size and value. Parts iii. and iv. have been recently issued, and although in the preface to part iii. Prof. Herdman expresses the hope that the whole will be completed in four parts, this has not proved possible, and a fifth part is now contemplated, to contain the concluding sections of the pearl-oyster work, several more supplementary reports of a faunistic character, and a general discussion of the faunistic results.

The two parts of the pearl-oyster report now under review give a summary of the results of the more recent investigations and inspections carried out by Mr. Hornell on the banks in the Gulf of Manaar, together with an account of the pearl fishery of 1905, which proved to be far in excess of any recorded fishery, both in the number of men and boats engaged, and in the quantity and value of the oysters taken, the nearest approach to it being the fishery of the previous year, 1904.

Prof. Herdman and Mr. Hornell have been exceedingly fortunate in being able, so soon after the commencement of their investigations, to study the exact conditions under which these two most successful fisheries have been carried out, and although they state that it does not seem likely that the 1905 results will be rivalled by any prospective fishery of the oysters now in sight upon the grounds, yet the knowledge and insight into the nature of the factors leading to a great and profitable fishery which have been obtained will be of the very highest value in suggesting rational measures for the future control and improvement of the beds; and a careful perusal of Prof. Herdman's reports leaves little doubt that in the case of these pearl-oyster beds, practical measures carried out upon a sufficiently large scale under adequate scientific control will be capable of effectively preventing, in most years, such total failures of the fishery as have been so often recorded in the past, and of ensuring to those engaged in the work a much more certain and uniform return for the labour and capital employed.

The investigations already made show clearly that the different beds or "paars" are subject to very different conditions, and whilst some, which are specially favourable for the growth and development of the oysters, are liable to receive only a small and inadequate fall of "spat," others almost invariably become covered at the breeding season with an abundant supply of the young brood. Since, however, the latter beds are situated further seawards and close to the deeper water, the young brood is frequently, if not generally, destroyed by the action of currents or by being overwhelmed by sand, so that the oysters never attain maturity. These circumstances naturally suggest that the transplantation of young brood oysters in large quantities from the outer exposed beds to the inner ones, which are favourable for their growth and development, will be a highly profitable operation in those years when the inner beds do not receive a natural fall of spat. Such transplantation constitutes one of the principal recommendations which Prof. Herdman and Mr. Hornell make for the development of the fishery, and work on these lines has already been commenced, although in 1905 it was not particularly called for, excepting on the grounds actually cleared during the fishing of the year, owing to a very extensive natural fall of spat on all the beds which had taken place in the autumn of 1904.

Other practical measures which are recommended include "cultching," or the deposit of suitable solid material, such as shells or broken stone, to which the young oysters can attach themselves, the thinning out of overcrowded beds, and the cleaning of the oyster banks by means of the dredge, thereby removing in as large numbers as possible such enemies of the oysters as starfishes, and also other animals which would compete with the oysters for the available supply of food.

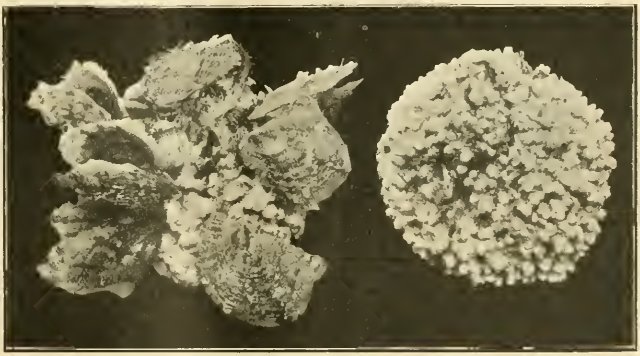

FIG. 1.—Natural cultch (Lithothamnion), and, to the left, a similar Nullipore ball with a dozen young pearl oysters attached. From "Report to the Government of Ceylon on the Pearl Oyster Fisheries of the Gulf of Manaar."

If we may venture upon a word of suggestion, we would express a hope that in the concluding volume Prof. Herdman will furnish us with a concise and sufficient summary of the whole of the pearl-oyster reports, since from the nature of the circumstances in which the series has been produced it is a little difficult to extract from them the essential features of the valuable work accomplished. We wander along pleasantly enough with Prof. Herdman on his explorations in the Gulf of Manaar, and accompany Mr. Hornell with pleasure during his inspections of the pearl banks from year to year; we traverse many an agreeable by-way under Mr. Hornell's direction, and not infrequently retrace our steps along the same paths with Prof. Herdman for our guide; we are allowed to see, as it were, the ideas gradually developing in the minds of the two investigators, and we watch with interest the new facts and suggestions of Mr. Hornell's various letters and reports becoming gradu-

[1] "Report to the Government of Ceylon on the Pearl-Oyster Fisheries of the Gulf of Manaar." By Prof. W. A. Herdman, F.R.S. With Supplementary Reports upon the Marine Biology of Ceylon by other Naturalists. Part iii., pp. viii+328 and plates; and part iv., pp. xvi+242 and plates. (Published at the request of the Colonial Government by the Royal Society, London, 1905.)

ally assimilated into Prof. Herdman's general scheme—all of which would be entertaining enough on a warm afternoon in summer, when we lay on some grassy cliff within sound of the sea, but is, it must be confessed, a little trying to busy individuals anxious to arrive at the kernel of the business in hand.

Of the supplementary reports in parts iii. and iv. the most important is probably Prof. Dendy's monograph on the sponges, which occupies some two hundred pages and is illustrated with sixteen plates. Prof. Dendy describes 146 species from Prof. Herdman's collection, of which 77 are new, and he considers that the most striking feature of the sponge-fauna of Ceylon, next to its richness, is its close relationship with that of Australia and the adjacent islands. On the other hand, it differs considerably from the sponge-fauna of the Red Sea, as well as from that of the south and east coasts of Africa.

In the case of the Alcyoniidæ, on the other hand, Prof. Arthur Thomson notes that there is a great difference between the Ceylon collections and those made off the Maldives by Mr. Gardiner and off New Britain and New Guinea by Dr. Willey.

It is impossible to refer in detail to all the memoirs in these volumes, which contain descriptions of a great number of new or little-known species, and it would be premature to attempt to anticipate the general discussion on the fauna of Ceylon which Prof. Herdman promises for the concluding part of the report. All the memoirs are well illustrated with a number of lithographic plates, of which the very beautiful series accompanying Mr. E. T. Browne's account of the Medusæ may be specially mentioned as doing credit to artist and lithographer alike.

THE ABORIGINES OF UNEXPLORED NEW GUINEA.[1]

In this work Mr. A. E. Pratt gives an account of the time he, with his son, a youth of seventeen, spent in New Guinea collecting zoological specimens during the years 1901–3. A short visit was paid to the Dutch settlement of Merauke, newly established among the Tugeri tribes of Netherlands New Guinea to check the raids into British territory of these enterprising savages, but owing to the unsettled condition of the country no attempt to leave the settlement was made. Mr. Pratt then shifted his quarters to Port Moresby, in British territory, whence moving to Yule Island he organised his expeditions to the mountainous hinterland of the Mekeo district of the Central Division, where almost the whole of his time was spent and where his collections were principally made. A large number of new Lepidoptera, a new fish, and a couple of new reptiles rewarded Mr. Pratt's efforts; but although the object of the expedition was to collect zoological and botanical specimens, Mr. Pratt devotes little space in his book to natural history, its bulk being given to a gossipy description of the author's journeyings, with remarks, too often inaccurate, on the natives he came in contact with.

Mr. Pratt on p. 291 points out that he "cannot pretend to be a trained ethnologist . . .," while his "notes, too, were fragmentary . . . owing to the stress of . . . journeyings and the pressure of work. . . ."

In these circumstances it is easy to forgive the omission of any mention of many problems of the greatest interest, *e.g.* the provenance of the Mekeo stone adze and "pineapple" club, upon which some light might have been thrown in the country visited by Mr. Pratt in his furthest journeys; but, reasonable as are these claims to consideration and forbearance, and difficult and trying as the present writer knows the Mekeo hinterland to be, they do not palliate the publication of such a mass of misstatements and inaccuracies as occur in this book, and are absolutely no excuse for such apparent "faking" of photographs or drawings as produce the ridiculous results shown in the plates facing pp. 168, 262, and 268.

Again, with a perversity that is as determined as it is misplaced, in the map given at the beginning of the volume a number of such well-known Mekeo villages as Aipiana, Inawi, and Rarai are bodily transferred from the right to the left bank of the St. Joseph River, to which Nara village is shifted some twenty miles northwards of its actual site.

Certain of the more glaring inaccuracies in print and picture may now be specified.

The description on p. 71 of Motu pot-making is inaccurate, nor are "several hundred large dug-out canoes brought together and moored side by side at the landing stages in groups of six or seven" (p. 72) to form the lakatoi used on the annual Motu trading expedition to the Papuan Gulf. The present writer has seen many Motu dances, and in 1903 watched the departures of a number of lakatoi from Port Moresby, but certainly never saw a Motu girl "spin round with a dizzying rapidity," and finds it difficult to believe that Mr. Pratt did; while Mr. Pratt's statement is not borne out by the plate, obviously a photograph, he quotes in support of it.

The plate facing p. 168, with its attached legend, "A piebald tribe: The Motu-Motu people of Hoods Bay . . ." constitutes perhaps the most grotesquely erroneous statement in the book, and is not unworthy of an imaginative traveller of the fifteenth century. The plate shows two natives, irregularly spotted with patches of white, wearing a form of perineal bandage which is not worn at Hulaa or anywhere on the Hood Peninsula; and the accompanying letterpress is scarcely less frankly imaginative; "the piebald people are one of the mysteries of New Guinea," says Mr. Pratt, "and their origin is unexplained." The origin of a piebald tribe in Hood Bay is pretty obviously in the fertile imagination of the author, who calls the tribe he has brought into existence the Motu-Motu, this as a matter of fact being the Motu name for the Toaripi of the Papuan Gulf living about 150 miles west of Hood Bay.

Of course "albinos," though they never have pink eyes, occur sporadically all over New Guinea, and are particularly abundant at Hulaa, where there are at least four of these "albinotic" individuals. But apart from elderly folk, in whom leucoderma of the hands and feet, spreading to the forearm and leg, is by no means rare all over British New Guinea, the writer, who has twice visited Hulaa, knows of but one case of partial albinism, a child of about eight years of age belonging to the Sinaugolo, a tribe in no way closely related to the Hulaa folk.

The astounding and wildly unnatural plates which face pp. 262 and 268 cannot be passed without remark. A glance at the latter plate will convince anyone that it represents no tropical jungle, while the whole story of the fishing-nets spun by spiders on bamboo loops erected for this purpose in the jungle, which these two plates illustrate, seems to be a far-off reminiscence of the kite-fishing with a bait of spider's web which skips along the surface of the water practised in the D'Entrecasteaux and other archipelagoes off south-eastern British New Guinea. There are many other inaccuracies and misstatements in the

[1] "Two Years among New Guinea Cannibals." By A. E. Pratt, with Notes and Observations by his Son, H. Pratt. Pp. 360; illustrated. (London: Seeley and Co., Ltd, 1906.) Price 16s. net.

book which for lack of space must pass unnoticed, but the above are probably the most glaring examples.

After such defects as have been discussed it seems almost hypercritical to mention minor blemishes, but it may be pointed out that proper names are often misspelt, and this is the case even with the names of such well-known New Guinea worthies as the Rev. Dr. Lawes. The frequency with which such slips occur suggests that the author may again be travelling, or at any rate that he has not had the opportunity of revising his book. The get-up of the book is good, and where the plates are not imaginative they are often interesting, as is the case with those facing pp. 108, 120, 144, 176, 236, and 244.

C. G. SELIGMANN.

THE ROYAL SOCIETY CONVERSAZIONE.

ON Wednesday of last week, May 9, there was a large assembly at the Royal Society on the occasion of the first of the two conversaziones held annually in the society's rooms at Burlington House. The guests were received by the president, Lord Rayleigh, and included, not only leading men of science, but also representatives of other branches of intellectual activity and national interests. There were numerous exhibits of objects and apparatus illustrating recent scientific work, and the following notes will give an indication of their character. Descriptions relating to exhibits belonging to the same departments of science have so far as possible been brought together. During the evening lantern demonstrations were given by Mr. G. W. Lamplugh, F.R.S., on the Batoka gorge of the Zambezi river, and by Prof. S. P. Thompson, F.R.S., on the electric production of nitrates from the atmosphere. For an account of the Batoka gorge reference should be made to a paper by Mr. Lamplugh in NATURE of November 30, 1905 (vol. lxxiii., p. 111); and the subject of Prof. Thompson's lecture will be found dealt with in NATURE of February 8, 1906 (vol. lxxiii., p. 355), and p. 65 of the present number. In several other cases descriptions of instruments and other objects exhibited have already appeared in the columns of NATURE, and references are given to them in the subjoined summary of the official catalogue.

Mr. T. E. Heath: Stereoscopic star charts and spectroscopic key maps.—*Rev. A. L. Cartie:* Photographs of the solar corona, 1905, August 30, taken at Vinaroz, Spain, with a 4-inch lens and 20-feet coronagraph.—*The Solar Physics Observatory, South Kensington:* (1) Photographs illustrating the eclipse camp at Palma, Majorca (August 30, 1905), and some of the results obtained. (2) Examples of stellar spectra taken with the 6-inch two-prism prismatic camera. (3) Some photographs taken with the spectroheliograph. These include a "disc" photograph taken on August 31, 1905, the day after the total solar eclipse of that year. (4) Curves to illustrate long-period barometric changes in operation in India, East Indies, Australia, and South America. They show the possible evolution of the nineteen-year variation in Australia from the eleven-year (about) variation in India, and the relation of the Australian to the South American changes. (5) Photographs and diagrams illustrating recent work done on the orientation of some British stone circles.—*The Royal Astronomical Society:* Six photographs of the Milky Way taken in 1905 by Prof. E. E. Barnard at Mount Wilson, California.—*The Astronomer Royal:* Photographic prints of the total solar eclipse of 1905, August 30, from negatives taken at Sfax, Tunisia.—*The Director, Meteorological Office:* (1) Antarctic meteorological records with charts and diagrams prepared in connection with the discussion of the results of the Antarctic expeditions. (2) Some recent meteorological results. (*a*) Meteorological charts of the Indian Ocean and Red Sea for the month of May, showing average winds, currents, and other meteorological information, including a reproduction of the chart for May of the tracks of hurricanes prepared by the late Mr. C. Meldrum, F.R.S. The chart is the first of a monthly series to be issued by the Meteorological Office for the use of seamen. (*b*) Diagram exhibiting the relation between Admiral Beaufort's numbers for wind force and the corresponding wind velocity and wind pressure.

Mr. R. Kerr: A torsion spring for transference of energy. (Exhibited on behalf of Prof. L. R. Wilberforce, of University College, Liverpool.)—*Mr. Joseph Goold:* Vibration experiments. Two distinct systems of vibration in the same steel plate are tuned closely to the same pitch. When either system is excited the other also becomes active: and their respective intensities go through a variety of fluctuations, producing remarkable disturbances of the compound node-lines.—*Prof. G. Forbes, F.R.S.:* Model of naval gun-sight, giving correct elevation for any variations of muzzle velocity, air density, and time of flight, as arranged for the 6-inch B.L. gun, Mark XI., under construction at Elswick for trial on H.M.S. *Africa*.—*Sir James Dewar, F.R.S.:* Metallic jacketed vacuum vessels. In these metallic vessels filled with liquid air the vacuum is produced by the use of cooled charcoal. The envelopes may be made of brass, copper, nickel, or tinned iron, with necks made of a bad conducting alloy. The necks can be covered with silvered glass vacuum cylinders which act as stoppers and at the same time utilise the cold of the slowly evaporating liquid. The efficiency of the best metallic flasks is equal to that of the average silvered glass vacuum vessels now generally used in low temperature investigations. Vessels of this type may be useful in industrial cryogenic operations and for the storage and safe transit of liquid air and oxygen.—*Mr. C. V. Boys, F.R.S.:* A gas calorimeter (see vol. lxxiii., p. 354, February 8, 1906).

Mr. G. F. Herbert Smith: A refractometer for liquids. By means of this instrument the refractive indices of liquid and semi-liquid substances may be easily and quickly determined in sodium light to the fourth place of decimals. —*Prof. W. F. Barrett, F.R.S.:* Entoptiscope, for the self-examination of obscurities and defects within the eye.—*Sir William Crookes, F.R.S.:* (1) The ultra-violet spectra of the metals, photographed with a quartz train of five double prisms. The spectrum of pure iron used as a standard. (2) Stereoscopic photographs, taken by Sir W. Crookes on the occasion of the visit of the British Association to South Africa in the autumn of 1905.—*Lord Blythswood:* Photographs of certain arc spectra. The spectra were produced by means of a Blythswood concave diffraction grating, the work being undertaken as a practical test of the gratings. The radius of the grating was 10 feet, the first-order spectrum being photographed. The total length given was about 40 inches, from λ 2100 to λ 7400. —*Dr. W. Marshall Watts:* Binocular spectroscope. The instrument consists of a field-glass, or other form of binocular, in front of the object-glasses of which two exactly similar transparent diffraction gratings are mounted on optically-worked plane glass. As the instrument has neither slit nor collimator it is applicable, in the first instance, only to luminous objects of definite form, such as vacuum tubes. For ordinary observations of flame spectra, or spark spectra, a metal or ebonite plate, with a slit, in front of the Bunsen or spark is employed.—*Mr. Edwin Edser and Mr. Edgar Senior:* Specimens of colour photographs, and photomicrographs. The exhibit included (1) Lippmann spectrum photograph bleached after Neuhauss's method; (2) colour photograph produced by exposing Lippmann film successively to two continuous spectrums, the red end of one being superposed on the blue end of the other; (3) three-colour photographs of coloured objects, including crystals under polarised light; (4) photomicrographs obtained through red, green, and blue colour screens; (5) photomicrographs obtained by the aid of Zeiss apochromatic objective, and other objectives.

Royal Microscopical Society: Micro-Daguerreotypes of blood, milk, and crystals, made by Léon Foucault in 1844. —*Messrs. R. and J. Beck, Ltd.:* Ultimate microscope resolving power with light of different wave-lengths. A specimen of *Amphipheura pellucida* was shown under 1/12 oil immersion 1·25 N.A. A single filament Nernst lamp on a small optical bench was the source of illumination. The beam was split up into a brilliant spectrum by means of a Thorp replica grating, and any portion of the spectrum can be used for illuminating the object. The experiment showed that whereas the diatom is brilliantly resolved with green light, the whole structure is invisible with yellow light.—*Mr. Julius Rheinberg:* (1) Production of achromatic interference bands by the double grating method; (2) photographs chiefly of diatoms, taken by Dr. A. Köhler with the Zeiss apparatus for ultra-violet light.—*Mr. W. Rosenhain:* Improved metallurgical microscope designed for the examination of metal specimens. The base and limb are of particularly rigid construction, and the tube is rigidly attached to the limb. The stage racks on the broad flange of the limb, and is provided with a fine adjustment placed in the line of the optic axis of the microscope. The internal reflectors employed for obtaining "vertical" illumination, instead of being carried on a detachable fitting, are inserted into the tube of the instrument, and are provided with adjusting movements which allow of complete control of the lighting. Special devices for the easy attachment and adjustment of oblique and other illuminators for low-power work are provided, while a detachable bridge can be fitted to the stage so as to adapt it for work with transmitted light. For purposes of photomicrography a focusing motion is provided whereby the eye-piece may be moved relatively to the objective.—*The Director of the National Physical Laboratory:* (1) Photomicrographs of the polished and etched surface of specimens of iron and steel taken during the progress of alternating stress tests, Dr. T. E. Stanton. (2) Photomicrographs, Dr. H. C. H. Carpenter. (3) An apparatus for tests on the strength of materials at very high temperatures, Dr. J. A. Harker. (4) *a*, Picou permeameter (by kind permission of Mr. J. H. Agar Baugh), *b*, Bifilar galvanometer free from zero creep, Mr. A. Campbell.

Dr. P. E. Shaw: An electrical measuring machine (see May 3, p. 22, and vol. lxxii., p. 495).—*Sir Oliver Lodge, F.R.S., and Dr. Alexander Muirhead, F.R.S.:* Wireless telegraphy apparatus for military field purposes. (1) A portable pack-transport set of wireless telegraphy apparatus for military field purposes, available for communications across country for distances up to fifty miles, or 150 miles over sea; with electric valves employed to accumulate the impulses of a small coil and battery, or small dynamo, so as to give discharges of energy only otherwise obtainable from a large and heavy source of electric supply. The arrangement needs no earth connection, nor must it have any when it is required to work over long distances with the greatest efficiency. (2) A vibrating needle point-oil-mercury coherer with telephone receiver.—*Mr. W. Duddell:* Some mechanical and electrical phenomena occurring in the telephonic transmission of speech. The apparatus is intended to demonstrate as curves on a screen the simultaneous movement of the microphone transmitter diaphragm, the current flowing into the telephone line, the current received at the far end of the line, and the movement of the receiver diaphragm when sounds or speech are being transmitted. The similarity of and the difference between these four curves can be examined by the aid of the apparatus, and the distortion and attenuation produced by the resistance, capacity, and self-induction of the line can be demonstrated, as well as the distortions produced by the diaphragms of transmitter and receiver. The characteristic shapes of the curves corresponding to the different vowel sounds and their dependence on the pitch on which they are sung can also be exhibited.—*Mr. L. H. Walter:* New magnetic detector, giving both alternating currents for telephonic reception and continuous currents for recording or visual signals. The detector is a form of differential dynamo in which electric oscillations are made to act upon one armature core only.—*Mr. K. J. Tarrant:* Photographs of electrical discharges, at atmospheric pressure and *in vacuo*.—*Mr. E. G. Rivers:* A new electric heater. The principle of construction departs from that usually adopted. The object in view is to secure a large heating surface at a moderate temperature, and the method exemplified is the use of silicated carbon upon a terra-cotta base, forming an "element." These "elements" assembled together constitute the heater.

Mr. J. E. Stead, F.R.S.: A triple alloy of tin-antimony-arsenic, polished and etched, showing bright curved crystals embedded in a soft matrix or eutectic.—*Dr. G. T. Moody:* Specimens illustrating the indifference of oxygen towards iron in presence of water and the effect of the admission of carbonic acid.—*Messrs. Wallach Bros.:* Oxygen rescue apparatus and other appliances. (1) The "Evertrusty" oxygen apparatus, used by the rescue parties at Courrières, consisting of two oxygen cylinders filled with oxygen, two regenerators through which the vitiated air passes and is regenerated, and which at the same time serve the purpose of ascertaining if the apparatus is in working order prior to use. (2) "Evertrusty" oxygen first-aid case for use in case of carbonic oxide poisoning, or after inhalation of smoke, poisonous fumes, &c., consisting of oxygen cylinder, reducing valve, pressure gauge, bag and mask, with back-pressure valve.—*Dr. O. Silberrad and Mr. H. A. Phillips:* A series of picrates. The salts of picric acid are of interest as having been the probable cause of some of the most disastrous lyddite explosions on record. The specimens exhibited were in many cases prepared in the course of an exhaustive investigation recently carried out at the research laboratories of the Royal Arsenal. Several of the salts exhibited have never before been prepared, and the majority have never previously been obtained pure or correctly analysed.

Director of the Geological Survey of Great Britain: Geological maps, recently issued by the Geological Survey and Museum.—*Prof. John Milne, F.R.S.:* Seismograms of recent earthquakes. (1) North-south and east-west components of the Formosa earthquake of March 16, 1906. (2) Two components of the Colombian earthquake of January 31, 1906. (3) An enlargement of the terminal vibrations of the upper part of Fig. 2. It shows the extinction of an earthquake in wave groups. Each group has a duration of about 2·5 minutes to 3 minutes, and contains about seven waves. One set of groups may approximately resemble another set of groups. (4 and 5) Open diagrams of the same earthquake. The pendulum which recorded the upper part of Fig. 4 weighs 8olb., and has a period of twenty-five seconds. That which recorded Fig. 5 weighs a few ounces, and has a period of fifteen seconds. Both have recorded the period for the large waves as seventeen seconds. (6 and 7) Open diagrams of the San Francisco earthquake of April 18, 1906. *Royal Observatory, Edinburgh:* Seismograph records. (1) Indian earthquake, April 4, 1905; (2) earthquake in Siberia, July 23, 1905; (3) earthquake in Calabria, September 8, 1905; (4) earthquake in Greece, November 8, 1905; (5) San Francisco earthquake, April 18, 1906.—*Mr. J. Stanley Gardiner:* Dredged rocks off Providence Coral Reef, 844 fathoms (H.M.S. *Sealark*). These rocks were obtained off the outer slope of a coral reef, half-way between the Amirante Bank and Madagascar. They consist of (1) volcanic ash in various stages of consolidation; (2) manganese nodules round nuclei of ash; and (3) coral rock coated with manganese.—*Prof. Wyndham Dunstan, F.R.S.:* (1) New or rare minerals from Ceylon. Many of the minerals exhibited have been collected during the progress of the mineral survey now proceeding in Ceylon in connection with the Imperial Institute. Others have been found in river gravels sent for examination to the Imperial Institute. These minerals illustrate the wide distribution of thorium in Ceylon. (2) Minerals from Canada.—*Dr. A. S. Woodward, F.R.S.:* Hind limb of the gigantic extinct marsupial *Diprotodon australis* from Lake Callabonna, South Australia. *Mr. F. J. Lewis:* Late Glacial and post-Glacial plant remains from the Scottish peat deposits and from Cross Fell. The remains were met with during an investigation of the peat deposits in Scotland and on Cross Fell, Cumberland. All the deposits so far examined show definite stratification—each layer has its own set of plants, and very different conditions are frequently shown by strata at different horizons in the same peat deposit.

The Director, Royal Botanic Gardens, Kew: (1) Precocious flowering of plants (exhibited by Mr. W. B. Hemsley, F.R.S.). (*a*) Seedling mahogany tree in flower when about 6 inches high. Leaves simple instead of pinnate; flowers very similar to those of the adult tree. (*b*) Seedling *Ailanthus glandulosa* in flower when about 3 inches high. Leaves trifoliolate instead of multifoliolate; flowers male. (*c*) Lilac flowering from the young suckers, with or without leaves; flowers normal in structure, fragrant. (*d*) Coco-nut flowering on its appearance from the shell of the seed. (2) Exalbuminous grass-seeds (exhibited by Dr. Otto Stapf). The structure of the seed is very uniform throughout the Gramineæ, the presence of a very copious farinaceous endosperm or "albumin" being characteristic of it. A remarkable exception (*Melocanna bambusoides*, which is exalbumiпous and at the same time viviparous) was recently described by Dr. Stapf, who has since discovered three more examples of exalbuminous grass-seeds, all in Bambuseæ.—*Prof. Wyndham Dunstan, F.R.S.:* Cyanogenetic plants. The specimens illustrated an investigation conducted by Prof. Dunstan and Dr. T. A. Henry to throw light on the origin of the prussic acid which is produced by certain plants. All the plants shown contain the same cyanogenetic glucoside (dextrose ether of acetone cyanhydrin), which has been named "phaseolunatin." Accompanying it in each plant is an enzyme capable of effecting its decomposition.—*Mr. J. Stanley Gardiner and Mr. H. P. Thomasset:* Photographs illustrative of the vegetation of the Seychelles Islands.

The Marine Biological Association: The habits of some fishes from the inshore waters. A small collection of living fishes from the shore and from shallow water was shown to illustrate the differences in habit and mode of life adopted by different species.—*Mr. Cecil Warburton:* Berlese's apparatus for capturing minute insects and arachnids.—*Prof. W. C. McIntosh, F.R.S.:* Thirteen coloured plates (original) for part iii. of the "British Annelids," to be published by the Ray Society, 1907. These are drawings, from life, of specimens procured from Shetland to the Channel Islands.—*Mr. J. E. S. Moore and Mr. C. E. Walker:* Recent researches in cell-division. (1) Leucocytes lying in cytoplasm of tissue cells in early stage of cancer. (2) First maiotic (heterotype) division in cancer of breast. Division figures in this form of cancer have been supposed to be rare. (1 and 2, joint research with Prof. Farmer, F.R.S.) (3) Specimen showing characteristic permanent forms in chromosomes of first maiotic (heterotype) division. (4) Specimen showing pluripolar mitoses and amitoses in myeloplaxes (bone marrow). (5) Specimen showing division figures in germinal area of lymphatic gland. (6) Specimen showing cells destined to become foot-cells in testis of embryo guinea-pig.—*Dr. Albert A. Gray:* Series of stereoscopic photographs of the membranous labyrinth illustrating the comparative anatomy of the organ. The examples shown were illustrative of Amphibia, reptiles, birds, and Mammalia.—*Dr. G. C. Chubb:* Yolk-nucleus in the oocyte of Antedon. The yolk nucleus of Antedon was shown to be merely a region of the egg-cytoplasm on to which has diffused a part of the material discharged from the nucleolus throughout the growth of the oocyte.

NOTES.

MME. CURIE has been nominated by the council of the University of Paris to succeed her husband, the late Prof. Curie, in the chair of general physics held by him at the time of his death. The nomination has been accepted by the Minister of Public Instruction.

DR. A. C. HADDON, F.R.S., university lecturer in ethnology, Cambridge, has accepted an invitation to give a course of Lowell lectures in Boston, Mass., during November next. He will discourse on racial problems, distribution of culture, and social and religious evolution in Melanesia.

THE Croonian lecture of the Royal Society will be delivered on Thursday, May 24, by Prof. J. N. Langley, F.R.S., "On the Presence of Special Excitable Substances in Striated Muscle and in Tissue Cells."

THE Cleve memorial lecture will be delivered at the Chemical Society by Prof. T. E. Thorpe, C.B., F.R.S., on Thursday, June 21.

PROF. J. B. FARMER, F.R.S., who is giving special attention to parasitic growths, would be glad to receive specimens of such growths. The specimens should be forwarded to Claremont House, Wimbledon Common, Surrey.

MR. R. MCG. DAWKINS, fellow of Emmanuel College, Cambridge, has been elected director of the British School in Athens, in succession to Mr. R. C. Bosanquet, lately appointed to the chair of archæology in the University of Liverpool.

ON Thursday next, May 24, Prof. W. J. Sollas will begin a course of three lectures at the Royal Institution on "Man and the Glacial Period." The Friday evening discourse on May 25 will be delivered by Mr. Leonard Hill, on "Compressed Air and its Physiological Effects."

A COMMITTEE has been appointed to make arrangements to commemorate the distinguished services rendered to archæology by Dr. Arthur Evans, F.R.S. It is proposed to place a portrait of Dr. Evans in the Ashmolean Museum, Oxford, of which he has long been keeper. The world-famed discoveries at Knossos have made Dr. Evans well known to students of archæology everywhere, and it may be expected that the plan suggested will meet with wide approval. Subscriptions may be paid to the hon. treasurer, Mr. G. A. Macmillan, St. Martin's Street, W.C., to the account of the "Arthur Evans Portrait Fund," London and County Bank, Henrietta Street, Covent Garden, W.C., or to Messrs. Barclay and Co., Old Bank, Oxford. The hon. secretaries of the movement are Messrs. D. G. Hogarth and C. F. Bell, Magdalen College, Oxford.

THE German chief burgomasters, burgomasters, and councillors who are paying a visit to England as the guests of the British committee for the study of foreign municipal institutions were entertained on Monday at a banquet over which Lord Avebury presided. Mr. Haldane proposed the toast of "The German Emperor and the German Empress and the other Members of the German Royal Family."; and in the course of his remarks he said that the present Kaiser united in himself the thinker and the man of action, and has organised his empire on an educational basis, paying great attention to technical and scientific instruction and investigation. Such institutions as that at Charlottenburg are instances of what is being accomplished in Germany to-day. The toast was acknowledged by the Ober-Bürgermeister of Berlin, who said that Mr. Haldane possessed a deep knowledge, not only of German history, but also of the German heart.

THE eleventh annual congress of the South-Eastern Union of Scientific Societies will be held at Eastbourne on June 6–9. The president-elect, Dr. Francis Darwin, F.R.S., will give his presidential address on June 6 at the Town Hall. The following papers will be presented:—Nature near Eastbourne, J. H. A. Jenner; the birds of Sussex compared with the list for Great Britain, W. Ruskin Butterfield; the educational value of museums, Dr. Jonathan Hutchinson, F.R.S.; sea erosion and coast defence, E. A. Martin; the geology of the Upper Ravensbourne valley with notes on the flora, W. H. Griffin; the flora of the Eastbourne district, Dr. Whitney; bird architecture, E. J. Bedford; nature-study, W. Mark Webb. The hon. general secretary is the Rev. R. Ashington Bullen, from whom all information can be obtained. The museum secretary, Mr. E. W. Swanton, Educational Museum, Haslemere, will have charge of the congress museum at the town hall. The photographic surveys of Surrey, Kent, and Sussex will be represented by a large series of photographs of scientific and antiquarian interest.

BARON TAKAKI, the Director-General of the Medical Department of the Japanese Navy, delivered last week a series of three lectures on the preservation of health amongst the personnel of the Japanese Navy and Army at St. Thomas's Hospital, at which medical school he was formerly a student. The subject of kak'ke or beri-beri was dealt with exhaustively. This disease was formerly very prevalent in the Japanese Navy, and, as the result of observations, Baron Takaki had come to the conclusion that its prevalence was largely due to a disproportion between the non-nitrogenous and nitrogenous elements of the food. By adding a larger proportion of nitrogenous elements to the food the disease has now almost disappeared from the Navy. Other diseases, such as typhoid, dysentery, and cholera have also almost disappeared in consequence of careful hygienic measures.

SINCE the discovery of a spirillar organism, the *Spirochaeta pallida*, in syphilitic lesions, a great deal of work has been done on the transmission and prophylaxis of this malady. Whether or no this microbe be the ætiological agent of the disease, and it cannot yet be said to have been proved definitely, its discovery has undoubtedly stimulated research, and it is now certain from a number of experiments, both in this country and abroad, that syphilis can be inoculated on the higher apes. Recently Prof. Metchnikoff, of the Pasteur Institute, demonstrated that the application of an ointment composed of calomel ten parts and lanolin twenty parts to the point of inoculation will prevent the development of the disease. This was proved by inoculating apes and also a healthy medical student (who offered himself as a subject for experiment) with syphilitic virus, and an hour later rubbing the inoculated spot with this ointment in the case of the student and of one ape. Neither man nor monkey suffered any evil effect, whereas the other inoculated monkeys which were untreated contracted syphilis. In the case of monkeys the ointment must be applied within twenty hours after inoculation, otherwise infection follows, but if this time limit be observed immunity is complete. It is noteworthy that Prof. Metchnikoff will shortly be visiting this country in order to deliver the Harben lectures at the Royal Institute of Public Health, 37 Russell Square, W.C. The lectures, which are delivered at 5 p.m., are as follows:—May 25, the hygiene of the inner tissues of organisms; May 28, the hygiene of the intestinal tract; May 30, syphilis.

THE proceedings on Commemoration Day at Livingstone College, Leyton, E., on Thursday, May 31, will include an address by Mr. James Cantlie, editor of the *Journal of Tropical Medicine*, whose opinion as to the necessity for the training given at the college is of special value, owing to his experience of the conditions of living in tropical countries. Cards of invitation may be obtained by writing to the principal of the college.

ON the morning of May 2, in the dynamite factory of the Nitroglycerine Company, Ltd., of Vinterviken, near Stockholm, there occurred three explosions in quick succession, which were heard all over the town, and resulted in the total wreck of the factory and the death of many of the workers; the cause of the explosion is at present unknown.

THE prize of 3000 francs offered by the International Medical Congress at the Paris meeting has been awarded by the Lisbon meeting to Prof. P. Ehrlich, of Frankfort-on-Main, for his researches on leucocytosis. British physiologists will approve of this recognition of the work of the great experimentalist and worker on the borderland of physiology and chemistry.

THE opinion has been frequently expressed that Scandinavia, with its huge waterfalls, will before very long be one of the most suitable places for large chemical works; indeed, it is claimed that with the future developments of electrochemical technology the greater part of the world's supply of soda, chlorates, nitrates, calcium chloride, and iron will be produced in the northern peninsula. Hence it is easy to understand the action of the Swedish and Norwegian Governments in protecting the falls against foreign capitalists. Sweden has passed a law that the use of the falls is reserved to the State, while a Bill is before the Norwegian Storthing in which it is prescribed that at least one-half of the capital laid out on the falls shall be Norwegian money, and the direction of the works be in the hands of Norwegians who are living in the land.

IN the *Chemiker Zeitung* for May 9 is an appreciative note from the pen of Prof. van 't Hoff on his conscientious co-worker and former student, the late Prof. Wilhelm Meyerhoffer, who, at the early age of forty-one, died of heart disease on April 21 in Meran, where he had gone for the benefit of his health. Meyerhoffer, although born in Russia, was on his father's side of Austrian descent, and was educated in German schools until his seventeenth year; after passing three years in the gymnasium of Czernowitz, he studied first under Bunsen at Heidelberg and then under Fittig at Strassburg, going from thence to Leipzig, Amsterdam, Paris, Vienna, and Berlin. A few years ago he declined an invitation to go to Prague, and only a few months ago received a call as *ordinarius* to the University of Aachen. In recognition of Meyerhoffer's experimental developments of Guldberg and Waage's principle, he was elected a corresponding member of the Scientific Society of Christiania, and at a more recent date to a similar honour by the society in Rotterdam.

DR. W. N. SHAW'S third lecture was delivered at the University of London on May 15, the subject under consideration being the normal general circulation of the atmosphere at the surface and in the upper air, and, in connection therewith, the relation of temperature and rainfall to the general circulatinn and local disturbances. We can only refer here to one or two of the many interesting points brought forward, *e.g.* the diagrams of the distribution of barometric pressure at the surface of the earth and at a height of 4000 metres showed that the gradients were quite opposite in character, but it was explained that when these two pressure distributions were combined they produced the general circulation observed at the surface. Another interesting feature of the lecture was a lantern slide showing the easterly drift of the surface wind-current at the winter quarters of the *Discovery* in the recent Antarctic expedition, and the westerly drift of the upper air shown by the smoke at the summit of Mount Erebus, also the confirmation of the latter motion by the observation of the upper clouds.

GRASSHOPPERS and crickets (Locustidæ and Gryllidæ) from Paraguay, by Mr. A. N. Caudell, form the subject of No. 1450 of the Proceedings of the U.S. National Museum.

THE life-history of the warble-flies, *Hypoderma bovis* and *H. lineata*, the larvæ of which do so much mischief to cattle in this country, is discussed by Mr. A. D. Imms in part ii. of the first volume of the *Journal of Economic Biology*. Although "warbles"—the tumours in the skin of cattle produced by the grubs of these insects—have been familiar to stock-owners and butchers from time immemorial, it appears that we are still completely in the dark as to the mode in which the larvæ effect an entrance into their hosts, as it is still undecided whether they do so by penetrating the skin or by way of the mouth.

THE *Naturalist* for May contains an excellent portrait and biography of Mr. H. C. Sorby, in the course of which reference is made to the fact that the mechanical theory of slaty cleavage is due to him, and that he was the first to make microscopic rock-sections. The articles include one on chalk belemnites, by Mr. C. D. Sherborn, and one on the senses of bats, by Mr. A. Whitaker, both illustrated. In the latter it is stated that bats "are now ranked as the first suborder of the second great order Carnaria, instead of the last suborder of the first order Primates," which leads us to wonder what text-book the author is in the habit of using.

OF the five articles in the March issue (vol. iv., part iv.) of *Biometrika*, three are devoted to the subject of heredity. In one of these Mr. E. Schuster, dealing with hereditary deafness in man, points out, in the first place, that deaf-mutes generally marry with persons similarly afflicted, with the results that might be expected; and, in the second place, brings out the normal, or even more than normal, fertility of such unions. A paper on Shirley poppies, by several workers, affords additional evidence of heredity in plants. On the other hand, Messrs. Barrington and Pearson, in discussing the heredity of colour in cattle, as exemplified in shorthorns and certain shorthorn crosses, do not find that this comes under the Mendelian law, at least in the shape of any simple formula.

PARASITIC invertebrates, or nearly related free-living forms, constitute the subject of the three articles in the April issue (vol. l., part i.) of the *Quarterly Journal of Microscopical Science*. The life-history of one of the Gregarinida, *Cystobia irregularis*, a species infesting the holothurian locally known in this country as the "cotton-spinner," has recently been investigated by Dr. H. M. Woodcock, who in the communication before us states that he has brought to light several interesting points in the life-cycle of the group in general. The hope of adding to our knowledge of the nature of the "cœlom" and the "nephridea" appears to have been the inducing cause which led Mr. F. H. Stewart, I.M.S., to take up the study of the free nematode worm *Oncholaimus* (or *Oncholaemus*) *vulgaris*. The author's conclusions are summarised at the end of his paper. In the third article Dr. Woodcock publishes the first part of a comprehensive review of the present state of our knowledge of the blood-parasites known as the hæmoflagellates, or trypanosomes. The author lays stress on the extreme rapidity with which investigations into the life-history of these minute organisms have been carried out, the realisation of the extreme importance of such knowledge in respect to the prevention of disease being mainly responsible for this advance.

CAPTAIN LAMB and Assistant-Surgeon Kesava Pai discuss the occurrence of Mediterranean fever in India (Sc. Mem. Gov. of India, No. 22). In seventeen cases carefully investigated, complete agglutination reactions (carefully controlled against normal individuals) were obtained, and, in addition, from eleven of these cases a coccus corresponding in all its characters with the *M. melitensis* was obtained by splenic puncture during life.

A CATALOGUE of microscopical slides, microscopes and accessories received from Messrs. Flatters and Garnett, Manchester, indicates that they are prepared to provide all requisites for microscopical work. The list of botanical and zoological slides is one of the most comprehensive and practical we have seen; a variety of articles for nature-study workers are also supplied.

WITH the view of helping visitors to appreciate the Royal Botanic Gardens, Glasnevin, a short guide, with plan of the gardens, describing the more important attractions, has been published by the director of the Science and Art Institutions, Dublin. In addition to the features of interest that the Glasnevin gardens show in common with similar institutions, the specimens of *Nepenthes distillatoria* raised from seed at Glasnevin, the original golden yew, and the fine collection of palms are especially worthy of notice.

DR. D. H. SCOTT paid a graceful tribute to a fellow-worker in fossil botany in presenting a sketch of the life and work of the late Dr. B. Renault as his presidential address to the Royal Microscopical Society. Renault's work ranged over the field of fossil vascular cryptogams and gymnosperms, within which the real triumphs of fossil botany have been won. To Renault we owe the reconstruction of that unique family the Botryopterideæ, at present regarded as the most authentic group of Palæozoic ferns, also the extraordinarily perfect knowledge that we possess of the gymnospermous Cordaiteæ. Dr. Scott's address, together with a list of Renault's more important contributions, is published in the April number of the Journal of the society.

Dr. R. Perotti, writing in the *Atti dei Lincei*, xv., 5, describes observations on the distribution of nitrifying bacteria in Italy. Samples of soil were taken from various districts, and cultures made by Beyerinck's method, and in every case nitrifying bacteria were found in greater or less abundance, the best results being obtained from Rieti, Messina, and Cerignola.

Prof. Giacinto Martorelli has had the rare fortune to obtain a specimen, believed to be the first, of Ross's polar gull (*Rhodostethia rosea*, Macgill.) from the Mediterranean, killed in the neighbourhood of Sardinia. The specimen in question reached him on January 10 of this year in the flesh, though decomposition was setting in. It appears to be a young bird, being 30 centimetres in length, and possibly this may account for its being found so far from its northern haunts. The discovery is announced in the *Rendiconto del R. Istituto Lombardo*, xxxix., 4, and the specimen has been stuffed and given to the Turati collection.

Dr. F. Eredia, of the Central Meteorological Office at Rome, has published in the official reports an account of a fall of dust on February 6. The occurrence was considered to be of sufficient importance to issue circulars to various observatories requesting particulars of the fall; the reports show that the dust was observed in Sicily, Lower Calabria, and other places, accompanied by thunderstorms, rain or hail, and strong south-easterly and south-westerly winds. The cyclonic conditions existing at the time would favour the conveyance of dust from Africa over the Mediterranean in the upper regions of the atmosphere, and although no analysis appears to have been made, the distribution of barometric pressure and other conditions seem to confirm the African origin of the phenomenon.

The director of the Mauritius Observatory contributed to the eighth International Geographic Congress a useful paper on the climate of Pamplemousses. The results of the observations at Port Louis for 1860–6 were communicated to the British Association in 1867 by the late Dr. Meldrum; those commenced at Pamplemousses in 1874 form the basis of the present paper. The following are the mean annual and absolute extreme values of some of the meteorological elements:—air temperature 73°·4, 94°·7 in December, 50°·8 in June; humidity 75·1 per cent., 98·5 per cent. in January, 34·0 per cent. in November; resultant wind velocity 9·2 miles per hour; the maximum velocity recorded in an hour was 103·3 miles (old factor 3) on April 29, 1892. Cyclones are said to be of immense benefit to the island, as one of the principal sources of rainfall. Taking an area of 20° square, of which Mauritius occupies nearly the centre, 237 cyclones were recorded in the years 1854–1903. The greater number occurred between December and March, and not one was recorded between June and September; their occurrence appears to be most frequent five years after, and least frequent one year before, the epoch of minimum solar activity.

The principal article in *Concrete and Constructional Engineering* (vol. i., No. 2) is by Captain Sewell, of the United States Army. It deals with the introduction of reinforced concrete in the United States, and is a commentary on the various systems and methods of applying this material adopted in that country. The article is illustrated by views and details of important buildings.

At the last meeting of the Institution of Mechanical Engineers an interesting paper was read by Mr. Louis Greaven on petroleum fuel in locomotives on the Tehuantepec National Railroad of America. It gives the actual results of a year's experience, and the information should prove of service to others who contemplate adopting oil fuel in railway working.

In a paper read before the Birmingham section of the Institution of Electrical Engineers on April 25, Dr. D. K. Morris and Mr. G. A. Lister proposed a standard test for transformers and transformer iron. The method involves but one set of connections, three instruments, and the normal supply, and necessitates the use of two similar transformers. It is a modification of that first described in 1892 by Ayrton and Sumpner, and is an application of the Kapp-Hopkinson or differential method of testing direct-current machines. The behaviour of a transformer when loaded at various power factors is, they find, best considered by means of a regulation diagram which they have constructed. The short-circuit test can equally well be carried out with the transformer core excited. The three-point wattmeter method is probably the most accurate means of measuring power factor and current when carrying out single-phase tests on transformers or motors from a three-phase supply. By bringing the supply to the middle point in the testing transformer when carrying out the differential test, symmetrical conditions are obtained, thus permitting of a normal determination of the various losses. By varying the voltage only and taking wattmeter readings the core loss of a transformer may be separated into hysteresis and eddy-current loss by the method of the total index. Wattmeter readings in combination with the three-point method serve as the best means of measuring the temperature rise in heating tests. The method of constant induced voltage affords a ready means of finding the true hysteresis loss, and is probably the best way of testing iron samples.

OUR ASTRONOMICAL COLUMN.

Comets 1906*b* and 1906*c*.—A set of new elements for the orbit of comet 1906*b* is published by Herr M. Ebell in No. 4087 of the *Astronomische Nachrichten*. An ephemeris for alternate days is also given, extending from May 4 to July 7, and shows that this comet is still in the southern part of the constellation Leo, about half-way between τ and υ Leonis. It is moving very slowly in a south-eastern direction, its present brightness being about 0·5 of that at the time of its discovery.

A set of new elements for comet 1906*c*, computed by Miss Lamson, of the U.S. Naval Observatory, appears in No. 4086 of the same journal.

The Astronomical and Astrophysical Society of America.—At the seventh annual meeting of this society, held in December last at New York, some forty papers on astronomical subjects were submitted.

Short abstracts of thirty-three interesting papers are given by Prof. H. Jacoby in No. 586 of *Science*, and amongst those which have not been noted previously in these columns may be mentioned the following:—A note on Prof. Burnham's forthcoming catalogue of double stars; a brief description of the vacant regions of the sky, by Prof. Barnard; an announcement concerning the publication of the observations of sun-spots made by the late Dr. C. H. Peters, extending over the period 1860–1870, and including the determination of more than 13,000 heliographic positions of spots on more than 1100 days; a paper by Prof. W. H. Pickering on planetary inversion, which the author illustrated by experiments with a gyroscope; and an account of the foundation, and the partial destruction by fire, of the Philadelphia Observatory, by Prof. M. Snyder.

SOLAR PROMINENCES DURING 1905.—The usual annual summary of the prominence observations carried out at the Catania Observatory during the past year is published by Prof. Mascari in No. 4, vol. xxxv., of the *Memorie della Società degli Spettroscopisti Italiani.*

The results show that the mean daily frequency of prominences observed was greater in 1905 than in 1904 and 1903, but the increase was not so great as might have been expected. As in previous years, it is seen that the increase in mean daily frequency corresponds with a decrease in heliographic latitude. In 1904 the mean daily frequency was 2·90 and the mean latitude 36°·6, whilst for 1905 the corresponding figures were 3·05 and 30°·8. The mean altitude of the prominences during 1904 was 43″·7, and in 1905 it was 44″·1; the corresponding extensions of the prominences along the solar limb were 7°·27 and 8°·77.

The greater frequency of prominences in the sun's northern hemisphere still persists, the values for 1905 being 1·77 for the northern and 1·28 for the southern hemisphere.

THE PERIOD OF β LYRÆ.—Referring to the recent note by Mr. Roberts on the increasing period of β Lyræ, Prof. Schaeberle suggests another possible cause which may account for that phenomenon.

It is now generally accepted that incandescent bodies have the power of repelling fine particles of their component matter to great distances, and Prof. Schaeberle suggests that, at a certain stage in the life-history of such a body, the decrease in mass may be so rapid as to cause an increase in the periodic time of any other body belonging to the system. If part of the ejected mass afterwards returns to the parent body other changes will obviously occur (*Observatory*, No. 370).

THE SIXTH INTERNATIONAL CONGRESS OF APPLIED CHEMISTRY.

WHEN the International Congress of Applied Chemistry, assembled at Berlin in 1903, chose Rome as its next meeting-place, the fear was expressed by some that the Italian chemical industry might not perhaps be of sufficient magnitude to ensure a large attendance at the next congress. The brilliant success of the meeting which has just terminated has shown, however, that these fears were entirely without justification, and the number of important communications from the Italian members of the congress proves the reality of the progress which Italy has made of late years in chemical industry.

The meeting was opened on April 26 under the most favourable auspices by the King and Queen in person, accompanied by the Minister of Public Instruction and other high officials. The place of meeting was the magnificent Palace of Justice, then brought into use for the first time; in fact, it is not yet wholly completed as regards the internal decorations. There being a large number of rooms in the building, space was easily found for the sixteen sections into which the congress was compelled to subdivide itself. The number of British members was more than thirty, and on the whole the attendance from other countries was very satisfactory, even China being represented. It is somewhat of a novelty to hear speeches in Chinese at European scientific meetings, and shows that the awakening of the Celestial Empire is becoming an accomplished fact. Such a congress is an interesting study in ethnology as well as philology. Officially only four languages are supposed to be used, namely, English, French, German, and Italian; but the greatest leniency is shown in this respect, and the reporters must sometimes rely on summaries made by the speakers themselves.

Among the papers read before the full meeting of the congress the most important was undoubtedly Dr. Adolph Frank's description of his process for the direct utilisation of the nitrogen of the atmosphere for the production of artificial manure and other chemical products. Dr. Frank's invention is not only ingenious, but its effects on the future of the human race will probably be of the greatest importance. The inventor is a veteran in agricultural chemistry; he it was who, more than fifty years ago, introduced the potash salts of Stassfurt to the notice of agriculturists. Now nearly three million tons of these salts are used annually by agriculturists all over the world. The problem of the fixation of atmospheric nitrogen has often been attacked, for the first time on a large scale during the French Revolution. At that time France, surrounded by her enemies, was cut off from the supply of saltpetre necessary for national defence. A committee of French chemists then established the saltpetre farms where the nitrifying organisms, with which we have since become more intimately acquainted, produced the necessary means of defence. We in Great Britain, however, are still entirely dependent upon foreign sources for the explosives necessary for our national defence, and it is only by the establishment of some such process as Dr. Frank's in Great Britain that we shall place ourselves in safety in this respect. The invention is not a complicated one, the difficulties consisting chiefly in the solution of new problems of chemical engineering. Calcium carbide is first produced and then heated with nitrogen obtained by the fractional distillation of liquid air. During this distillation oxygen is obtained as a by-product, and may be utilised for the production of nitric acid from ammonia, which, again, is one of the substances produced by Dr. Frank. The first raw material obtained is calcium cyanamide, and it is this that is used as a nitrogenous manure, numerous experiments having shown that the nitrogen which it contains can be easily assimilated by plants. For countries such as Italy, and more especially India, with large agricultural populations who do not possess sufficient cattle to supply the requisite nitrogenous manure, this direct utilisation of the inexhaustible nitrogen of the atmosphere cannot fail to be of enormous importance; but to the chemist the calcium cyanamide has other attractions. From it have been produced, not only ammonia and nitric acid, but also urea and guanidine. We are therefore on the high road towards the artificial production of the alkaloids, and the next step will probably be the building up of substances directly assimilable by human beings, in other words, artificial foods.

But while chemists revelled in these anticipations they did not forget more practical subjects. An excellent paper by Sir William Ramsay gave a clear and exhaustive account of the present state of the sewage question in Great Britain. Special attention was given by the author to the bacterial methods of sewage disposal which are now being so widely adopted. M. Moissan, whose work with the electric furnace is so well known, gave the results of his experiments on the distillation of metals. All metals, indeed all substances, are volatile at a temperature below 3500° C., therefore M. Moissan draws the conclusion that the temperature of the sun cannot exceed this; it must, indeed, be somewhat less, as the bulk of the elements of which it consists are volatile at a lower temperature than the maximum mentioned. No doubt the data with which Prof. Moissan has furnished chemists will be utilised for practical purposes, especially in the purification of metals.

Many of the papers read before the various sections contained matter of great scientific interest. The report of the International Committee on the Unification of Analytical Methods was presented by Dr. Lunge, and will be of great assistance to analysts in different countries who wish to secure uniform results. Prof. W. N. Hartley's paper on the use of the spectrograph in analysis aroused much interest in the photographic section. It is certainly a great advantage to be able to make a quantitative analysis of a rare object in metal without defacing it in any way, and the convenience of the method will no doubt ensure it general acceptance when it becomes better known. Another communication made to the inorganic chemistry section was of interest, inasmuch as it holds out hopes of a considerable reduction in the price of photographic and other glass of high quality. Hitherto such glass has been made in the expensive pot furnaces, but the author of the paper, Herr F. Heller, states that he has succeeded in making such glass in the cheaper tank furnaces. In order to do this he divides the melting operation into three phases, each of which is carried out in a separate tank furnace at a definite temperature. The raw materials are first melted down at about 1400° C., the fused mass is then run into a second furnace at about 1200° C., in which the glass is clarified, and finally the clear glass is run into a working tank furnace of about 1000° C. The hope was expressed that the principle might be applied to optical glass of high quality. To the same section Sir William Ramsay contributed a paper on the Bischof process for manufacturing white lead, one of the chief advantages of which is that the workpeople are not exposed to the deleterious action of the dust which renders such stringent precautions necessary in other works. Messrs. G. Giorgis and G. Gallo contributed an essay on the hydraulic properties of various kinds of puzzuolanas, between some of which there are great differences both in time of setting and in the ultimate strength attained. The subject is of great importance in Italy, where puzzuolana mortars largely replace those made in other countries with Portland cement. Sands of the nature of puzzuolana are to be found in other volcanic countries, and merit more attention than they have hitherto received. The remarkable state of preservation of the old Roman buildings in Italy is largely due to the fact that the mortar used in their construction was hydraulic.

The sulphur industry being of such importance to Italy, it was to be expected that it would receive considerable attention. Mr. B. Reinitzer discussed the origin of natural deposits of sulphur, and Prof. N. Rossi described a new method of extracting poor sulphur ores by means of bisulphide of carbon. It was stated that there are very considerable quantities of sulphur ores containing less than 20 per cent. of sulphur, below which percentage it is not at present remunerative to work them. The author proposes to lixiviate these by means of bisulphide of carbon, and has designed plant for that purpose. It must be remarked, however, that similar efforts have hitherto resulted in failure, and the author's apparatus met with some adverse criticism by chemical engineers familiar with such subjects. It is to be hoped that a practical test may be made with the apparatus, as the Sicilian sulphur industry is being seriously threatened by the discovery of the Louisiana deposits.

Prof. L. Ricciardi, of Naples, communicated the results of a number of analyses of eruptive rocks, from which he draws the important conclusion that volcanoes at first emit rocks of an acid nature, but that subsequently the products are basic in their character. The author is of opinion that volcanic phenomena are similar throughout the world, and the rocks which give rise to them are granitic in their nature.

Prof. A. C. Vournasos, of Athens, reported the discovery of a large deposit of asphalt in Greece, which is already being worked on an industrial scale, and appears to be a valuable addition to our supplies of that useful substance. At the same time the author communicated a new method for testing asphalt which he had recently devised.

The section of the congress dealing with the industry and chemistry of sugar was the medium for the communication of a large number of papers, chiefly of industrial interest. Nearly every European country except Great Britain has now a large sugar industry; in fact, the International Congress of Applied Chemistry originated in a meeting of chemists engaged in the sugar industry. A paper by Mr. C. H. Neumann on the testing of the germinating power of sugar-beet seeds shows the amount of specialisation which has taken place. The author found that the best medium for ensuring the regular germination of the seeds was a damp mixture of sand and sawdust, the temperature being carefully regulated.

In the section on explosives Mr. R. Villanis presented a detailed memoir on the state of the explosives industry in Italy in which the various factories and their products were described, together with the regulations in force. The erosion and corrosion of firearms by smokeless powders gave rise to two communications by Dr. V. Reuhi and by Mr. Gey van Pittius. The former referred to the use of nitro-guanidine as an explosive, this being one of the products of Frank's discovery mentioned already.

Several authors dealt with the use of alcohol and petroleum products as sources of power. In Great Britain, where petroleum is admitted free of duty, there can be no doubt that it is at present the cheapest liquid in use for the production of power. Some Continental countries, however, in order to foster the alcohol industry and the important agricultural interests depending upon it, have imposed heavy duties on all competing liquids, and there is naturally continuous rivalry between the various interests thus created.

The section dealing with wine was also of more importance to Continental than to British members, and the same may be said of the agricultural chemistry section, in which matters connected with Continental husbandry were fully discussed. Prof. J. Stoklasa dealt with the enzymes which produce lactic and alcoholic fermentation in the tissues of plants. The author agreed with Messrs. C. Golenski and Mazé that such fermentation is in reality the intramolecular respiration of plants, and a number of experiments were described corroborating this view.

The final plenary sitting of the congress was mainly occupied in passing resolutions confirming recommendations by the sectional committees. Among these may be mentioned the appointment of a committee to elaborate uniform methods of testing explosives, the unification of methods of sugar analysis, especially between the Custom House officials of different countries, and the unification of methods for the analysis of malt in breweries. The transport of dangerous substances by rail was also referred to, and recommendations made as to the patenting of inventions by employees and upon international trade marks.

At the close of the meeting an invitation to the congress to meet in London in 1909 was given by Prof. Tilden, as representing the British Government, and Dr. L. Mond, Prof. E. Divers, and Prof. R. Meldola as representing a joint committee, consisting of practically every British society connected with chemistry, which had been formed on the initiation of the Society of Chemical Industry. The invitation was unanimously accepted.

During the session of the congress a number of social gatherings and excursions took place which afforded excellent opportunities for the delegates of the various nations to become acquainted with each other. The largest excursion was to Tivoli, where about 1500 members were present. The beauties of that lovely spot are too well known to require description, but the remarks of some of the electrochemists led one to believe that they considered a large amount of water-power was being wasted. It would be well, in view of the utilitarian character of modern industry, if the different States were to secure one or two of their most picturesque waterfalls before they have all been absorbed for the production of electrical energy. Many members of the congress visited the sad scenes in the neighbourhood of Vesuvius. One member who had collected the volcanic dust, soon after the eruption, at Addlestone, in the Thames valley, and again on a roof at Turin, was enabled to satisfy himself of the identity of these specimens with the Naples dust.

Excursions were proposed to Sicily and to Elba, but an inopportune strike of the sailors of the Italian Steam Navigation Company put an end to these. Many who were visiting Rome for the first time found many objects of interest, apart from the inexhaustible art treasures of the city. One naturalist collected three varieties of Helix on the walls of the castle of St. Angelo, while a botanist directed attention to the presence of pellitory of the wall on the same building. English tradition says that it was introduced into England by monks, and in some districts it is only found on old monastic buildings. In some rubbish that was being cleared out of the dungeons of St. Angelo numerous fragments of marble cannon-balls were found. During times of siege it is related that large numbers of statues were converted into cannon-balls, and the great variety of marbles to be found among the fragments lends support to this statement. Another enthusiastic lover of nature in all her forms collected a number of live scorpions in the Forum. He stated that they soon became tame, and took live ants from the fingers. His statements were accepted without discussion.

The meeting of the congress was brought to a close on May 5 by a state banquet given by the King of Italy at the Quirinal to the delegates of foreign Governments and societies. Both the King and Queen received the visitors, among whom were six British delegates. After the banquet the King, who takes great interest in the industrial revival now taking place in Italy, held a reception, several of the Italian ministers being present. The next day most of the members of the congress departed from the beautiful and hospitable city which had been the scene of their labours, many with the intention of returning if possible.

THE SURVEY OF INDIA.

THE report[1] of the Indian Survey Committee recently received is contained in two volumes, the size of which should be sufficient testimony to the exhaustive nature of the inquiry. The result, on the whole, should be satisfactory to those who for years past have been protesting against the short-sighted policy of the Indian Government, which, under financial pressure, has often forced reductions on the Survey Department until its efficiency has become seriously impaired. There is hardly a reform suggested by the committee which has not been urged previously in India. Sir John Farquharson (president of the committee, whose death so soon after his return to England was almost tragic) but expressed the opinions of many who have been closely associated with the Indian Survey Department, modified more or less by his own experiences as chief of the Ordnance Survey in England.

The main results of the committee's recommendations are, first, the strengthening of the department in men and money, and secondly, the separation of the cadastral (or revenue) from the topographical and trigonometrical branches in order that proper supervision may be given to the latter, and that the general military maps of the peninsula and the frontier may be brought (and kept) up to date. Cadastral surveys will in future be relegated to local governments, who will be responsible for the maintenance of their own revenue maps; but scientific supervision of this local work will be provided from the department. This indeed is essential, as everybody knows who has had experience of the terrible results of local meddling with original survey mapping by half-trained, or wholly ignorant, native employees. Nor is the fact overlooked that all the extreme refinement of the most accurate geodetic triangulation has its final expression in these revenue maps. The larger the scale and the more restricted the area, the greater the necessity for a positively accurate basis for local traversing. Every little village plan must take its place accurately in the provincial map if titles to property are to be of any account.

The recommendations of the committee regarding the topographical mapping of India and the reproduction of maps appear on the whole to be excellently well adapted to the end in view, in spite of a certain amount of dissent in matters of detail recorded by the present Surveyor-General. Due acknowledgment is made to the late Surveyor-General (Colonel Gore) for the accuracy of his estimate of the amount of revision necessary, and the cost in time and money of carrying it out; and a most appropriate despatch from a former Secretary of State for India (1876) is quoted, in which the fallacy of expecting to effect economies by the reduction of well-trained survey parties is emphatically maintained. That fallacy was, however, supported by the then Government in India, and was supported by every Government since, until the arrival of a geographical expert as Viceroy in Lord Curzon. The topographical maps of all India, on the 1-inch per mile scale, are to be thoroughly revised and completed. It is something of a surprise that mapping on this scale was not completed long ago, as there has been nothing important missing from the general map of India for several years past. The method of reconstruction recommended by the committee is not altogether approved by the present Surveyor-General, who is in favour of more decentralisation in order to gain efficient supervision; but there was no dispute as to the paramount necessity of maintaining one standard map of the whole of India in a state of absolute completeness. Nor can the recommendations with reference to frontier mapping be regarded with anything but satisfaction. The appointment of a special superintendent on the frontier to rank with the superintendent of trigonometrical surveys, with five working parties under him, and three officers attached to each party, and with the headquarters office at Simla in touch with the Intelligence Department, is indeed a big concession to military requirements. A similar, but much smaller, scheme was suggested nearly ten years ago, in the days when two or three officers and one elastic party were considered ample to deal with the Indian borderland from the Indus to the Euphrates; but it was not entertained. Trans-frontier surveys, apart from political boundary requirements, were not recognised as of any importance. It depended entirely on the enterprise of the officer in charge of the frontier party whether any such work was carried out at all; it was regarded as rather beyond the scope of strict departmental business—to be permitted (if no complications with tribes-people were involved), but hardly to be approved.

Any effort to render frontier mapping more effective by ensuring its proper distribution amongst the military offices of the frontier was perhaps beyond the scope of the committee's proceedings, but it can hardly be denied that proper map distribution is only second in importance to map making.

The reproduction of maps has always been the great difficulty of the Indian Survey Department. Climate, material, and personnel are all against the reproduction of clear, readable, and artistic maps from the excellent material which is found in the original field-sheets. Dr. Stein's evidence on this point is very suggestive. Whilst condemning the printed maps, he paid a graceful tribute to the artistic value of the originals. Photozincography has had much to answer for; misplaced economy, resulting in inferior material and a staff absolutely inadequate to deal with the mass of work thrust upon it, has completed the tale of ultimate inefficiency. We doubt if the well-meant efforts of the committee will really do much to raise the low standard of Indian map publishing so long as cheap rates form the ruling motive of the publishing office. Partial engraving and heliozincography are steps in the right direction, however, but it has always appeared to us that the employment of a first-class firm in England to undertake all the finer work of the department is the real panacea for the ills that beset Calcutta map printing. There is no dealing with the inertness of the native by means of committees. Colonel Grant points out that one girl in England will do as much as two (native) men in the Calcutta office. It may be so (so long as girls do not subscribe to trades unions), but he ignores the effects of a climate that affects Europeans and natives alike.

The general report on the Indian Survey for 1903–4[2] serves as a useful commentary on the recommendations of the committee which was sitting at the time that this rather belated report was under compilation. From it we are able to gather an idea of the enormous expansion in the widely diffused work of the department which has occurred within late years, and of the mass of material which has been crowded into the over-weighted publication offices. The report deals with certain administrative changes (such as the amalgamation of the forest surveys) which are unimportant when considered by the light of the subsequent recommendations of the committee; and much of it is concerned with the progress of cadastral, or revenue, surveys, which will in future probably form but an insignificant feature in the general programme.

Referring to the developments that are proposed in topographical (or military survey) branches of the department, we naturally turn to the map published in the report to illustrate the actual position of these surveys at present. The completion and maintenance of a 1-inch per mile map of the whole peninsula area, and the extension of accurate surveys into extra-peninsula regions, is one of the main features of the revised programme. The map, however, for this purpose is rather misleading, for we find a great part

[1] "Report of the Indian Survey Committee, 1904–5." Part i., The Report, pp. vi+151. Part ii., pp. v+223. (Simla: The Government Central Printing Office, 1905.)

[2] "General Report on the Operations of the Survey of India administered under the Government of India during 1903–4." By Col. J. R. Hobday, I.A. Pp. iv+62+xlii. (Calcutta: Office of the Superintendent of Government Printing, 1905.) Price 3s.

of the Madras province left blank as if it had never been surveyed (whereas the old Madras revenue surveys furnish excellent material for any 1-inch reproduction), and a fairly wide area of Baluchistan territory near Quetta, which has been most carefully surveyed on the scale of 2 inches to the mile and has stood the test of a whole series of military manœuvres most successfully, classed as "geographical reconnaissance"—which it certainly is not, nor is the mass of ½-inch work which has been completed in that country.

The fact is that, for the completion of the 1-inch topographical map of all India, only a small portion of the Rajputana desert really requires first survey. There must, however, be an enormous amount of revision necessary.

During the year under review, 34,000 square miles of detail survey were completed, and (according to the general summary) about 24,000 square miles of geographical reconnaissance. Elsewhere we find records of 15,000 square miles of Seistan geography, no less than 58,000 square miles in Tibet, and the invaluable work of Colonel Wahab in South Arabia (of which we have heard so little and would like to know so much), amounting to 6000 square miles. Presumably the 24,000 square miles with which the summary deals is independent of these special outturns. The chief interest of the report lies in the appendix dealing with these special performances, and we cordially welcome a return to even this partial recognition of the absorbing interest which is to be found in the story of Indian surveying. The kernel of the report was extracted when the "narratives" went out of it. Even here we do not find the story of the death of that gallant native geographer and explorer Sheikh Mohiudin, whose determined (reckless, for a surveyor) search after information in Seistan led to his being found at last, dead, with his horse dead beside him—dead of thirst in that thirsty country; whilst his plane-table sheets had been stripped from the board and wound round the body of one of his native assistants, who was finally rescued by a friendly Afghan out of a far-away pool of water in which he was lying insensible. Such little incidents as this, or the death of Colonel Wahab's native surveyor, who was shot at his work in Arabia, excite little public comment in India.

In the scientific branches of the department there is much good work to record. The great arc of principal triangulation which terminates with the Dehra Dun base has been extended into the Himalayas, and connected with the peaks of the Snowy Range. Valuable results have been obtained from the comparison of geodetic with astronomic determinations for latitude, the tendency of them being to prove that large northerly deflections of the plumb-line continue to prevail in the heart of the Himalayas. Pendulum observations to determine the force of gravity have been resumed, and magnetic work has also been a feature of the scientific branch of the department supervised by Lieut.-Colonel Burrard, R.E., F.R.S. That officer has also added a useful chapter to the report on the value of principal triangulation and scientific surveying. All this is most valuable work, and should go a long way to satisfy financial critics that the Government of India gets its money's worth out of the scientific investigations of the Survey Department.

The official report of the observations made by Captain Wood, R.E., in Nepal to determine the position of the Everest peak relatively to the Gaurisankar group is included in this volume. It is hardly necessary to refer again to the conclusions which have been formed on a subject which has already been discussed in the pages of Nature. A most useful map of part of Nepal, and the panoramic views which accompany Captain Wood's report should be convincing evidence of the isolated position of the highest peak in the world, if any further evidence were needed. A re-perusal of the exact conditions under which these observations were made is most interesting, and fully confirms the opinion expressed by Colonel Gore (the late Surveyor-General) that "those who trust to their appreciation of characteristic forms and their mountaineering instincts, as a means for identifying peaks from widely different points of view, are apt to be frequently misled."

THE IRON AND STEEL INSTITUTE.

The annual meeting of the Iron and Steel Institute was held in London on May 10 and 11, Mr. R. A. Hadfield, the president, in the chair. The president referred to the loss the institute had suffered by the deaths of Sir David Dale and Mr. J. T. Smith, past-presidents, and votes of sympathy were accorded. The report of the council, read by the secretary, Mr. Bennett H. Brough, showed that the membership amounted to 2033, and that in 1905 the income was 6271*l.* and the expenditure 5257*l.* The Bessemer medal was awarded to Mr. F. Osmond, the eminent French metallurgist. Carnegie research scholarships of 100*l.* were awarded to Dr. C. A. F. Benedicks (Sweden), Mr. O. Stutzer (Germany), Mr. E. Hess (United States), and Mr. E. F. Law (London). Grants were also made to Mr. H. C. Boynton (United States), Dr. L. Guillet (France), Mr. W. H. Hatfield (Sheffield), Mr. E. G. L. Roberts (London), Mr. W. Rosenhain (Birmingham), Mr. E. A. Wraight (London), and Mr. A. Campion (Glasgow). The Carnegie gold medal for research was awarded to Dr. L. Guillet, and the silver medal to Mr. W. Rosenhain.

In the first paper read Mr. A. J. Capron (Sheffield) described a new method of compressing steel ingots in the mould which has been successfully adopted in Sheffield. The ingot moulds are placed inside the press, the steel being run into the moulds in this position, so that they have not to be transported with the liquid steel in them, and the press practically forms the casting pit.

Prof. T. Turner (Birmingham) gave the results of observations on the volume and temperature changes during the cooling of cast-iron. Apparatus was designed in order to measure the changes of length of a test-bar, whilst cooling curves were taken of the specimens at the same time with a Le Chatelier pyrometer. The curves obtained may be divided into four classes, depending upon the number of arrests observed in the normal rate of contraction of a cooling solid.

Mr. E. Adamson (Seaton Carew) read a paper on the influence of silicon, phosphorus, manganese, and aluminium on chill in cast-iron. The depth of chill is primarily dependent upon the percentage of combined carbon and the temperature of casting. Combined carbon 0·67 per cent. gives 1/16-inch chill, and combined carbon 0·88 per cent. gives ¾-inch and 1-inch, but the latter was cast at a much higher temperature. These figures are taken from the silicon and phosphorus tests. The manganese tests also show an increase in true chill with increasing manganese up to combined carbon 1·60 per cent. The tests described were made from coke irons, and suggest that under proper treatment coke irons are as good as charcoal irons for high mechanical tests and depth of chill.

On May 11 Prof. J. O. Arnold and Mr. F. K. Knowles (Sheffield) read a preliminary note upon the influence of nearly pure metallic manganese alloyed with varying proportions of nearly pure metallic iron. A series of alloys ranging in manganese from 0·3 per cent. to 36 per cent., and in carbon and silicon from 0·05 per cent. to 0·2 per cent. each, was prepared in special crucibles. In the finished bars, each 12 feet long, liquation of a remarkable character took place which rendered the completion of the research difficult. It is possible, but hardly probable, that some of these costly alloys may prove of practical importance.

Mr. C. de Schwarz (Liége) read an interesting paper on the use of oxygen in removing blast-furnace obstructions. The difficulties caused by the tap-hole of a blast furnace becoming closed up by solid iron have been overcome by the application of compressed oxygen. The process has been adopted at several works in England and on the Continent with satisfactory results. At the conclusion of the paper a practical demonstration of the process took place at the works of the Brin Oxygen Co. in Westminster.

Mr. E. F. Law (London) described an extended investigation into the causes which underlie the production of brittle and blistered tin plates. He showed that oxidised steel will give rise to blistered sheets, and that this defect is more liable to occur with Bessemer than with open-hearth steel. Steel high in sulphur and phosphorus will cause brittleness in sheets, especially if the sheets are rolled from large and slowly-cooled ingots in which the maximum of segregation has taken place.

Mr. P. Eyermann (Benoit, Wisconsin) submitted a lengthy paper on the manufacture of solid rolled steel wheels and tyres. The average life of a cast-iron wheel is 56,000 miles in passenger service, while steel-tyred wheels have a life of 265,000 miles. The author considers it probable that before long the solid rolled steel wheel will replace the existing tyres in Great Britain.

Mr. E. Lelong (Couillet, Belgium) described a new method of manufacturing chains by machinery in which the successive convolutions of spiral links are continuous. Chains made by this process are 20 per cent. stronger than those made by the usual methods.

Mr. C. O. Bannister (London) discussed the relation between type of fracture and microstructure of steel test-pieces, showing that valuable conclusions may be drawn from the examination of the fractured surface.

The effect of copper in steel was discussed by Mr. F. H. Wigham (Wakefield). Copper is very difficult to alloy with steel so as to obtain a homogeneous mass containing more than 2 per cent. even with the addition of aluminium. In steel containing 0·5 per cent. or more of carbon it is not of practical value to use more than 0·6 per cent. of copper. The steel with 0·25 per cent. of copper and alloys up to 0·25 per cent. of copper with high carbon (0·70 per cent.) give, with or without a high percentage of manganese, a good quality of wire. In fact, copper to the extent of 0·25 per cent. is no disadvantage in the manufacture of the best classes of steel wire.

The reports of research work carried out during 1905–6 by holders of Carnegie research scholarships, which were submitted, represented a large amount of work of great interest. An exhaustive study of quaternary steels was submitted by Dr. L. Guillet (Paris). For the research 250 varieties of steel were prepared, including nickel-manganese steels, nickel-chromium steels, nickel-tungsten steels, nickel-molybdenum steels, nickel-vanadium steels, nickel-silicon steels, nickel-aluminium steels, manganese-silicon steels, manganese-chromium steels, and chromium-tungsten steels. The area for the commercial employment of these steels is considerably restricted, and is limited to the nickel-vanadium steels, the nickel-tungsten steels, and the chromium-vanadium steels containing comparatively low proportions of foreign elements.

The report by Mr. W. Rosenhain (Birmingham) on the deformation and fracture of iron and mild steel constitutes a continuation of his previous paper on the plastic yielding of iron and steel. He gives further observations on slip-bands, and deals with the modes of fracture under various conditions. In tensile fractures the break runs almost indifferently through ferrite and pearlite, owing to the fact that the previous extension of the metal has weakened, and in part even ruptured, the pearlite; in shock fractures the pearlite is able to assert its superior strength and is avoided by the fracture, while fissures are formed in the ferrite. The features of bending fractures are found to be of an intermediate character. The results of the examination of these fractures are discussed both from the point of view of the relative behaviour and interaction of ferrite and pearlite under breaking stresses and from the point of view of the general theory of deformation and fracture which is presented in the paper. In conclusion, the author points out the possibilities of practical application which his method of studying fractures opens up. This detailed study of fractures makes it possible to locate accurately the causes of weakness and strength in a given microstructure, and by comparing the behaviour of the constituents when broken in different ways to gain a deeper insight into their mutual interaction; while the study of "mysterious" fractures occurring in service—as rendered possible by this method—should make it easier to trace the causes of fracture—if any—which are present in the metal.

Dr. H. C. Boynton (Harvard, U.S.A.) dealt with the determination of the hardness of the constituents of iron and steel with the aid of Jaggar's microsclerometer. Reduced to a common unit, the hardness of pure ferrite, the average hardness of the constituents was found to be as follows:—

Constituent	Present in	Average Hardness	Ratio
Ferrite	Electrolytic iron	460	1
,,	,, ,, quenched	990	2·15
,,	Average of all unhardened samples	610	1·03
,,	Commercial wrought irons	686–1643	1·5–3·6
Pearlite	Series 0·13–1·52 per cent. carbon	842–4711	1·8–10·3
,,	Series 0·35–0·86 per cent. carbon	1745–2150	3·8–4·2
Sorbite	0·48 and 0·58 per cent. carbon steel	2400–24,650	5·2–53·6
Troostite	Steel, 0·58 per cent. carbon	40,564	88·2
Martensite	Series 0·20–1·52 per cent. carbon	17,896–120,330	38·9–261·6
Austenite	White cast iron (3·24 per cent. carbon)	47,590	103·4
Cementite	White cast iron (3·24 per cent. carbon)	125,480	272·8

Mr. J. D. Brunton (Musselburgh) submitted an elaborate report on the heat treatment of wire, particularly wire for ropes. He showed that the usual methods of obtaining the best wire by means of torsion and tensile tests are not altogether trustworthy for determining the best point for the wire to perform useful work. Annealing of the rod before the final annealing does not, in any way, produce better material, as it has been thought to do, and is, therefore, not necessary.

The research carried out by Messrs. E. G. L. Roberts and E. A. Wraight (London) comprised a series of 150 experiments and complete analyses, dealing with the constitution of ferromanganese and the efforts made to deprive this alloy of its carbon.

It was announced that the next meeting would be held in London at the end of July, when members of the American Institute of Mining Engineers would be the guests of the institute.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Prof. William Schlich, F.R.S., St. John's College, has been constituted by H.M. Secretary of State for India professor of forestry so long as he shall be continued in his present position and be resident within the University.

The first of two lectures on "The Teaching of Science in Schools" was given by Dr. Bevan Lean, headmaster of Sidcot School, on May 10 at the lecture room of the delegacy for the training of secondary teachers. The second lecture is to be delivered to-day.

CAMBRIDGE.—A Grace authorising the general board of studies to appoint, subject to confirmation by the special board for medicine, Mr. G. H. F. Nuttall, Christ's College, to be reader in hygiene in connection with the special board for medicine, the University lectureship in bacteriology and preventive medicine to terminate on his appointment as reader, will be offered to the Senate to-day.

Mr. W. J. Sell, Christ's College, has been approved by the general board of studies for the degree of Doctor in Science.

A university lectureship in mathematics will be vacant at Michaelmas, 1906, by the resignation of Mr. Whittaker. The general board of studies will shortly proceed to appoint a lecturer to hold office from Michaelmas, 1906, until Michaelmas, 1911. Candidates are requested to send their applications, with statements of the subjects on which they are prepared to lecture, and with testimonials if they think fit, to the Vice-Chancellor on or before May 31.

The Vice-Chancellor has been informed by the clerk to the Worshipful Company of Girdlers that the company is prepared to continue its grant of 100*l*. a year towards the teaching of economics for a second period of three years. The board of economics is of opinion that this offer should be gratefully accepted.

THERE seems every possibility of the Hamburg University being very quickly established. Three million marks have already been voluntarily subscribed, two millions of which have been given by Mr. Alfred Beit. It is proposed that only one-half of the lectures shall be given for direct preparation for any particular profession, while the other half are to be for the further extension of the general education of the inhabitants of the town.

HIGHER education is mostly left to take care of itself in this country, with the result that our statesmen and Governments do not know exactly where it is being carried on, or what provision has been made for it without their assistance. On the principle that what is everybody's business is nobody's business, no serious attempt has been made to take stock of our national resources as regards higher education, so it comes about that the committee recently appointed by the Chancellor of the Exchequer to advise the Treasury as to the distribution of the sum voted by Parliament for grants in aid to university colleges has sent an intimation to the public Press with the object of bringing the conditions under which grants are made under the notice of colleges which have not as yet communicated with the committee. It is obvious that if our higher education were properly organised by the State, the Minister of Education would have detailed particulars of institutions devoted to it, and such an announcement as that just issued, suggesting that there are many colleges unknown to the official mind, would have been unnecessary. The grants are given only to those institutions which afford education of a university standard in great centres of population in England. To qualify for a grant at present, a college is required to show that its local income for work of a university character is not less than 4000*l.*, and that of this sum at least 1500*l.* is derived from fees. Any college wishing to be included in the list of those receiving grants should send in an application not later than June 13. Applications should be addressed to the secretary to the committee, Mr. R. G. Hawtrey, at the Treasury, S.W.

PRESENTATION DAY was celebrated at the University of London on May 9, when Sir Arthur Rücker, the principal, read his annual report on the work of the University. An important event of the year was the recasting of the schemes of examination for the B.A. degree. Up to the present the course of study from the matriculation stage onward has been, with the exception of mathematics, entirely literary. The opinion that a mixed course of literature and science would be of the utmost value to many pass students has, however, for long been gaining in strength, and effect has now been given to it in the following manner. In future either Greek or Latin, but not both, will be compulsory both in the intermediate and in the final examinations for the B.A. degree. Another language will also be compulsory; while the other subjects required may be chosen from a list of languages, pure and applied mathematics, and the more fundamental sciences. The examinations in science will be identical with those for the corresponding subjects for the B.Sc. degree. It will thus be possible for a candidate for a pass B.A. degree to take either an exclusively literary course or a mixed course including Latin and one other language. Sir Arthur Rücker announced that the Senate has invited the University of Paris and the Collège de France to visit the University of London at Whitsuntide. This will be a unique event, no formal visit having hitherto been made by a French to an English university. A large number of distinguished guests are expected, and it is hoped that the occasion will bind closer the intellectual links which unite the two countries.

A DEPUTATION of the council of the Association of Technical Institutions was received by the President of the Board of Education on May 4. Sir William Anson, as president of the association, introduced the deputation, and stated that its object was to bring before the Board the importance of increasing the rate of grants to the day technical institutions and for instruction in the more technical subjects in evening classes. Sir William Anson referred to the importance of efficiently maintaining facilities for technical instruction, and pointed out the tendency of local authorities to devote their funds chiefly to elementary education, to the possible detriment of higher work. Sir Philip Magnus urged the importance of technological subjects in evening classes, and the great cost involved in their maintenance. Unless education authorities are encouraged to conduct such classes there is grave fear of their being neglected for subjects, not so important to the industries of the country, which receive higher grants. Sir William Mather spoke of the great importance of technical education for the maintenance of the industries of the country, and the need for watching that money intended by Parliament for the maintenance of such work should not be diverted for other work. He thought an appeal might well be made to employers to contribute towards the cost of technical education. Mr. Birrell, in reply, said that the deputation might rest assured that the Board has every sympathy with the request put forward for increased grants for work in day classes in technical institutes. The Board fully realises the importance of the work which is done. Mr. Birrell, however, reminded the deputation that there are many other important branches of education which are in need of increased grants. In conclusion, he cordially supported what Sir William Mather said as to the importance of employers contributing to technical institutes. Mr. F. G. Ogilvie dealt with the way in which the Board is trying to include technical subjects as eligible for their grants, and so far as possible at the same rate as science subjects.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 5.—"On the Distribution of Radium in the Earth's Crust, and on the Earth's Internal Heat." By the Hon. R. J. **Strutt,** F.R.S.

Summary of Conclusions.—(1) Radium can easily be detected in all igneous rocks. Granites, as a rule, contain most radium, basic rocks the least. (2) This distribution of radium is uniform enough to enable a fair estimate to be made of the total quantity in each mile of depth of the crust. (3) The result indicates that the crust cannot be much more than forty-five miles deep, for otherwise the outflow of heat would be greater than is observed to be the case. The interior must consist of some totally different material. This agrees entirely with Prof. Milne's conclusion drawn from a study of the velocity of propagation of earthquake shocks through the interior. (4) The moon probably consists for the most part of rock, and, if so, its internal temperature must be far greater than that of the earth. This explains the great development of volcanoes on the moon. (5) Iron meteorites contain little, if any, radium. Stony ones contain about as much as the terrestrial rocks which they resemble.

Challenger Society, April 25.—Mr. E. W. L. Holt in the chair.—*Exhibits.*—Four species of Cephalodiscus, of which three had recently been described by the author, who also referred to others from the *Discovery* and *Antarctica* expeditions: Dr. S. F. **Harmer.**—Charts of positions in the North Sea, where, by means of a heavy conical dredge with canvas lining, samples of bottom deposits had been taken by the Marine Biological Association's steamer *Huxley*: J. O. **Borley.** Mr. Borley showed in action a sifting machine, designed by Mr. Todd and himself, for grading these deposits; sieves of various mesh, hung in water, were made to vibrate horizontally at high speed by an excentric worked by an ordinary whirling-table. There were also exhibited specimens of the gravel, fine sand, and silt met with, charts of their distribution showing the extreme uniformity of bottom found over large areas in the eastern part of the North Sea, and diagrams indicating the very definite meaning attaching to fishermen's descriptive terms for the bottom.—Preliminary paper on Medusæ collected in H.M.S. *Research* by Dr. Fowler in the Bay of Biscay: E. T. **Browne.** The Trachomedusæ predominated over the other orders, three species forming about 85 per cent. of the specimens collected (*Aglantha rosea*, 42 per cent.; *Aglaura hemistoma*, 27 per cent.; *Rhopalonema coeruleum*, 15 per cent.). These were chiefly taken between 50 fathoms and 100 fathoms. A few rather rare species were taken below 100 fathoms; for example, *Colobonema sericeum*, one of the new deep-sea Medusæ discovered by the *Valdivia*. The most interesting find was a Narcomedusan, probably a new species of Cunoctacantha, which had a number of medusa-buds in all stages of development upon the stomach-pouches; the buds were not parasitic, as in other species of Cunoctacantha and Cunina, but develop directly from outgrowths of the stomach-wall. This forms a straightforward case of asexual gemmation, such as occurs in some Anthomedusæ.

Geological Society, April 25.—Dr. J. E. Marr, F.R.S., vice-president, in the chair.—Trilobites from Bolivia, collected by Dr. J. W. Evans in 1901–1902: P. **Lake**. Several horizons are represented by these fossils. Descriptions are given of the new species and other forms mentioned. It is worthy of remark that, while the earlier forms show affinities with the contemporaneous European fauna, the Devonian species are much more closely allied to those of South Africa and North America.—Graptolites from Bolivia, collected by Dr. J. W. Evans in 1901–1902: Dr. Ethel M. R. **Wood**. In black pyritic shales from three localities several specimens of Didymograptus were collected: one referable to *bifidus*, one of the type of *affinis*, and one of the *Nicholsoni* type. Phyllograptus, Glossograptus, Cryptograptus, and Diplograptus were also obtained. A pale, silky-grey shale shows also rare graptolites, belonging to a species comparable with *Climacograptus confertus*. These forms indicate that both the black and the pale shales belong to horizons in the Upper Arenig rocks (Lower Llanvirn of Hicks).—The Phosphatic Chalks of Winterbourne and Boxford (Berkshire): H. J. Osborne **White** and Llewellyn **Treacher**. Data collected in the district dealt with in this paper suffice to show that the more or less Phosphatic Chalks above the Uintacrinus-band lie in a trough or basin, the formation of which antedates the deposition of the Reading beds. When the area of observation is extended, it is found that the Uintacrinus-Chalk of that tract itself lies in a structural depression. The Phosphatic Chalks of Winterbourne and Taplow evidently mark places on the sea-floor particularly liable to the impingement of strong currents, and may mark places above which the water commonly had a gyratory motion. In any case, their zonal range argues a marked degree of stability in the current-system of the body of water in which they were laid down.

Physical Society, April 27.—Dr. C. Chree, F.R.S., vice-president, in the chair.—Some simple questions on the images of microscopes and telescopes: W. B. **Croft**. It may have been noticed that when a microscope is focused visually, an image is formed on the focusing-glass of a camera, into which the microscopic eye-piece is inserted after removing the camera-lens. This image remains more or less in focus at variable positions of the camera-screen. Although it is not always perhaps true, yet it is surprising how often the pencil emerging from a microscope eye-piece behaves like a single concentrated line of light. Several photographs of microscopic details were exhibited to intimate how often the author had found, when projecting from an optical eye-piece, that no change can be detected in the definition of the image as the screen of the camera is moved. If a camera-lucida is placed on the eye-piece, the image of a stage-micrometer can be thrown on a scale at 10 inches distance or at 40 inches distance. The parallel rays emerging from the eye-piece give the image of a point along a direction, at no definite position. The image can be imagined at 40 inches distance as easily as 10 inches. Mr. Croft also showed some photographs taken from sections of the human eye; he indicated that a divergent pencil from a small aperture or from a convex reflecting surface of large curvature will give the Purkinje figures as bright radiating lines, whereas the usual method of sending light through the side of the sclerotic gives them as shadows. Several different specimens were shown of magnetic oxide of iron and magnetic sulphides of iron. The power of nickel and cobalt to receive permanent magnetism was illustrated with a compass-needle of nickel.—The lateral vibration of bars subjected to forces in the direction of their axes: J. **Morrow**. Three cases of unloaded bars are dealt with, namely, those under the following end-conditions:—"supported-supported," "clamped-clamped," and "clamped-supported." Expressions are obtained from which the frequencies may be calculated, and the results are stated in a form such that the determination of stresses, terminal couples, &c., may be easily made. The case of greatest interest is that of a stretched bar clamped at each end. Approximate solutions of this problem have been arrived at by both Seebeck and Donkin. These are on the assumption that the vibration is but slightly affected by the rigidity of the material. An assumption of a very different character, and one generally fulfilled in structural work, is made in this paper, namely, that the longitudinal force is not very great. Solutions are thus found for the period of the fundamental or any harmonic.

Mathematical Society, May 10.—Prof. A. R. Forsyth, president, in the chair.—The substitutional theory of classes and relations: Hon. B. **Russell**. The object of the paper is to explain a solution of the contradictions discovered by Burali-Forti and the author. The solution is sought in the substitutional theory, sketched in a previous paper by the author, according to which statements apparently about a class are significant only when they can be analysed into statements about all or some of the members of the class. The substitutional theory is extended to propositions and relations.—The expansion of polynomials in series of functions: Dr. L. N. G. **Filon**. The question is that of expanding a function $f(x)$ in a series of functions of the form $\phi(\kappa_n, x)$, where the numbers $\kappa_1, \kappa_2, \ldots$ are the roots of a transcendental equation. The method is analogous to Cauchy's method of expansion of functions in Fourier's series, and depends upon the calculus of residues. In Cauchy's method a subsidiary function $F(\kappa)$ is introduced through a knowledge of the form of the coefficients of Fourier's series; in the present paper a rule is given for determining this subsidiary function *a priori*, and the rule is shown to be applicable to many classes of functions $\phi(\kappa, x)$ when the function $f(x)$, of which the expansion is desired, is a polynomial. The subsidiary function $F(\kappa)$ being known, the coefficients in the expansion of $f(x)$ can be obtained explicitly.—The motion of a swarm of particles the centre of gravity of which describes an elliptic orbit of small eccentricity round the sun: Dr. E. J. **Routh**. It is proved that for a spherical swarm the period equation takes the Lagrangian determinantal form, and the conditions of stability can be completely exhibited. The problem of a swarm of unequal thicknesses in different directions is illustrated by a discussion of the case in which the boundary is ellipsoidal; and the changes of length of two diameters in the plane of motion, one of which passes through the sun, are investigated in detail.—The theory of integral equations: H. **Bateman**. The partial integral equation

$$\int_a^1 \kappa(s, x) f(x, t)\, dx = \int_a^b f(s, x)\, h(x, t)\, dx$$

is regarded as the characteristic equation of a transformation by which the properties of the function $h(s,t)$ are deducible from those of $\kappa(s,t)$. This transformation leaves unaltered the numbers λ_n for which the homogeneous equation

$$\phi_n(s) = \lambda_n \int_a^b \kappa(s, t)\, \phi_n(t) dt$$

possesses a solution different from zero. The numbers λ_n are important in the theory of the potential and in connection with a certain theory of the origin of spectral lines.—Linear differential equations of rank unity: E. **Cunningham**. The paper is concerned with an extension of Laplace's method of solution of linear differential equations by means of definite integrals. The proposed solution takes the form of a double integral involving a subsidiary function which satisfies a certain partial differential equation. Particular forms of this subsidiary function are developed, and the appropriate domains of integration determined.

PARIS.

Academy of Sciences, April 30.—M. H. Poincaré in the chair.—Diphenyl or alkylphenyl camphomethane and methylene: A. **Haller** and E. **Bauer**.—Simple relations between the "statical actions" of muscle with the energy which produces them: A. **Chauveau**.—The doubly infinite varieties of points of a quadric in space of four dimensions applicable to a plane: C. **Guichard**.—Contribution to the study of the infra-red spectrum: Milan **Stephanik**. In the study of the infra-red region of the spectrum three methods have hitherto been used, the thermometric method, the photographic method, and the utilisation of the phenomena of phosphorescence. In studying the eclipse of August 30, 1905, the author noticed that when a deep red screen was placed in front of the slit of the spectroscope a portion of the infra-red spectrum became visible. This method has been followed up at the Meudon Observatory, various screens being tried. It was found that the best results were obtained when the screen absorbed nearly the whole of the luminous spectrum, leaving only the extreme red and infra-red rays. The ultra-red spectrum has been mapped out in this way down to 1 μ, and, in certain circumstances, a little further with some difficulty.—A theorem of J. Clark: Maurice **d'Ocagne.**—The result of the experimental study of a centrifugal ventilator: Henri and Léon **Bochet.** A study of the Capell ventilator, for which an abnormal yield had been claimed by the inventor. The results generally support the inventor's views.—A galvanometer with a movable needle for alternating currents: Henri **Abraham.** The instrument is of the d'Arsonval type, the permanent magnet being replaced by an electromagnet excited by an alternating current of the same frequency. In delicate measurements the best results are obtained by exciting the electromagnet by a small auxiliary transformer. Details are given of the sensibility obtainable.—The spectra of alloys: J. **de Kowalski** and P. B. **Huber.** Copper-magnesium and copper-zinc alloys were studied. By interposing self-induction in the discharge circuit a larger number of lines disappear from the spectrum when the electrodes consist of the pure metal than when an alloy is used. The lines which have disappeared in the spectra of the alloys are the same for the copper-magnesium and the copper-zinc alloys, and belong to copper. The results can be explained by Prof. J. J. Thomson's views, or by supposing that the mean temperature in the oscillating discharge between the electrodes is higher in the case of the alloy than with the pure metal.—The synthesis of $\beta\beta$-dimethyl- and $\beta\beta$-trimethylpimelic acids: G. **Blanc.** The starting point of this synthesis is the anhydride of $\beta\beta$-dimethylglutaric acid. This is reduced by sodium and absolute alcohol to a lactone, and the latter, treated by phosphorus pentabromide and alcohol consecutively, gives the ethyl ester of δ-bromo-$\beta\beta$-dimethylvaleric acid. The condensation of this bromo-compound with the sodium derivative of malonic ester leads to the desired $\beta\beta$-dimethylpimelic acid. The substitution of the sodium derivative of methyl-malonic ester in this condensation gives the trimethylpimelic acid.—The chemical composition of glauconite: Léon W. **Collet** and Gabriel W. **Lee.** The analysis of a fresh sample of glauconite from the collection of Sir John Murray, of the *Challenger* Office, showed that it is a ferric and not a ferrous silicate.—Overlapping strata in Sicily: Maurice **Lugeon** and Émile **Argand.**—The existence of phenomena of drift earlier than the Stephanian in the region of Saint-Etienne: P. **Termier** and G. **Friedel.**

DIARY OF SOCIETIES.

THURSDAY, MAY 17.

ROYAL SOCIETY, at 4.30.—Determinations of Wave-Length from Spectra obtained at the Total Solar Eclipses of 1900, 1901 and 1905: Prof. F. W. Dyson, F.R.S.—Some Stars with Peculiar Spectra: Sir Norman Lockyer, K.C.B., F.R.S., and F. E. Baxandall.—An Apparent Periodicity in the Yield of Wheat for Eastern England, 1885–1905: Dr. W. N. Shaw, F.R.S.—Some Physical Constants of Ammonia: a Study of the Effect of Change of Temperature and Pressure on an Easily Condensible Gas: Dr. E. P. Perman and J. H. Davies.

CHEMICAL SOCIETY, at 8.30.—The Relation between Absorption Spectra and Chemical Constitution, part vi., The Phenyl Hydrazones of Simple Aldehydes and Ketones: E. C. C. Baly and W. B. Tuck.—Aromatic Compounds obtained from the Hydroaromatic Series, part ii., The Action of Phosphorus Pentachloride on Trimethyldihydroresorcin: A. W. Crossley and J. S. Hills.—Studies of Dynamic Isomerism, part v., Isomeric Sulphonic-derivatives of Camphor: T. M. Lowry and E. H. Magson.—Studies on Basic Carbonates, part i., Magnesium Carbonates: W. A. Davis.

ROYAL INSTITUTION, at 5.—The Influence of Ptolemaic Egypt on Græco-Roman Civilisation: Rev. J. P. Mahaffy.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Notes on Overhead Equipment of Tramways: R. N. Tweedy and H. Dudgeon.

FRIDAY, MAY 18.

ROYAL INSTITUTION, at 9.—International Science: Prof. A. Schuster, F.R.S.

SATURDAY, MAY 19.

ROYAL INSTITUTION, at 3.—The Old and New Chemistry: Sir James Dewar, F.R.S.

ADOLF VON BAEYER'S COLLECTED WORKS.

Adolf von Baeyer's gesammelte Werke. Herausgegeben zur Feier des siebzigsten Geburtstages des Autors von seinen Schülern und Freunden. Erster Band, pp. cxxxii+990. Zweiter Band, pp. 1194. (Brunswick: F. Vieweg und Sohn, 1905.)

AS we examine these two splendid volumes we cannot but feel that no better way of commemorating the seventieth birthday of Adolf von Baeyer could possibly have been found than that of collecting together his researches and publishing them so that they might be studied in their entirety by all students of chemistry.

The publication of the complete researches of an investigator who has had a profound influence on the scientific thought of his time has much to recommend it, since the collected works form not only a memorial to the investigator, but also enable others to gain an insight into the train of thought which preceded the gradual development of each important discovery.

The present volumes have, moreover, a special interest since they have been produced under the personal supervision of Baeyer himself, with the result that the vast amount of work which he has accumulated during the fifty years of his active life is arranged in the manner which he himself wished and thought most suitable.

These volumes contain as frontispiece a strikingly lifelike portrait of Baeyer. The introduction contains a most interesting sketch of Baeyer's life (1835–1905) from his own pen, which enables the reader to form a very vivid idea of the difficulties Baeyer had to encounter in the earlier days of his scientific career. Not only were the schools of chemistry which existed at that time few in number and the appliances even in the best of them only of a very elementary kind, but research in organic chemistry was still quite in its infancy, and therefore every new development was of the nature of pioneer work.

Although in his grandfather's house Baeyer was in his early years brought into contact with Paul Heyse, Geibel, Fontane, and other literary giants of the time, he showed no inclination towards literature, and soon began to develop a love for science by taking a keen interest in chemistry, botany, physics, and mathematics.

In 1856 he decided to devote himself seriously to chemistry, and became a student in Bunsen's laboratory at Heidelberg at a time when Roscoe, Pebal, Lieben, Beilstein, Lothar Meyer, and others were working in the laboratory, and when Bunsen's reputation as a teacher and investigator was at its highest. His first original investigation was a continuation of the work of Bunsen and Roscoe on the combination of hydrogen and chlorine, and this, as well as his next research, on methyl chloride, were suggested by Bunsen. After this Baeyer worked entirely on his own initiative, and gradually laid the foundations upon which the great edifice of his life-work was subsequently raised.

The papers collected together in the two volumes before us have been grouped by Baeyer under the following headings: (1) The organic arsenic compounds; (2) the uric acid group; (3) indigo; (4) papers arising from the researches on indigo; (5) pyrrol and pyridine bases; (6) experiments on the elimination of water and on condensation; (7) the phthaleins; (8) the chemistry of the hydroaromatic compounds; (9) the terpenes; (10) nitroso-compounds; (11) furfurol; (12) acetylene compounds and the "Spannung's Theorie"; (13) peroxides; (14) the basic properties of oxygen; (15) dibenzalacetone and triphenylmethane; (16) various researches in the aromatic series; (17) various researches in the aliphatic series; (18) nomenclature; (19) diversa.

The titles alone will serve to convey some idea of the immense range of subjects which have claimed the attention of Baeyer, and as we study each of these sections we meet always the same characteristics—great skill in overcoming experimental difficulties (often necessitating the working out of entirely new methods of attack), and great ability in deducing the correct theoretical explanation from the results of experiment.

Within the necessarily limited space of this review it is, of course, impossible to discuss in any detail even the most far-reaching of Baeyer's discoveries or to attempt to follow their historical development.

Attention may, however, be briefly directed to some characteristics of Baeyer's work which will probably strike the reader most as he studies the successive sections into which these researches are divided.

The researches on uric acid, which date from 1860, are marvels of experimental skill, including, as they do, the discovery and characterisation of barbituric acid, violuric acid, and many other new members of this important group, and this at a time when the structure and relationship of the more important members of this section of organic chemistry were little understood. Baeyer was naturally interested in the problem of the synthesis of uric acid, and in 1863 he endeavoured to accomplish this by combining uramil with potassium cyanate, when he obtained pseudo-uric acid, an acid which contains one molecule of water more than uric acid itself. The synthesis was completed in 1895, when E. Fischer and L. Ach showed that pseudo-uric acid is converted into uric acid when it is melted with anhydrous oxalic acid.

Of great interest, not only from a purely scientific, but also from the commercial point of view, are the sections on the phthaleins and on indigo. The researches on the phthaleins must have required exceptional skill, ingenuity and patience, because it must be remembered that this work was absolutely new, and, moreover, the substances belonging to this class are, at the present day, some of the most difficult to deal with experimentally.

The well-known papers on indigo should be read in connection with a most interesting sketch of their historical development (p. xxxviii) which Baeyer himself has contributed.

The labour entailed in carrying out these researches must have been very great, and it is instructive to read that, after a certain time, Baeyer became so wearied with indigo that he was quite unable to continue experimenting on the subject, and had to allow the various problems connected with the commercial development of his discoveries to pass into other hands. In search of fresh fields for investigation, Baeyer commenced an inquiry with the object of discovering whether carbon atoms, uncombined with hydrogen, are capable of uniting to form long chains, and, in order to determine this, he synthesised a number of poly-acetylene compounds, including tetracetylenedicarboxylic acid

$$CO_2H.C\equiv C-C\equiv C-C\equiv C-C\equiv C.CO_2H.$$

This remarkable acid is quite colourless, but is readily blackened by the action of light, and compounds of this type were found to be so explosive that their further investigation had to be abandoned. One of the fruits of the consideration of the properties of these compounds was the enunciation of the well-known "Spannung's Theorie," which has given rise to so much discussion, and proved to be of such value in suggesting new lines for experimental inquiry.

Section viii., which Baeyer has placed directly after the phthaleins, deals with the chemistry of the hydroaromatic compounds and the constitution of benzol. These researches date from the year 1866 when, in conjunction with Graebe, Born, Mohs and others, he first investigated the behaviour of phthalic acid and terephthalic acid towards sodium amalgam.

Baeyer repeatedly returned to this subject in later years, but it was not until 1888 that the epoch-making series of papers "Ueber die Constitution des Benzols" began with the exhaustive study of the products which are formed when terephthalic acid is reduced with sodium amalgam. These researches on the reduction products of the phthalic acids and of benzene itself are well known, but they have perhaps hardly received the close attention which they merit, owing partly, no doubt, to their difficult and intricate nature. The careful study of these papers will, however, more than repay the time spent, and to the young investigator they may well serve as an example of the patience and endurance which he must be prepared to face if he wishes to attempt the solution of a problem of really first-rate importance.

It is perhaps a consequence of the study of these artificially prepared reduction derivatives of benzene that Baeyer was led to investigate that wonderful series of naturally occurring reduced benzene derivatives—the terpenes the constitution of which has offered one of the most difficult problems to the modern organic chemist. During the course of his experiments on the oxidation of substances which, like the terpenes, contain unsaturated closed chains, Baeyer commenced to experiment with Caro's acid, and, among many other interesting results, showed that this acid was a most valuable reagent for the conversion of ketones into lactones. Further experiments resulted in the discovery of the remarkable series of peroxidised substances of which benzoylhyperoxide and diethylperoxide may be taken as types, and led to a development of Collie and Tickle's important work on the tetravalent nature of oxygen and the oxonium theory.

Baeyer's latest publications deal with the vexed question of the relation of colour to constitution, and are concerned especially with the reason for the coloured nature of certain salts derived from dibenzalacetone and from triphenylcarbinol. One of the most remarkable results of this investigation is the proof that the coloured salts of triphenylcarbinol are in reality esters possessing the properties of salts, and that they cannot be regarded as quinoid compounds.

Baeyer is, at the present time, occupied with the further development of this important matter.

It is impossible to close the volumes before us without marvelling at the immense amount of work which it is possible for one man to carry out, and without a deep impression of the enormous influence which the work of Baeyer has had on the development of modern chemistry. The list of papers published from Baeyer's laboratory occupies no less than sixty-three pages of closely-printed matter, and when we look at the names attached to these papers we are able to form some idea of the magnitude of the school which he has founded, and of the extent to which many of the greatest chemists of the day owe their training in research to Baeyer.

W. H. Perkin, Jun.

A STANDARD TREATISE ON ELASTICITY.

A Treatise on the Mathematical Theory of Elasticity. By A. E. H. Love. Second edition. Pp. xviii+552. (Cambridge: University Press, 1906.) Price 18s. net.

INSTEAD of merely revising his former treatise, Prof. Love has written a new one; the result is that we have two works by the same author, in some ways contrasting, in others complementary. And as in the similar cases of Maxwell's "Electricity," and Thomson and Tait's "Natural Philosophy," the prudent will buy the new book without parting with the old.

Naturally one feature in the new edition is the inclusion of important or interesting results obtained since the appearance of the earlier one. In some branches of mathematics the proportion of English workers is distressingly small; but in elasticity this is happily not the case, and the recent researches of Michell, Filon, Dougall, and others, besides those of veterans that need not be named, receive in these pages their due recognition. So also do those of their Continental *confrères*, more particularly Voigt; but it is hard to avoid the impression that the deaths of Kirchhoff and Hertz have left vacancies which have yet to be worthily filled.

It is interesting to compare the historical introduction in its old form with its successor. The former was in some places controversial, and the author seems to have thought some of the statements too dogmatic, at any rate in form. However this may be, the new introduction is strictly impersonal, and shows clearly enough how recent physical theories and discoveries affect the subject of elasticity. A great deal of the polemic about the number of elastic constants was as illogical as the quarrel about *vis viva*. As an abstract mathematical theory, the 21-constant hypothesis is as legitimate as its rival and conversely; the question that interests physicists is which of the two, if either, best corresponds to the properties of elastic bodies. Saint-Venant rightly argued that this could not be settled *a priori*, but only by experiment; and at the present day his justification on this point is complete, although he was led to adopt the rari-constant theory by relying upon inconclusive experiments. As Prof. Love points out (pp. 14, 15) our views of the ultimate structure of matter are being profoundly modified, and until they are cleared up it is premature to propose an "atomic" theory of elasticity. Meanwhile we can make a working hypothesis by assuming the existence of a strain-energy-function which is a quadratic function of the components of strain. In all probability the ultimate theory, if we could only reach it, is kinematical; the stresses set up in a strained body being an aspect of a new distribution of kinetic energy in space.

The results of the theory, as applied to the arts, are, of necessity, only approximate; and great care must be taken to see that, when an approximate solution has been obtained, it is really applicable to the concrete case. An excellent example is given on p. 140, relating to a sphere strained by its own gravitation. If we put in the numerical values of g, r_0, ρ, and any reasonable values for λ, μ, when the sphere in question is the earth, we find that the condition that U/r should be small for $r_0 > r > 0$ cannot be satisfied, although this is one of the assumptions on which U has been calculated. This point was brought out in the previous edition (i. 220); it is a pity that this warning has been suppressed, though another, equally instructive, has been given.

Again, take the condition (or conditions) for rupture taking place (pp. 117 *sqq.*). This cannot be given by the ordinary theory, which is only applicable when the elastic limit is not exceeded. Nevertheless, attempts have been made to express the condition in terms of the components of stress. This is entirely illogical, and hence, as usual, a contest between rival formulæ. It may, of course, happen that one formula, as against the other, may have a wider range of applicability; but it ought to be treated as purely empirical, and not rashly applied to untested cases. On this point the author might have been more dogmatic than he is.

A very interesting section is that on the deformation of plates. This is a famous problem, historically, and even lately gave rise to a controversy, now satisfactorily settled. To get a reasonably simple approximate solution some kinematical assumption must be made, and this must be compatible with the boundary conditions. Prof. Love pointed out that, strictly speaking, a vibrating plate with free edges cannot satisfy the condition that the middle surface is unstretched; Mr. Basset and Prof. Lamb showed that the boundary condition could be satisfied without supposing any considerable stretching except near the edge. An interesting statical illustration due to Lamb is given on p. 521. On p. 506 Prof. Love obtains, by a method of his own, second approximations for stress and strain in a curved shell, agreeing to that order with results of Mr. Basset's.

In this, as in other parts of the book, the analysis is very elegant, and is given in sufficient detail for really competent readers to follow. But the author follows the general tendency now in vogue, of suppressing details of calculation, and emphasising results of practical value, rather than examples of mainly æsthetic interest. In his preface he expresses a hope that his book will be useful to engineers; how far they do so depends, of course, upon them as well as upon him. They will find among the subjects treated the buckling of plates, the collapse of boiler-flues, the whirling of shafts, the stability of slender columns, and other such things; it is to be hoped that they will also appreciate the general theory, as the author presents it. Every student, not an expert, should follow the advice given in the preface of proceeding to chapter v. as soon as possible.

It is a great advantage that the author of this book is a mathematician of wide as well as accurate attainments. As an illustration, it will be enough to refer to p. 306, dealing with the torsion of a rectangular prism; it is at once clear that the author's knowledge of Fourier expansions is quite different from that of the average physicist. Similar examples of rigour free from pedantry may be found throughout the volume.

At the end of the introduction occurs the sentence: "Most of the men by whose researches it [the mathematical theory of elasticity] has been founded and shaped have been more interested in Natural Philosophy than in material progress, in trying to understand the world than in trying to make it more comfortable." It may be added that most of the comfort we enjoy, and most of our civilisation that is worthy of the name, is due to men who have endured discomfort, in pursuance of ideal ends. Apart from the poets and the philosophers, where should we be?

G. B. M.

PROTEID CHEMISTRY.

Chemistry of the Proteids. By Dr. Gustav Mann. Based on Prof. Otto Cohnheim's "Chemie der Eiweisskörper." Pp. xviii+606. (London: Macmillan and Co., Ltd.; New York: The Macmillan Co., 1906.) Price 15*s*. net.

DR. GUSTAV MANN started this work with the modest idea of producing an English translation of Prof. O. Cohnheim's well-known monograph on the chemistry of the albuminous substances. But it has developed into a volume of a much more ambitious nature, and has culminated in a book twice the size of that on which it is founded. The subject in many parts is treated much more fully, and a good deal of new matter introduced. In many places, moreover, Cohnheim's own views are adversely criticised, so that the present volume bears witness to the originality of the English author.

Those who know Dr. Mann best as a histologist may be surprised that he should have the necessary knowledge to write on a subject at first sight so far removed from the microscope. His previous book on Physiological Histology has, however, shown the connection between the two. The fixing action of preservatives on tissues, the staining reactions of cells and nuclei, are ultimately chemical in nature, and much of macro-chemistry can be learnt from micro-chemistry. Dr. Mann's sympathies are mainly physiological, not anatomical. Physical chemistry also is more than a hobby with him, and the sections relating to speculations of a physico-chemical nature form pleasant oases in what as a rule is rather solid reading. His histological proclivities have led him in some cases to devote a good deal of space to subjects which some might regard as of secondary importance —for instance, his lengthy description of the interactions of proteids with mercury compounds evidently springs from the extensive use he has made of corrosive sublimate as a fixative.

Cohnheim's book in the original state cannot be described as an ideal one. It lacks the imaginative faculty, and reflects the stolid, plodding German worker, anxious to omit no reference to literature that can possibly be dragged into a footnote. To some investigators this is of course advantageous; they will profit by the diligence of the author, and easily be able to consult the memoirs quoted in reference to any special point they are interested in. But to the student who desires to obtain a general insight and a wide outlook on the general relationships of the subject, this compression of material is a distinct hindrance; he will be apt to lose sight of the wood on account of the trees.

Dr. Mann follows on very much the same lines, and though it is impossible to restrain one's admiration for his labours in hunting up literature, quoting authorities as far back and as far forward as possible, one cannot but regret that the text does not as a consequence run easily, and most of it will form stiff reading even for advanced students. In some places the pages abound with chemical formulæ without a sufficient guidance in words. Here, again, anyone but an accomplished organic chemist will have difficulty in finding his way along.

Dr. Mann also has certain mannerisms of style, but one does not complain of these unduly, for they stamp the pages with the author's individuality; but there is one of these faults which many will find annoying and even confusing, and that is a looseness and inexactitude in the use of terms. For instance, on the title-page we find the word "proteid" used as a general expression for all the albuminous substances; within the pages of the book "proteid" is employed only for a certain group of these materials. Albumin also is sometimes used as a generic term, and at other times applied to a specific group; sometimes it is used as opposed to globulin, sometimes it includes the globulins, and sometimes it includes everything. In one place we read that lactalbumin is one of the few true albumins; on another page it is alluded to as a hypothetical substance. The author has dedicated his work to his father, and in the dedication tells us something of his father's life-work. It would be interesting to know something more about his ancestry—whether, for instance, he has any Irish blood in him. The use of the expressions "true pseudo-acid" and "true pseudo-base" is distinctly Hibernian.

The same kind of carelessness is shown in the spelling. Albumin is sometimes spelt with an *i*, sometimes with an *e*. The nomenclature committee of the Chemical Society tried to introduce uniformity into spelling, and assigned certain meanings to certain terminations. A word ending in *ine*, for instance, means an alkaloidal material; a word ending in *in* does not; similarly, the terminations *ol* and *ole* have a distinct chemical significance. But Dr. Mann has paid no attention to such rules. "Vitellin," for example, is sometimes spelt with, sometimes without, a final *e*. "Gelatine" and "cholin" are spelt as just printed in direct contravention of the rules of the Chemical Society. The names of investigators are also often mis-spelt; Waymouth Reid, Curtius, Claude Bernard, and Lane-Claypon are among the sufferers.

The whole question of nomenclature in chemistry is very difficult, especially in translations. It is hopeless to try to reconcile English with German usages, but there ought to be an attempt on the part of English writers to adopt some sort of uniformity. This difficulty is accentuated in relation to proteid nomenclature, and one can only hope that the joint committee of the Physiological and Chemical Societies now sitting on this very subject may put forward some practicable suggestions. Dr. Mann is therefore not wholly to blame for his misdeeds.

In spite of the blemishes to which I have devoted so much space, I believe the book will have a useful career in front of it. Its many excellences can be discovered by reading it and using it, and Dr. Mann is to be congratulated in having produced such a valuable addition to scientific literature.

W. D. H.

STATISTICAL SEISMOLOGY.

Les tremblements de terre. Géographie Séismologique. By Comte F. de Montessus de Ballore; with a preface by Prof. A. de Lapparent. Pp. v+475. (Paris: Armand Colin, 1906.) Price 12 francs.

WITH the growth of their science seismologists have become more and more specialised, and devoted themselves to the cultivation of a limited portion of their domain, but none have marked out for themselves a more clearly defined plot, or cultivated it with greater assiduity, than the Comte de Montessus de Ballore. Leaving to others the study of the nature and effect of earthquakes, he has confined himself to the consideration of their cause, and attacked the problem by the statistical way, believing that a detailed study of the distribution of earthquakes in time and space will most conclusively indicate their cause. By no means the first cataloguer of earthquakes in point of time, for the great lists of Mallet and Perrey are well known, to say nothing of the numerous local catalogues compiled by others, our author stands preeminent in the number of earthquakes which he has tabulated, and the work before us deals with the records of 171,434 distinct shocks. The labour involved in this compilation would have formed no light task for any man, and when we remember that, besides being a specialist in seismological statistics, the author is an officer on the active list of the French Army, the result seems almost miraculous.

In summing up the results of all this compilation the author holds that he has conclusively established the independence of earthquakes and volcanoes, and the greater prevalence of the former along those tracts where the surface relief shows the steepest and longest gradients. Both these conclusions had been reached by Prof. Milne while working in Japan, and the second of them is only an empirical, and not invariable, way of expressing the general principle that earthquakes are most abundant where the crust-movements have been greatest and most recent, while they become rarer as these movements are older and have more or less completely died out; but we must remark that earthquakes seem to be more particularly associated with the changes resulting from, or accompanied by, compression, for the dropped valleys of the Jordan, the Red Sea, and of Central Africa are not specially affected by earthquakes.

Comte de Montessus attempts to carry his conclusions still further, and finds that earthquakes are almost confined to certain bands which correspond with the secondary geosynclinals of Haug, and are said to lie along two great circles, making an angle of 67° with each other. We have had the curiosity to plot these bands, as shown on the map accompanying the book, upon a globe, and have failed to find any correspondence between them and the great circles as defined, or, indeed, with any other great circles; approximately, they seem to form a network of arcs of great circles, joining up in groups of three and four, an interpretation which is more probable than the other, though the departures in detail render the correctness of either view doubtful. However this may be, the fact remains that nine-tenths of the shocks recorded have originated in regions which cannot cover more than one or two per cent. of the globe and are almost all distributed along certain lines, of which the most important are the great girdle of the Pacific, the line which runs up from the Sunda Islands, through Arracan, the Himalayas, Caucasus, and Alps to the western Mediterranean, and another which runs up from the Caucasus through the mountains of Central Asia to Lake Baikal, possibly continuing to somewhere in the neighbourhood of the Bering Straits.

Though, in the main, the distribution of the more violently shaken regions shows no change from that drawn by Mallet in 1858, there is a radical difference in the character of the two maps. In Mallet's the frequency of earthquakes was indicated by the depth of tint, and the dark patches shaded off gradually into the white; de Montessus, believing that it is a mistake to treat an essentially discontinuous phenomenon as a continuous one, has made the limited areas, where destructive earthquakes are known to originate, black, and left the rest of the map blank. This abrupt boundary between the regions classed as seismic and the much more extensive ones classed as peneseismic or aseismic, is held to be a better representation of what is actually the case than any gradual shading of the one into the other. The difference between the two maps is, in fact, one of principle; Mallet's was meant to indicate the frequency with which earthquakes were felt, that of de Montessus the frequency with which they originate. Each of these facts is interesting in itself, but their delineation must necessarily differ, apart from any question of increasing perfection of the data.

We have indicated some of the conclusions drawn in this book, which do not seem to be so fully established as its author suggests, but this must not be taken in derogation of the value of his work in statistical seismology. We welcome this summary of his researches, and regret that he should have followed the custom, so common in France, of omitting a subject index.

OUR BOOK SHELF.

Notes on Shipbuilding and Nautical Terms of Old in the North. By E. Magnusson. Pp. 62. (London: A. Moring, Limited, 1906.) Price 1s. net.

THIS small volume reproduces a paper read before the Viking Club Society, and its appearance will be welcomed by all who are interested in the history and development of shipbuilding. Although it deals chiefly with Scandinavian records and discoveries, it contains an excellent summary of Greek and Latin references to ancient ships, and does not leave unnoticed much older Egyptian types. In short it is a scholarly performance, and the writer has a full appreciation of technical developments which have accompanied progress in shipbuilding. Wide reading and research must have been undertaken to provide the materials; they have been dealt with in a terse but clear style, and the result is of permanent value as a book of reference and a bibliography of the subject. An excellent glossarial index is appended. The only regret one feels is that there are no illustrations. The rock-carvings of ancient ships found in Egypt, Sweden, and Norway are described and compared; but simple illustrations would have emphasised the deductions made by the author. Again, the details of methods of construction which Mr. Magnusson gives are readily understood by experts in shipbuilding, but would be grasped by general readers also if diagrams of a simple nature had been given. The ancient ships found in Scandinavia and preserved in museums might also have been pictured with great advantage. Of course size and cost would be increased if this were done, but that action is well worth the consideration of both author and publisher, as the permanent value of the book would be greatly increased thereby, and its place in the libraries of all interested in shipbuilding would be assured.

A book so condensed in form and substance must be read to be understood. Mr. Magnusson does not claim originality in discovery or treatment. He starts with the log and raft of the stone age, passes to the canoe hollowed from a single log by the use of fire and flint implements; traces the development of the coracle and other hide-covered vessels, with internal framework; shows how these "skins" were replaced by wood planks, first fastened by thongs or withes, and later on by iron nails; and so he arrives at methods of building which persisted, with trifling variations, until wood gave place to iron in the last century. As regards propulsion a similar advance is traced from the single oar, to the rowing boat, and the galley with its banks of oars, coming at last to the use of masts and sails, as navigation took a wider and over-sea range. The special provisions made in vessels used for purposes of war are described, including that most ancient method of attack—the ram-bow. Altogether the book is an excellent piece of work.

W. H. W.

A First German Course for Science Students. By Prof. H. G. Fiedler and F. E. Sandbach. Pp. x+99. (London: A. Moring, Ltd., 1906.) Price 2*s.* 6*d.* net.

It is essential that students who intend to devote serious attention to science should be able to read scientific works in French and German, and, if possible, also in Italian. By the use of the present book a working knowledge of the German language can be obtained through lessons based upon work in elementary physics and chemistry. The book consists of a series of reading lessons describing simple experiments and principles such as are included in the rudimentary courses of schools. The words and phrases used in the various reading-passages are graded in such a way that the principal rules and grammatical forms are illustrated by the text. A short outline of grammar essential for the purpose in view follows the series of lessons, and there is a full vocabulary.

The book is printed in English characters, but the text and illustrations have a decidedly German appearance, as is appropriate in this case. Though the course covered by the lessons is similar in substance to that taken as introductory science in many schools, no doubt most teachers will prefer to follow English text-books for the actual work of the class-room and laboratory, and to use this book as an auxiliary aid or an incentive to the study of German. For pupils who are familiar with the experiments described, the book will be found very useful, and it will make them acquainted with the German equivalent of many technical terms not to be found in the ordinary reading books of the language. As an attempt to coordinate the teaching of modern languages and science, it will no doubt be appreciated, and for the finer feeling of literature pupils may still read extracts from the works of standard authors.

Personal Hygiene Designed for Undergraduates. By Dr. A. A. Woodhall. Pp. vii+221. (London: Chapman and Hall, Ltd., 1906; New York: John Wiley and Sons.) Price 4*s.* 6*d.* net.

Personal hygiene is an important branch of hygiene which does not receive its full measure of treatment in any text-book, but this small work does not pretend to offer to its readers more than a clear and elementary statement upon the hygienic needs of the body. It is intended for undergraduate students, and it consists of the substance of lectures upon personal hygiene delivered by the author during the past few years. Exercise, food, clothing, habits, and similar matters of daily individual concern, are here dealt with in language as free from technical terms as possible. We are told in the preface that the constant aim of the writer has been to present actual conditions in the simplest language, and it must be said that he has achieved this object. We may add that the work is free from "Americanisms"—either of wording or spelling.

Only such elementary facts of anatomy and physiology as are necessary to the reasonable understanding of the subject are introduced, and some hints as to "first aid" are here and there given in the text, but this subject is otherwise omitted.

The chapters on alcohol, tobacco, and exercise are particularly good. They are discussed in tolerant language and with much sound common-sense. After reading the following opinion (p. 157) the reader will think twice before he refuses an offer of confectionery. "Where the taste has not been vitiated, in a degree by tobacco but chiefly by alcohol, sugar is as acceptable to the normal civilised man as it is to savages, and his disposition toward candy is no bad test of his drinking habits."

The following criticism of our national game of cricket will scarcely meet with approval in this country:—"Cricket, an exotic that has never taken wide root on our soil, lacks many of the qualities of a good game, chiefly because of the long waits before going to the bat and the limited number actively engaged." But though the author does not write in his usually well-informed manner upon this particular item, the following statement (p. 88) will serve to acquit him of the charge of bias towards *every thing* American:—"The misnamed nasal twang with which some Americans are justly charged is due partly to chronic catarrh, blocking the nasal passages, and partly to that curious and unconscious imitation by which in youth we acquire the tone most commonly heard. Unfortunately, as a people all our voices are too sharp and rasping. . . . We are so accustomed to strident voices that we fail to recognise their inherent infirmity."

Life and Matter. A Criticism of Prof. Haeckel's "Riddle of the Universe." By Sir Oliver Lodge. Pp. ix+200. (London: Williams and Norgate, 1905.) Price 2*s.* 6*d.* net.

It is difficult to pardon Prof. Haeckel for his dogmatism and his over-statements, and no less for his having furnished the peg on which have been hung many dull books and reviews. Forgiveness becomes easier when his work evokes a first-rate criticism like that in the volume before us. Sir Oliver Lodge contests chiefly (*a*) the right by which the name of Monism is arrogated to the Haeckelian philosophy; (*b*) Haeckel's statement of the "Law of Substance," the true account of which, according to the critic, is that "anything which actually exists must be in some way or other perpetual"; (*c*) Haeckel's account of the development of life, and particularly the theory which endows the atoms of matter with life, will and consciousness.

The later chapters of the book state with great clearness Sir Oliver Lodge's own constructive views. He regards it as possible that life is a basal form of existence, as fundamental an entity as matter and energy. "It can neither generate nor directly exert force, yet it can cause matter to exert force on matter, and so can exercise guidance and control." His view occupies a middle position between the so-called monistic one and that, for example, of Prof. James Ward, who argues that the laws of physics are only approximate and untrustworthy.

The author, who understands well that effective illustration is half the difficulty, and that the "analogy of experience" is one of the soundest of philosophic principles, develops a fascinating comparison between life and magnetism. If we understand his views aright they imply that possibly mind can exist apart from terrestrial brains, and life apart from living creatures or plants as we know them—that is, that the phenomena of life and consciousness which surround us are due to the interaction of something material and something spiritual, or (to express it otherwise) to the fact that something spiritual uses the material as its instrument or organ. This seems to imply a dualism, but he also holds it possible that "there may be some intimate and necessary connection between a generalised form of matter and some lofty variety of mind."

The arrangement of the various topics is not always the best possible. This is partly caused by the inclusion of reprints from well-known journals—a practice which is open to criticism. But apart from these slight defects the book deserves hearty commendation.

The Fox. By T. F. Dale. (Fur, Feather, and Fin Series.) Pp. xiii+238; illustrated. (London: Longmans, Green and Co., 1906.) Price 5s.

"THE fox," writes the author in his opening paragraph, "is at home in Europe, Asia, including India, a great part of Africa, the whole of North America, and a distinct but allied species, *Canis virginianus*—known as the grey fox in the United States—is found in South America." If he had tried to compress as many errors as possible into a single sentence, he could scarcely have succeeded better. The fox is unknown in India proper, it inhabits only the northern fringe of Africa, and the grey fox (*Urocyon cinereo-argenteus*) is a native of North and not of South America. This is one of those numerous instances where authors of works on popular natural history will go out of their way to refer to subjects which they do not understand, and which do not concern them. Had Mr. Dale kept within his proper limits, we should have had nothing but commendation to bestow upon his work, in which the fox is discussed from the point of view of the sportsman and the farmer in a very thorough manner. The eight illustrations by Messrs. Thorburn and Giles are all that can be desired, although one of them follows somewhat closely on the lines of a well-known sketch by the late Mr. Wolf.

R. L.

Oologia universalis palæarctica. By Georg Kause. Part i. (Stuttgart: Fritz Lehmann, Verlag; London: Williams and Norgate.)

THIS is the first part of a beautiful egg book, printed entirely on separate sheets of cardboard, two sheets being devoted to each species—one of coloured figures of the eggs, the other of letterpress, backed with references to the specimens figured. The text is in German and English, and comprises a large number of synonyms and local names, and a short description of the range of the bird, its breeding habits, nest, eggs, &c. The four species treated of in the first part are the golden eagle, quail, song thrush, and raven, as many as sixteen (odd) eggs of the last-named bird (from different localities) being figured. In the case of the song thrush we have five "clutches," and in that of the golden eagle a clutch of two eggs and three single ones. The colour printing has been very successful, and admirers of eggs will welcome the excellent selection of varieties which has been figured, of each of which the "data" are given. We cannot extend the same praise to the English version of the letterpress, which is crude, too literal, and disfigured by unfamiliar words and expressions. However, it is possible to understand what is meant, although the remark on the quail that "the ♀ only breeds, the male is polygamons," reads strangely until we substitute broods for breeds and correct the misprint.

The work is to be complete in 150 parts, and Messrs. Williams and Norgate point out that on the publication of Part ii. the price per part will be raised from fifteen to eighteen pence.

LETTERS TO THE EDITOR

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Osmotic Pressure.

IN the concluding sentence of his most interesting letter on this subject in your issue of May 17 (p. 54) Mr. Whetham states that "The theory of ionic dissociation rests upon electrical evidence, and by such evidence it must be tried." It is unnecessary to dwell on the importance of the pronouncement.

Will Mr. Whetham kindly tell us *how* we *know* all the things which—in the final paragraph of his letter—he so confidently asserts that we know; in fact, what *precisely* the *electrical evidence* is upon which the theory of ionic dissociation *now rests*. He is a recognised master of lucid exposition and will be able, I am sure, as counsel of the whilom advocates of the doctrine of molecular suicide in solution, to state the case fully and fairly on their behalf. When we have this statement it will perhaps be possible to consider the validity of his modest contention and whether electricians alone have the right to pronounce judgment. A plaintiff is usually sure of his case before his cross-examination takes place.

This request is preferred in no adverse i(r)onical spirit, simply because I feel that it really is necessary that we should be informed where we are exactly. Our friends the ionic dissociationists are incorrigible squatters and seem to think that they have acquired the right of preemption over their adversaries' property; it is difficult to know, as they object to stock-taking, whether they have given anything in exchange for that they have lifted and what they have jettisoned of their original property; and until the electricians' title-deeds are shown and submitted to careful scrutiny, chemists can scarcely be expected to admit that they are ousted from possession.

As a chemist and a friend of the poor molecules, I feel that the aspersion of immorality should not be allowed to rest upon them for ever unless the evidence be really condemnatory beyond question. In any case, it is important that we should discover the true nature of the crime committed in solution; to cloak the inquiry by restricting it to thermodynamic reasoning—a favourite manœuvre of the mathematically minded—is akin to using court influence in abrogation of full and complete investigation; such a course may satisfy the physicist but is repulsive to the chemist, who, although able, perhaps, to imagine the existence of a frictionless piston, yet desires, in the first place, to get nearer to a knowledge of what happens to the real tangible piston of practice.

HENRY E. ARMSTRONG.

MR. WHETHAM'S letter in NATURE of May 17 (p. 54) raises clearly the whole question of the applicability of thermodynamic reasoning to osmotic phenomena. As my views as to the value of thermodynamic reasoning appear to be somewhat heterodox, may I indicate some criticisms of his remarks?

All thermodynamic proofs assume the truth of the "second law." Now the machinations of Maxwell's demon have shown clearly that the meaning of this law, when interpreted in terms of the molecular theory, is merely that, in the processes considered, no differential treatment is applied to the molecules in virtue of their different velocities. The law may or may not be true in any particular case. It cannot be said that there is any *a priori* support for it, or that a proof of its validity for one small branch of phenomena would justify its application to a totally different branch.

In all treatises with which I am acquainted, when the law has been stated, the only reasons alleged for believing it to be true are those derived from our inability to construct a heat engine which will work without equalising temperature. A few pages, before or after, will be found the statement that we cannot construct a reversible heat engine; but it is not pointed out that the irreversibility of all actual engines would mask the effect of a violation of the second law, unless that violation were very complete and the separation of the molecules into high and low velocity groups very nearly perfect. A demon might be slaving with the most commendable energy, but all his exertions would be rendered inoperative by the imperfections of our apparatus. To my mind, the evidence for the second law, even applied to the best actual heat engines, is extremely slight.

But even if the evidence were overwhelming, there would be no justification for applying the law to a process of such an entirely different nature as osmosis, where, moreover, there is some presumption that it is not true. No actual membrane is perfectly semi-permeable; some molecules of the solute pass through; it is not wildly improbable that these molecules possess velocities within some narrow range. But if this is so, Maxwell's demon is at work, the second law is not applicable, and thermodynamic reasoning is absurd. Definite experimental proof must be offered before the validity of the law for osmosis can be considered even probable. Some progress might be made by examining the same membrane at different temperatures; if its "degree of imperfection" did not vary rapidly with the temperature, the existence of such a separation as has been suggested would be rendered less probable.

Mr. Whetham has offered some proof already. He points out that there are five assumptions involved, and asserts that the truth of all of them is proved by the agreement between theory and experiment. But he ignores the possibility that two or more of the assumptions may be incorrect and that the errors thus introduced may cancel each other. He offers a particular solution of an equation containing five variables, and assumes that it is the only solution possible.

It must be remembered that there is not perfect agreement between theory and experiment. The errors are larger than those involved in the direct measurement of the pressure and the other quantities involved; there is a systematic error. But this is due, say the thermodynamicists, to the imperfection of the membrane. Exactly so; but that imperfection may invalidate the whole proof; in order to support their proof they may be denying one of their fundamental assumptions.

Mr. Whetham says that to reject the theory because there is no perfect membrane would be as absurd as to reject all thermodynamics because there is no reversible engine. I agree; but then I am such a heretic that I reject both. Our inability to construct a perfectly reversible engine is connected with the impossibility of handling individual molecules; friction and the rest would vanish if we could replace the material cylinder by a swarm of trained demons. When we have constructed a perfectly reversible engine we shall be possessed of the powers of those demons, and we shall be no longer bound by the second law, which merely asserts that we do not possess those powers. So far as physicists are concerned, reversible thermodynamics *is* "a vain thing."

Neither am I convinced of the perfection of Mr. Whetham's two perfect membranes. They are doubtless perfect so far as the solute is concerned, but his assumption (2) may be violated by the molecules of the solvent. It is quite possible that it is the swifter molecules which escape in the vapour and the slower which escape into the solid, and that, if our experimental devices were sufficiently delicate, we could use the separation thus effected to perform useful work. At any rate, proof is required to the contrary before thermodynamic deductions can be made with accuracy.

So far as I can see, thermodynamic reasoning applied to osmotic phenomena, as to most others, proves nothing but that the sum of the errors introduced by the various rather doubtful assumptions is not very different from zero —a result that does not seem to me worth the labour that has been expended in obtaining it.

NORMAN R. CAMPBELL.

Trinity College, Cambridge, May 20.

The Oscillation of Flame Cones.

PROF. GALLOWAY (NATURE, April 19, p. 584) considers that my explanation of the phenomenon described by Mr. Temple in his letter (March 29, p. 512) is inadequate, and he offers a different explanation. With the view of deciding the question some experiments have been made here by Mr. C. E. Whiteley. I may perhaps repeat that the phenomenon in question is the continued descent and re-ascent of the inner cone of a coal-gas and air flame when a suitable mixture of the two is ignited at the end of a glass tube fixed so as to form a prolongation of the metal tube of a Bunsen burner.

The following results were obtained by Mr. Whiteley:—(1) The continued oscillation of the inner cone could not be established with a forced supply of both gas and air, but only when the air was sucked in by the injector action of a gas jet, as in the ordinary Bunsen burner. (Mr. Temple informs me that this was also his method of working.) (2) The continued oscillation of the inner cone could be maintained when the apparatus was tilted even to horizontality or beyond. (3) When the inner cone began to descend a back pressure was immediately produced in the ascending current of gas and air.

I think the determining influence is clear from these observations. When the cone begins to descend and causes a back pressure this will momentarily check the indraught of air without materially checking the supply of gas. A stratum of mixture containing less air is thus produced; its rate of inflammation is less than its upward velocity, and so the cone is carried to the top of the tube. Soon the normal air supply is re-established, a mixture with a higher rate of inflammation is restored, and the cone again descends.

A confirmation of this explanation is afforded by two further observations:—(4) a shortening of the glass tube increases the rapidity of oscillation in conformity with the shorter distance to be traversed by the altered stratum; (5) a "capacity" in the form of a globe at the bottom of the glass tube stops the oscillation. Such an arrangement would both damp the back-pressure impulse and obliterate stratification.

Observations (2) and (5) show, I think, that the chimney-like action suggested by Prof. Galloway cannot be the determining cause, and indeed this could hardly be expected, inasmuch as such action would increase the aspiration of air and produce a mixture having a higher rate of inflammation, a condition which would oppose the other effect, viz. the increased upward velocity of the mixture to which alone Prof. Galloway alludes.

My own previous explanation was inadequate to explain the continued oscillation, and only important in relation to the lighting back of Bunsen flames.

ARTHUR SMITHELLS.

Ancient Fire Festivals.

IN reference to your series of articles which have recently appeared in NATURE on Stonehenge and the ancient festivals, I send you the following notes on a Wiltshire celebration of the August fire customs. Tan Hill Fair is held on August 6, and the coincidence of the name Tan (Celtic for fire) and the date point to a time long prior to our era, when the fire festivals were annually held.

This fair, the origin of which is lost in antiquity, is held in the very last place likely to be chosen for such a purpose, and must have had its beginning at a time when men assembled there for some purpose very different to what brings them there now, for neither roads nor waterways (conditions essential to most fairs) lead to Tan Hill.

Tan Hill is on the highest part of the downs (near Devizes, north Wiltshire), 958 feet above sea-level, looking down on Avebury and dominating the whole country, and crossed only by British trackways which lead to the fair.

Sacred fires lit of old on this Tan Hill would have been seen from Martinsell (near Marlborough), Hackpen, Oldbury, and for miles around, and were probably eagerly watched for by the people taught to expect the blessing on the crops of the ensuing year consequent on these fires; and it is on this bleak, desolate down that one of the largest fairs of the country is held.

Fairs in Ireland and in Wales carry on the same tradition of the ancient fire festival held in August, as well as this one at Tan Hill.

In ancient Ireland this August celebration was called "*the Lugnassad*," the feast of Lug (a sun god), and according to Prof. Rhys "this festival was the great event of the summer half of the Celtic year, marking the victorious close of the sun's contest with the powers of darkness . . . when the crops were fast coming to maturity," and he suggests that the great festival held on the first of August "at Lyons (ancient *Lugduna*) superseded an older feast held on that day in honour of Lug, and was the Gallo-Roman continuation of the Celtic custom of old days." Gwyl Awst (the Yule of August) is the name by which this same August festival was known in ancient Wales.

He remarks that "the Lugnassad was, so to speak, the Summer Solstice of the Celts, whereas the longest day was then of no special account" (Rhys, Hibbert lectures).

Very interesting accounts of an August festival are given by Mr. Frazer ("Golden Bough") as celebrated by the Creek Indians and also by the Natchez tribe on the Lower Mississippi, when fires were lighted to destroy what was old before the ceremonial renewal of new fire took place by the priests by the friction of two pieces of wood, on the appearance of the first ray of the rising sun.

Among the special marks distinguishing the primitive ritual of heathendom from later customs, Mr. Frazer remarks that there were no temples, but that the celebrations took place by brooks, in woods, barns, harvest-fields, &c.

This interesting fair is clearly a survival from pre-Celtic days, but the interest in the place has unfortunately been much obscured by the alteration of the old name Tan to St. Anne's Hill on all modern maps.

It was a very common and well-known custom of the Church in late times to alter the name of a place to that of a saint, where, finding large gatherings assembled for religious ceremonies, their object was to substitute Christian for heathen ideas. *Caer Anna* in Brittany became St. Anne d'Auray, and Tan Hill became St. Anne's Hill. St. Anne's Day was not fixed for the whole Latin Church until 1584, when Gregory XIII. appointed the feast to be held on July 26 (August 6); the name of St. Anne does not occur in the older church calendars, and her cult is a very late one.

THEREZA STORY-MASKELYNE.

Carbon Dioxide in the Breath.

THE presence of 0·06 per cent. of carbon dioxide in the atmosphere is held, I believe, to render the air unfit for breathing purposes, whereas 0·03 per cent. may be taken as normal. A consideration of the quantity of this gas which must be continually present in the lungs makes such sensitiveness on their part to appear rather extraordinary.

Taking an average expiration as 300 c.c. and the reserve "air" in the lungs as 2000 c.c., and assuming that the atmosphere contains 0·03 per cent. of carbon dioxide and expired air 4 per cent. of carbon dioxide, we have the following figures (a homogeneous mixture in the lungs is imagined for simplicity):—

Just before expiration		Just after expiration		Just after inspiration		
2208	...	1920	...	2219·91	...	c.c. air
92	...	80	...	80·09	...	,, CO_2
2300	...	2000	..	2300	..	,, in lungs.

Hence before the next expiration 11·91 c.c. of carbon dioxide must accumulate to make up the original 92 c.c., the corresponding oxygen being absorbed.

Now if conditions remain the same, excepting that the atmospheric carbon dioxide reaches 0·06 per cent., we have

Just before expiration		Just after expiration		Just after inspiration		
2208	...	1920	..	2219·82	...	c.c. air
92	...	80	...	80·18	...	,, CO_2
2300	...	2000	..	2300	...	,, in lungs.

Before the next expiration 11·82 c.c. of carbon dioxide are required to make up the original 92 c.c.

Comparing these numbers, 11·91 and 11·82, we find that in the case of a person breathing at the rate of sixteen times a minute, only one more respiration would be required every seven minutes to get rid of the extra carbon dioxide due to an increase of 0·03 per cent. in the atmosphere.

One is tempted to wonder, therefore, whether carbon dioxide *per se* in these small quantities can have any appreciable effect. Or, on the other hand, is it possible that this gas in the lungs is in some manner "vitalised," as questioned by Prof. Meldola some time ago (see NATURE, 1902, vol. lxvi., p. 492), and that on reaching the outer world it is in a short time changed into the ordinary and more poisonous form?

F. SOUTHERDEN.

Royal Albert Memorial College, Exeter, April 25.

AMERICAN PALÆOBOTANY.[1]

THESE two volumes form the second instalment, under the editorship and to some extent the authorship of Mr. Lester Ward, of a detailed report on the Mesozoic floras of the United States, the first part of which appeared in the twentieth annual report

FIG. 1.—Jurassic Ginkgo leaves from Oregon. (From "Status of the Mesozoic Floras of the United States.")

of the U.S. Geological Survey published in 1900. The second paper deals with Triassic, Jurassic, and Lower Cretaceous floras, and includes observations on the stratigraphical relations of the plant-bearing strata.

The excellent quality of the plates, many of which consist of photographic reproductions of specimens, is in welcome contrast to the unsatisfactory figures

[1] "Status of the Mesozoic Floras of the United States." Second Paper. By Lester F. Ward, with the collaboration of William M. Fontaine, Arthur Bibbins, and G. R. Wieland. Part i., Text. Part ii., Plates. Pp. 616; Plates i–cxix. Monographs of the U.S. Geological Survey, vol. xlviii. (Washington, 1905.)

in some of the earlier monographs on American fossil floras. Under the head of Triassic floras an account is given of the results of an expedition into Arizona in 1901, which seems to have been more successful in discovering fossil vertebrates than the remains of vegetation. Reference is made to the "inexhaustible quantity of silicified wood," some specimens of which are included in the genus Araucarites, a type widely distributed in Mesozoic strata in many parts of the world. By far the most important part of the report is that by Mr. Fontaine, which deals with the rich Jurassic flora of Oregon. An inspection of the photographs and drawings reveals the interesting but not unexpected fact that the general facies of the vegetation exhibits a striking agreement with that which has been described from the Oolite rocks of East Yorkshire, Siberia, and other Old-world localities. A few species occur which appear to be identical with Wealden plants, while others are reminiscent of the older Rhætic floras. We welcome this exceedingly valuable addition to palæobotanical literature, but it is unfortunate that the author has

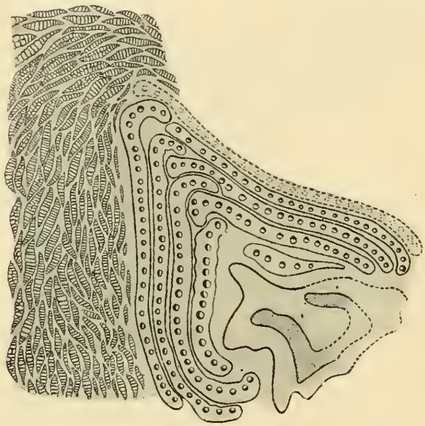

FIG. 2.—Unexpanded Frond of *Cycadella utopiensis*, Ward, showing the rachis with two rows of young pinnæ and a mass of ramental scales. (From "Status of the Mesozoic Floras of the United States.")

not exercised more self-restraint in his use of recent generic names in cases where there is no proof of close relationship between the Jurassic and existing plants. Fragments of fern fronds are designated species of Dicksonia and Thyrsopteris on wholly insufficient grounds. So long as palæobotanists continue the practice of labelling fossil species with the names of recent genera merely because of superficial resemblances presented by vegetative organs, their lists of species cannot be accepted as trustworthy contributions towards a fuller knowledge of the plant-distribution of former ages. Ferns and Cycads are well represented, and the abundance and variety of leaves referred to the genus Ginkgo—that striking embodiment of the "past in the present"—constitutes a notable feature of the Oregon flora (Fig. 1). The volume also contains an account of Lower Cretaceous floras, together with much information on the plants of the older Potomac formation, and descriptions of additional specimens of silicified Cycadean stems from the Jurassic rocks of Wyoming and the Potomac beds of Maryland. Mr. Wieland gives a particularly interesting figure of a young frond of a species of Cycadella in which the rachis is traversed by a U-shaped vascular band bearing a much closer resemblance to the meristele of a fern petiole than to the conducting strands in the rachis of a Cycad (Fig. 2). The notes which Mr. Wieland has already contributed on the morphology of Mesozoic Cycads have raised a keen desire for further information, and embolden us, who wait with envy and impatience, to urge him to publish with all speed an instalment of his promised monograph.

By the publication of these volumes Mr. Lester Ward has laid his fellow-workers in palæobotany under a further obligation. Although there are various matters of detail which we should venture to criticise if space permitted, there can be no doubt as to the value of this latest contribution from the veteran author and editor.

A. C. SEWARD.

RECREATIONS OF A NATURALIST.[1]

THE "naturalist" on the present occasion is Mr. J. E. Harting, from whose pen we have welcomed during the past forty years (*eheu! fugaces*) many volumes on many aspects of sport and natural history. Among his recreations are outings on the moor, the hill, and into the quiet byways of the

FIG. 1.—A Kingfisher hovering. From "Recreations of a Naturalist."

country, with gun or rifle (in their proper season), or with neither with equal enjoyment to him, and, as frequently as fortune favoured, with what it is easy to see he perhaps loves best of all, "a cast of hawks." Another form of "recreation" has been—metaphorically speaking—"finding a hare in the library and hunting it through the preserves of ancient authors until the hunt had a happy termination, or the literary hare escaped to give sport another day."

No doubt the writing of the essays that describe these recreations formed a supplementary one, not improbably combined with "business" as an enhancement to the diversion; for most of the forty essays in the present volume have previously appeared elsewhere, chiefly in the columns of *The Field*. Mr. Harting's library hunts are fewer in number and less engaging than those pursued by him out of doors. Of these one here and there might, perhaps, have been omitted, as somewhat belated, such as the account of "Swan-upping," in which the information is eleven years old, while the "Horse and its Historians" is a review of a work published in 1888.

[1] "Recreations of a Naturalist." By James Edmund Harting, author of a "Handbook of British Birds," &c. With 81 illustrations. Pp. xvi+433. (London: T. Fisher Unwin, 1906.) Price 15*s*. net.

though since then has not the "Thoroughbred Horse" been written by Prof. Ridgeway?

The majority of the other essays are, however, worth issuing in collected form. In reading them we recognise the spirit of the genuine sportsman naturalist the best combination in a human being for the full enjoyment of the external world—and follow with deep satisfaction his excellent companionship out into the open in his "Marsh Walk in May," "On the Hill," and "Bird Life on the Broads." An interesting chapter on "Small Birds on Migration carried by Large Ones" leaves the question as undecided as before. It may be worth recording, however, that many years ago the present writer listened with intense interest to his *vis-à-vis*, at a Lisbon hotel *table d'hôte*, relating how he had seen in Egypt small birds landing from the shoulders of an immigrant crane. The writer on inquiry learned that the name of his co-resident was "von Heuglin."

In his essay on the "Fascination of Light," Mr. Harting records some circumstantial evidence for believing that the powder-down patches of certain herons are phosphorescent, and probably provide a "living light" for alluring fishes to the surface of the water, and within sight of the foraging bird during the darkness. It is suggested also in regard to the common kingfisher that its orange-coloured breast may serve the same purpose when the bird is hovering (during daylight) over water "on the feed." While it would be very difficult to prove the latter suggestion experimentally, it seems that the former might be investigated with much chance of success by a couple of unprejudiced, enthusiastic and properly equipped ornithologists spending a few dark nights in a punt in the quiet haunts of the heron.

These "Recreations" may be cordially recommended to the lover of nature as a companion on his summer holidays. The book is full of delightful illustrations—those especially by Joseph Wolf and George Lodge—and, as a specimen, the beautiful hovering kingfisher, by the latter artist, is reproduced here. F.

FORTHCOMING VISIT OF REPRESENTATIVES OF UNIVERSITY EDUCATION IN FRANCE.

THE Senate of the University of London has invited representatives of the University of Paris (Faculty of Letters and Faculty of Sciences) and of the Collège de France to visit London at Whitsuntide. These representatives will be accompanied by the highest officials of the French Ministry of Public Instruction and by a number of representatives of the French provincial Universities. The Société des Professeurs de Langues vivantes and of the Guilde Internationale will be simultaneously entertained by the Modern Language Association, and the University has arranged for the representation of all these bodies at the various ceremonies. The French delegations will be headed by M. Liard, the Vice-Rector of the University of Paris.

The King has graciously expressed his desire to receive a number of the French visitors at Windsor on Thursday afternoon, June 7.

The general programme will include the following items:—Monday, June 4, an informal dinner at the Royal Palace Hotel, Kensington, at which the guests of the University will stay. Tuesday, June 5, a reception at the Foreign Office by Lord Fitzmaurice and by Mr. Lough, Parliamentary Secretary of the Board of Education, at noon; luncheon at the University; addresses at the University by Sir Edward Busk, Vice-Chancellor, M. Liard, Sir Arthur Rücker, and Prof. Sadler (on behalf of the Modern Language Association); informal receptions of French and English specialists. Wednesday, June 6, visits to Westminster Abbey, to Westminster School, and to some of the London County Council educational institutions, followed by a luncheon to be given by Mr. Evan Spicer, chairman of the County Council, at Belair, Dulwich; in the evening a dinner at University College, and various private dinners, followed by a reception by his Excellency the French Ambassador at the French Embassy. Thursday, June 7, addresses by the Deans of the Faculties of Arts and Science of the Universities of London and Paris, by Sir William Ramsay, K.C.B., and by representatives of the Collège de France, the French provincial Universities, and the French Modern Language Association; and in the evening a conversazione at the University. It is understood that a number of the French guests will, on Friday, June 8, visit the Universities of Oxford and Cambridge.

The guests will include the following representatives of science in France:—

University of Paris: M. Liard, Vice-Recteur de l'Université; Profs. Appell, G. Bertrand, Léon Bertrand, Vidal de la Blache, Borel, Boutroux, Bouty, Bouveault, Dastre, Delage, Fernbach, Hérouard, Houssay, Joannis, Lapicque, Leduc, Lippmann, Matignon, Matruchot, Painlevé, Pellat, Perrin, Pruvot, and Puiseux.

Collège de France: Profs. Henneguy and Pierre Janet.

University of Bordeaux: Prof. Lorin.

University of Caen: Prof. Guinchant.

University of Lille: Prof. Ponsot.

University of Nancy: Prof. Cuénot.

NOTES.

GREAT surprise and regret have been caused in German chemical circles by the announcement that Prof. W. Ostwald has requested the Saxony Minister of Education to allow him to give up the position which he has held in the University of Leipzig for so many years. German scientific journals and papers are unanimous in saying that of living chemists not one has exercised so great an influence on the progress of modern chemistry as Prof. Ostwald in his almost twenty years of academic teaching. But Prof. Ostwald finds the direction of a large university laboratory making so many calls on his time as to prevent his carrying out the amount of original and private work which he would like, with the result that he has decided to retire to his country house at Grossbothen (Saxony), where a small private laboratory has been arranged, and devote himself to literary and experimental work, dealing in the first instance with the technology of painting.

AT the invitation of the Anglo-German Friendship Committee a number of editors of German newspapers will visit London shortly. According to present arrangements, the visitors will arrive in London on June 20. Among the many entertainments provided is a visit to the Natural History Museum on Sunday, June 24, under the guidance of Lord Avebury and Prof. Ray Lankester. On Wednesday, June 27, the party will go to Cambridge to be entertained at one of the colleges and taken over the University.

THE President of the Board of Trade has appointed Major P. A. MacMahon, F.R.S., to be Deputy Warden of the Standards, to succeed the late superintendent of weights and measures, Mr. H. J. Chaney.

THE Friday evening discourse at the Royal Institution on June 1 will be delivered by Prof. H. Moissan, on "L'Ébullition des Métaux," and on June 8 by Sir James Dewar, on "Studies on Charcoal and Liquid Air."

The anniversary meeting of the Royal Geographical Society was held on Monday, May 21, when the medals and other awards announced in Nature of April 5 (p. 541) were presented.

A feature of the "Country in Town" Exhibition which will be held on July 5–19 in the Whitechapel Art Gallery will be photographs illustrating what can be done to beautify urban gardens, streets, and parks. Photographic prints for the exhibition will be gladly received by the honorary secretary, Mr. Wilfred Mark Webb, at Toynbee Hall, Whitechapel, E.

The death of Mr. Charles Eugene De Rance occurred on May 9, after eleven days' illness, the result of an unfortunate accident. Although Mr. De Rance began and ended his professional career as a civil engineer, he was for thirty years an officer of the Geological Survey of England and Wales. During this period he was engaged in the south of England and upon the Coal-measures of Flintshire and elsewhere, but most of his work was among the Triassic rocks of Lancashire and Cheshire, and the Glacial deposits of the same districts. He contributed to several memoirs of the Geological Survey, but his principal published work was the "Water Supply of England and Wales" (1882). For sixteen years he acted as secretary of a committee of the British Association on the circulation of underground waters; he was associated also with a committee on coast erosion. Problems of water supply always enlisted his attention; one of his last acts was an appeal for information as to the influence of the recent earthquakes on the flow of water in wells.

We notice with regret the announcement of the death on May 1 of Prof. I. C. Russell, head of the Department of Geology at the University of Michigan. He was for a short time assistant professor of geology at Columbia University, and became geologist in the U.S. Geological Survey in 1880. In 1892 he became professor of geology in the University of Michigan. Prof. Russell was vice-president of the American Association in 1904, and was president of the American Geological Association at the time of his death.

Messrs. C. Venkataraman and V. Apparan, of the Presidency College, Madras, write to describe a modification of Melde's experiment with a weighted string attached to the prong of a tuning-fork. When the string to which the pulley is attached is held so as to be neither parallel nor perpendicular to the vibration of the tuning-fork, then, if the tension is properly adjusted, the string takes up a stationary form of vibration capable of simple explanation.

Referring to the correspondence on "Sounding Stones" published in our issue for January 4 (vol. lxxii., p. 222), Mr. E. M. Buchanan, writing from Henzada, Burma, directs attention to the resonant properties of fossilised wood and a long established custom in Upper Burma, where such wood is common. The natives collect pieces of a kind with even grain, obtainable in lengths of 4 feet to 6 feet, and convert them into gongs by polishing them slightly. In the monasteries or shrines the monks accompany their recitations at matins and vespers with the music of their stone gongs, which are usually well attuned and give a pleasing effect.

We learn from the *Times* that the Government has given its sanction to a scheme for the organisation of the Archæological Department of India on a permanent and improved footing. Although much has been done since a Director-General of Archæology was appointed in 1902 for a period of five years, the experience gained has proved that the task of restoring and conserving the antiquities of India will always require trained ability for its adequate discharge. The present Director-General of Archæology is confirmed in his appointment. In lieu of the present Government epigraphist for Madras, the scheme provides for the appointment of a Government epigraphist for the whole of India, whose duty it will be to organise and collate the results of the epigraphical work of the provincial surveys. At the same time, the importance of Madras for this form of research and its special linguistic conditions necessitate the retention of a special epigraphical expert in that presidency.

The chief annual meeting of the Verein Deutscher Chemiker will be held this year at Nurnberg on June 6–9. Prof. C. Duisberg, of Elberfeld, will report on the work of the commission appointed by the Gesellschaft Deutscher Naturforscher und Aertze to consider the science teaching in German schools; Herr A. von Baeyer will lecture on the anilin dyes; Dr. Lehner, of Zürich, on artificial silk; Prof. Stockmeier, of Nurnberg, on explosions in the aluminium bronze colour industries; Prof. F. Haber, of Karlsruhe, on the optical analysis of coal gas; Prof. A. Werner, of Zürich, on valency; Dr. F. Raschig, of Ludwigshafen, on catalysis; Prof. M. Busch, of Erlangen, on new methods of determining the amount of nitrogen in nitrocellulose; Dr. Ed. Jordis, of Erlangen, on the chemistry of silicates; Dr. L. Eger, of Munich, on the examination and evaluation of railway materials; Dr. O. Röhm, on the manufacture of illuminating gas; and Dr. M. Neumann, of Cronberg, on the theory of the Glover process and the manufacture of sulphuric acid in towers. Visits will be paid to several chemical works and large engineering works in the neighbourhood, including Messrs. Siemens and Schuckert's, while excursions to Erlangen on June 8, to Rothenburg a.T. (Württemberg) on June 10, and to the Jubilee exhibition on June 9 are to be arranged.

The Connecticut Agricultural College has been authorised to accept the Edwin Gilbert bequest consisting of a farm of 350 acres at Georgetown, Conn., together with a fund of 12,000*l*. for the maintenance of the farm. The tract of land is, according to *Science*, to be used for experimental purposes in connection with the work of the agricultural college, but it is not intended to establish a branch of the college at Georgetown. From the same source we learn that the additional appropriation of 1000*l*. for the agricultural experiment stations, provided by the Adams Bill, has now been paid. This Bill increased the present appropriation of the agricultural stations under the Hatch and Morrill Acts by 1000*l*. for the year ending next June, and by an additional 400*l*. annually above the amount of the preceding year for the next five years. At the end of the five years this will amount to an increase of 3000*l*., bringing the total appropriation to each experiment station to 6000*l*. annually. The funds are to be applied only to original researches or experiments bearing directly on the agricultural industry of the United States, with due regard to the varying conditions and needs of the States in which the stations are located.

The contents of the May number of *Naturen* include articles on mosquitoes and gnats, on the Yangtse-kiang district and its products, and on dogs—prehistoric and modern—the last of these being by Dr. Reinhardt.

Owing to the advent of abnormally high temperatures at an unusually early period, which rendered collecting in the desert practically impossible, Dr. C. W. Andrews, of the Natural History Museum, has returned from his Egyptian trip. We understand that he has obtained some important specimens from the Fayum deposit, but that he was unable to visit the zeuglodon-beds of the Mokattum range.

The greater portion of the April issue of the *Museums Journal* is taken up by an illustrated article by Colonel Plunkett, director of the Dublin Museum, on the methods employed at that institution in circulating objects of art, or reproductions therefrom, among schools and other local establishments. A special endeavour has been made to reduce so far as possible the labour and expense connected with handling, packing, receiving, and dispatching the circulation sets, and although the scheme has only been in operation for a couple of years, it appears to be a conspicuous success.

An important paper by Mr. F. W. Thyng appears in the Proceedings of the Boston Society of Natural History (vol. xxxii., No. 11) on the squamosal bone of the skull in four-footed vertebrates. After maintaining, in opposition to the views of Gadow, Broom, and others, that the mammalian incus corresponds to the reptilian quadrate, the author proceeds to demonstrate that, of the two bones lying between the parietal and the quadrato-jugal in the labyrinthodont skull, the lower one, as not overlying the otic capsule, represents the squamosal of mammals, while the upper one should be called the supratemporal. According to the generally accepted scheme of cranial osteology, these names are transposed. The author's re-determination is largely based on the evidence afforded by the larval skull of the limbless amphibians, or cæcilians, which appear to come the nearest of all living groups to the labyrinthodonts.

The articles in the combined second and third parts of vol. lxxxi. of the *Zeitschrift für wissenschaftliche Zoologie* are only three in number, but each is of unusual length. In the first Mr. Hans Dunker discusses the homology of the cirri and the elytra in the "sea-mouse" (Aphrodite); the second is a continuation of Dr. L. Böhmig's studies of the planarian worms of the Tricladida group; while the third, by Mr. C. von Janicki, of Basle, is devoted to certain new or little-known cestode parasites infesting marsupials, bats, insectivores, rodents, and edentates. In the case of the last paper, especial interest, from a geographical point of view, attaches to the discovery in a Brazilian opossum of a new species of tape-worm belonging to the genus Linstowia, which was established by Zschokke in 1898 for the species *L. semoni* infesting one of the Australian bandicoots, but included another species found in the Echidna or spiny anteater of the same region. The new evidence is of the highest importance in confirming the opinion as to the close affinity of the South American to the Australasian marsupials, and also as to the relatively late date at which the two groups were sundered. Whether the common habitat of the ancestral type was, as has been suggested, in south-eastern Asia or in a sunken southern land remains to be determined.

Some cultural notes by Mr. H. Drion on hardy bamboos, continued from the previous number, are published in the April number of *Le Bambou*. Prof. E. de Wildeman contributes a note on the bamboo-hat industry in Java, that gives employment to a large number of natives. The hats are made double and in various qualities depending upon the degree of fineness of the woven strips. Their cost varies from four pence to eighteen pence; the chief defect is their tendency to become discoloured.

The Para rubber tree and its cultivation, also the cultivation of other American rubber trees, have attracted a great deal of attention lately, but *Ficus elastica*, the source of india-rubber, is seldom mentioned, and its cultivation is by no means fully understood. A small brochure written by Mr. C. Bald contains much information on the subject that will be useful to rubber planters in the north of India and elsewhere. Wild plants generally begin life as epiphytes, but the writer describes how seedlings can be readily germinated and transplanted, or a branch may be specially prepared for layering, whereas artificial attempts at epiphytic germination have mostly failed.

The third number of the Kew Bulletin for this year contains a series of identifications of new plants by workers in the herbarium. Dr. Stapf contributes a decade of African plants and a selection from various countries, including four species of Icacineæ from Borneo. Among the new orchids named by Mr. Rolfe are a Catasetum from Colombia and a Pteroglossaspis that is interesting as the first American record of a genus hitherto known only from Africa. Mr. G. Massee concludes an account of animal and plant parasites destructive to beets and mangolds by pointing out the risk of growing two root crops in succession.

In the Bulletin of the Department of Agriculture, Jamaica, vol. iv., part iii., an article by Mr. H. Q. Levy is published on the cultivation and marketing of oranges and grape fruit. Mr. Levy treats the subject from the point of view of the small grower, and gives advice on the laying out of the plantation, suitable catch crops, and the diseases of citrus fruits; the varieties of orange recommended are the seedless Petersfield navel and the seeded Pineapple. The hints on grading and packing the fruit are pertinent and practical. The part also contains a list compiled by Mr. Wm. Harris of the seasons and prices in Kingston for fruits, vegetables, and other products.

Mr. E. P. Stebbing writes a short note in the *Indian Forester* (March) on *Termes gestroi*, a termite that attacks Para rubber trees. This parasite has been reported previously from Borneo, Singapore, and the Straits Settlements, and now from the Mergui plantations in Burma. Little appears to be known of the habits of these white ants except that they hollow out their galleries in the crown of the root, where they collect and store the latex, and that they have increased greatly owing to the favourable conditions they find in the plantations of this exotic tree. Further information with regard to their life-history is required before satisfactory methods of treatment can be suggested.

Although an exhaustive investigation into the methods of cultivating and manufacturing natural indigo in India was carried out by Mr. Rawson a few years ago, and valuable suggestions were made by him for effecting improvements, the importance of the subject warranted further experiments that have been undertaken by Mr. C. Bergtheil, the agricultural bacteriologist to the Government of India. In the recent report of the Indigo Research Station at Sirsiah the superiority of the Natal plant, *Indigofera arrecta*, as improved by cultivation in Java, over the ordinary Bengal plant, *Indigofera sumatrana*, is clearly established, except under certain conditions. Mr. Bergtheil also emphasises the importance of seed selection. In the manufacturing processes the chief point inculcated is the necessity for maintaining the steeping vats at a temperature of 90° F.

Mr. E. R. Pratt, of Ryston Hall, Norfolk, writes an interesting article on the East Anglian timber willow in the recently published Journal of the Royal Agricultural Society. The supply of timber suitable for their trade has in recent years caused manufacturers of cricket-bats some anxiety. In East Anglia, and apparently in other parts of England, all large willows have been felled, except those kept by landowners for ornamental purposes, and the price of timber good enough for bat-making has risen to 5*s.* per foot. Two varieties of willow are purchased, the "close-bark," which is considered much the best, and the "open-bark." Growers of willows have found it a difficult matter to ascertain what variety the bat-maker wants, as his descriptions of the tree have been very vague. Mr. Pratt has gone carefully into the question of variety, and has examined a great many willows in the eastern counties. On the authority of a botanist who has given special attention to the genus (Rev. E. F. Linton, of Edmondsham, Salisbury), he states that the "close-bark willow" is not *Salix alba*, but *S. viridis*, a variable hybrid between *S. alba* and *S. fragilis*. Many of Mr. Pratt's specimens closely approached the former species, but could always be distinguished by the bronze-red winter shoots. He believes that the genuine *S. alba*, of which he has cultivated specimens obtained from Kew, is very rare in the eastern counties. Mr. Pratt further states that the "open-bark willow" of the bat-maker is *S. fragilis*, the crack willow, or its variety, *S. Russelliana*, the Bedford willow. In his experience *S. viridis* is much more common in East Anglia than *S. fragilis*.

In the *Engineering Review* (vol. xiv., No. 5) illustrations are given of the works at Notodden where the synthesis of nitrates from the air has been found commercially practicable.

Some very useful hints for horseback travel and transport are given in an article by Mr. F. L. Waldo on outfitting for the prospecting trail in northern Mexico in the *Engineering Magazine* (vol. xxxi., No. 1). During a ten years' residence in Mexico the author's attention has many times been directed to the incongruity of the outfits prepared and brought into that country by those whose business or pleasure call them into the Sierras. While the suggestions given refer specifically to a certain region, many of them will be of value elsewhere.

A Bulletin (vol. iii., No. 54) has been issued by the Department of Agriculture, Madras, describing experiments on well irrigation made by Prof. A. Chatterton at Metrosapuram in 1902–5. The results show that with adequate pumping power it is possible to improve the water supply and to cultivate a very considerable tract of land from a single well. If in the future oil engines and pumps are extensively used for well irrigation in India, it appears certain that the 3-inch centrifugal pump will be most largely employed, and that such a pump will water six acres per day of twelve hours, and will be suitable for areas ranging from thirty to fifty acres.

The annual progress report of the Geological Survey of Western Australia for 1905 (Perth, 1906) shows that much valuable work has been done. The Wodgina tinfield has been carefully examined, and it is believed that it will prove an important tin and tantalite producer. About 1 cwt. of tantalite specimens have been presented to the Survey museum. During the year there was a sudden demand for tantalum ores which had hitherto been considered useless. Considerable interest has been taken locally in deposits of graphite, and those on the Donnelly River have been worked to a slight extent. A sample of laterite iron ore from Comet Vale, North Coolgardie, proved of great interest on account of the occurrence in it of a notable proportion of chromium, mostly in the form of a hydrate. A large portion of the report is devoted to the results of examinations of the various goldfields, full reports of which will be published in due course.

The weather report of the Meteorological Office for the week ending Saturday, May 19, shows that the recent rains were excessive in places, while in other parts of the United Kingdom the rainfall was below the average. In the east of Scotland and in the north-east of England the aggregate fall was at least four times the average. The measurements due to the exceptionally heavy rains of Saturday, May 19, were:—2·53 inches at North Shields, 2·40 inches at Alnwick Castle, and 2·23 inches at Seaham. Both France and the Spanish Peninsula participated in the heavy rains of Saturday, the measurement for the twenty-four hours at Lyons being 2·25 inches, and at Corunna 2·40 inches.

We have received copies of the *Boletim mensal* of the Observatory of Rio de Janeiro, issued under the auspices of the Ministry of Industry. Anyone wishing to study the climate of that part of the Atlantic shore lying between the mouth of the Amazons and Rio de Janeiro will find trustworthy statistics for several of the coastal stations. The data are chiefly for ten-day means, with monthly means and extremes, but for Rio de Janeiro the actual observations for three-hourly periods are given in addition, and furnish most valuable details for all meteorological elements.

The Republic of Uruguay has recently established a National Institute for Weather Prediction, with its central observatory at Monte Video; the meteorological observatory at that place was founded by the municipal authorities in 1895. Observations have been made at several stations for some years, and the new institution has commenced its operations by the collation and discussion of the means and extremes already available, and by the investigation of the characteristics of the severe storms which affect the navigation of the estuary of the Rio de La Plata. The most dangerous storms are those from the south-east, as they usually occur with a rising barometer, in connection with anticyclonic conditions over the Atlantic, and are frequently accompanied by thick fog on the coast. The first number of the bulletin of the institute contains an exposition of the hydrography of the estuary, and tables showing, *inter alia*, the effect of the various winds upon the tides of the river.

Two reports have recently been issued on rates of deck watches and of box and pocket chronometers on trial for purchase by the Board of Admiralty at the Royal Observatory, Greenwich, in the latter half of last year. The number of deck watches on trial from August 5 to November 25, 1905, was 125, and the makers of the first five in the list, in which the watches are arranged in order of merit, are:—(1) W. Potts and Son, Leeds; (2) L. Hall, Louth, Lincs; (3) S. D. Neill, Belfast; (4) and (5) J. Player and Son, Coventry. The makers of the first five box chronometers of those on trial from June 17, 1905, to January 6, 1906, are:—(1) Kullberg, London; (2) and (3) Johannsen, London; (4) Lilley and Son, London; (5) M. F. Dent, London. In the same period the makers of the leading five pocket chronometers are:—(1) Newsome and Co., Coventry; (2) and (3) Kullberg, London; (4) Lindqvist, London; (5) Newsome and Co., Coventry.

Prof. B. Walter states in a brief note published in the *Annalen der Physik* (vol. xix., p. 874) that the ultra-violet portion of the spectrum of a high-tension arc in air shows a series of bands identical with those observed by Eder in 1892 as characterising the combustion of ammonia, and considered by him as ammonia bands. It would appear probable that these bands are to be attributed rather to an oxide of nitrogen, produced in both cases, than to the cause suggested by Eder.

Some successful attempts, made in the geophysical laboratory of the Carnegie Institution, to prepare small plates of quartz glass suitable for the construction of lenses, mirrors, or other optical apparatus, are described by Messrs. Arthur L. Day and E. S. Shepherd in *Science* (vol. xxiii., No. 591). The glass obtained was nearly free from air bubbles, and was only slightly discoloured by the presence of silicon. The conditions for obtaining such a material by the fusion, in a small graphite box, of pure crystallised quartz or tridymite, are summarised as follows:—an initial temperature of 2000° or more without pressure, so as to allow of the production of sufficient vapour to drive out the air between the grains, followed by pressure (at least 500 lb.) and a reduced temperature of about 1800°, with time for the quartz to flow compactly together without being attacked by the graphite.

An interesting contribution to the study of fluorescence is contained in a paper published by Mr. Harry W. Morse in the Proceedings of the American Academy of Arts and Sciences (vol. xli., No. 27) under the title "Studies of Fluorite." The fluorescence and thermoluminescence of fluorite and the nature of the gaseous and liquid inclusions in fluorspar are dealt with under different headings. The fluorescence spectra shown by fluorite when excited by the light of the condensed electric spark between electrodes of certain metals contain sharp lines and narrow bands; the lines of these fluorescence spectra do not appear to belong to any known substance, and are remarkable inasmuch as different lines are obtained with different exciting sources. The spectrum also varies sharply from crystal to crystal with the same means of excitement. The cause of fluorescence, whatever be its nature, is removed or destroyed by heating at a temperature of about 300° C. At the same temperature the colouring matter of the different varieties of fluorite is destroyed; the nature of this colouring matter is discussed by reference to the gaseous products liberated at higher temperatures. As these consist of hydrogen, carbon monoxide, and carbon dioxide, the colouring matter would appear to be organic in its origin; the gases are probably produced by its undergoing a process of destructive distillation

No. 3, vol. xxiii., of the *Astrophysical Journal* contains an important paper by Mr. Theodore Lyman on the extreme ultra-violet spectrum of hydrogen. Part of this spectrum was previously photographed and investigated by Dr. Schumann, whose work was briefly described in vol. lxix. (p. 262) of Nature. Unfortunately Dr. Schumann, although he photographed the spectrum down to λ 1270, was unable to give the wave-lengths beyond λ 1850, but this omission has now been rectified by Mr. Lyman, who has not only determined the missing wave-lengths, but has also extended the known spectrum down to λ 1030 (see Nature, p. 465, vol. lxix., and p. 110, vol. lxx.). In the present paper the author describes the apparatus and methods employed in great detail, "in the hope that an exact knowledge of the conditions necessary to success may prove of value to investigators who work in this field"; he also gives reproductions of his spectrograms, with wave-length scales, for the region between λ 1670 and λ 1270.

The Watkins Meter Co., Hereford, has published a third edition of "The Watkins Manual of Exposure and Development," by Mr. Alfred Watkins.

The report for the year 1905 of the council of the Hampstead Scientific Society has been received. The Christmas juvenile lectures, and those on nature-study, intended to encourage the teaching of this subject to children, proved very successful. Among lectures delivered at the general meetings of the society may be mentioned those by Prof. Marcus Hartog, on the end and beginning of individuality as shown in the living cell; Dr. R. S. Clay, on the peculiarities and paradoxes of fluid pressure; Sir Samuel Wilks, F.R.S., on spirals; Dr. C. W. Andrews, F.R.S., on fossil hunting in the Libyan Desert; and Mr. F. W. Rudler, on the geology and scenery of the British Isles.

The seventy-second annual report of Bootham School (York) Natural History, Literary, and Polytechnic Society shows that the pupils of this school continue to receive every encouragement to devote their leisure hours to the outdoor study of natural phenomena. During 1905 the boys were particularly successful in discovering rare plants, and though we have been unable to find a specific caution in the report, we trust that all observers are urged not to uproot plants or in any other way to assist the disappearance of rare species. It is satisfactory to find that attention is given to many branches of natural science so that the predilections of as many boys as possible may be satisfied.

OUR ASTRONOMICAL COLUMN.

Spectrum of Nova Aquilæ No. 2.—A visual observation of the spectrum of Nova Aquilæ No. 2, made at the Lick Observatory on September 5, 1905, showed a number of bands, the brightest of which was recognised as Hβ. Hγ and a band near λ 4600 were distinguished with difficulty owing to their extreme faintness.

Photographs obtained with the one-prism spectrograph on September 6 and 10 (exposures three and four hours respectively) confirmed the visual observation, the intensities of the bands at λ 4600 and Hγ being respectively one-fifth and one-tenth that of Hβ. Hδ was also seen, but was very faint.

A faint continuous spectrum was seen to extend from about λ 4500 to the region of the Hγ band. Hε and the so-called nebular lines were not visible.

Visual and photographic observations made on October 11, 1905, agreed in showing a marked diminution in the brightness of Hβ, which was then no brighter than Hγ (*Astrophysical Journal*, vol. xxiii., No. 3).

A number of magnitude observations of this Nova, made on various dates between September 20 and November 24 at the Utrecht Observatory, are recorded in No. 4089 of the *Astronomische Nachrichten* by Dr. A. A. Nijland.

Stereo-comparator Discoveries of Proper Motions.—At a meeting of the Paris Academy of Sciences, held on May 7, Prof. Loewy announced that Prof. Max Wolf had met with considerable success in discovering and measuring stellar proper motions by means of his stereo-comparator.

In one instance a star of known proper motion was seen to be obviously displaced after the very short interval of four years. When the two photographs, taken at this interval, were placed in the stereoscope, the star in question was seen to stand out in a plane considerably different from that in which the neighbouring stars appeared to be set.

Prof. Wolf has also been able to show that a ninth-magnitude star in the constellation Leo has a proper motion hitherto unsuspected, and he has obtained a value for the motion which he believes to be more correct than could be determined by ordinary micrometric measures. In this case a period of fourteen years separated the times of taking the photographs (*Comptes rendus*, No. 19, 1906).

MEASURES OF DOUBLE AND MULTIPLE STARS.—The measures of 1066 double and multiple stars are published in vol. ii., part iii. (astronomical series), of the Publications of the University of Pennsylvania by Prof. Doolittle.

The measures were made with a wire micrometer attached to the 18-inch refractor of the Flower Observatory, and include, among others, 733 Burnham stars, 109 OΣ, and 102 Σ stars. Four hundred and ninety-two stars from Prof. Hough's catalogue have also been re-measured but are not included; it is Prof. Doolittle's intention to re-measure all the stars discovered by this observer.

The micrometer, the corrections of the instrument, and the method of observing are all fully discussed in the present publication, which is a continuation of part iii., vol. i.

Part ii., vol. ii., of the same publications gives the results of the observations made with the zenith telescope of the Flower Observatory from October 1, 1901, to December 28, 1903, and also contains a re-discussion of the 1896–1898 series, of which the details appeared in part ii., vol. i., in 1899.

OBSERVATIONS OF COMET 1905*c*.—Numerous observations of comet 1905*c* are recorded in No. 4090 of the *Astronomische Nachrichten*.

This object was observed at Vienna from December 17, 1905, to January 14, 1906, and during that time its apparent diameter increased from 2′ to 4′–5′, the length of its tail from 5′ to 40′, and its total magnitude from 9·5 to 4·0. On December 30 a nucleus of magnitude 6·0 was observed.

Heliometer observations at the Cape Observatory showed the comet as a faint nebulous mass with no visible nucleus. Observations of position were recorded from February 5 to February 20, 1906.

The observations at Strassburg Observatory extended over the period December 10 to March 21, and the apparent position, the total magnitude, and the diameter were recorded on eleven different dates.

A LUNAR TIDE ON LAKE HURON.—Whilst examining the curves showing the periodical oscillations of the *seiches* on Lake Huron, Prof. W. J. Loudon, of Toronto University, was struck by the regularity of their general outline, which seemed more marked in calm weather. Further investigation of the matter showed a well-marked and regular rise and fall twice a day, and also showed that no oscillation of the lake could have a period of more than four hours.

From these facts Prof. Loudon concluded that a true lunar tide occurs on Lake Huron, a conclusion which his further experiments seemed to verify.

THE HAUNTS OF THE OKAPI.

ACCORDING to a report in Monday's *Times* (May 21) the expedition to the Congo Free State under the charge of Captains Boyd Alexander and C. B. Gosling has been successful, not only in procuring a fine skin (and it may be hoped a skeleton) of the okapi, but likewise in obtaining some important particulars with regard to the habits of this animal. The specimen, which it is stated will ultimately find a home in the Natural History Branch of the British Museum, was obtained at Bima, on the River Welle, in the northern territory of the Congo State. It is mentioned in the letter that the animal was seen alive by the expedition, but further particulars on this point are desirable, as it is not stated whether anyone but the Portuguese collector by whom it was trapped had this good fortune. The animal was caught in a pit according to native fashion, previous attempts to shoot it having proved ineffectual.

Hitherto the only definite account of the kind of country inhabited by the okapi and the probable nature of its food is one given by Mr. J. David under the title of "Weitere Mitteilungen über das Okapi," and published in vol. lxxxvi. of *Globus* (1904). Captain Alexander's notes, which differ in some respects from the former, are therefore of great value and interest, and may be quoted in full.

"The okapi here is generally found singly or in pairs, but Mobatti hunters state that sometimes three may be found together. An essential to the life of the okapi is a small stream of water with some muddy and swampy ground on either side. In this grows a certain large leaf that on its single stalk attains a height of 10 feet. It is the young leaf of this plant that is the favourite food of the okapi, and I venture to say that where the plant is not to be found the animal will not exist. During the night he will wander along in the mud and water in search of it. Here he may be found feeding as late as 8 a.m. in the morning, after which he retires to the seclusion of the forest, where he remains until nearly dusk. On the three occasions that I was at close quarters with the beast, he was perfectly concealed in this swamp leaf. Near the River Welle I found his spoor on ground frequented by buffalo and waterbuck, but this is unusual, and his companions in the forest are the elephant, the greater bushbuck, the yellow-backed and small red duikers. The okapi is very quick of hearing, and in that respect is classed by the Mobatti with the bushbuck (local name 'bungana'). In the forest here I consider this latter beast to be more difficult to obtain than the former. On the hunting ground of the first village that I visited I estimated the number of okapi as five or six, at the second and third nil; and twenty miles south in the forest, on very likely ground where my guide said they were formerly numerous, there was one only, probably owing to rubber-collectors who had been there."

Several specimens had been speared, shot, or trapped by natives shortly before the date of Captain Alexander's visit, but time did not admit of further investigation. The sex of the new specimen is not stated, but it is to be hoped that it will prove to be a male, as Sir Harry Johnston's example, now exhibited in the Natural History Museum, is a female. A pair of okapis are exhibited in the Congo Free State Museum at Tervueren, near Brussels, which also possesses other skins; and there are likewise a few other examples in Europe, notably one in Italy and another in Mr. Rothschild's museum at Tring. It is a great pity that the Belgian Government does not take immediate steps to publish coloured figures of its specimens in order to aid in solving the question as to whether there is more than one species (or race) of okapi. Important information on this point will, however, doubtless be afforded by the Alexander-Gosling specimen, which, it may be hoped, will also indicate (if a male) whether the tips of the horns always protrude through the skin, and thus foreshadow the antlers of deer.

THE TARAWERA VOLCANIC RIFT, NEW ZEALAND.

MR. JAMES MACKINTOSH BELL, director of the New Zealand Geological Survey, contributes a paper to the April number of the *Geographical Journal* describing the present topography of the great volcanic rift of Tarawera, in the north island of New Zealand, and the changes which have taken place in the configuration of the region since the great eruption of Mount Tarawera on June 10, 1886, which is memorable for the destruction of the famous pink and white terraces, and their submergence in Lake Rotomahana.

Mount Tarawera lies near the centre of the Taupo volcanic zone, and about 135 miles south-east of Auckland. This zone, which has a breadth of some twenty-five miles, extends from near the great volcanic cones of Ruapehu, Tongariro, and Ngaurahoe north-eastwards to White Island, on the Bay of Plenty, a distance of nearly 160 miles. A great rift, which was the scene of greatest intensity of the 1886 eruption, stretches from near Lake Okaro along the Tarawera range to Mount Wahanga, in the most north-easterly part. This rift, really a line of craters, forms a huge fissure about nine miles in length, cutting the summit of the range, and appearing on its south-western slope. It is divided into several somewhat distinct craters by low partitions, and on the south-west side a long narrow rift extends to the base of the hill, so far as the edge of Lake

Rotomahana. Lake Rotomahana is a sheet of dirty, muddy green water, some three and a half miles long by less than two miles in the opposite direction, and with a maximum depth of 427 feet. In continuation along the same line, beyond Lake Rotomahana, are the deep holes forming the Black, Fourth, Waimangu, Inferno, Echo Lake, and Southern craters. Hot water and steam issue in larger or smaller quantities from these craters, the water finding its way to Lake Rotomahana.

The most remarkable feature of the region during the last few years has been the great geyser of Waimangu. This geyser was discovered in January, 1900, and is believed to have become active only a short time before that date. While playing, outbursts occurred nearly every day, and sometimes more frequently. Mud, sand, and immense boulders were shot up in huge columns of dirty black water. At some hundreds of feet above the water the column broke, showering boulders, mud, and sand back into the pool, and even high up on the walls surrounding it.

In July, 1904, the great geyser suddenly ceased, and remained dormant for seven weeks and five days; then it again burst into action, and until November 1 following outbursts occurred almost daily. Then it stopped, and since then there has been no further explosive activity. We reproduce a photograph of the highest known eruption of Waimangu, from the illustrations accompanying Mr. Bell's paper. It is estimated that this "shot" ascended 1500 feet above the water, and carried a volume of 800 tons.

FIG. 1.—Highest known eruption of Waimangu.

HYDROLOGY IN THE UNITED STATES.

THE papers relating to the hydrological work in the United States which are issued by the department of the Geological Survey have from time to time been noticed in NATURE. We have now to acknowledge twenty-six of the papers last issued. The greater part of these relate to the progress of stream measurements in the different States, and to other matters which are of local interest. There are, however, some of the papers that deserve the attention of those engaged in works of water supply.

On a previous occasion, in NATURE of December 21, 1905, we gave a short account of the investigations that are being made as to the movement of underground water. A further paper on this subject has now been issued as the result of investigations made by Prof. Slichter, No. 140, on field measurements.

This paper presents an amplified exposition of the method of measuring underground water as described in his former paper of 1902. It contains descriptions of the apparatus used for the laboratory study of wells controlling horizontal and vertical movements, and the result of these studies confirms the conclusions described in the former paper as to the possibility of measuring the flow of subsurface water with trustworthy accuracy. Some improvements that have been made in the apparatus as the result of experience are described.

The author shows that the flow of water in a given direction through a column of sand is proportional to the difference in pressure at the ends of the column, and inversely proportional to the length of the column, and is also dependent upon a factor which he terms the transmission constant of the sand.

Experiment shows that the resistance to the flow of water through sand is very great, the water having to pass through pores, usually capillary in character, and the diameter of which varies from one-fourth to one-seventh of the diameter of the sand particles. When the sand is not of uniform size, and is mixed with grains slightly larger, the effect is to increase the capacity of the sand to transmit the water. Where particles seven to ten times the diameter of the original sand grains are added, each of these tends to block the course of the water. For example, a boulder placed in a mass of fine sand checks the passage of the water, and the rate of flow decreases in proportion to the number of such boulders until the amount of the large particles is equal to about 30 per cent. of the total mass. After this the flow increases until the mass of fine particles becomes negligible, and the capacity to transmit approaches that of the mass of large particles alone.

These facts are shown to have an important bearing upon the capacity of gravels to furnish water to wells, or to transmit it in the underflow to rivers.

Tables are given showing the transmission constant for sands and gravels of different sizes and different degrees of porosity.

It is also shown that the rate of flow is affected by temperature, a change from freezing point to 75° nearly doubling the power of the soil to transmit water. This paper contains a great deal of information as to the discharge from wells used for irrigation or other purposes.

Paper No. 144, by Mr. Daniel D. Jackson, deals with the normal distribution of chlorine in the natural waters of New York and New England. The author shows that, with the exception of local deposits, the normal chlorine in natural waters is derived from the salt of the ocean, blown over the land by storms, and that it diminishes in amount as the distance from the ocean increases. This decrease is so definite that equal amounts of chlorine are found along lines generally parallel to the sea coast, thus affording a basis for the establishment of *isochlors*. Charts and tables are given showing the proportion of chlorine at different distances from the coast. The samples were taken from ponds or open water basins as far removed from human habitation as possible. The charts show that the quantity of chlorine near the coast amounts to 6 parts in a million, at 4 miles away to 5 parts, at 20 miles to 3 parts, at 40 miles to 1 part, and at 100 miles to 0·4 part.

The fact that chlorine exists in rain water to a large extent near the sea coast was stated in the report on domestic water supply of the Rivers Pollution Commission in 1874. It was there shown that on the coast of Devonshire, where with south-west winds sea spray is blown over the land, the amount of chlorine varies from 1·20 to 2·10 parts in 100,000, and at the Land's End, with a strong south-west wind blowing, it amounts to as much as 21·8 parts. Inland the average quantity of chlorine diminishes to 0·39 part; increases to 0·99 part at Liverpool and 0·79 part at Newcastle.

Paper No. 151, by Mr. Marshall O. Leighton, deals with the field assay of water, and describes the methods which have for some time been used in connection with the investigations into the quality of water in various parts of the United States. The methods described relate, not to laboratory experiments, but to simple tests to ascertain the general character of the water by methods which can be carried out on the spot. These field determinations give the turbidity and colour of the water, the presence of chlorine, carbonates, calcium, and iron, and the amount of hardness; also the amount of suspended matter. The former are more particularly required in water for domestic supply, and the latter for that used for irrigation purposes. The amount of gradient to be given to a canal for conveying water for irrigation is governed to a great extent by the solid matter in suspension, and this also affects the capacity of the storage reservoirs. The method for determining turbidity, accompanied by an illustration of the gauge used for this purpose, was given in NATURE of January 7, 1904. A description and illustration of the Geological Survey field case is given in the paper.

Paper No. 143, by Mr. J. H. Quinton, details the experiments made under the direction of the Reclamation Department on steel concrete pipes for the purpose of determining the durability and permanence of these structures in connection with the supply of water for irrigation purposes. The pipes experimented on were 5 feet in diameter, 20 feet long, and 6 inches thick, of concrete, enclosing an armour of steel rods sufficient to resist a head of 150 feet of water with a factor of safety of 4. The experiments showed the difficulty, even with the closest attention to the construction, of making pipes of this kind that would stand a head of 100 feet.

Paper No. 150, by Mr. Robert E. Horton, gives the results of an investigation of the theory of weir measurements, and the discharge over different forms of weirs. The various coefficients of Bazin, Fteley, Stearns, and Hamilton Smith are analysed. A further description is given of the experiments performed at the Cornell University laboratory, where a closely regulated volume of water was passed over weirs of different forms placed across an experimental canal, and the results obtained compared with the different formulæ for obtaining the discharge. Tables are also given for calculating the discharge over weirs.

GREENWICH OBSERVATIONS.[1]

IN the introduction to the first work mentioned below, an opinion is expressed that the revision of an old catalogue must always be a source of anxiety to those who advise and undertake the revision, and that only the final result can justify the expenditure of the time and labour. Those who are responsible for this work need be under no apprehension that their efforts have been misspent. It would rather seem that in this case they have fulfilled a necessary duty, and discharged an honoured trust. It has always seemed to the writer that the ancient authorities at Greenwich were a little wanting in patriotism and enterprise in entrusting to a foreigner, however eminent, the reduction and discussion of Bradley's observations. Groombridge's observations, in a sense, may not be so completely a national possession as those of Bradley, but certainly it is not unfitting that at the Royal Observatory, almost within the shadow of which Groombridge erected his transit circle, his observations should be examined and discussed.

There are several circumstances which tend to give distinction to Groombridge's work. At the beginning of the last century his instrumental equipment was equal to, if not more powerful than, that of any other observer in Europe. The fact that, as an amateur, he gave his time and leisure to the repetition of the same mechanical performance shows that he was a lover of order and accuracy. Pond, the Astronomer Royal, whatever his failings may have been, appreciated the necessity for certainty and accuracy, and he must have impressed these qualities upon Groombridge. Further, the lapse of time, that factor which has increased the value of so much astronomical work and enhanced the reputation of so many worthies, has fought on the side of the retired West Indian merchant.

The method to be pursued in the reductions, how far the observations are to be treated as independent, how far they are to be regarded as differential, are points which must be left to the decision of the computers. They must accept the entire responsibility, since the knowledge and experience is theirs. In this case it is not impossible but that they have had the assistance of tradition. The interesting remarks of Colonel Colby and Dr. Firminger quoted by the revisers, probably do not exhaust the information at their disposal. It would be an impertinence for anyone who has not even seen the originals to offer any criticism on the methods employed by those who have gained familiarity and experience by long contact with Groombridge's figures. These methods are described with clearness and in sufficient detail, but the revisers must know so much more than they can set down.

The result is to obtain a catalogue for the equinox of 1810 of 4239 stars. The number in the original Groombridge catalogue was 4243, but of these nine have been rejected on various grounds, and five have been added as separate stars. The places of a few more stars have been considered discordant, and have not been used in the subsequent discussion of proper motion. The accuracy of the catalogue and the care of the observer can both be estimated in some measure from the fact that a discrepancy of four seconds of arc in either right ascension or polar distance has been considered a proper limit to warrant the exclusion of the observation. The number excluded is 75 in right ascension and 214 in polar distance, slightly more than 1 per cent. of the total number of observations.

The peculiar value of this catalogue lies in the fact that its epoch is 1810. Therefore, by comparison with modern observations, it offers the means for a new determination of the precessional constant, while the new proper motions which it makes available should give greater certainty to researches into the amount and direction of the solar motion. The length of time elapsed since Groombridge's day is not much less than that available in the case of Auwers-Bradley, and the accuracy of the observations would seem to be of the same order; but Bradley's optical means were smaller, and the average of his stars considerably brighter. Groombridge's stars include many of the ninth magnitude, and fill a gap between those to which Bradley's observations refer and the results that will be derived from photography. On the other hand, Bradley's stars were better distributed over the whole sky. Groombridge limited his observations to the circumpolar regions. Against this drawback, as against many others, the Greenwich authorities have struggled with apparent success, and a few of their final results may be given.

We have, in the first place, the proper motions of more than four thousand stars determined by comparison of places at intervals of approximately ninety years. These proper motions have been derived for the most part by a

[1] "New Reduction of Groombridge's Circumpolar Catalogue for the Epoch 1810–0." By F. W. Dyson, F.R.S., and W. G. Thackeray. Under the direction of Sir William H. M. Christie, K.C.B., F.R.S., Astronomer-Royal. (Published by order of the Board of Admiralty in obedience to His Majesty's command. Edinburgh: Neill and Co., Ltd., 1905.) Price 24s.

"Telegraphic Determinations of Longitude made in the Years 1888–1902, under the direction of Sir W. H. M. Christie, K.C.B., F.R.S., Astronomer-Royal. (Published by the Board of Admiralty in obedience to His Majesty's command. Edinburgh: Neill and Co., Ltd., 1906.) Price 15s.

simple comparison of positions at the extreme limits of time. It is not made clear why observations at intermediate dates, such as those of the Radcliffe Observatory, have not been used. The plan adopted seems the more strange, since the precessional variation has been applied and a comparison has been instituted. Considering the important part these proper motions were to play in the subsequent discussion, it would seem that too much care could not be exercised in their determination. These proper motions have been arranged in tables according to their amount, or the magnitude of the stars, or the character of spectrum, and, indeed, in every way that ingenuity could suggest as likely to be useful. This method of distribution cannot but be of essential service to those who wish to make further use of the material.

Next we have a determination of the precessional constants. The final result may not possess more than an academic interest, but the research is thorough and valuable. It would serve no useful purpose to enter into details, since those who are interested in such recondite questions must refer to the original sources for information, but the numerical results may be quoted, since they differ from Newcomb's values by a greater amount than would have been anticipated. For the centennial values of m and n we have:—

	m	n
Newcomb	$4607''\cdot11$ ...	$2005''\cdot11$
Dyson and Thackeray ...	$4607''\cdot57$ ...	$2005''\cdot31$

Another result which follows incidentally from the method of discussion is to show that, so far as this material is available, there is no reason to suspect any rotation of the brighter stars, as a whole, relatively to the fainter stars.

Lastly, the authors assign a direction to the solar motion, or rather many directions, for the material is discussed in many ways, all interesting. Here, again, we must content ourselves with the final result, which places the apex of the sun's motion in right ascension 275° and north declination 37°, referred, presumably, to the equinox of 1850.

In tendering our congratulations to Messrs. Dyson and Thackeray, and all who have been engaged in this work, we cannot help remarking that, as in the past, the Royal Observatory has distinguished itself by its energy in laboriously piling up observations, so in this instance, it demonstrates equally happily its power to make the accumulated material available for the advance of philosophical astronomy.

The title of the second book reminds us how loyally the Greenwich Observatory has served the purposes of its foundation. To determine, or to supply the means for determining, the longitude has constantly figured in its programme of work. The times have altered, the conditions of the problem have changed, and, above all, accuracy has increased, but, steadfast to its original design, the Royal Observatory has always been willing to assist in such inquiries, whether in the interests of navigation or for the purposes of geodesy. The Paris meridian seems to have been a constant source of anxiety to Greenwich, and the present volume gives the history of no less than three attempts to grapple with the difficulty. The two earlier results, 9m. 20·85s. and 9m. 20·79s. west of Greenwich, seem fairly accordant to the lay mind, but since they both differed in the same direction from the results of the French observers, the small discrepancy led to a third attempt in 1902, from which it appeared that Paris was west of Greenwich 9m. 20·932s., with a probable error of only 0·006s. Since this probable error is equivalent to about the length of an ordinary writing table, it would seem to possess the necessary accuracy, and the problem of the distance between the meridians of Greenwich and Paris may be considered as laid aside for some time to come. The remaining portion of the book is concerned with the longitudes of Montreal, Waterville, and Canso, and of stations incidentally connected with the scheme of operations. The result is to place Montreal in west longitude 4h. 54m. 18·62s., with an uncertainty of about 20 feet. Doubtless the day will come when this error will be felt to be intolerable, but if a demand is made for a fresh inquiry, we may be sure that the best traditions of Greenwich will respond to the appeal. W. E. P.

ANTI-TYPHOID VACCINE.

A MEMOIR "On the Standardisation of Anti-typhoid Vaccine," by Captain George Lamb and Captain W. B. C. Forster, has just appeared (Scientific Memoirs of the Government of India, No. 21. Calcutta: The Government Printing Office, 1906. Pp. 15. Price 7*d*.). After reviewing the various methods which have been proposed for the standardisation of Wright's anti-typhoid vaccine, Captains Lamb and Forster come to the conclusion that the virulence of the organisms used in the preparation of the vaccines must be taken into account. Since it appears that virulence is in direct proportion to the number, or avidity for immune body, of the receptors, an estimation of these latter in any vaccine will take cognisance of the virulence of the organism from which it was prepared. Admitting this as a basis, the method of standardisation suggested by Captains Lamb and Forster is to estimate what dilution of the various vaccines when mixed in equal parts with serum is able to remove completely the bactericidal power of that serum; in other words, to determine in what dilution of vaccine the receptors completely neutralise the amboceptor content of the serum. This is carried out by preparing a number of different dilutions of the vaccine, which are each mixed with the same amount (100 c.cm.) of fresh goat serum, and left in contact for an hour at 37° C. At the end of this period a small quantum of living typhoid culture is added to each tube, the several tubes are incubated for about twenty-four hours, and then sterile broth is added to each tube in order to ascertain whether the bacilli have been killed or no, and in this way various vaccines may be compared. The memoir must be consulted for the details of the method. R. T. HEWLETT.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The thirteenth "Robert Boyle" lecture of the Junior Scientific Club will be delivered by Prof. J. H. Poynting, F.R.S., on Wednesday, May 30, upon the subject of "The Pressure of Light."

Mr. J. S. C. Douglas, Christ Church, has been elected to the Radcliffe travelling fellowship for 1906.

Prof. Ritchie, fellow of New College, has been nominated as an examiner in preventive medicine for 1906, 1907, and 1908.

The 284th meeting of the Junior Scientific Club was held on May 16, when Mr. P. W. Robertson read a paper on "A New Method of Estimating Quinine," and Prof. E. G. Hill one on "Chemistry in India."

CAMBRIDGE.—The museums and lecture rooms syndicate has reported that the chemical laboratory of Gonville and Caius College will be closed at the end of the academic year 1906–7. It will therefore be necessary to provide further accommodation in the University for the students who have hitherto found places in the chemical laboratory. The museums and lecture rooms syndicate recommends that a site in the museums' grounds contiguous to the buildings of medicine should be set apart for this purpose. It is also recommended that the proposed extension of the Cavendish Laboratory should take place on a site with a frontage to Free School Lane to the north of the existing building. Lord Rayleigh's gift of 5000*l*. of the Nobel prize will, it is hoped, enable this building shortly to be begun.

The Vice-Chancellor has been authorised to convey to the Worshipful Company of Goldsmiths the thanks of the University for its munificent gift of 5000*l*., to be applied to the present needs of the University library.

The well-known authority on coral reefs and oceanography, Mr. J. Stanley Gardiner, has been nominated by the master and fellows of Gonville and Caius College to be pro-proctor for the ensuing year.

Dr. Bonney will lecture at 5 p.m. on Thursday, May 31, in the Sedgwick Museum, on "Volcanoes and Man's Experience of them."

Steps are being taken for the provision of a permanent endowment to place the Balfour library in a secure position. The library owes its origin to the generosity of the family of the late Prof. F. M. Balfour, who after his death in 1882 presented his scientific books to the University for the use of the zoological laboratory. The library so constituted was housed in a room adjacent to the laboratory, and has ever since been freely open to all members of the University and to others qualified to make use of it. The library has been maintained hitherto out of the fees paid by students attending the classes; and the burden which it thus places upon the resources of the laboratory is undesirable. A committee has therefore been formed for the purpose of collecting subscriptions, and of establishing a fund to be called the Balfour Library Endowment Fund, with the object of putting the library on a secure and satisfactory basis. The committee at its first meeting agreed that the fund, when established, "be offered to the University at such time and under such conditions as the subscribers shall hereafter determine, provided that the management be closely connected with the zoological laboratory, and that the library be freely open to students." Subscriptions may be paid to the Balfour Library Endowment Fund, at Messrs. Barclay's Bank, or to the treasurer, Mr. Adam Sedgwick, Zoological Laboratory, New Museums, Cambridge. The sum already received or promised amounts to about 500*l*.

The King and Queen will visit Newcastle on July 11 to open the new wing that completes the Armstrong College. The King will also open the new university buildings at Aberdeen on September 24.

It has been resolved by the Corporation of McGill University, Montreal, to confer the honorary degree of LL.D. on Dr. D. Macalister, president of the General Medical Council of the United Kingdom.

It is announced from the Agricultural Department of the University of Edinburgh that Mr. E. Thompstone has been appointed assistant deputy director of agriculture for Bombay Presidency, and Mr. Roger Prosser will go to La Germania, Argentina, to investigate salt soils.

There is a vacancy for a junior assistant secretary, holding a science degree or possessing equivalent qualifications, in the office of the department of technology of the City and Guilds of London Institute. Applicants for the appointment should communicate with the superintendent, Exhibition Road, London, S.W.

According to the *Chemiker Zeitung*, the University of Basle has fallen into line with the German universities, and now requires from all German doctor candidates the leaving certificate of a nine-year gymnasium or of a corresponding Swiss institution. The German Government had threatened not to recognise the doctor's degree if the University continued to grant it on the old conditions.

A general meeting of old students of the Technical College, Finsbury, was held on May 8 to discuss the proposal to form an Old Students' Association. In a short opening speech Sir Owen Roberts, who occupied the chair, expressed his approval of such associations, and said that it gave him great pleasure to preside at the organisation meeting of such a one as this promises to be. Dr. M. O. Forster, F.R.S., was elected president of the association.

It is announced in *Science* that Mr. Andrew Carnegie has made a donation of 20,000*l*. to Lehigh University; and that the movement to increase the endowment of Victoria University, Toronto, by 60,000*l*. is now practically completed. The amount has been raised all but 2400*l*., counting the 10,000*l*. given by Mr. Carnegie. The latter gift was conditional upon the raising of an additional 10,000*l*., but no trouble in fulfilling the condition is expected. According to the N.Y. *Evening Post* Sir William McDonald, of Montreal, has given 11,000*l*. for the purpose of erecting an extension to Prince of Wales College, Charlottetown, P.E.I. Additional facilities will be provided for teaching nature-study, domestic science and kindred subjects, and for training teachers.

The commission appointed by the German Association of Naturalists and Physicians at Breslau in 1904 to consider the mathematical and scientific instruction in German schools held a general meeting in Elberfeld on April 9–11, and discussed the following questions at length:—the syllabus of the mathematical and scientific teaching in the girls' high schools, in the six-class Realschulen and in the Reformschulen; the science teaching of the elementary and continuation schools, as well as that of the commercial and special schools; certain hygienic and sexual questions in connection with school life; the chemical instruction given in the training colleges. While the results and reports of these discussions will be laid before the society at the Stuttgart meeting in the autumn, it has been decided to issue a report on the form of instruction recommended for the girls' high schools as early as possible.

An addition to the many proofs which have reached us of the active interest taken on the Continent in the reform of mathematical teaching is afforded by the publication of a German translation of the address delivered to the *Mathesis* Society by Prof. Gino Loria on April 22, 1905, at Milan. The translation, which is literal, has been made by Dr. H. Wieleitner, and is published by G. J. Göschen, of Leipzig, under the title of "Vergangene und künftige Lehrpläne." The address affords evidence of a general tendency on the Continent to attach less importance in school curricula to the performance of gymnastic exercises of little educational value, and to introduce the wider ideas of higher mathematics at an earlier stage in the curricula. The object of mathematical teaching should be to give the pupils as wide an insight into mathematical methods, especially higher methods, as is consistent with thoroughness. It is impossible to study a paper like this without seeing how much better off in this respect our Continental rivals are than we are. This difference is due partly to the fact that under our university systems a large proportion of the mathematical teachers of our schools never learn any higher mathematics whatever, whereas in Germany or Italy every student has the opportunity of studying under specialists. A second cause of difference is due to the lesser importance attached on the Continent to examinations and syllabuses. In illustration of the spirit of the paper, Prof. Gino Loria considers that "elementary conics" is of little value as usually studied, as the subject contains no new ideas, and the pupils are only wearied with complicated exercises. This is certainly true of the subject as commonly taught, but, at the same time, a course of elementary mathematics ought to contain some introduction, however small, to the study of common curves, their tangents, and their other simpler properties treated geometrically and not as graphs.

The conditions of admission of students to college not only vary in different countries, but also often in the colleges and universities of the same country. This subject is receiving interested attention among educationists in the United States. *Science* for April 27 prints an address by President G. E. MacLean, of the State University of Iowa, which discusses the question: Can there be a coordination of the examining, certificate, and accrediting (including school inspection) systems for admission to college, looking toward a common or national administration in the interests of students, colleges, and the preservation of standards? The American procedure in this matter is not uniform. The western plan may be said to be the admission of students to colleges and universities by certificates from duly inspected secondary schools, while in eastern States the method is to admit only by examinations conducted by representative boards or otherwise. Some valuable opinions are collected in the address as to the relative value of the two courses. President MacLean says that the accrediting system has raised the standard of the work done. It has linked the secondary school into one system with the college. It has given an increase of students entering college, and with better average preparation. It is sometimes alleged that the scholarship of students admitted on certificate is lower than that of students who are required to pass examinations, but President Schurman, of Cornell, says the experience at his university does not support the contention. On the other hand, Prof. Hadley, of Yale, believes that the examination method is fairer to boys who come from a distance to the university. Yet, with the exception of Harvard, Yale, and Princeton, practically a coordination of the examining, certificate, and accrediting system has been reached inasmuch as testimonials issued by the college authorities are interchangeable. President MacLean concludes by urging the need for liberty to each institution, and records his belief that it is a question of evolution—the best system or combination of systems will survive.

SOCIETIES AND ACADEMIES.

LONDON.

Zoological Society, May 1.—Dr. Henry Woodward, F.R.S., vice-president, in the chair.—Skin of a remarkable new duiker from Nyasaland, presented to the British Museum by Mr. S. W. Frank: Oldfield **Thomas.** The animal was named *Cephalophus walkeri*, sp.n.—Further notes on anthropoid apes: Hon. W. **Rothschild.** The author exhibited five mounted specimens, one skeleton, six skulls, and a photograph of the following races:—*Gorilla gorilla*, dark-headed race, *G. gorilla*, red-headed race, *G. gorilla matschiei*, *G. gorilla diehli*, *Simia vellerosus*, and *S. vellerosus fuliginosus*.—Mammals collected in South-West Australia for Mr. W. E. Balston: Oldfield **Thomas.** Thirty-two species and subspecies were enumerated, of which the following were described as new:—*Scoteinus balstoni*, sp.n., *Tachyglossus aculeatus ineptus*, subsp.n.—A series of papers on the Lepidoptera collected in South Tibet by the officers during the recent expedition to that country under Colonel Sir Frank Younghusband. Mr. H. J. **Elwes** gave an account of the butterflies contained in the collection, which comprised thirty-three species and varieties, four of which were described as new. The moths, exclusive of the Tineidæ, have been worked out by Sir George **Hampson,** Bart., who enumerated the sixty-three species of which specimens were obtained. Of these, examples of thirty-six species were taken at moderate elevations in Sikhim, and belonged to the Indian fauna, two being described as new; twenty-seven species belonged to the Palæarctic fauna, of which nine were widespread and eighteen Tibetan; ten of these were described as new. An account of the Tineidæ was supplied by Mr. J. Hartley **Durrant**; they were referred to four species, two of which were new. Contributions to the knowledge of the vascular and respiratory systems in the Ophidia and to the anatomy of the genera Boa and Corallus: F. E. **Beddard.**

Chemical Society, May 3.—Prof. H. E. Armstrong, F.R.S., past-president, in the chair. The chairman gave expression to the sense of loss sustained by the Chemical Society in the death of Prof. Pierre Curie. The meeting endorsed the letter of condolence addressed by the president to Mme. Marie Curie, an honorary and foreign member of the society.—The relation between absorption spectra and chemical constitution, part v., the *iso*nitroso-compounds: E. C. C. **Baly,** Miss E. G. **Marsden,** and A. W. **Stewart.** From observations of the absorption spectra of several *iso*nitroso-compounds in neutral and alkaline solution it is found that the free substances most probably have the

$$\text{constitution}\quad \begin{matrix} R.C:O \\ \cdot\ * \\ R.CH.NO \end{matrix}\quad \text{but in presence of sodium hydroxide}$$

the starred hydrogen atom is replaced by sodium and becomes labile. *Isorropesis* then takes place between the >C:O and >C:N groups, a tautomeric process being the actuating mechanism.—The residual affinity of coumarin as shown by the formation of oxonium salts: G. T. **Morgan** and Miss F. M. G. **Micklethwait.** Platinichlorides of coumarin, 6-aminocoumarin, ethyl-6-aminocoumarin, dimethyl-6-aminocoumarin, acetyl-6-aminocoumarin, and a coumarin hydriodide periodide were described. The formation of these salt-like additive compounds of coumarin agrees with the results of earlier investigators. Coumarin also exhibits an amphoteric character in combining with metallic oxides and hydroxides.—Brazilin and hæmatoxylin, part vii., some derivatives of brazilein: P. **Engels** and W. H. **Perkin,** jun. Brazilein is the colouring matter produced when brazilin is oxidised in alkaline solution by means of air. Trimethylbrazilein, trimethylbrazilein formic acid, trimethyl*iso*brazilein sulphate, and trimethylbrazilein hydroxylamine were described.—The action of tribromopropane on the sodium derivative of ethyl malonate: W. H. **Perkin,** jun., and J. L. **Simonsen.**—Pipitzahoic acid: J. McConnell **Sanders.** The author considers that the composition is best represented by the formula $C_{10}H_{11}O_2$, it being thus isomeric with camphorquinone, and similar to, although not identical with, the *iso*camphorquinone discovered by Manasse. The acid seems to behave as a hydroxy-ketone, forming a resinous acetyl compound and a greenish-brown copper derivative.—The constitution of the hydroxides and cyanides obtained from acridine, methyl-acridine, and phenanthridine methiodides: C. K. **Tinkler.** The constitution of ammonium amalgam: Miss E. M. **Rich** and M. W. **Travers.** The results of determinations of the freezing points of a series of samples of ammonium amalgam have led the authors to the conclusion that it is a true solution of ammonium in mercury.—Action of light on potassium ferrocyanide: G. W. A. **Foster.** When a neutral or alkaline solution of potassium ferrocyanide is exposed to light, a purely photochemical action ensues, and ferric hydroxide is slowly precipitated. A mercury vapour lamp was used as a source of light.—Note on the constitution of cellulose: A. G. **Green** and A. G. **Perkin.** The supposed tetra-acetate of cellulose has been re-investigated and found to be in reality a triacetate. This affords further evidence of the correctness of Green's formula for the nucleus of the carbohydrate.—Some new derivatives of pinene: F. P. **Leach.** When pinene nitrosochloride is treated with potassium cyanate in alcohol at 50° to 60°, a compound, $C_{12}H_{17}O_2N_3$, separates. When heated with concentrated sulphuric acid it yields a *base*, $C_{10}H_{18}ON_2$. This is amphoteric, and appears to be an amino-oxime; it is also obtainable from pinene nitrosochloride by the action of ammonia.—Glutaconic and aconitic acids: S. **Ruhemann.** A criticism of Rogerson and Thorpe's work on these acids.

Anthropological Institute, May 8.—Mr. H. Balfour, ex-president, in the chair.—Phonograph records of native songs from the Congo, collected by Dr. J. L. **Todd,** were exhibited. The songs were all collected in the upper waters of the Congo, and were of great interest as specimens of native African music.—Notes on the ethnography of the Ba-Mbala: E. **Torday** and T. A. **Joyce.** The data on which the paper was based were collected by Mr. Torday. The Ba-Mbala are a Bantu tribe inhabiting the district between the Kwilu and the Inzai, tributaries of the Kasai, in the Congo Free State. The country had not previously been visited by a white man, at least for many years. The most interesting feature connected with these people is perhaps the fact that they are cannibals, men, women, and children all indulging, with the exception of a particular class known as *Muri*, who are distinguished by wearing a particular kind of bracelet. Another interesting feature of these people is that they appear to have borrowed all their knowledge of crafts from the neighbouring tribes. The paper was illustrated by a collection of specimens sent home by Mr. Torday, and also by lantern-slides.

Physical Society, May 11.—Dr. C. Chree, F.R.S., vice-president, in the chair.—The dead points of a galvanometer needle for transient currents: A. **Russell.** When many types of needle galvanometer are connected with a condenser and a battery in the ordinary manner by a charge and discharge key the following phenomena can easily be observed. When the needle is initially at right angles to the axis of the galvanometer coil, and the spot of light is in the centre, X, of the scale, the throws on charge and discharge are equal. If the controlling magnet be turned through a small angle, or if the suspending fibre be twisted slightly so that the spot of light is not in the centre of the scale initially, the throws on charge and discharge are not equal. The algebraic difference between them, however, is constant. Hence, for an initial position P_1 of the spot of light there is no throw on charge, and similarly for another initial position P_2 there is no throw on discharge. The author shows that these effects can be explained with considerable accuracy by supposing that the magnetism of the needle consists of two parts, one permanent and the other proportional to the magnetising force. He finds that it is easy to arrange with a low-resistance galvanometer so that a, relatively speaking, gigantic charge can be passed through the coil without producing any throw at all. He also finds that all the galvanometers he has tested, whether needle or moving coil, will produce throws when certain transient currents pass through them, even although the integral value of these currents is zero. It also appears that the effective internal resistance of ordinary condensers is appreciable in certain cases.

Royal Meteorological Society, May 16.—Mr. Richard Bentley, president, in the chair.—An instrument for testing and adjusting the Campbell-Stokes sunshine recorder: Dr. W. N. **Shaw** and G. C. **Simpson.** Experience has shown the necessity of an instrument for testing the shape and dimensions of recorders, and for verifying their adjustment when installed. But it is not at all easy by mere inspection or simple measurements with ordinary measuring instruments to check the adjustment, nor is it possible on a sunless day, without some special instrument, to check the orientation, and so the time-scale of the sunshine recorder. The authors have devised an instrument for this purpose, which they fully described in the paper.—The development and progress of the thunder-squall of February 8, 1906: R. G. K. **Lempfert.** This squall was first noted at Stornoway soon after midnight, and the last station in England to feel its effects was Hastings, over which it passed at about 4 p.m. The rate of progress was nearly uniform, though it increased somewhat in the south-east of the country, where the thunder and hail storms were most intense. The average speed of advance of the line of squall was about thirty-eight miles per hour. The most marked feature of this squall was the sudden shift of the wind in the course of a few minutes from south-west to north-west, and it was during this period that the thunderstorm occurred, accompanied by a rise of barometric pressure and a fall of temperature.

Society of Chemical Industry (London Section), May 7.—Mr. A. Gordon Salamon in the chair.—Notes on the Gutzeit test for arsenic: J. A. **Goode** and Dr. F. Mollwo **Perkin.** Owing to the difficulty of obtaining zinc free from arsenic, the authors used an ammonium salt—preferably the chloride—and metallic magnesium. Numbers are given showing the solution potential of magnesium in ammonium chloride and sulphuric and hydrochloric acids, also the difference produced by the addition of cadmium salts. The potential found was always lowered by the addition of the cadmium salt. Attempts to obtain a permanent stain were unsuccessful. The authors, however, do not consider that this is a matter of great importance, because as the test is so readily carried out it is easy to conduct several experiments simultaneously, one to produce a standard stain, one a blank, and the other with the substance under examination. The authors found that mercuric bromide is more delicate than mercuric chloride, and the stain is more intense. With mercuric bromide it is possible to detect 1/2000 mg. of arsenic. Although magnesium and ammonium chloride were employed by the authors, they also used zinc and acids, and obtained results equally as good. In fact, they consider that zinc and acid is fractionally more sensitive than magnesium and an ammonium salt.—The separation of brucine and strychnine by nitric acid; influence of nitrous acid: W. C. **Reynolds** and R. **Sutcliffe.** The authors have examined the processes proposed by Keller (*Zeit. Oesterr. Apoth, Ver.*, 1893, 542), Stoeder (*Ned. Tydschr. Pharm.*, 1899, xi., 1–5), and Gorden (*Arch. Pharm.*, 1902, ccxl., 641–4), and show under what conditions brucine can be completely oxidised with the minimum loss of strychnine. They have also investigated the part played by nitrous acid in the oxidation, and the action of alkalis on the products.—Absorption of gallic acid by organic colloids: W. P. **Dreaper** and A. **Wilson.** The absorption of gallic acid by silk and hide powder is shown to be of a similar nature to its absorption by gelatin or albumin. The influence of general reagents and the curves obtained indicate that the reactions are due to absorption. The precipitation of these colloids by tannic and gallic acids indicates, when studied in detail, that the solution state is a determining factor in the production of these coagula. The influence of gallic acid on the nature of a tannic acid gelatin coagulum is also observed. The results confirm the pseudo solution theory of dyeing, and indicate the nature of tanning.

CAMBRIDGE.

Philosophical Society, April 30.—Mr. J. J. Lister in the chair.—Demonstration of new apparatus for psychological tests: W. H. R. **Rivers.**—The measurement of the earth air current and the origin of atmospheric electricity: C. T. R. **Wilson.** The experiments, so far as they go, yield no support to theories which attribute the positive electrification of the air to effects of its contact with bodies at the earth's surface, *e.g.* to friction, or to greater loss of negative than of positive ions on account of their greater mobility. In an article in NATURE in June, 1903, it was suggested that the precipitation theory of the origin of the electrical field might have to be abandoned on account of the difficulty of explaining how positively charged air could be carried from wet-weather regions for any considerable distance without losing practically all its charge, and another possible origin of the electrical field was suggested, *i.e.* the arrival at the earth's surface, from external sources, of negatively-charged particles of the nature of extremely penetrating kathode rays. This hypothesis has been made less unlikely by the recent experiments of Campbell and Wood, which suggest the existence at the earth's surface of rays from cosmical sources. On the other hand, the difficulty in the way of the precipitation theory is removed if the current from the wet- to the fine-weather regions is regarded as due to conduction in the upper atmosphere, and not merely to convection of the positive charge by winds.—A class of integral equations: H. **Bateman.**—A suggestion as to the nature of the horny teeth of the Marsipobranchii: H. W. Marett **Tims.** It is difficult to accept the homologies which have been proposed between the horny teeth of the Marsipobranchii and the teeth of higher vertebrates. The published accounts of the development of the former appear to the writer to harmonise more closely with the development of the teleostean scale, from which it is suggested in the present paper that the horny teeth may have been derived.

EDINBURGH.

Royal Society, May 7.—Dr. R. H. Traquair, vice-president, in the chair.—Vibrating systems which are not subject to the Boltzmann-Maxwell law: Dr. W. **Peddie.** In this paper the question of the partitioning of energy in a system of mutually influencing masses is considered, the law of action assumed being the generalised Hooke's law. It is shown that equipartition of energy is in general impossible. An infinity of cases with a given number of degrees of freedom in which equipartition holds is possible, but the order of the infinity of cases in which it does not hold is greater. A method of time averages for a single system is used. When equipartition cannot hold in the case of any one system, the same result must be true for the space averages of a large number. In the course of the work a very symmetrical condition for the reality of the roots of an n-ic is found.—The superposition of mechanical vibrations upon magnetisation, and conversely in iron, steel, and nickel: James **Russell.** The wire under examination was, when required, set into mechanical vibration by means of an electric bell, to the sounding part of which the one end of the wire was fixed. The investigation was a systematic comparison of the temporary and residual magnetisations of these materials in various cyclic fields, according as the material was or was not in a state of vibration. The influence also of the condition of the wire, according as it was annealed or "quenched," was carefully studied. Of the many results obtained the following may be mentioned:—With permanently acting vibrations hysteresis loss is increased when the limiting fields are low, increased when they are high, but always decreased when the comparison is made with the limits given inductions instead of fields. In the annealed condition of all three metals, vibrations greatly increase the effects of "field on" and "field off." When the vibrations are not maintained permanently, but are superposed upon the magnetised condition at different stages of the cycle, the results are very different. Thus with continuous vibration the slope of the curve decreasing from the same maximum is always greater with vibration than without. On the other hand, when the vibration is superposed an increase of induction always occurs on the down curve as the cyclic extreme is departed from, and this increase passes into decrease in the opposite sense as the other cyclic extreme is reached.—*Neobythites brucei*, Poisson abyssal nouveau recueilli par l'Expédition Antarctique Nationale Ecossaise: Louis **Dollo.** This is a unique specimen of a new fish (family Brotulidæ) which Mr. W. S. Bruce found in the Weddell Sea at a depth of 2500 fathoms, 800 feet deeper than the deepest sounding obtained by the *Challenger* in the same region.—The Nematoda of the Scottish National Antarctic Expedition: Dr. v. **Linstow.** Seven species were described, five of the parasitic genus Ascaris, of which two were new species, and one undetermined. The others were a new species of Monorygma and a free-living Thoreostoma. Mr. Bruce exhibited the specimens, the *Monorygma dentatus* found in the stomach of the Weddell's seal being specially interesting.—A Pfaffian identity and related vanishing aggregates of determinant minors: Dr. Thomas **Muir.**

PARIS.

Academy of Sciences, May 7.—M. H. Poincaré in the chair.—The discovery of the proper motions of the stars by the aid of the stereoscopic method of Dr. Max Wolf: M. **Lœwy.** The method consists of a comparison in a stereoscope of two photographs of a given portion of the sky taken at several years' interval. Among the photographs shown was one bringing out the proper motion of a star of the ninth magnitude in the constellation of Leo. The proper motion can be evaluated stereoscopically with a greater precision than by the ordinary micrometric methods.—Remarks on the twelfth volume of the "Annales de l'Observatoire de Bordeaux": M. **Lœwy.**—The methods for the detection of aggregations of luminous particles, mixed with the gases and vapours in the lower part of the solar atmosphere, at other times than during eclipses: H. **Deslandres.** Very little has been done on the composition and distribution of the non-gaseous portion of the solar atmosphere. The author reviews the difficulties of the subject, and gives suggestions as to the best mode of attacking the problem.—The nidification of bees in the open air: E. L. **Bouvier.** An account of two cases in which domesticated bees have built hives in the open air on the branches of trees, and of the modifications in the structure necessitated by the exposure to wind and rain. Owing to the neighbouring buildings, one side of the hive was more exposed than the other. This fact was appreciated by the bees, and the exposed side was strengthened accordingly.—The conglomerates from the explosions of Vesuvius, their minerals, and their comparison with the trachytic conglomerates of Mont Dore: A. **Lacroix.**—Remarks by M. Albert Gaudry on the forthcoming International Congress of Anthropology and Prehistoric Archæology at Monaco.—The synthesis of penta-methyl-ethanol: Louis **Henry.** The substance $(CH_3)_3—C—C(OH)—(CH_3)_2$ was obtained in an attempt to prepare

$$(CH_3)_2—CCl—C(OH)—(CH_3)_2,$$

by the interaction of magnesium methyl-bromide and ethyl chlorisobutyrate or the corresponding bromo-compound. The method described is the most advantageous one for the preparation of this alcohol.—Researches on the whitening of fur and feathers in winter: El. **Metchnikoff.** Observations are given showing the probability of the view that the blanching of the hair and feathers, in animals periodically and in man through old age, is due to the activity of living amœboid cells, chromophages, sensible to external influences, and capable of moving and attacking the pigment grains.—The generalisation of trigonometrical series: A. **Buhl.**—Certain asymptotic series: L. **Schlesinger.**—The acceleration of spherical waves of shock: M. **Jouguet.**—The application of the principle of superposition to the transmission of alternating currents over a long line. Its graphical representation: A. **Blondel.**—The interference effects produced by a grating limiting a thin plate: Georges **Meslin.** The theory of interference rings which appear when a grating is placed on the convex surface of a lens of small curvature, and are distinct from Newton's rings. These fringes can be applied practically to the verification of a surface without the use of monochromatic light, and this testing can be carried out without interrupting the working of the surface, owing to the fact that the diffraction grating may be placed at a distance of some millimetres from the surface without interfering with the production of the fringes.—The action of ammonia gas on anhydrous neodymium chloride: C. **Matignon** and R. **Trannoy.** Neodymium chloride forms seven different combinations with ammonia, containing respectively one, two, four, five, eight, eleven, and twelve molecules of ammonia to one of $NdCl_3$. These compounds form a further confirmation of the trivalency of neodymium, as the assumption of divalency for this metal would lead to improbable formulæ for these addition products.—The existence of sulphides of phosphorus; mixtures of phosphorus and phosphorus sesquisulphide: R. **Boulouch.** A criticism of a paper on the same subject by H. Giran, and a discussion of the nature of the eutectic mixture formed by phosphorus and the sulphide P_4S_3.—Some special brasses: Léon **Guillet.** The addition of an element such as aluminium to a brass containing copper and zinc only yields an alloy possessing mechanical properties and a micrographic structure corresponding to a pure copper-zinc brass of quite different composition. From numerous experiments on the addition of various elements, a quantitative expression is developed referring the properties of the alloys thus formed to the pure copper-zinc brasses of corresponding properties.—A method for the detection and estimation of small quantities of iron: A. **Mouneyrat.** The method is based on the production of a green colour in dilute solutions of iron salts by the action of sulphuretted hydrogen in ammoniacal solution. It is shown that the reaction is specific to iron and is of extreme delicacy, serving to estimate this metal between the limits of 1/1000 and 1/1,000,000.—The production of aromatic sulphamates by the reduction of nitro-compounds with sodium hydrosulphite: A. **Seyewetz** and M. **Bloch.** Nitrobenzene is reduced by sodium hydrosulphite in presence of sodium phosphate to the sodium salt of phenylsulphamic acid. The reaction is general for aromatic compounds, and has been extended to the three nitrotoluenes, metanitroxylene, and α-nitronaphthalene.—A seismic disturbance recorded at the Observatory of Ebro on April 18: P. **Circra.**

NEW SOUTH WALES.

Linnean Society, March 28.—Annual General Meeting.—Mr. T. Steel, president, in the chair.—Annual address: the **President.** The question of rabbit destruction was dealt with, the proposal to introduce disease for the purpose being condemned, on the grounds that not only would it not affect the desired extermination, but also that it was extremely undesirable to introduce a foreign pathogenic microbe of unknown potency under changed conditions, to be broadcasted over the land. Attention was directed to the indiscriminate destruction, wilful as well as inadvertent, of useful and harmless indigenous animals, and the deplorable results in loss of crops through attacks of insects which are sure to follow the killing off of insectivorous birds. Taking as the special subject of his address that of oceanic physics, the president briefly sketched the formation of the primary ocean, showing that it was in all probability highly saline and that calculations of the age of the earth, based on the present rate of transport of salt from the land to the sea, are misleading. Regarding the observed rate of increase in temperature downwards in the earth's crust, which has been found to be about 1° F. for each 51 feet of descent, reasons were given for considering that this rate is not maintained, and that a maximum temperature of about 7000° F. is reached at a depth of some 800,000 feet, after which the temperature to the earth's centre remains practically unaltered. Dealing with the phenomenon of wind-raised waves, it was shown that these have well-defined properties, waves of any given size having all their other functions in unison, the height, length, frequency, velocity, &c., being fixed and invariable, relative to one another. Allusion was made to the enormous amount of energy involved in the evaporation which takes place daily from the ocean surface, and to the profound effect on climate caused by the transference of heat absorbed in vapourising water from the sea and again liberated at the places where this vapour condenses to form clouds and rain. The address concluded with an examination of the possibilities in regard to the withdrawal of water from the ocean to be stored as ice at the poles, and the result on the relation of land and water levels, also on the adequacy of change of land level at the poles to account for the known former existence there of a comparatively mild climate.—The first recorded occurrence of Blastoidea in New South Wales: T. G. **Taylor.** The Australian Blastoids at present known comprise three species from the Gympie beds (permo-Carboniferous) of the Rockhampton district, and provisionally referred to the genera Metablastus, Granatocrinus, and Tricœlocrinus. The two specimens now recorded are different from the Queensland forms, and were obtained from the Glenwilliam (permo-Carboniferous) series at Clarence Town, New South Wales. They are provisionally classed as species of Metablastus.—A collection of Crustacea from the Port Curtis district, Queensland: F. E. **Grant** and Allan R. **McCulloch.** The paper deals with a collection of more than 100 species of Brachyura and Macrura taken in Port Curtis and at the extreme south of the Great Barrier Reef, in October, 1904. Five species are described as new. Twenty-one species are recorded as new for Australia.

CALCUTTA.

Asiatic Society of Bengal, April 4.—Notes on the tank fauna of India: Dr. N. **Annandale.** A cockroach of the genus Epilampra is recorded as being aquatic in Chota Nagpur, and a peculiarity in its spiracles and in those of some other members of its family is noted. A general account is given of the respiratory system of an aquatic glow-worm, probably the larva of a Luciola. Some further diagnostic characters (distinction of the sexes, structure of the eggs, relative proportion of body and tentacles) of *Hydra orientalis* are put on record. Two protozoa are noted as having been found associated with it, and the part played in its migrations by Paludina is pointed out. An account is given of a chironomid larva which binds both the polyp and certain Vorticellids and rotifers to a temporary protective case, and then devours them at leisure. The character of the food commonly eaten in the Calcutta tanks by Hydra is indicated.—Silver dioxide and silver peroxynitrate: E. R. **Watson.** If the crystalline substance formed during electrolysis at the anode from aqueous solutions of silver nitrate be washed and dried with sufficient care, it may be isolated pure, and proved to have the formula Ag_7NO_{11}, which Sûlc gave to it. On heating this silver peroxynitrate, the decomposition proceeds in two stages; for at first oxygen is given off, but later NO_2 as well as O, white silver being left. This behaviour suggested to Sûlc the structural formula $AgNO_3 3Ag_2O_2.O_2$; Mulder and Haringa suggested later the formula $AgNO_5.3Ag_2O_2$. To both suggestions there are considerable objections. Alternatives still under investigation are $Ag_7(NO_3)O_8$ and $Ag_7(NO_4)O_7$.—The Hindu method of manufacturing spirit from rice, and its scientific explanation: J. C. **Ray.** The fungus used in Orissa is prepared in small balls by the hill-people; it is mixed in a basket with wet steamed rice in the proportion of one to one hundred parts of dry rice. The mixture heats during the next twenty-four hours, after which it is made into circular cakes and exposed upon an earthen platform for three or four days, during which the mycelium so spreads as to make the grains in the cakes cohere. The cakes are now piled up, and in four or five days become black. Next the cakes are put with water into vats sunk in the floor of a shed, and an equal quantity of fresh, well-steamed rice is added. The vats before being charged are fumigated by burning straw. Fermentation is allowed to go on for eight to ten days, until bubbles cease to rise. Distillation follows. The average yield of spirit in a good distillery is 4 gallons, proof, from 82 lb. of rice. The maximum yield of 4·5 gallons is obtained in January, the minimum of 3·66 gallons in October. Experiments show that the caking is very essential to the process. The essential mould is believed to be *Mucor racemosus*; other moulds get mixed with it.

DIARY OF SOCIETIES.

THURSDAY, MAY 24.

ROYAL SOCIETY, at 4.30.—Croonian Lecture: On Nerve Endings and on Special Excitable Substances in Cells: Prof. J. N. Langley, F.R.S.
ROYAL INSTITUTION, at 5.—Man and the Glacial Period: Prof. W. J. Sollas, F.R.S.
UNIVERSITY OF LONDON, at 5.—The Atmospheric Circulation and its Relation to Weather: Dr. W. N. Shaw, F.R.S.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Annual General Meeting.—Report of Council and Election of the New Council.
SOCIETY OF ARTS, at 4.30.—The Parsis of Persia: Major P. M. Sykes C.M.G.
LINNEAN SOCIETY, at 3.—Anniversary Meeti

FRIDAY, MAY 25.

ROYAL INSTITUTION, at 9.—Compressed Air and its Physiological Effects: Leonard Hill, F.R.S.
PHYSICAL SOCIETY, at 5.—Colour Phenomena in Photometry: J. S. Dow.—Exhibition of an Automatic Arc Lamp: H. Tomlinson and Rev. G. T. Johnston.—The Theory of Moving Coil and other Kinds of Ballistic Galvanometers: Prof. H. A. Wilson, F.R.S.—Exhibition of a Bifilar Galvanometer free from Zero Creep: A. Campbell.

SATURDAY, MAY 26.

ROYAL INSTITUTION, at 3.—The Old and the New Chemistry: Sir James Dewar, F.R.S.

TUESDAY, MAY 29.

ROYAL INSTITUTION, at 5.—Northern Winter Sports: Colonel V. Bulck.
ZOOLOGICAL SOCIETY, at 8.30.
SOCIETY OF ARTS, at 8.—Glass Cutting: Harry Powell. (Paper to be read at the Whitefriars Glassworks.)

THURSDAY, MAY 31.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* On the Main Source of "Precipitable" Substances and on the *Rôle* of the Homologous Proteid in Precipitin Reactions: D. A. Welsh and H. G. Chapman.—The Viscosity of the Blood: A. du Pre Denning and J. H. Watson.—The Affinity Constants of Amphoteric Electrolytes, part i., Methyl Derivatives of Para-Aminobenzoic Acid and of Glycine: J. Johnston.—Part ii., Methyl Derivatives of Ortho- and Meta-Aminobenzoic Acids: Dr. A. C. Cumming.—Part iii., Methylated Amino-Acids: Prof. James Walker, F.R.S.
ROYAL INSTITUTION, at 5.—Man and the Glacial Period: Prof. W. J. Sollas, F.R.S.

FRIDAY, JUNE 1.

ROYAL INSTITUTION, at 9.—L'Ébullition des Métaux: Prof. H. Moissan, For. Mem. R.S.

CONTENTS.

THURSDAY, MAY 31, 1906.

FAMILY ABILITY.

(1) *Noteworthy Families (Modern Science).* By Francis Galton, F.R.S., and Edgar Schuster. Pp. xlii+96. (London: John Murray, 1906.) Price 6s. net.

(2) *Mental and Moral Heredity in Royalty.* By Frederick Adams Woods, M.D. Pp. viii+312. (New York: Henry Holt and Co., 1906.)

(1) IN the spring of 1904 a circular was issued to all Fellows of the Royal Society whose names appeared in the year-book for 1904 in which they were asked to give particulars of the achievements of their relatives. A statistical examination of the information thus furnished is made by Dr. Galton in the preface to the volume before us, while Mr. Schuster has selected from the returns particulars of sixty-six families containing at least three noteworthy kinsmen. The prominence given to the latter part of the work suggests that the primary object of the inquiry was not statistical, but was to form an index of those families now represented by men of science among what might be described as "the intellectual aristocracy."

When applying statistical methods to the information furnished Dr. Galton was confronted by several difficulties; only 207 of the 467 persons addressed sent serviceable replies, and of these only about one-half gave complete returns, so Dr. Galton found he had only 100 families to consider. In order to make any comparison between the kinsfolk of Fellows of the Royal Society and the generality it was therefore necessary not only to form a conjecture of the proportion of noteworthy persons in the community, but also to consider the reasons which prompted the large proportion of Fellows who abstained from replying—if, as Dr. Galton suggests, they were of a poorer class than those who replied, weight must be given to this consideration in the comparisons. The much debated question of environment is also referred to, and Dr. Galton gives two tables from which he concludes that if ability and environment are positively correlated, the association between success and ability becomes closer. We are not quite convinced by the tables, as it is hard to see the reason for splitting the nine possible combinations of ability (high, medium, and low) and environment (high, medium, and low) into three grades of success in Table II., which gives "ability independent of environment," while in Table III., showing "ability correlated with environment," the nine groups are distributed into five grades. The average number of relations which each individual has in a stationary community had to be considered, and this affords Dr. Galton the opportunity of giving the interesting note which appeared in NATURE for September 29, 1904 (vol. lxx., p. 529). The conclusion reached after making allowance for the various points mentioned is that able fathers produce able children in a much larger proportion than the generality, but as the statistics cannot be thrown into a form suitable for obtaining the usual coefficients of correlation, it is impossible to compare the results with recent statistical work on heredity.

The book is the first volume issued by the Eugenics Record Office of the University of London, a fact that gives it an additional interest, and encourages us to look forward to further work on the interesting subject which the office has—as the result of Dr. Galton's generosity—been established to investigate.

(2) This book gives us the result of an attempt to study some of the problems of heredity with the help of statistics drawn from the Royal Families of Europe. Dr. Woods has collected information from various sources, and whenever possible he has considered the view taken by more than one authority in the hope of eliminating the personal element which most people connect closely with historical work. The method adopted was to record every individual in every degree of relationship and also everything which could assist an estimate of the mental or moral status of any historical character considered. Dr. Woods then decided into which of ten groups showing grades of intelligence each person in his royal population should be put, and in order to give readers the opportunity of verifying his particulars he has given a list of the persons in their grades of intelligence. A similar plan was followed for morality.

The various Royal Houses are then examined in turn; a genealogical table of each is given showing the grades assigned to each person whose name occurs, and Dr. Woods points out the recurrence of marked characteristics in successive generations such as the Bourbon insanity or the Hapsburg "lip," though the latter is the only physical characteristic examined at any length. Throughout this, the main part of the work, an attempt is made to show that heredity can account for the total or partial recurrence of the type of mind exhibited by an ancestor, and although at times Dr. Woods seems to try to explain too much, he has certainly succeeded in giving a clear impression of his opinion of the statistics he has collected. He frequently suggests when discussing family traits, that inheritance seems alternative rather than blended, but if this leads the reader to expect an illustration of Mendel's laws in the statistical part of the volume he will be disappointed by Dr. Woods's footnote to p. 274, in which he says that he has not been able to detect the existence of "dominant" and "recessive" types, and adds:—

"Although the mind seems in its inheritance to roughly obey the principle of alternative inheritance and thus indicate segregation in the germ-cells, I do not feel that this is sufficiently clearly defined to enable one to classify according to hard and fast types, as is possible in dealing with the features of certain plants and animals like the colours of mice, whether albino or gray; or the shapes of peas, whether round or angular."

Dr. Woods points out that the large amount of inbreeding which has taken place in some of the Royal Families has certainly not led to sterility, though it is, we think, probable that it has helped to accentuate in offspring some of the noticeable characteristics on which the author dwells.

In the statistical treatment Dr. Woods first examines the interesting question of whether there is any connection between mental and moral qualities, and by means of Pearson's "fourfold-table" method finds the high value of $0{\cdot}3403 \pm 0{\cdot}0419$ for the coefficient of correlation, and he then proceeds to show that the average number of adult children increases with the higher grade of morality of the parent. It is a pity that no correlation table is given in this last case, as the result is interesting. It is, of course, a conclusion that would be expected from general considerations; for the dissolute members of any community tend to die at an early age, which leads one to expect them to have few children, while the fact of their being dissolute generally means that the children born are less healthy and therefore more often die in childhood. The other statistical results can be conveniently summarised as follows:—

	Coefficients of correlation between		
	Offspring and fathers	Offspring and grandfathers	Offspring and great-grandfathers
Mental qualities ...	0·301 ...	0·161 ...	0·153
Moral qualities ...	0·298 ...	0·175 ...	not calculated

The first four of these agree closely with the 0·3 and 0·15 expected by the Law of Ancestral Heredity. In comparing the figures given with those obtained from other sources it should be borne in mind that assortative mating is probably very slight among members of Royal Families, while elsewhere it plays an important part. We think it would have been well to give some information about the correlation between brothers, and also between offspring and mothers; the maternal lines have in fact been neglected almost entirely in the statistical work.

Dr. Woods states as his reason for using the "fourfold-table" method for finding coefficients of correlation, that his grades do not necessarily represent quantitative measurements, "for we do not know that grade (4) is twice as intellectual as grade (2), &c." This is incorrect; the ordinary method merely requires the groups to be equidistant, and the remarks on pp. 19 and 20 on the distributions of the people in their grades of intelligence or morality leave the impression that Dr. Woods attempted to make them so. In his correlation tables he always divides the offspring and parents into "below the mean" and "above the mean," instead of saying "grades (1) to (5)" and "grades (6) to (10)." The latter represents the real division, as the mean cannot be fixed without knowing the relative distances between the grades.

The book would be the better for a good index, and one or two misprints such as Frederic*k* Harrison and homogomy and father for brother on p. 235 have been allowed to pass, while we think the description of the condition of Portugal during the reign of Alfonso IV. as "progress, especially against the infidels," an unhappy one.

The conclusions reached in the two books are much alike, as the authors find a few centres about which the intelligence seems to collect rather than a chance-distribution of highly intelligent individuals through the population. We cannot help feeling, however, that there is some doubt as to whether the collection of information among special groups is as satisfactory as the investigation of random samples of the population. This objection can be urged against the "Noteworthy Families" rather than against the "Royalty," because in the former work we do not know for certain how many very able persons spring from the general public, but a similar question does not arise in dealing with Royalty, and the only point is how far we may apply results obtained from one class to persons in another.

We are inclined to think that both books may find readers among those who have not made a special study of the statistics bearing on heredity, for both give information in a clear and interesting manner, and the lists of families in the one case and the discussion of Royal personages in the other will attract many who would never look at a work containing nothing but statistical investigation. Is it too much to hope that some of these readers may be led to appreciate that the ultimate proof of historical or biological theories must have a statistical basis? That they will appreciate the painstaking energy of the authors is beyond doubt. I.

TOPOGRAPHICAL SURVEYING.

Text-book of Topographical and Geographical Surveying. By Major C. F. Close, C.M.G., R.E. Pp. iv+288. Printed for H.M. Stationery Office. Price 3*s.* 6*d.*

THE art of topographical surveying was almost invariably known in this country until recent years as "military topography," a phrase which may be taken to mean not that the topography of a region presented special features to the soldier, but that little attention was paid to topographical surveying of any sort until military necessity arose. The fact that interest in and knowledge of surveying of this kind is no longer confined to the Army is largely due to the active influence of the Royal Geographical Society in London and in the Universities of Oxford and Cambridge, as a result of which an increasing number of intending travellers, explorers, naturalists, and colonists go through some training in surveying before setting out for distant parts, but it is scarcely less due to the work of the Royal Engineers in constantly developing and testing new instruments and methods in the field, and in making the results of trial and experiment generally accessible.

That the extent of the field before the topographer is great is abundantly evident from Major Close's statement in an introductory paragraph that "excluding Canada, Australia, New Zealand, and India, the total unmapped area of the British Empire amounts to about 3,700,000 square miles." Now we cannot expect that the whole of this area will be mapped for purely military purposes. It is to be hoped that sooner or later Government surveyors will lay down a primary triangulation over it for the benefit of the topographer who may follow, but we can scarcely expect more. The topographic map must in the end be made by the civilian who is to use it; the most he can look for from outside is a number of fixed points upon which to "hang" his own surveys.

Thus we arrive at the conclusion that more provision must be made for the training of civilian topographers in this country, and we are at once confronted by great difficulties. Students learning surveying are usually studying other subjects at the same time, and in the more open parts of these islands where alone it is easy to do small-scale work extending over any considerable area, opportunities of studying other subjects are necessarily limited. The question of time also becomes troublesome, much of what is available being soon spent in getting to and from the scene of operations; and the climate, difficulties connected with trespass, setting up marks, getting unskilled assistance, and so on, are all against the student. Work with ordinary "classes" is for the most part restricted to mapping on a scale of at least three inches to a mile, with "demonstrations" of the nature of secondary triangulation, and bicycle expeditions for practice in rapid sketching over larger areas; beyond this it is necessary to depend on "vacation courses" extending over a week or ten days in the summer. The expedients, however, are more or less of the nature of makeshift, and the student cannot hope to acquire the eye for country, and the facility in representing it, which is characteristic of skilled surveyors in constant practice, like the native topographers in the survey of India.

But the difficulty does not end here, for it affects the civilian teacher as well as the student. However great the skill and experience of the latter may be, it is scarcely possible for him to keep "up to date" without direct contact with actual modern survey work, and this is difficult to achieve. The importance of this is clearly shown in Major Close's book, in which, as he says, "the field methods described are, for the most part, those in use by the Survey of India; but advantage has been taken of recent experience in mapping and exploring various territories in Africa and elsewhere to include useful methods which are not commonly employed in India."

Hence, for many reasons, it is to the advantage of all topographers in this country to keep up as close acquaintance as possible with the service work in all its branches, and amongst the many efforts which military surveyors have always made to render this easy, few have been more entirely adequate than the publication of this book. There are few subjects in which books by themselves are of less assistance than topographical surveying, but Major Close has succeeded fully in doing what can be done by this means.

The body of the book consists of seventeen chapters on instruments and methods, sketching, map projections, the reproduction of maps in the field, field astronomy and the determination of positions, and the theory of errors as applied to topographical work. Some of these chapters have been partly written by officers who have given special attention to the subjects treated of, others are drawn from published papers, and the sections on field astronomy have been revised by Mr. A. R. Hinks, of Cambridge Observatory. The eighteen tables giving the quantities usually required for plotting graticules, computing astronomical results, and so on have been specially revised, and in some cases recalculated. Ten appendices give various useful lists, explanations, and formulæ. The thirty-four plates, which include admirable examples of sketch maps of different kinds, specimen sheets of British and foreign topographical maps on different scales, and four new star charts, are almost the best features of the book. It would be difficult to suggest a better exercise in map reading for the student than a study of the reproductions of maps executed by the Ordnance Survey.

Taking the book for what it is, we find, as might be expected, little or nothing to criticise; it would be easy to criticise it for what it is not, and does not profess to be. As a text-book, experience has proved its excellence, but it must be fully realised that it is true to its name, and that while it supplies the text, the teacher must preach the sermon. Many chapters are distinctly of the "pemmican" order, and would prove extremely difficult to a reader altogether unacquainted with the subject. The difficulty is no doubt got over to some extent by the excellent lists of references given. These lists might perhaps be made more complete, but in some cases satisfactory books are still to be written. We may take as an example the chapter on map projections—largely reprinted from Major Close's "sketch" of the subject—and venture to express the hope that the author will one day give us an authoritative text-book on this alone. Another chapter about which the same remark might be made—indeed the author himself makes it—is that on the adjustment of errors, a subject we have always found of great value and interest even to elementary students dealing with comparatively rough observations. It is true that a good deal of help can be obtained here from the methods ordinarily employed by engineers, but for topographical purposes many useful results can be got by graphic extensions of these methods.

H. N. D.

GARDEN SHRIMPS.

The British Woodlice, being a Monograph of the Terrestrial Isopod Crustacea occurring in the British Islands. By Wilfred Mark Webb and Charles Sillem. Pp. x+54; with 25 plates and 59 figures in the text. (London: Duckworth and Co., 1906.) Price 6s. net.

AT present in England there are only two dozen species of these little land crustaceans on record. The number, combined with their love of obscurity, may remind us of the regal feast at which four-and-twenty blackbirds were served up concealed in a pasty. When the pie was opened, the birds began to sing. In correspondence with the daintiness of such a dish, the apostles of œcology are now earnestly trying to persuade society that all nature is tuneful. Those who are afflicted with toneless ears may assume a haughty indifference towards the resounding harmony, while they are themselves the objects of pity rather than of pride. The bright little volume under review is an excellent example of what can be done under the new impulse given to the old practice of "nature-study." It shows how members of our fauna, that have long suffered from negligent and contemptuous treatment, may in friendly hands receive their proper meed of appreciation. Though, out of deference to tradition, the book goes by the unprepossessing name of "The British Woodlice," its subtitle redeems the subject from prejudice by assigning it to its true place in classification. The many scurrilous colloquial terms that have been applied to these terrestrial isopods have, to the ordinary observer, obscured the fact that they are really made of one flesh and blood with the epicure's cherished treasures, the lobster and the prawn. Their use medicinally in old times would probably have been robbed of half its charm had this been understood, since in those days curative agencies seem to have been valued in proportion to the pain and disgust they inflicted on the patient. So lately as 1883, W. G. Black, in his "Folk Medicine," writes:—

"A relation of mine was in the cottage of a wise woman at Penzance about two years ago, and found that she was still in the habit of prescribing in scrofulous cases grammar sows, sow-pigs, millepedes or woodlice, to be swallowed as a pill. According to the Penzance woman, the sufferer must himself secure his medicine, but she had a corner in her little garden where nothing was grown but mint and thyme, and there the sow-pigs were reared. As a concession to modern feelings, patients are now allowed to wear this disagreeable medicine in a little bag round the neck, if they shrink from the heroic remedy of swallowing it."

One may wonder whether the man who first ate a shrimp thought himself a hero! It will be noticed that the wise woman of Penzance had to foster her colony of animated pills. Mr. Webb also recounts the efforts of industrious research on the part of himself and others by which the present small total of British species has been slowly ascertained. Some of the species, indeed, are known to be widely distributed, and in places to be very abundant. But there is little proof that even those which have the worst repute for depredation do any serious amount of harm in our gardens. They are chiefly to be found in rubbish heaps or nests of garden pots, or under flat, neglected stones. Many of the species are the rare prizes of diligent collectors. Mr. Webb has given a very full and faithful record of published captures, the only work of importance which he does not appear to have thoroughly examined being the Transactions of the Devonshire Association. Ireland, with a list of species not quite equal to that of England, still in *Trichoniscus vividus* (Koch) keeps one form exclusively to herself. In the very large number of European species all of ours are included, and twenty of them have been described by Prof. G. O. Sars in his admirable work on the Crustacea of Norway.

The authors of the present volume are most scrupulous in acknowledgment of assistance they have received from various sources. They are to be congratulated on their own accuracy and diligence. The results of their good work in the field, with the microscope, and in the study of the available literature on the subject are presented in a compendious and excellently illustrated treatise. Marine isopods are sometimes found with the front half of the body much narrower than the after part. Light is thrown upon this odd appearance by one of the incidents of exuviation. The animal sheds the hind part of its skin first, while the more dilatory front remains still incapable of expansion in its old armour. Messrs. Webb and Sillem explain that this is just what happens with our garden shrimps, there being an interval of three days or so between the two strippings. Their authority on this point, Mr. J. B. Casserley, has also observed that the thrifty creature eats the skin which it has shed. What fortunes there are to be made out of waste products! The habit is no doubt widely diffused among crustaceans, otherwise their innumerable cast skins would be more frequently met with.

The well-drawn plates of this commendable volume are not coloured, but the student whom it inspires to take up the subject may find exceptional attraction in the specific names of *Armadillidium pulchellum*, the beautiful little Armadillo, *Porcellio pictus*, the painted Porcellio, and above all *Trichoniscus roseus*, the rose-tinted Trichoniscus. T. R. R. S.

AUSTRALIAN ETHNOLOGY.

Ethnological Notes on the Aboriginal Tribes of New South Wales and Victoria. By R. H. Mathews. Pp. xiv+183. (Sydney: F. W. White, 1905.)

THE author of this work has published numerous articles on Australian anthropological subjects during the past ten years, but they have either been ignored or dismissed in a footnote by experts such as Dr. Howitt and Prof. Baldwin Spencer. A careful examination of his contributions does not give a high opinion of the author's qualifications for his task. The present volume contains a bibliography of the author's articles and some assertions as to the importance of this new contribution, of which the following sentences are specimens:—"Those portions of my book dealing with sociology," at pp. 5–15 and 84–103, will completely revolutionise all the old school notions respecting the organisation of Australian tribes "which have been published up to this date" (p. 4). "I have adopted none of the opinions nor followed any of the methods of other Australian authors, but have struck out on my own lines" (p. 2). "Since the time of Mr. Ridley and Mr. Bridgeman down to the present day, nothing important has been added to our knowledge of the Kamilaroi organisation" (p. 13).

It requires self-assurance to make the last of these three assertions, for Mr. Mathews can hardly expect his readers to be so ignorant as never to have heard of Dr. Howitt, whose "Native Tribes," published the year before last, contains much information on the subject, even if we neglect "Kamilaroi and Kurnai," published by him nearly five-and-twenty years ago in collaboration with Dr. Fison. In the work before us the main novelty in the way of sociological information appears to be the statement that the Ngeumba tribe is divided into "castes" and "bloods" as well as kins and phratries. The Ngeumba, whom another writer seems to have termed Nyamba, are near neighbours of the Euahlayi on the Narran River, and the names for the "blood" divisions in the Ngeumba tribe are virtually identical with those given as phratry names by Mrs. Langloh Parker for the Euahlayi. That being so, we have the choice of three theories:—(1) that both authors are correct; (2) that Mr. Mathews has confused two tribes; or (3) that Mrs. Parker's information is incomplete. In view of the fact that she resided twenty years among them and gained the full confidence of the Euahlayi, the latter seems improbable; we are therefore left to choose between a superposition of organisations or a confusion created by Mr. Mathews. He does not work out how the "blood" organisation affects the ordinary social organisation.

The "castes" are stated to have reference to the manner of camping and to denote the shade of various parts of a tree; our confidence in this explanation is not increased by the discovery that one of the words, *nurai*, is the ordinary name for the black snake totem in two or three adjoining tribes. It is to be hoped that some anthropologist of reputation will turn his attention to the tribe. If Mr. Mathews's information turns out to be correct, he will have done something towards establishing his reputation.

N. W. T.

THE BREEDING INDUSTRY.

The Breeding Industry. By Walter Heape, F.R.S. Pp. xii + 154. (Cambridge: University Press, 1906.) Price 2*s.* 6*d.* net.

THE author of the present volume has long been distinguished for his investigations in vertebrate embryology and the physiology of vertebrate reproduction. He has also paid considerable attention to the practical aspects of the subject, in so far as they concern the methods adopted by the animal breeder and the needs of the breeding industry. In the light of the special knowledge and experience which he has thus gained, Mr. Heape has become firmly convinced that the breeder will derive "inestimable advantage from the right application of science to the industry with which he is concerned," while it is no less his strong belief "that the field of scientific biology will be broadened, the number of workers therein increased, and the means available for their work augmented, as the result of . . . . more intimate relations between scientific and practical biologists." Those who read this volume, and all others who are familiar with the nature of the questions discussed therein, can have little difficulty in realising that Mr. Heape is right.

The first chapter, which is introductory in character, deals with the present position of the breeding industry in our own country. The scientific man and the breeder are too frequently antagonistic, and tend to distrust one another. This antagonism, which is quite unnecessary, is as much the fault of the man of science as of the practical man, and it is to be partly ascribed to the unsympathetic attitude of the former towards many of the facts and problems of practical breeding, as well as to the general neglect by professed biologists of that wide field of investigation comprised within the physiology of reproduction. All this is pointed out in somewhat different language by the author, who lays great stress on the enormous advantages to be gained by the introduction of scientific method into the industry of breeding, just as it has proved invaluable to other industries.

The second chapter consists of a concise, clear, and eminently business-like calculation of the value of the breeding industry to the country. As a result of this calculation Mr. Heape arrives at the truly remarkable conclusion that the total sum invested in live-stock in the British Islands is scarcely less than 450,000,000*l.*—an estimate which does not appear to err on the side of excess. Added to this the capital invested in various accessories—vehicles, machinery, housing, &c.—the total becomes still more gigantic. And yet, in the words quoted from Mr. Bateson, the breeding industry is one "to which science has never yet been applied."

In a further chapter the author deals with the nature of the work required for the advancement of the breeding industry. This is comprised under three heads—(1) the keeping of records, (2) the carrying on of research, and (3) the work of administration—all of which are shown to be of the utmost importance. Under the heading of research the author alludes to the special nature of certain of the problems which require elucidation, and particularly those relating to the physiology of the generative system. He might have added that proper facilities for carrying out this kind of research are at present practically non-existent. Such as do exist are due almost entirely to private enterprise and generosity. In order to conduct on any considerable scale investigations upon questions involving the maintenance of animals under reasonably natural conditions and for prolonged periods of time, as well as for the study of the phenomena of inheritance and variation, the creation of some sort of experiment station or biological farm has become a matter of urgent necessity. For carrying on the work of administration Mr. Heape advocates the institution of a State department of animal industry, which would form a section of a new Board of Agriculture.

In the final chapter the management and work of the present Board of Agriculture are discussed, and it is pointed out that there is a want of confidence in its methods and an inadequacy about its organisation which compare unfavourably with those of the corresponding American department.

Mr. Heape's book is well calculated to arouse public interest, for the problem with which it deals is the concern, not only of the man of science, but of all who have regard for the welfare of one of the greatest industries of the nation.

FRANCIS H. A. MARSHALL.

OUR BOOK SHELF.

The Elements of Geology. By Prof. W. H. Norton. Pp. x+461. (Boston, New York, and London: Ginn and Co., n.d.) Price 6*s.* 6*d.*

THIS is a further addition to the well written and well printed introductions to physical geography and geology which have been produced of late years for American schools. We do not quite agree with the author as to the novelty of the arrangement of his material, but it is certainly effective, and the questions attached to many of the illustrations are such as will draw out the reasoning powers of the pupil. Chemical and mineralogical considerations are kept in the background, and rocks are very broadly dealt with, as when syenite is defined (p. 274) as consisting of "feldspar and mica," and diorite as being "still less siliceous, composed of hornblende and feldspar—the latter mineral being of different variety from the feldspar of granite and syenite."

The book, however, hardly suffers from this, as explanations are brought in at the proper points, and a certain chemical knowledge seems to be presupposed. Zoological definitions are given from time to time in the stratigraphical portion, but we still think that the study of geology is held in too light estimation when it is thus regarded as elementary and independent, and not to be preceded by an outline of other branches of natural history. The geographical study of surface-features may, of course, be linked with geological considerations quite early in the curriculum of a school, and the portion of Prof. Norton's book that deals with the shaping of the earth's surface strikes us as especially admirable. It is confessedly and worthily based on the methods of Prof. W. M. Davis, who contributes a note of introduction.

The illustrations, moreover, are well selected throughout, and, where they have been borrowed, acknowledgment is made in most cases of the source. Mr. Welch's famous pot-hole in Glenariff, which was introduced to geologists in an English work in 1895, does duty here for the fourth or fifth time; but the numerous photographs of American scenery will prove of special interest to readers on this side of the Atlantic. The book is modern and very carefully thought out. On p. 246 volcanic phenomena are "extra illustrated" by the ruins of St. Pierre; on p. 306 the latest views are expressed on the gneisses of the "fundamental" Archæan complex; the Mesozoic reptiles receive attractive treatment on pp. 385–392; while on p. 446 a "restored" head of Pithecanthropus finds a place among relics of primitive man. This last instance errs, however, in showing much that is prophetic of future discoveries. Prof. Norton still translates *roches moutonnées* as "sheep backs," but the mention of this detail is only a tribute to his general accuracy. G. A. J. C.

Letters from the Dead to the Dead. By Oliver Lector. Pp. 101. (London: Bernard Quaritch, 1905.) Price 6*s.* net.

THE fact that the letters attributed to Bacon, Shakespeare, Napier, Henry Briggs, and Guy Fawkes have dates attached to them about the years 1904 and 1905 should convince most readers that the book ought to be regarded in the light of a practical joke, in fact, a "take off" of the antique. As another example we may take the "Notes to Henry Briggs's letter," in particular the supposed proof (p. 75) that Napier's true base is the reciprocal of e and not e itself. As the difference depends entirely on whether $\log \sin 45^{\circ}$ has a plus or minus sign attached to it, it is interesting to speculate on how many readers will be deceived by what is, after all, a somewhat clever hoax.

Atlas colorié des Plantes et des Animaux des Côtes de France. By Dr. M. Langeron. Translated and adapted from P. Kuckuck's work. Pp. vii+67; with 24 coloured plates. (Paris: J. B. Baillière et Fils, 1906.) Price 7.50 francs.

THIS attractive publication is an adaptation, so far as the marine flora and fauna of France are concerned, of the well-known work of M. Kuckuck. It consists of three parts, dealing respectively with the phanerogams living in the neighbourhood of the sea, marine algæ, and marine fauna. The book is intended for the use of young students with a love of natural history, and should prove a useful companion during seaside holidays. The plates are instructive and well produced.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Osmotic Pressure.

AT Prof. Armstrong's request, published in NATURE of May 24 (p. 79), I willingly summarise the electrical evidence on which the theory of ionic dissociation seems to me to rest, though a full discussion of that evidence would, I fear, be too long for a letter in this place. Perhaps Prof. Armstrong will allow me to refer him to two papers in which I have written more fully what follows; one paper is in the *Philosophical Magazine* for February, 1903, and the other in the *Electro-Chemist* for July of the same year.

It will, I think, be admitted that we must accept the general view of electrolysis which we owe to Faraday and Kohlrausch, and imagine that opposite parts of the electrolyte move in opposite directions through the liquid. Such a view seems necessary to explain the appearance of the products of chemical change at the electrodes only, and may be verified by direct visual observation, as in the experimental measurements of the velocity with which those parts travel. It need involve no further assumption if, for convenience, we agree to call the moving parts ions. Controversy begins when we attempt to explain how and by what mechanism the ions move. The dissociation theory represents the ions as free from each other (though probably combined with the solvent) during that fraction of their lives in which they are concerned actively in conveying the current. Prof. Armstrong, on the other hand, rejects the idea of any kind of permanent or semi-permanent dissociation, and holds that the electrolyte exists in solution as combined molecules of, let us say, potassium chloride. On the latter theory the mobility of the ions must be secured by some mechanism which involves a series of interchanges between the opposite parts of the molecules. Grotthus pictured the molecules arranged as the links of a chain extending all the distance from one electrode to the other. This particular hypothesis would be exempt from the following criticism, but I suppose it would not be upheld by anyone at the present day. It conflicts too clearly with our knowledge of other phenomena. From our modern kinetic point of view, we should regard the molecules as in continual irregular motion, and suppose the ionic interchanges to occur at the instants when two molecules come within each others' sphere of influence.

Such, I imagine, is the alternative to the theory of ionic dissociation; let us trace its consequences. The greater the frequency with which molecular collisions occur, the more often can ionic interchanges take place, and the faster will the ions work their way through the liquid. Thus the ionic velocities will depend upon and increase with the frequency of collision—a frequency which, on the kinetic theory, varies as the square of the concentration. Thus, on the hypothesis we are considering, the velocities of the ions will increase with the concentration, and be proportional, approximately at any rate, to the square of the concentration. The conductivity, which is measured by the product of the number of ions and their mutual velocity, will then vary approximately as the cube of the concentration. But the facts are quite at variance with these conclusions. The velocities of the ions are found to be constant in dilute solutions, and to decrease slowly with increasing concentration when the solutions are stronger, while the conductivity of a dilute solution is proportional at most to the first power of the concentration.

We must, therefore, it seems to me, abandon the theory of ionic interchanges at the instants of molecular collision, and turn to the rival hypothesis. There are several pieces of positive evidence in favour of the view that the ions migrate independently of each other through the solution. Of these pieces of evidence I may mention three:—(1) the calculated velocity of an ion, as calculated from the conductivity and the migration constant, is independent of the nature of the other ion present when the solution is dilute—the velocity of chlorine is the same whether the other ion be potassium, or lithium, or sodium; (2) the difference of potential observed between two solutions of different concentrations can be calculated numerically on the assumption that the ions migrate independently of each other until the electrostatic forces of attraction prevent further separation; (3) it is possible to explain satisfactorily the curious relation between the valency of the metallic ion of a salt and its specific coagulative power on certain colloid solutions on the assumption that coagulation is due to the effect on the surface conditions produced by a certain minimum electric charge brought together by the chance conjunctions of isolated ions (*Phil. Mag.*, 1899).

The evidence sketched above has been obtained by observations on aqueous solutions. It remains a further question whether similar relations hold for solutions in other solvents and for such electrolytes as fused salts. In the latter case, at any rate, the conditions may be fundamentally different, and it seems necessary to wait for further investigation.

Such, it seems to me, is the present case for the theory of ionic dissociation when put in brief form and restricted to direct evidence. The indirect evidence, based on the success of similar ideas in coordinating and explaining the conduction of electricity through gases, however, must now be taken into account in any full discussion of the subject. I confess that to me the cumulative evidence seems overwhelming. But I hold no brief for the theory, as Prof. Armstrong seems to imagine, and if ever it ceases to be the best hypothesis in the field I shall willingly abandon it. Consistency always seems to me to be the meanest of the virtues, and in matters scientific it may become the most deadly of the vices.

I have endeavoured, as well as the exigencies of space admit, to comply with Prof. Armstrong's request. May I ask him in return to state his own view of the mechanism of electrolysis, to explain, in effect, what is the alternative he proposes to the theory of ionic dissociation?

I am glad to have given an opportunity for Mr. Norman Campbell to explain in public his interesting views on the subject of thermodynamics—views which we have discussed more than once in private without coming to an agreement, though, for my part, I have learnt much by Mr. Campbell's clear-sighted criticism. He will know what my answer to his letter must be, though I have no hope that he will be convinced thereby.

I do not wish to discuss the whole question of the theory of thermodynamics; I am not entitled to do so. But Mr. Campbell holds that, even if general thermodynamics be sound, its application to osmotics is not justified. Now it is here that we do not agree, and I should like to explain the grounds of my belief that not only is the application of thermodynamics to osmotics successful, but that the success is one of the strongest arguments we possess for the general validity of reversible thermodynamics as an ideal towards which practical arrangements may approximate.

Referring to the concordance between the theoretical value of the osmotic pressure of dilute solutions and that observed experimentally, Mr. Campbell says:—"It must be remembered that there is not perfect agreement. . . . The errors are larger than those involved in the direct measurement of the pressure and the other quantities involved; there is a systematic error. But this is due, say the thermodynamicists, to the imperfection of the membrane." I am not sure that I like to be called such a bad name, even by Mr. Campbell, but may I point out that Mr. Campbell has not put forward the whole of the evidence?

The direct measurement of osmotic pressure may not be a very accurate performance, though experience shows that as our membranes become more and more perfect the observed values more nearly approach that indicated by theory as the ideal case. But let us pass that by for a moment, and consider the relation between the osmotic pressure of a solution as defined theoretically and its freezing point. To do so we must use again thermodynamical reasoning, and introduce its necessary assumptions. But most of the assumptions will be the same as we made in deducing the theoretical value for the osmotic pressure, and they, at any rate, do not really add to the total number. Having obtained the well-known relation between osmotic pressure and freezing point, let us calculate numerically what the freezing point of the solution would be if the osmotic pressure possessed the theoretical value. With the most probable number for the latent heat of fusion, the molecular depression of the freezing point of water by the solution in it of a small quantity of any substance should be 1°·857 C. Mr. Griffith's experiments, made with all the refinements of platinum thermometry, gave for the molecular depression of solutions of cane-sugar (from a concentration of 0·0005 to 0·02 gram-molecules per litre) the number 1°·858. The limiting number for solutions of potassium chloride was 3°·720, half of which is 1°·860. Now these numbers agree with astonishing closeness; the opposite errors on Mr. Campbell's hypothesis must balance each other to within very little more than one part in a thousand. I cannot disprove his contention, but I think the balance of probability is against him, and, after all, any evidence which involves experiment must be merely a question of less or greater probability.

Now it seems to me that in this concordance we have a very strong piece of evidence in favour of the existence of an effectively reversible operation in the process of freezing—an operation much more nearly truly reversible than any it is possible to obtain with the rough and crude arrangements of even the best practical heat engines. Hence my present opinion is that, not only is the application of thermodynamics to osmotic phenomena in their theoretical aspect justified, but that it gives one of the most valuable confirmations we possess of the general validity of thermodynamic reasoning as a means of discovering an ideal limit towards which practical processes may tend.

In conclusion, may I point out the great interest of Mr. Campbell's argument that it may be "the swifter molecules which escape into the vapour and the slower which escape into the solid." The contention seems reasonable; and, though I feel that the strength of the case I have stated above is so great as to indicate that such a sifting of molecules cannot affect appreciably the thermodynamic result, it is clear that Mr. Campbell's point should be considered. Has Mr. Campbell really caught a Maxwellian demon? If so, all the world will crowd to study the specimen. But this letter is too long already, and I must leave the discussion to some one more learned than I am in this particular branch of demonology.

Trinity College, Cambridge, May 26.

A New Vesuvian Mineral.

AMONG the ejected masses that strew the flanks of Vesuvius many minerals of known species are to be recognised, and will be referred to in a publication now in preparation.

Perhaps the most interesting among a large number of blocks that I broke open after the eruption were two containing fine crystals of halite associated in spots with a canary-yellow mineral. This latter occurs in crystals up to several millimetres in diameter, and, so far as I have yet examined it, appears to be in rather flat rhombohedra. It is somewhat deliquescent, and therefore requires special attention for its preservation. This is, no doubt, due to the small proportion of magnesium chloride.

A preliminary analysis affords the following result :—

Moisture	0·12	$MgCl_2+6H_2O$	0·22
Insoluble matter ..	0 65	$Na_2SO_4+10H_2O$ ...	1·95
$MnCl_2+4H_2O$	38·97	Fe_2O_3	traces
KCl	57·71		
NaCl	0·32	Total	99 94

From this analysis it appears that we have to do with a double chloride of manganese and potassium for which I propose the name of *chlormanganokalite*, at any rate provisionally until more complete studies can be made of this undescribed species and proper proportions attributed to the combined molecules.

The associated minerals have been deposited as sublimates in the interspaces of scoriaceous masses forming the upper part of the great cone.

The halite probably is rich in potash, but I have not yet had time to make an analysis.

H. J. JOHNSTON-LAVIS.

THE PHOTOGRAPHY OF THE FUNDUS OCULI.

IT is not surprising that the idea of photographing the fundus of the eye followed quickly upon the discovery of the ophthalmoscope by von Helmholtz in 1851. The many attempts made by Noyes (1862), Rosebrugh, Dor, Howe, Bagneris, and others on animals met with only partial success, whilst Gerloff, Thorner and others, who attacked the more difficult problem of the human eye, obtained very inferior results. The best photographs of the human fundus have been taken by Prof. Dimmer, of Graz, who records his experiments in the *Sitzungsberichte der kaiserlichen Akademie der Wissenschaften zu Wien, Math.-Naturwissensch. Klasse* (Bd. cxiv., Heft ix., 1905).

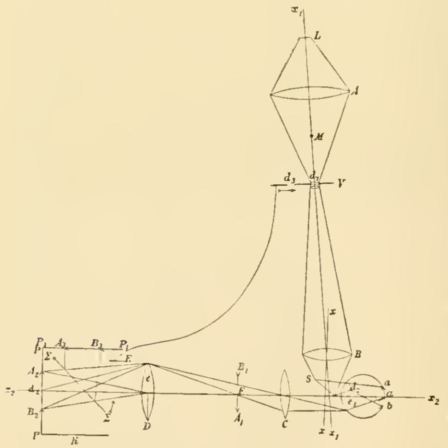

FIG. 1.—Diagram of apparatus.

The chief difficulties which have to be contended with are (1) that of keeping the eye immobile; (2) the necessity for very powerful illumination, which may have a deleterious effect upon the eye; (3) the reflexes formed by the surfaces of the dioptric media—corneal, lenticular, and fundal. Of these the complete abolition of reflexes has as yet proved insuperable. Prof. Dimmer has succeeded in reducing the corneal and lenticular reflexes to a minimum, but the shimmering reflexes at the fundus, which vary so much in different eyes, have resisted all efforts. Nevertheless, an encouraging degree of success has been attained.

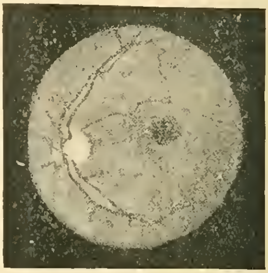

FIG. 2.—The normal fundus.

The method adopted was as follows:— The source of light was a 20–30-ampere arc lamp (L). The light was concentrated on a small diaphragm (d_1), which may be regarded as the immediate source of illumination. A second condenser system (B) formed an image of the diaphragm at the level of the pupil of the eye (d_2). The light and condenser systems were centred on an axis at right angles to the optic axis, the cone of rays being reflected into one half of the pupil by an oblique mirror (S) immediately in front of the eye. This arrangement has the advantages of illuminating a maximum field of the fundus, of reducing the corneal and lenticular reflexes to a minimum, and of leaving the other half of the pupil free for the emergent rays. The last device is that adopted by Bagneris, and by Wolff in his electric-light ophthalmoscope.

The image of the fundus is that of the ordinary indirect method of ophthalmoscopic examination. A convex lens (C) forms a real inverted image at or near its principal focus (F), according to the refraction of the eye. A second convex lens (D) is used to form an erect image upon the sensitive plate (PP). An oblique mirror (ΣΣ) in the camera reflects the image on to a ground glass screen (P_1P_1) at right angles to the position of the plate until the moment of exposure; this facilitates focusing, &c.

Fixation is maintained by an object (M) in the axis of illumination, the diaphragm being covered by a smoked glass. At the moment of exposure, which is instantaneous, a blank diaphragm (d_3) is shot into position by a simple electromagnetic arrangement. Orthochromatic plates are, of course, used to minimise the inopportune colour of the image.

Prof. Dimmer has photographed several normal and pathological eyes. No evil effects have apparently ensued, owing to the shortness of the exposure required. The results are better than any previously obtained, but they are far from perfect. Those who saw the original photographs at the International Ophthalmological Congress at Lucerne in 1904 will, however, condole with the author for the inferior halftone reproductions of the Imperial Academy.

We are forced to admire Prof. Dimmer's pertinacity in this research, at which he has been occupied since 1899. Considering the well-known dangers of very bright illumination upon the retina, the mediocre results obtained, and the doubtful utility in ophthalmic surgery, we cannot but hope that future experiments will be confined for the present to animals.

J. HERBERT PARSONS.

THE BIRDS OF THE ISLE OF MAN.[1]

THE present volume forms an addition to the now considerable list of those well-known and trustworthy "Faunas" of counties or special areas which have from time to time issued from the publishing house of David Douglas in Edinburgh. It is not an unworthy companion to them. The majority of its predecessors, however, have included the complete vertebrate fauna of the region dealt with, and, remembering the limited area of the Isle of Man, the present volume might well have done the same without increasing very seriously the labours of the author or the size of the book. It would then have been a useful complement to the "Vertebrate Fauna of Lakeland," by the late Rev. H. A. Macpherson, in the same series, and would have filled a blank.

It is rather surprising that, amid the numberless local faunas that have been published, we have as yet no complete work on the natural history of the Isle of Man, considering the numerous contributions, scattered, no doubt, through many periodicals, to its botany, zoology, geology, and antiquities that have been made by excellent and systematic observers from the days of Sir William Jardine and Edward Forbes onward. The present very complete volume on the birds is, however, heartily welcome. Its author, Mr. Ralfe, is well known in ornithological literature as one who has devoted much time to the study of the feathered fauna of his native Mona, "in the intervals of daily occupation and in more than usual isolation from the resources of science." He fully acknowledges his indebtedness to Mr. Kermode, whose name also, as he indicates, might well be bracketed with his own on the title-page, so intimately have they been associated together in bird-observation and record.

The detailed account of the species frequenting the island is prefaced by an introductory chapter containing sections on, among others, the topography of Man; on the history of Manx ornithology, in which the chief writers and their contributions are referred to; on Manx bird-names, so often expressive and musical; and on migration in Man. The latter is very disappointing. From so competent an ornithologist as Mr. Ralfe, with his residence on the island, which is a special rest-place on the main west coast fly-line, we might have looked for that chapter on the autumn and spring movements of the migratory stream which has yet to be written.

Nestling in the large north-western bight between England and Scotland, the Isle of Man has relationships with Lancashire, Lakeland, the three southernmost Scottish counties on its northern side, as well as with Ireland. Mr. Ralfe has carefully noted this relationship, where possible, by reference to the work of Service, of Gray and Anderson, of Macpherson and Mitchell, of Aplin, Coward and Oldham, and of Ussher and Warren. If we compare the number of species of birds recorded from Lancashire, as a neighbouring, accurately defined and well-worked area, with that from Man, we have 269 species from the several-times-larger county, against 183 from the smaller isle, indicating a fairly rich avifauna, notwithstanding its disadvantageous isolation, its bare heights, and its poverty in woodland and shrubberies. There are 75 residents and 18 summer visitors among the 93 nesting species of Man, against the 93 residents and 43 summer visitors comprising the 136 breeding birds of Lancashire. "Almost all birds generally distributed through the British Isles, at least as far as our latitude, are present. . . . Man agrees with Ireland and differs from the opposite counties of England in the absence or rarity of various small summer migrants," such as the garden warbler, redstart, tree-pipit, woodpecker, and others. The island, however, "is rich in rock-breeding coast birds, but rather lacking in shore-frequenting waders." Such is a summarised account.

The author has narrated concisely all that is worthy of record about the commoner species, reserving his space for fuller details in the history of others of special interest to the island. We find in regard to the carrion crow that it is the grey-headed form which is resident in Man, while the black race is practically absent, and, therefore, the island follows Scotland and Ireland and differs from England in the distribution of this bird. The following problem has often presented itself to us:—When the dimorphic forms (*cornix* and *corone*) of this species interbreed in considerable numbers on the border-line (*i.e.* along the line from the Firth of Clyde to the Adriatic) of their defined areas, and rear families of, say, three individuals of the *cornix* and three of the *corone* race in each nest, what induces the "greynecks" on the approach of the breeding season to hurry off to their proper side of the line, while their black nest-fellows feel constrained to reside to the southward of it? Ornithologists will be gratified to have Mr. Ralfe's assurance that the chough is not diminishing in numbers, but displays its scarlet beak and legs "abundantly on the steep brows which fall from the rocky hill-tops to the . . . . luxuriantly

foliaged sea-cliffs"; and that the peregrine falcons still occupy the ancient eyries in which they were protected for 300 years, although now their names are, strangely enough, not among those scheduled in the Wild Birds Protection Act. On the other hand, they will note with regret the extinction of the rock-dove and of the shearwater (which derives its name from the island), which were once so abundant among its cliffs.

This volume, if not perhaps quite up to the standard of some others of the series, is a conscientious and careful contribution to the natural history of Man. It is beautifully illustrated by two maps, as to the excellence of which no more need be said than that they are by Bartholomew, of Edinburgh, and by fifty full-page blocks of Manx scenery (most of them of favourite nesting-places of different species), a specimen of which, by the publisher's courtesy, is here reproduced. F.

THE BEAUFORT SCALE.[1]

ABOUT a hundred years ago, Admiral Beaufort, having felt the want of some scheme by which the winds could be classified according to their force, devised a plan which has been in uninterrupted use ever since. In the absence of mechanical anemometers he had to trust to personal experience and the observed effects of wind on the objects moved by it. As a sailor, he naturally selected ships as the objects moved. Calling a calm zero, and representing a hurricane, or a wind in which no ship could carry any canvas, by 12, he endeavoured to assign the intermediate numbers to winds the force of which could be gauged by the amount of sail that a well-conditioned ship of specified rig could carry. In the lapse of time sailing ships altered their rigging or disappeared altogether, with the result that the gallant Admiral's nomenclature became obsolete or unmeaning. Anemometers depending upon the application of some mechanical principle came into general use, and from the fact that these instruments gave a continual record, right or wrong, their register tended to supersede a plan, which relied simply on tradition and probably varied in individual observers. But it has always been felt that there existed some relation between the records of the anemometer and the Beaufort Scale, and various authorities have attempted from time to time to bring the two into accord, or to supply the means of expressing any given number in the Beaufort Scale as velocity reckoned in miles per hour. These well-meaning attempts have not enjoyed the unquestioned confidence of meteorologists, nor have they ensured uniformity in practice. Of late the Meteorological Office has instituted a rigorous inquiry into the estimates of wind force as made in the Beaufort plan and as recorded by anemometers, and have now issued their report.

A preliminary question presents itself to which it is difficult to give a completely satisfactory answer. Is the Beaufort Scale worth preserving? or, in other words, relying as the scale does on personal experience, is it capable of being reproduced with sufficient accuracy to ensure the maintenance of constancy in all circumstances and in all localities? This question must have presented itself to the Meteorological Office and been answered in the affirmative. The decision taken is probably justified. In many positions at sea it is not possible to use mechanical anemometers. In lawsuits and Board of Trade inquiries the vocabulary of the Beaufort Scale is in frequent use, and nautical assessors have to attach a definite meaning to it. On the other hand, are we sure that the automatic registration by anemometers has been correctly interpreted? Dr W. N. Shaw himself raises the question whether the hourly velocity is a suitable element for comparison. It is probably the best that can be done, but it may be that we are trying to compare a scale of doubtful utility with a record that is only imperfectly understood.

The anemometers in use in this country are of two kinds, that known as the Robinson, which gives us with accuracy the number of times that a system of hemispherical cups rotates in any specified interval, when mounted in a particular manner. The error, or possible error, in the use of this apparatus enters when we pass from the velocity of the cups to that of the wind. For years it was assumed that the wind velocity was three times that of the cups, a round number which of itself suggested that it was a rough approximation. The factor 2·1 or 2·2 is now proposed as more appropriate. But there is this further difficulty: that while the velocity of the wind in an hour is not constant, the method of registration smooths out the irregularities, so that the variations in the velocities become indistinguishable in the record. The other form of anemometer, known as the Dines Pressure Tube, shows the variation in the wind velocity by recording a succession of oscillations of considerable magnitude. The trace is such as results from a pen moving vertically with comparative rapidity over paper moving more slowly horizontally. To determine the mean velocity from this trace is a matter of some uncertainty. The eye naturally selects a line which may be taken as representing the mean velocity during the interval under examination. But the number of miles per hour indicated by the position of this line can only be known from experimental inquiry. These experiments have been conducted by Mr. Dines in an exhaustive manner, but the results must nevertheless be considered as empirical. It is upon these experiments that the constant for the Robinson anemometer has been changed. Finally, therefore, the problem resolves itself into reading the results derived from the experiments of Mr. Dines into the phenomena observed by sailors and others in deciding on the numbers used in the Beaufort Scale.

But assuming that the hourly wind velocity is correctly known at any moment, it would seem a tolerably simple matter to assign to each of the Beaufort numbers the corresponding wind velocity. We have simply to take the mean value of the velocities for all winds estimated as being of a given Beaufort number to get a scale equivalent in miles per hour. This has been done more than once, and a table of such equivalents has been issued under the sanction of the Board of Trade. Such a simple solution, however, by no means disposes of all the difficulties. Prof. Köppen pointed out that a different scale of equivalents was obtained, when the mean value of all the velocities assigned by estimate as of a given Beaufort number was taken, from that which resulted from taking the mean of the Beaufort numbers corresponding to given velocities. The first method of treatment may be described as that of Curtis, the second as that of Köppen. To explain the cause of the difference betwen the two methods was the problem submitted to Mr. G. C. Simpson, and very ably he has dealt with it. Unfortunately we cannot follow him in his details; we can only point out some of his results. The following table shows the relation between the Beau-

[1] "Report of the Director of the Meteorological Office upon an Inquiry into the Relation between the Estimates of Wind-Force according to Admiral Beaufort's Scale and the Velocities recorded by Anemometers belonging to the Office; with a Report by G. C. Simpson, M.Sc., and Notes by Sir G. H. Darwin, W. H. Dines, and Commander Hepworth." (Printed for His Majesty's Stationery Office. London, 1906.)

fort Scale numbers and the wind velocity measured in miles per hour as derived from the methods of Curtis and Köppen.

Beaufort No.	Miles per hour Curtis	Köppen	Beaufort No.	Miles per hour Curtis	Köppen
0	3·0	0·0	6	24·5	28·0
1	5·0	2·0	7	30·0	34·5
2	8·0	6·0	8	36·0	42·0
3	11·0	10·5	9	44·0	50·0
4	15·0	16·0	10	53	59·0
5	19·5	22·0			

Mr. Simpson not only shows the reason for the discrepancy between these two sets of numbers, but discusses the special problems to which each set is applicable. This part of the report is particularly interesting, since it displays the intricacy of the problems connected with anemometry. Besides the difficulties of a theoretical character, there is the additional fact that the scale is not sufficiently definite, nor the estimates sufficiently accordant, to warrant the presentation of an authoritative table of equivalents applicable to each number of the Beaufort Scale, and the Director contents himself with offering a less detailed statement which for practical purposes expresses the relation between Beaufort numbers and hourly velocities.

Beaufort Scale Nos.	Corresponding Wind	Limit of hourly velocity
0	Calm	Under 2
1–3	Light breeze	2–12
4–5	Moderate wind	13–23
6–7	Strong wind	24–37
8–9	Gale	38–55
10–11	Storm	56–75
12	Hurricane	Above 75

This table shows that 12 was too high a number, or the steps of the scale too small. The difference of velocity must be considerable before it becomes apparent to rough methods of observation.

W. E. P.

PROF. METSCHNIKOFF'S HARBEN LECTURES.

THE Harben lectures of the Royal Institute of Public Health have just been delivered by Prof. Elie Metschnikoff, of the Pasteur Institute, Paris, and Foreign Member of the Royal Society. The lectures, which contained matter of the greatest interest, and were admirably delivered, attracted large and appreciative audiences.

In the first lecture, delivered on May 25, Prof. Metschnikoff directed attention to the fact that persons may harbour disease germs without themselves manifesting any ill effects. A notable instance of this is the case of a woman, the proprietress of a bakery, who suffered from typhoid fever ten years previously, and whose employees always suffered from more or less gastro-intestinal disturbance, two of them dying from typhoid fever. Investigation proved that this woman was excreting numbers of typhoid bacilli. Why should such an infected person remain apparently well? Undoubtedly because she had acquired an immunity, the result of modifications of living parts of the body, in all probability of the phagocytic cells. All the evidence points to the phagocytes being the great line of defence against disease germs. Recently Dr. Wright advanced the hypothesis that the fluids of the body prepared the microbes for ingestion by the phagocytic cells by means of substances named *opsonins*; but experiments were quoted suggesting that phagocytosis takes place without any addition of opsonins. All observations lead to the conclusion that immunity against infective agents is the result of phagocytic action, is a function of the cells.

Persons addicted to alcohol are far less resistant to infective diseases than abstemious individuals, and experiments show that animals subjected to the influence of alcohol become more sensitive to harmful microbes, because the alcohol has a deleterious action on the phagocytes. It was therefore suggested that it might be wise to eschew alcohol (and other drugs) in the treatment of infective diseases. On the other hand, normal blood-serum and weak saline solutions increase the resistance towards pathogenic microbes, and cases were quoted showing the beneficial action of these substances in grave cases of disease and in major operations.

The second lecture, delivered on May 28, was on the hygiene of the alimentary canal. In all probability microbes frequently gain access to the circulation through the intestinal wall, and Prof. Metschnikoff supported the view that the virus of tuberculosis frequently gains access to the body by this portal. Parasitic worms are also a source of danger, and many cases of appendicitis can be ascribed to this cause. The data collected indicates that it is high time to undertake a campaign against the entozoa. To obviate the risk of intestinal infection, much may be done by taking cooked food only—boiled water and milk, boiled vegetables, cooked and not raw fruit, and no raw salads. The precautions suggested may appear difficult to carry out, but, once accustomed to them, they enter into practice without difficulty.

The third lecture, delivered on May 30, was devoted to a consideration of hygienic measures against syphilis. It was pointed out that the sufferers from this malady are very largely innocent victims. The subjects of anti-syphilitic sera and of anti-syphilitic vaccination were considered, and it was shown that both of these are at the present time impracticable. It has been shown that apes can be inoculated with the syphilitic virus, which gives a means of testing prophylactic measures, and as a result of experiment it has been found that the application of a calomel ointment well rubbed into the seat of inoculation will prevent infection if applied within twenty hours of inoculation. The results obtained on lower monkeys and on anthropoid apes agree so well as to justify the conclusion that the same method may also serve for the prevention of syphilis in man. It has been tried with successful results in the case of a medical student who volunteered for the experiment.

No considerations of a moralising tendency should be opposed to the prevention of so disastrous a calamity as syphilis. True morality should rather contribute as much as possible to the prophylaxis of this and many another disease.

The lectures will be published in full in the forthcoming numbers of the *Journal of Hygiene*.

NOTES.

BARON C. R. VON DER OSTEN SACKEN, author of numerous books and papers on the classification of Diptera, died at Heidelberg on May 20 in his seventy-eighth year.

NOTICE has been received that the title of the Field Columbian Museum, Chicago, has been altered. The institution is now designated the Field Museum of Natural History.

THE death is announced of Dr. Ernst Schellwien, professor of geology and palæontology, and director of the Amber Museum, Königsberg University, in his fortieth year.

DR. E. V. DUNGERN, professor of bacteriology and hygiene in the University of Freiburg (Baden), has been appointed director of the scientific section of the Krebsinstitut, Heidelberg.

PROF. ROBERT KOCH has written to the Berlin Medical Society resigning his position on the presidential board on the ground that he expects to remain at least two years in Africa in order to continue his investigations on sleeping sickness in conjunction with the German Imperial Expedition, of which he is the head.

DR. K. PAPE, formerly professor of physics in the University of Königsberg, died at Steglitz on May 9. He was born in Hanover in 1836, and held the professorship of physics in the agricultural academy in Proskau from 1866–1878, that is, until his appointment to the Königsberg chair, which he held until 1904.

IN No. 41 of the *Chemiker Zeitung* is a very useful *résumé* of the experimental advances made during 1905 in the subjects of physics and physical chemistry in so far as they appeal to the chemist. The report deals chiefly with radio-activity, stoichiometry, chemical dynamics, thermochemistry, photochemistry, and electrochemistry.

THE third International Conference on Plant Breeding, whether by hybridisation or by cross-fertilisation, will be held in London on July 30 to August 3 under the auspices of the Royal Horticultural Society. Successful conferences on this subject were held in London in 1899 and New York in 1902. The president of the forthcoming conference will be Mr. W. Bateson, F.R.S.

THE German Bunsen Society for applied physical chemistry held its annual general meeting in Dresden under the presidency of Prof. Nernst on May 20–23. The business of the meeting included some thirty-five papers, in a group of five of which the value and methods of the fixation of nitrogen for industrial and agricultural purposes were discussed, in another group colloidal bodies were considered, whilst other subjects brought forward were such as technical methods for examining explosives, radiation laws, &c.

THE hygienic exhibition in Vienna was opened by Duke Leopold Salvator in the presence of a distinguished company, including some of the chief representatives of Austrian and foreign science, industry, and commerce. Although originating from a private source, the exhibition has, under the support of the municipal and Imperial authorities, and the keen interest displayed by many European exhibitors, proved a great success; the practical results of the more important chemical, hygienic, and medical investigations of the last ten years are well brought out by the numerous exhibits, which have been divided into nine groups:—(1) domestic hygiene; (2) personal hygiene in health and sickness; (3) public hygiene; (4) general industrial hygiene; (5) chemistry, pharmacy, and investigations of foods; (6) hygienic precautions necessary in the liquor and food industries; (7) clothing industries and laundries; (8) travel and association with strangers; (9) hygiene of sport.

ON the recommendation of the Home Secretary, a Royal Commission has been appointed to inquire into the health and safety of miners. Lord Monkswell is chairman of the commission. Science is represented by Dr. J. S. Haldane, F.R.S., university lecturer in physiology, Oxford, and mining engineering by Sir Lindsay Wood, Bart., past-president of the Institution of Mining Engineers. The remaining six members of the commission are politicians and officials of eminence. The secretary of the commission is Mr. S. W. Harris, of the Home Office. Among the questions referred to the commission is whether any change is desirable in the present system of examination for managers' and under-managers' certificates of competency; whether the managers of metalliferous mines should be compelled to hold such certificates; and whether certificates granted by colonial Governments should not be accepted in this country. In view of the great importance of this branch of the inquiry, it is perhaps to be regretted that the commission does not include some recognised authority on mining education. Not any of the commissioners appear to have passed any examination in mining.

DR. L. A. BAUER, who has been in charge of the magnetic survey and observatory work of the United States under the auspices of the Coast and Geodetic Survey since 1899, has accepted an offer, made to him by the Carnegie Institution of Washington, of the post of permanent director of its department of terrestrial magnetism. Since the establishment of this department in 1904, Dr. Bauer has filled the duties of director in conjunction with his official duties in the Coast and Geodetic Survey, but soon after July 1 he will devote his entire time to the Carnegie Institution work, which has developed into what practically amounts to a general magnetic survey of the globe. The annual grants to the department are sufficient to keep in progress continuously an oceanic magnetic survey, besides the sending of expeditions to land areas where no magnetic surveys have as yet been made, and also for conducting various auxiliary investigations. An attempt is to be made to secure the completion of a general magnetic survey of the globe within a period of about fifteen years. During Dr. Bauer's administration of the Coast and Geodetic Survey magnetic work, covering a period of seven years, he has organised and trained a corps of observers, has put in operation five magnetic observatories, has inaugurated magnetic work on the Coast Survey vessels, has practically completed the general magnetic survey of the United States (the three magnetic elements having been observed at about 2500 stations distributed over the United States and outlying territories), and has issued various publications relating to the work.

A PAPER by Mr. Edgar Schuster, on the inheritance of deafness (*Biometrika*, vol. iv., part iv.), was referred to in NATURE of May 17 (p. 63). It was stated in the abstract supplied with the journal that an important point brought out in the paper is "the normal, or even more than average, fertility of deaf-mutes," and this point was mentioned in the note in NATURE. Mr. Schuster writes to say that the meaning can be better expressed by the conclusion "deaf-mutes have on an average the normal or rather more than the normal number of brothers and sisters, although they appear to have considerably less than the normal number of children."

We have received from Mr. T. P. Mallock, the well-known taxidermist and anglers' outfitter at Perth, an excellently illustrated catalogue of apparatus connected with salmon and trout fishing.

The crawfishes of the genus Cambarus inhabiting Mexico, Central America, and Cuba form the subject of a paper by Mr. A. E. Ortmann published in the Proceedings of the Washington Academy of Sciences (vol. viii., pp. 1–24), in the course of which several new forms are described.

The various modes in which insects are naturally protected—whether by mimicry, by resemblance to their surroundings, or by the offensive weapons with which they are furnished—form the chief subject of discussion in the May issue of *Museum News*. We note that the next number of that periodical will not make its appearance until October.

Mr. E. J. Spitta records some experiments relating to the compound eyes of insects (Journ. Quekett Microscopical Club, April). From these it is suggested that the facets of the insect cornea may be nothing but little holes, filled with some non-refractive medium, by which images may be formed in the same way as a pin-hole forms them. Many difficulties presented by the current theories of insect vision would on this hypothesis be obviated.

The articles in part v. of the fifth volume of *Annotationes Zoologicae Japonenses* comprise one by Dr. A. Oka on a new genus (Aphanibranchion) of ascidians from Japan; a second on variations in toads and in an isopod crustacean, by Mr. S. Goto; and a third, by Mr. A. Izuka, on collateral budding in an annelid. In the case of the toad the variations consist of the fusion of the seventh and eighth vertebræ, and of the formation of the sacrum by the tenth instead of by the ninth vertebra.

No. 3 of the Philippine Journal of Science (vol. i.) contains the second part of an article by Mr. C. S. Banks on the principal insects attacking the cocoanut palm, and another by the same author on some new Philippine insects. Messrs. W. R. Brinkerhoff and E. E. Tyzzer contribute an elaborate study of experimental variola and vaccinia in quadrumana, in which it is shown that vaccinia protects against variola and *vice versâ*, and that the structures described by Councilman, Magrath, and Brinckerhoff as intracellular parasitic protozoa (the *Cytoryctes variolae*) are present in the lesions.

The April number of the *Emu* opens with an account of a visit to an ibis "rookery" in a swamp in the Casterton district, Victoria, during the breeding season. The species breeding in the swamp are the straw-necked and the white ibises (*Carphibis spinicollis* and *Ibis molucca*). The firing of a shot reveals the enormous numbers of birds frequenting the rookery. "In a moment there is a wild commotion and the air seems whistling with the sounds of hundreds and thousands of wings, and then in one mighty cloud the whole assembly takes flight, making the sky look black and white; the effect being heightened by the long bills, outstretched necks, and general peculiar appearance of the birds." The coachwhip bird (*Psophodes crepitans*) and its nest form the subject of two excellent reproductions from photographs.

The work done on the insect-collection of the Oxford University Museum during the past year, and the condition and extent of the collection itself, receive special attention in the report of the delegates of the museum for 1905 (issued as a supplement to the *Oxford University Gazette*). Prof. Poulton lays great emphasis on the value of the services of Mr. R. Shelford, who has gained wide experience and knowledge as curator of the Sarawak Museum. Mr. Shelford's efforts have been chiefly directed to reduce to order the collection of Orthoptera, which, although one of the finest in the world, has hitherto been of little use to entomologists on account of want of proper arrangement and classification. In several sections of the collection—notably the one made by Burchell in South Africa—the insects were altogether unnamed, but this serious deficiency is being rapidly put right by Mr. Shelford's labours. In the course of handling the collection a large number of type-specimens have been identified. Many important additions have been made during the year to the collections generally, the curator of the Pitt-Rivers Museum reporting the acquisition of a number of specimens illustrating the ethnology of many parts of the world.

Has the Federal Government of the United States power to take remedial measures to prevent the spread of noxious insects, like the cotton-boll weevil or the gipsy-moth, in cases when individual States in the Union are not doing all in their power in this direction or are unable to do sufficient? Such is the question asked by Prof. E. D. Sanderson in the May number of the *Popular Science Monthly*, and from precedents derived from other legislation answered in the affirmative. It is, however, not only in the case of States that refuse to do their duty that the interference of the supreme Government is invoked. A case in point is afforded by the visitation of the gipsy-moth in Massachusetts. At the present time New Hampshire is able to defend its frontier from the pest, but a time will come when action in Massachusetts will alone prevent an invasion of the neighbouring State. Is it fair, it is asked, that one State should be thus heavily penalised for the common good? Individual adaptation to environment forms the subject of an article in the same issue by Prof. J. H. Blair; while Dr. R. W. Shufeldt communicates an illustrated paper on bird-photography in Norway.

In accordance with instructions of the Government of India, a Bombay correspondent of the *Pioneer Mail* reports, a provincial research laboratory has been established in connection with the existing plague research laboratory at Parel. The main objects of the laboratory are:—(*a*) To afford assistance to all Government medical officers in the discharge of their duties by fulfilling the functions of a "pathological diagnosis institute," to which specimens of all sorts may be sent for opinion. (*b*) To train hospital assistants and others in elementary clinical pathology, performance of inoculations and hypodermic injections, the preparation and use of disinfectants, and other duties they may be called upon to perform in connection with their duties as public health officials. (*c*) To afford opportunities to medical men who may wish to do original work for themselves or to practise or be instructed in new methods of diagnosis.

A report of the fruit conference held in October of last year under the joint auspices of the Royal Horticultural Society and National Fruit Growers' Federation is contained in the April number (vol. xxx.) of the journal of the former society, just issued. The volume includes much information of value to all who are interested in the cultivation of fruit.

IN the Trinidad Bulletin (April) Mr. J. H. Hart gives a list, with descriptions, of fourteen varieties of orange of which well-established plants can be supplied from St. Clair experiment station. The Pineapple and Jaffa are especially recommended; the list also includes Homosassa, Parson Brown, and Washington Navel; in fact, all the varieties have been carefully selected. A new edition of the guide-book to the Trinidad Gardens is to be published shortly, in which there will be special references to the features depicted by Kingsley in "At Last."

THE North American species of Festuca are collated by Mr. C. V. Piper in vol. x., part i., of the Contributions from the United States National Herbarium. In North America twenty-two perennial and twelve annual species are recognised, as compared with twenty-eight perennial and twenty-six annual species in Europe. In addition to the sheep and red fescues, *Festuca altaica* and *Festuca viridula* are regarded as excellent fodder grasses, and *Festuca octoflora* is valuable in semi-arid districts. The term "lemma" is adopted to signify the outer or lower palea. A number of plates accompany the text, and a tentative list of Mexican species is appended.

BOTANISTS who have attempted to classify the different varieties of such plants as rice, cotton, &c., that are extensively cultivated in India have noted the extraordinary power of discrimination manifested by the peasant cultivators. In a Bulletin (No. 55) recently published by the Madras Department of Agriculture on the great millet, *Sorghum vulgare*, a plant grown very widely as a food and fodder crop, Mr. C. K. Subba Rao enumerates with comparative notes more than sixty forms referable to seven botanical varieties. Three of these varieties are represented in other parts of India, and in addition there are the forms that would be grouped under fifteen varieties that are not represented in the presidency.

THE latest number, vol. xix., part i., of the Transactions of the Royal Scottish Arboricultural Society contains, as usual, a number of interesting papers on forestry subjects. A working plan for the Alice Holt woods in the east of Hampshire has been prepared by Dr. Schlich. In 1812 an Act was passed providing for the cultivation of navy timber in the forest, but owing to the low standard of the oak trees that occupy 95 per cent. of the area it is proposed to plant certain portions with beech, larch, and Douglas fir, and others with spruce and pine. Dr. R. S. MacDougall reports the discovery of larvæ of the chalcid species *Megastigmus spermotrophus* in seed of the Douglas fir received from Aberdeenshire, and adduces evidence to prove that the larvæ are really plant parasites. Mr. G. Brown provides some figures in connection with the natural regeneration of Scots pine at Beauly, and Prof. T. Hudson Beare points out a few of the difficulties in obtaining accurate results when testing timbers.

AN excess of rain is again shown by the weekly weather report of the Meteorological Office to have occurred over the entire country for the period ending May 26. The heaviest rains were experienced in the south-west of England, the measurement for the district being 1·64 inches, which is more than three times the average. The rainfall was about double the average in different parts of the kingdom. The aggregate rainfall for the spring months is deficient in the Midland counties and in the south and east of England, as well as in the Channel Islands, but mostly in excess in other parts of Great Britain. The total measurement since the commencement of the year is everywhere considerably in excess of the average.

THE eighth Bulletin of North Queensland Ethnography is entitled "Notes on Government, Morals, and Crime," but the four plates and part of the text deal with message sticks. Dr. Roth takes the view that they are merely mnemonic, and convey no communication properly so called. This statement seems to require qualification outside the area with which he deals; for instance, among the Mundainbura of Durham Downs certain marks have recognised meanings, and indicate the marriage classes; in a case reported by Dr. Howitt another tribe with the same classes interpreted correctly a stick sent to put this question to the test. The ordinary use of the stick is, however, mnemonic, and it also guarantees the *bona fides* of the messenger. In North Queensland the stick is sometimes carried at the end of a rod, as shown in NATURE of April 26 (vol. lxxiii., p. 610), but held vertically; the object of this is unknown. In addition to being figured in the plates, the thirty-three specimens are elaborately described. The purely mnemonic character of Dr. Roth's specimens is shown by the accompanying figures, which are alternative forms of stick for the same message. Interesting information is also given on customs of inheritance, a remarkable feature being the succession of females only to property in certain edible plants.

a *b*

FIG. 1.—So-called "letter" or "message" sticks, Boinjé tribe, Boulia. (*a*) Length, 6½ in.; breadth, ⅞ in. (*b*) Length, 5½ in.; breadth, ⅝ in., made in place of (*a*), which was stated to have been lost, in order to ascertain whether the same message necessitated similar markings, which it clearly did not.

WE have received a copy of the meteorological report of the Survey Department of Egypt for the year 1903, containing hourly observations at Abbassia Observatory (Cairo), monthly summaries at eighteen climatological stations in Egypt and the Sudan, and some additional rainfall results. The value of the work is much enhanced by graphical representations of the Abbassia observations. In a preliminary examination of some of the data, the superintendent points out that the rainfall at Abbassia and the southern Delta generally is small and irregular, but that it was thought worth while to see whether it showed any signs of periodicity such as that assigned to it in India or Mauritius by Sir Norman Lockyer. A smoothed rainfall curve for the years 1888–1900 shows some resemblance to the inverse sun-spot curve, especially in the coincidence of the maximum of the sun-spots and the minimum of the rainfall in the year 1893.

DR. W. N. SHAW's lecture at the University of London on May 24 brought this most interesting series to a close. The audience no doubt shared the lecturer's views as to the difficulty of dealing sufficiently with the subject in the space of four hours; we hope that the matter will not be allowed to drop, and that the example set by the London University will be followed by other institutions. The subjects specially dealt with in this last lecture were the variations in the several elements from year to year, the relation of the yield of wheat to rainfall in the British Isles, and illustrations of sequences in seasonal variations in various parts of the globe. Some slides lent by Dr. Lockyer showed very clearly the opposite variations of the pressure curves for different localities, and the similarity between the march of rainfall and inverted pressure curves. The lecturer pointed out that several such relations were beginning to be detected, but that more work was wanted; some of the results could only be considered as temporary at the present time. Some very remarkable illustrations were given of the apparent dependence of the yield of wheat on the rainfall of the previous autumn, although other factors, *e.g.* temperature and spring rainfall, undoubtedly exert an influence on the general result. The values seemed to show an unmistakable relation to an eleven years' periodicity. Diagrams were also shown exhibiting an apparent notable connection between the south-east trade wind velocity in the Atlantic and English rainfall (see also NATURE, December 21, 1905).

The Maryland Geological Survey has established a permanent State mineral exhibit in the old House of Representatives at Annapolis. We learn from *Science* that the materials forming this exhibit have been gradually collected by the survey during the last few years, the nucleus being the Maryland mineral exhibit at Buffalo in 1901. This was materially added to in the preparation of the State's exhibit at Charleston the following winter, and was still further increased for the Maryland exhibit for the Louisiana Purchase Exposition at St. Louis in 1904. The latter display has again been much enlarged for the present purpose, and is intended to illustrate thoroughly the mineral resources and industries of the State.

We have received a copy of the report issued by the Home Office (Cd. 2911, price 1*s.* 9*d.*) on statistics relating to persons employed, output, and accidents at mines and quarries in the British colonies and in foreign countries in 1904. The number of persons employed at home and abroad was about five millions, of which one-fifth were employed in the United Kingdom and one-third in the British Empire. More than half the total were employed in getting coal, of which the world's production was 886 million tons, valued at 295 million pounds sterling. Of the world's gold output, 16,593,856 oz., valued at 67,000,000*l.*, the British Empire supplied 60 per cent., the Transvaal contributing $22\frac{3}{4}$ per cent., Australia $22\frac{1}{2}$ per cent., and Canada $4\frac{3}{4}$ per cent. The United States contributed $23\frac{1}{2}$ per cent. In coal mines the death-rate from accidents per 1000 employed was 1·24 in the United Kingdom, 1·24 in the British Empire, 1·90 in Germany, and 3·35 in the United States.

The *Pioneer Mail* states that the establishment of permanent wireless telegraph stations at Frasergunj and Akyab is now under the consideration of the Government of India.

The April and May numbers of the Journal of the Franklin Institute are devoted almost entirely to a report of the proceedings on the occasion of the 200th anniversary of Franklin's birth. An address delivered by Prof. Edwin J. Houston, on Franklin as a man of science and an inventor, is printed in full, and gives an extended account of the life-work of the great discoverer. An account is also given of the Benjamin Franklin trust funds to the cities of Boston and Philadelphia. The Journal of the Society of Arts for April 27, referring to the bicentenary celebration, of which an account was given in NATURE of May 10 (p. 36), provides interesting particulars of Franklin's relations with the Society of Arts.

Messrs. Dickinson and Shields, Alliance Mills, Stoke Newington, have sent us a short pamphlet with respect to their bubble fountain, the chief fault of which is that it does not contain any description of how the bubble fountain is formed. However, assuming it to be formed, the bubble fountain consists of a series of soap bubbles, made even at the rate of 20,000 per minute, which may be blown with coal gas, and sent up by day or by night, when, if illuminated by the sun or artificially, it affords an interesting and beautiful phenomenon. At night, further interest may be given by firing the fountain, when the flame will run up the stream of bubbles. Intermittent groups of bubbles are suggested as an excellent target for gun practice, cheaper than glass or clay, and obviously it is more humane than the murder of live pigeons. It is stated that a large example may shortly be seen at the Crystal Palace.

On the British Association journey to and from South Africa a careful watch was made by many members of the party for the "green ray" visible for an instant just at the time of disappearance of the setting sun below a clear horizon. A note has been contributed on this subject to *Symons's Meteorological Magazine* for March and April by Prof. Rambaut, F.R.S., who was one of the party. Prof. Rambaut finds that the phenomenon can be entirely accounted for by the generally received view of the chromatic dispersion of the atmosphere combined with selective absorption. It is not necessary to make elaborate experiments or to go a sea voyage in order to observe the "green ray." By fixing a screen half covering the focal plane of a telescope, or, better still, a diaphragm with a narrow diametral slit, a green or blue flash can be seen at the top of the sun's disc and a red fringe at the bottom any time that the sun is near the horizon, and the observation can be repeated as often as desired.

"The Grape Curculio" is the title of the 100th Bulletin of the West Virginia University Agricultural Experiment Station at Morgantown, in which Mr. F. E. Brooks deals with the damage inflicted on vineyards by the weevil *Craponius inaequalis*. For several years past complaints have come from vine-growers in Virginia in regard to insects that "sting" grapes, causing them to become "wormy" and to drop from the vines while unripe. The insect is the above-named weevil, and careful experiments have been conducted with the view of mitigating the damage caused by its attacks. Spraying and protecting the clusters by enclosure in bags are recommended as the most effectual remedies.

The first division of the third part of the catalogue of the Indian decapod crustacea in the collection of the Indian Museum has been received. Part iii. deals with the Macrura, and in the section just issued Dr. A. Alcock, F.R.S., describes the prawns of the Peneus group.

In the notice of the okapi in our last week's issue (p. 88) the description of the animal's habitat should have been attributed to Captain Gosling instead of to Captain Alexander.

Messrs. Philip Harris and Co., Ltd., have just issued an illustrated catalogue of instruments for practical work in geography. The catalogue includes descriptions of simple instruments for map making and other field work, determination of position, and meteorological observations.

In the notice of "Oologia Universalis Palæarctica" in Nature of May 24 (p. 79) reference was made to the shortcomings of the English text. Messrs. Williams and Norgate ask us to state that arrangements have been made with Mr. Oliver G. Pike to revise the English text, so that in future the work may not suffer from imperfections of expression due to poor translation.

The "Statesman's Year-book" (Macmillan, price 10s. 6d. net) continues to grow in size and value. The 1906 issue is some 150 pages larger than its immediate predecessor. Separate notices of the States included in the American union have this year been introduced for the first time. Recent important events have led to other changes in the year-book, and among these may be mentioned the dissolution of the union between Sweden and Norway, the peace between Russia and Japan, the mission to Tibet, and the last general election. The maps and diagrams, which are always an attractive feature of the publication, this year deal with the economic development of the United States, the new provinces of Canada, the division of Bengal, the Anglo-Portuguese Barotse boundary, the political changes in the Far East, the races of Russia, and the tariff chart of the world. The volume now runs to lxiv+1604 pages. The editor, Dr. J. Scott Keltie, is to be congratulated upon the forty-third issue of this indispensable work of reference.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in June:—

June 2. 15h. Conjunction of Venus and Neptune. (Venus 2° 24′ N.).
7. 10h. 45m. to 11h. 51m. Moon occults μ Sagittarii (mag. 4·0).
10. 3h. Jupiter in conjunction with the Sun.
,, 13h. 43m. to 14h. 46m. Moon occults ι Capricornii. (mag. 4·3).
12. 18h. Saturn in conjunction with the Moon. Saturn 0° 56′ N.).
15. Venus. Illuminated portion of disc = 0·849. Of Mars = 0·997.
16. 10h. 19m. Minimum of Algol (β Persei).
21. 21h. Sun enters Cancer. Summer commences.
24. 10h. Venus in conjunction with the Moon. (Venus 2° 29′ N.).
26. 5h. 3m. Moon approaches very near to α Leonis (Regulus).
28. 16h. Uranus in opposition to the Sun.
,, Saturn Outer major axis of outer ring = 41″·47. Outer minor axis of outer ring = 2″·31.

Photographing the Corona without a Total Eclipse.—Numerous experiments have been devised and carried out in the attempt to obtain photographs of the solar corona during ordinary sunlight, without waiting for the rare occasions on which the sun is totally eclipsed. Hitherto no decided success has rewarded these efforts, but another attempt is to be made by MM. Millochau and Stefanik with an equipment mounted on the summit of Mont Blanc.

These observers propose to employ a spectroheliograph such as is now used at several solar physics observatories to obtain monochromatic images of the chromospheric clouds and prominences, but, instead of using one of the calcium or hydrogen lines on the second slit, they propose to isolate the chief corona line, at λ 5303, and to eliminate the light of other radiations by means of an appropriate green screen.

Preliminary experiments with this apparatus at Meudon have given encouraging results, and the observers hope that, in the clear atmosphere of the mountain summit, indubitable success will be attained (*Comptes rendus*, No. 17, 1906).

Terrestrial Temperatures and the Solar Radiation.—In the report of the Smithsonian Institution for the year ending June 30, 1905, Mr. C. G. Abbot, who has charge of the Astrophysical Observatory, discusses the recent observations of solar radiation and its connection with terrestrial temperatures.

This matter was discussed by the late Prof. S. P. Langley in the *Astrophysical Journal* for June, 1904, who then arrived at the conclusion that the evidence available indicated that the total solar radiation may vary in comparatively brief periods, and that the irregular variations were frequent and large enough to produce considerable changes of the earth's mean temperature.

In the present communication Mr. Abbot summarises the results obtained since 1902, and, by comparing the values found for the transmission of the solar envelope, and the consequent transmission of the solar radiations to the earth, with the variations of temperature at a number of stations situated in the terrestrial north temperate zone, he has deduced evidence which strongly supports Prof. Langley's theory.

High values of solar radiation and solar transmission appear to precede and to accompany high temperatures in the north temperate zone, and *vice versâ*.

The tables and curves which appear in the report substantiate this view, and Mr. Abbot expresses the hope that the study of the solar radiation will soon prove a valuable aid in forecasting climate.

The Distribution of the Stars.—In No. 7 of the Publications of the Groningen Astronomical Laboratory Prof. Kapteyn published the material on which he based his studies on the distribution of the stars in space, the distribution of cosmical velocities, &c., and also gave the results of five separate computations based on three different values of the precession and three different positions of the apex of the solar motion.

In this publication 2640 stars of Bradley's catalogue were grouped in ten degrees of declination, and the results given in two tables, the first of which contained the stars having spectra of Secchi's second type, the second the stars of type i. and unknown spectra.

No. 9 of the same publications contains the results of a *sixth* computation based on more refined data and arranged in a different manner. Instead of grouping the stars according to declination, Prof. Kapteyn has arranged them in zones of Galactic latitude, because, in considering the structure of the universe, it is obviously desirable to take the Milky Way as the fundamental plane. Also, instead of including the stars having unknown or peculiar spectra with those of type i., he has placed them in a table by themselves. In this way he has discussed the distribution and proper motions of 1093 stars belonging to type ii., 1144 stars belonging to type i., and 381 stars the spectra of which have not yet been recognised as belonging to either of Secchi's groups.

The complete catalogue should prove of exceptional interest and usefulness to anyone engaged in any discussion on cosmical evolution, and it would be exceedingly interesting to see what modifications might be necessary if the stars were divided into subgroups according to their ascending and descending temperatures as given in Sir Norman Lockyer's classification.

Observations of Comets.—The results of a number of observations of various comets, made at the Chamberlin Observatory (Denver) by Prof. H. Howe during the period November, 1904, to June, 1905, appear in No. 4091 of the *Astronomische Nachrichten*.

Six comets are included, of which comet 1905 i. (Encke) was observed from November 11 to December 27, 1904, and at times appeared to have a faint nucleus and an eccentric, fan-shaped tail. At 6h. 20m. (local M.T.) on December 5 a star of mag. 9·0 shone so lustrously through the comet that the nucleus was invisible.

Half an hour later the nucleus, which was near the following end of the comet, was plainly visible.

THE TARPAN AND ITS RELATIONSHIP WITH WILD AND DOMESTIC HORSES.[1]

SO much progress has been made during recent years in working out the origin and history of domesticated horses that the time has now come when inquiries may be profitably pursued along certain definite lines.

In the first place (assuming that horses have had a multiple origin), inquiries should be instituted with the view of ascertaining so far as possible the characteristics of the post-Glacial species and varieties which have taken part in forming the present domestic races and breeds; in the next place, inquiries should be instituted with the view of ascertaining to which of the lower Pleistocene species the more immediate ancestors of the living horses are most intimately related; and, in the third place, an attempt should be made to determine from which of the ancestral forms the various domesticated breeds have inherited their more striking characters, *i.e.* to ascertain to which ancestral types the Shire, Clydesdale, Percheron, and other heavy breeds, the Barb, Arab, thoroughbred, Kattiawar, and other slender-limbed breeds, are indebted for their chief peculiarities.

In this paper I shall not attempt to show that either Prejvalsky's horse, the Celtic pony, or the Libyan variety recently described by Prof. Ridgeway[2] is genetically related to pre-Glacial species, or entitled to be regarded as an ancestor of one or more domestic breeds.

Sufficient data for a discussion of this kind is not yet available. I propose now, by way of clearing the ground for the investigations mentioned above, to inquire whether the Tarpan (long regarded as the wild progenitor of the common horse of Europe) deserves a place amongst the ancestors of living races and breeds.

The first account of the Tarpan[3] we owe to Gmelin, who came across a troop near Bobrowsk during his journey through Russia between 1733 and 1743. He describes them as mouse-coloured, with a short, crisp mane; the tail always shorter than in domestic horses, sometimes full, sometimes only furnished with short hair; the legs dark from the knees and hocks to the hoofs; and the head thick, with the ears sometimes long, sometimes short.

Since this description appeared, some Continental naturalists have regarded the Tarpan as a true wild species; others, like Dr. Nehring, considered it the last survivor of the ancient prehistoric horses of Europe modified by an infusion of domestic blood; while not a few agreed with Pallas that the Tarpan herds might very well be the offspring of escaped domestic horses.

English naturalists have, as a rule, adopted the view of Pallas.

Notwithstanding all that has been written on the subject since Gmelin's time, hippologists agree with Salensky that the relationship of the Tarpan with wild and domestic horses has not yet been cleared up.[4]

During the nineteenth century very little was done towards determining the systematic position of the Tarpan; but in 1866 a Tarpan foal was captured in the Zagradoffe Steppe and reared by a domestic mare. When about eighteen years old this specimen was sent to the Moscow Zoological Garden, and eventually described in a paper published by Schatiloff.

This, like Gmelin's specimen, had a somewhat coarse head, was of a mouse colour, with legs black below the knees and hocks. The mane, however, instead of being short and crisp, as in Gmelin's specimen, was 48 cm. in length and hanging to one side of the neck.

As clearly realised some years ago by Gray, of the British Museum, certain vestigial structures, known as callosities, warts, or chestnuts, are of considerable taxonomic value. Warts or chestnuts, as is well known, are present on both the fore and hind limbs of the common horse, and they also occur on the hind as well as the fore limbs of Prejvalsky's horse; while in the Celtic pony, as in asses and zebras, the hind chestnuts are completely absent. It is especially worthy of note that though the hind chestnuts were not invariably present in Tarpans (they were absent in a Tarpan described by Krymsch), they were present in the Moscow specimen.

It thus appears that the Moscow Tarpan agreed in its colour with the specimens referred to by Gmelin and Pallas, but differed in the mane and tail, in both of which, as in its callosities, it resembled the common horse, *Equus caballus*. Two Tarpan skeletons have been preserved. The chief point of interest about these skeletons is that, as in the kyang and Prejvalsky's horse, and in certain Arabs, there are only five lumbar vertebræ.

In having only five lumbar vertebræ these Tarpans differed from the common horse of Europe, at least from the forest variety *E. caballus typicus*, in which I have invariably found eighteen pairs of ribs and six lumbar vertebræ.

G. A. Ewart.

FIG. 1.—The mouse-dun Tarpan-like cross between a Shetland mare and a black Welsh pony. This pony, though a cross, looks as if it belonged to an old-established race. It has a striking, well formed, massive head, well-placed ears, full eyes, good quarters, and excellent limbs. The mane is, however, short and semi-erect, while the tail consists of three kinds of hair which differ in structure, thickness, colour, and arrangement. From a photograph taken September, 1905.

From this striking difference in the skeleton it follows that, even should the Tarpan turn out to be a true wild species, it cannot be regarded as the sole ancestor of the common horse of Europe.

As to the skull of the Moscow skeleton, Czerski came to the conclusion that it has, on the one hand, all the characteristics of Oriental horses, while on the other it approaches the Scottish breed to which belongs the pony.

The skull of the Tarpan in the St. Petersburg Museum resembles skulls of immature specimens of *E. prejvalskii*, but the bones of the limbs and limb girdles are decidedly more slender, and have less pronounced muscular ridges than in the wild horse of Central Asia.

It may here be mentioned that for more than a century all the horses living in a wild state in Europe, which happened to be of a mouse-dun colour, seem to have been regarded as Tarpans.

Seeing that herds of mouse-dun wild horses no longer occur in Europe, and have not during recent years been met with in even the most remote parts of Central Asia, it might perhaps be assumed that the Tarpan's place in nature must for ever remain a mystery.

[1] By Prof. J. C. Ewart, F.R.S. Abridged from the Proceedings of the Royal Society of Edinburgh, Session 1905–6, vol. xxvi., part i.

[2] "Origin and Influence of the Thoroughbred Horse" (Cambridge, 1905).

[3] By the Tarpan I mean the mouse-dun horse of Russian and other Continental naturalists, not the so-called "true" Tarpan of Hamilton Smith ("Naturalists' Library," vol. xii., 1841).

[4] The chief papers on the Tarpan are mentioned by Salensky, "Monograph on Prejvalsky's Horse" (St. Petersburg, 1902).

This was the conclusion I arrived at when my attention was first directed to the subject. But having ascertained that, by crossing carefully selected forms, remote types are sometimes restored in all their original purity, I thought it worth while to make some experiments.

I selected for my Tarpan experiments a mouse-dun Shetland pony mare, which seemed to me to be a blend of at least three varieties—in its head it suggests the wild horse; in its mane, tail, and trunk it takes after the forest variety; while in the limbs and hoofs it approaches the Celtic pony. This mare was crossed with a black Welsh pony, which belongs to an ancient British race, and doubtless has in its veins not a little Celtic blood.

The first foal, black like the sire, but Celtic in make, failed to throw any fresh light on the question at issue.

G. A. Ewart.

FIG. 2.—Tail and hind quarters of the Scottish Tarpan from a photograph taken at the same time as Fig. 1. As in the wild mare the hair of the tail consists of three portions. The basal portion only essentially differs from the corresponding portion in Fig. 3 by being of less extent and lighter in colour; the middle portion is also lighter in colour and more plentiful than in the wild mare, while the hair growing from the end of the dock in the Tarpan very closely agrees in colour and amount with the terminal portion of the tail in Prejvalsky's horse.

Though in the first foal the Celtic blood prevailed, the second foal by the same sire has developed into an animal (Fig. 1), now three years old, which, though bred in Scotland, will, I believe, be regarded by Continental naturalists as typical a Tarpan as ever roamed the Russian steppes.

This Scottish Tarpan, a mouse-dun with black points, has a distinct dorsal band (10 mm. to 15 mm. in width) and faint bars above the knees and hocks, a somewhat heavy head, but a short body and well-formed limbs. The mane, of a light colour along each side, but dark in the centre, is semi-erect, some of the hair arching to the right, some to the left, and some forwards between the ears to form an imperfect forelock. The mane, which resembles that of zebra-horse hybrids, conforms to the description of the mane given by Pallas, but differs from the short crisp mane of Gmelin's specimen, and still more from that of the Moscow Tarpan, which, it will be remembered, reached a length of 45 cm., and hung to one side of the neck. In the dun Shetland dam, the mane lies close to the right side of the neck, but never exceeds a length of 35 cm. In the Scottish Tarpan the mane, from 15 cm. to 27·5 cm. in length, is either nearly upright, or, as already mentioned, arches outwards well clear of the neck (Fig. 1), whereas in a Fetlar (Shetland-Arab) pony of the same age the mane reaches a length of 45 cm. and clings to the side of the neck. The tail of the new Tarpan (Fig. 2) is even more remarkable than the mane. The dock, which is 27·5 cm. in length, is furnished with three kinds of hair. The basal portion for 6·5 cm. carries fine hair nearly circular in section, which, except in the part continuous with the dorsal band, is almost colourless; the middle portion of the dock—about 13·75 cm.—carries thicker hair, slightly oval in section, with a thick cortex containing in some cases a considerable amount of pigment; from the terminal part of the dock—about 7·5 cm.—spring coarse black hairs, which are now long enough to reach the ground. These long hairs are oval in section, have a very thick cortex, and only a small central axis or medulla.

The fine, short, light-coloured hairs (7·5 cm. to 15 cm. in length) at the base of the tail form a conspicuous somewhat lozenge-shaped bunch (Fig. 2); the thicker hairs growing from the middle section of the dock reach a length of 30 cm. They emerge from under the light-coloured root hairs and expand to form a sort of fringe, from which escape the relatively few long black hairs of the distal part of the dock.

G. A. Ewart.

FIG. 3.—Hind quarters and tail of a three-year-old wild mare (*E. prejvalskii*) from a photograph also taken in September, 1905. In the upper part of the tail the hair, light in colour and relatively fine, grows obliquely outwards from the caudal portion of the dorsal band; the hair of the middle part of the tail, darker and stronger than that of the root, lies nearly parallel with the dock and reaches to the level of the hocks; the hair of the tip, black, coarse and scanty, but long enough to reach the ground, emerges from within the hair forming the middle part of the tail. Like the hair of the mane, the light hair at the root of the tail is shed annually.

In having a limited number of long hairs growing from the distal end of the dock, this cross-bred pony decidedly differs from the Celtic as well as from the forest types of horses. The interest of the tail in the Scottish Tarpan is not so much that it suggests a mule as that it has a very striking resemblance to the tail of Prejvalsky's horse (Fig. 3). The only difference is that in the true wild horse the upper or light-coloured section of the tail is longer than in the Shetland-Welsh cross, which has, in fact, the kind of tail one would expect in a Prejvalsky hybrid in which the wild blood was dominant.

A study of the mane and tail of the Shetland-Welsh cross, and of certain other crosses and breeds, strongly suggests that we must include amongst the ancestors of our domestic horses a species having a mane and tail such as we find in the wild horse still living in Central Asia. In the body hair and the foot-locks the Scottish Tarpan closely resembles the wild horse. Further, it resembles the wild horse in having a very short flank feather, but differs in having the face whorl situated above the level of the eyes, as in the Celtic pony; in Prejvalsky's horse, as in the kyang, this whorl lies well below the level of the orbits.

In the Shetland mare the dorsal band is nearly as narrow as in the Celtic pony; the right hind chestnut measures 1·5 cm. by 0·4 cm., while the left is only 0·5 cm. in diameter; the front ergots are absent, and the hind ergots are very small. In all these points the Shetland mare approaches the Celtic type. In the Scottish Tarpan the front ergots are small, the hind normal; the front chestnuts are oval as in the wild horse, but decidedly smaller, while the hind chestnuts are only one-fifth the length of those in the wild horse. Finally, in the head, ears, form of the limbs and hoofs, the Tarpan-like Shetland-Welsh cross is as nearly as possible intermediate between a wild horse and a Celtic pony. Of the skeleton it is, of course, impossible to speak, but, judging by the shortness of the trunk, the form of the head, and the conformation of the limbs, the probability is that there are only five lumbar vertebræ, as in the Moscow and St. Petersburg skeletons, and that the skull and limb bones resemble those of a young Prejvalsky horse. After very full consideration, Salensky some years ago came to the conclusion that the Tarpan is a type specialised more to the side of *E. caballus* than to *E. prejvalskii*.

When all the facts now available are taken into consideration, there seems no escape from the conclusion that the Tarpan, once common in the east of Europe, cannot be considered as a true wild species.

Further, it may be assumed that the Tarpan herds were derived from at least three primitive stocks, viz.:—(1) from a variety or species identical with or closely related to the wild horse (*E. prejvalskii*) still surviving in Central Asia; (2) from a variety having the characteristics of the Celtic pony—*E. c. celticus*; and (3) from a variety resembling the forest horse—*E. c. typicus*. It is only by assuming the multiplex origin of Tarpans that it is possible to account for some of them having a heavy head, long ears, a nearly upright mane, a mule-like tail, and five lumbar vertebræ, thus suggesting *E. prejvalskii*; for others, wanting the hind chestnuts and possessing a skull like that of certain Scottish ponies, thus suggesting *E. c. celticus*; and for others having a thick head, full mane and tail, and hind as well as front chestnuts, thus suggesting *E. c. typicus*.

By experiments now in hand I hope to settle what part Prejvalsky's horse has taken in forming the Tarpan. If I succeed in showing that crosses between Prejvalsky's horse and either the forest, Celtic, or Libyan variety are practically identical with the cross between the Shetland mare and the Welsh pony stallion, I shall prove that at least certain of the domesticated breeds are indebted to Prejvalsky's horse for some of their characteristics, and at the same time bring additional evidence in support of my view that domesticated races have had a multiple origin, and include plain as well as striped forms amongst their less remote ancestors—have not, in fact, as Darwin thought, descended from a single dun-coloured more or less striped primitive stock.

THE FIGURE AND STABILITY OF A LIQUID SATELLITE.[1]

MORE than half a century ago Edouard Roche wrote his celebrated paper on the form which a liquid satellite will assume when revolving, without relative motion, about a solid planet.[2] As far as I know, his laborious computations have never been repeated, and their verification and extension form a portion of the work contained in the present paper.

Two problems involving almost identical analysis, but very distinct principles, are here treated simultaneously. If we imagine two detached masses of liquid to revolve about one another in a circular orbit without relative motion, the determination of the shapes of each of them is common to both the problems; it is in the conditions of their secular stability, according to the suppositions made, that the division occurs.

The friction of the tides raised in each mass by the attraction of the other is one cause of instability. If now the larger of the two masses were rigid, whilst still possessing the same shape as though liquid, the only tides subject to friction would be those in the smaller body. It amounts to exactly the same whether we consider the larger mass to be rigid or whether we consider it to be liquid, and agree to disregard the instability which might arise from the tidal friction of the tides generated in it by the smaller body. Accordingly I describe secular stability in the case just considered as "partial," whilst complete secular stability will involve the tidal friction in each mass.

The determination of the figure and partial stability of a liquid satellite is the problem of Roche. It is true that he virtually considered the larger body or planet to be a rigid sphere, but in this abstract the distinction introduced by the fact that I treat the planet as ellipsoidal may be passed over. It appears that, as we cause the two masses to approach one another, the partial stability of Roche's satellite first ceases to exist through the deformation of its shape, and certain considerations are adduced which show that the most interesting field of research is comprised in the cases where the satellite ranges from infinite smallness relatively to the planet to equality thereto.

The limiting partial stability of a liquid satellite is determined by considering the angular momentum of the system, exclusive of the rotational momentum of the planet. This corresponds to the exclusion of the tidal friction of the tides raised in the planet. For any such given angular momentum there are two solutions, if there is any. When these two solutions coalesce for minimum angular momentum, we have found a figure of bifurcation; for any other larger angular momentum one of the solutions belongs to an unstable series and the other to a stable series of figures. Thus, by determining the figure of minimum partial angular momentum, we find the figure of limiting partial stability.

The only solution for which Roche gave a numerical result was that in which the satellite is infinitesimal relatively to the planet. He found that the nearest possible infinitesimal satellite (which is also in this case the satellite of limiting partial stability) has a radius vector equal to 2·44 radii of its spherical planet. He showed the satellite to have an ellipsoidal figure, and stated that its axes were proportional to the numbers 1000, 496, 469. In the paper the problem is solved by more accurate methods than those used by Roche, and it is proved that the radius vector is 2·4553, and that the axes of the ellipsoid are proportional to 10,000, 5114, 4827. The closeness with which his numbers agree with these shows that he must have used his graphical constructions with great care.

For satellites of finite mass the satellite is no longer ellipsoidal, and it becomes necessary to consider the deformation by various inequalities, which may be expressed by means of ellipsoidal harmonic functions.

The general effect for Roche's satellites of finite mass in limiting partial stability is that the ellipsoidal form is very nearly correct over most of the periphery of the satellite, but at the extremity facing the planet there is a tendency to push forth a protrusion towards the planet. In the stable series of figures up to limiting stability this protrusion is of no great magnitude, but in the unstable series it would become strongly marked. When the unstable figure becomes much elongated, we find that it finally overlaps the planet, but before this takes place the approximation has become very imperfect.

Turning now to the case of complete secular stability, where the tidal friction in each mass is taken into account, we find that for an infinitely small satellite limiting stability occurs when the two masses are infinitely far apart. It is clear that this must be the case, because a rotating liquid planet will continue to repel its satellite so long as it has any rotational momentum to transfer to orbital momentum through the intervention of tidal friction. Thus an infinitesimal satellite will be repelled to infinity before it reaches the configuration of secular stability. As the mass of the satellite increases, the radius vector of limiting stability decreases with great rapidity, and for two equal masses, each constrainedly spherical, the configuration is reached when the radius vector is 2·19 times the radius of either body.

When we pass to the case where each liquid mass is a figure of equilibrium, the radius vector for limiting stability is still infinite for the infinitely small satellite, and diminishes rapidly for increasing mass of the satellite. When the two masses are equal the radius vector of limiting stability is 2·638 times the radius of a sphere the mass of which is equal to the sum of the masses of the two bodies. This radius vector is considerably greater than that found in the case of the two spheres, for the 2·19 radii of either sphere, when expressed in the same unit, is only 1·74. Thus the deformations of the two masses forbid them to approach with stability so near as when they were constrainedly spherical.

[1] By Sir G. H. Darwin, K.C.B., F.R.S. Read before the Royal Society on February 8.

[2] Mém. Acad. Sci. de Montpellier, vol. i., 1847–50, p. 243.

In all these cases of true secular stability, instability supervenes through tidal friction, and not, as in the case of Roche's problem, through the deformation of figure.

When Poincaré announced that there was a figure of equilibrium of a single mass of liquid shaped something like a pear, he also conjectured that the constriction between the stalk and the middle of the pear would become developed until it was a thin neck; and yet further that the neck might break and the two masses become detached. The present revision of Roche's work was undertaken in the hope that it would throw some light on the pear-shaped figure in the advanced stage of development.

As a preliminary to greater exactness, the equilibrium is investigated of two masses of liquid each constrainedly spherical, joined by a weightless pipe. Through such a pipe liquid can pass from one mass to the other, and it will continue to do so until, for given radius vector, the masses of the two spheres bear some definite ratio to one another. In other words, two spherical masses of given ratio can be started to revolve about one another in a circular orbit, without relative motion, at such a distance that liquid will not pass through a pipe from one to the other.

The condition for equilibrium is found to be expressible in the form of a cubic equation in the radius vector, with coefficients which are functions of the ratio of the masses. Only one of the three roots of the cubic has a physical meaning, and in all cases the two masses are found to be very close together; but the system can never possess secular stability.

When the masses are no longer constrainedly spherical the equation of condition for equilibrium, when junction is effected by a weightless pipe, becomes very complicated, and can only be expressed approximately. It appears that in all cases, even of Roche's ellipsoids in limiting stability, the masses are much too far apart to admit of junction by a pipe; but when we consider the unstable series of much elongated ellipsoids, it seems that such junction is possible, although the approximation is too imperfect to enable us to draw the figure with any approach to accuracy. If two ellipsoids are unstable when moving detached from one another, junction by a pipe cannot possibly make them stable. This then points to the conclusion that the pear-shaped figure is unstable when so far developed as to be better described as two bulbs joined by a thin neck.

Mr. Jeans has considered the equilibrium and stability of infinite rotating cylinders of liquid.[1] This is the two-dimensional analogue of the three-dimensional problem. He found solutions perfectly analogous to Maclaurin's and Jacobi's ellipsoids and to the pear-shaped figure, and he was able to follow the development of the cylinder of pear-shaped section until the neck joining the two parts had become quite thin. The analysis, besides, points to the rupture of the neck, although the method fails to afford the actual shapes and dimensions in this last stage of development. He is able to prove conclusively that the cylinder of pear-shaped section is stable, and it is important to note that he finds no evidence of any break in the stability up to the division of the cylinder into two parts.

The stability of Maclaurin's and of the shorter Jacobian ellipsoids is well established, and I imagined that I had proved that the pear-shaped figure with incipient furrowing was also stable. But M. Liapounoff[2] now states that he is able to prove the pear-shaped figure to be unstable from the beginning. For the present at least, I still think it is stable, and this belief receives powerful support from Mr. Jeans's researches.

But there is another difficulty raised by the present paper. I had fully expected to obtain an approximation to a stable figure consisting of two bulbs joined by a thin neck, but although the present work indicates the existence of such a figure, it seems conclusive against its stability. If then Mr. Jeans is right in believing in the stable transition from the cylinder of pear-shaped section to two detached cylinders, and if I am now correct, the two problems must part company at some undetermined stage. M. Liapounoff will no doubt contend that it is at the beginning of the pear-shaped series of figures, but for the present I should dissent from that view.

[1] Phil. Trans., A, vol. cc., pp. 67–104.
[2] Acad. Imp. des Sci. de St. Pétersbourg, vol. xvii., No. 3, 1905.

One question remains: If the present conclusions are right, do they entirely destroy the applicability of this group of ideas to the explanation of the birth of satellites or of double stars? I think not, for we see how a tendency to fission arises, and it is not impossible that a period of turbulence may naturally supervene in the process of separation. Finally, as Mr. Jeans points out, heterogeneity introduces new and important differences in the conditions.

THE RUSTING OF IRON.

THE first view taken of the atmospheric corrosion or rusting of iron was that it was due to a simple process of oxidation. In 1888 Prof. Crum Brown suggested, on the basis of experiments described by Crace Calvert in 1871, that the first stage in the rusting of iron is the production, under the influence of carbonic acid, of ferrous carbonate, which is subsequently converted, by atmospheric oxygen in presence of moisture, into ferric hydroxide or rust. In 1898, however, Prof. Dunstan, in a lecture delivered to the Royal Artillery Institution, put forward another explanation; he considered that pure oxygen in presence of water is capable of attacking iron, giving rise to ferrous oxide and hydrogen peroxide, part of the latter then converting the ferrous oxide into rust, while the remainder directly attacks the iron, giving rise to a fresh quantity of ferrous oxide, which in turn is again oxidised in a similar manner.

A detailed account of the experiments made in conjunction with Drs. Jowett and Goulding, and of the theory, which may be called the hydrogen peroxide theory of rusting, was published in October of last year in the Transactions of the Chemical Society (vol. lxxxvii., p. 1548). The theory was based on certain phenomena of oxidation in which hydrogen peroxide was known to be formed, and on the consideration that certain substances which decomposed hydrogen peroxide were found to prevent the conversion of iron into rust by damp air. The older theory, that rusting was due to carbonic acid, was considered "quite untenable, since it has been shown that rusting can take place in the absence of carbonic acid"; the part played by carbonic acid was regarded as "subsidiary and not essential," and it was held to be proven that the "aërial oxidation of iron can take place in the absence of carbonic acid." This view was arrived at as the results of experiments in which the authors failed, by attempting to exclude carbon dioxide, to prevent iron from rusting in presence of oxygen and water.

In the April number of the Transactions of the Chemical Society, however, Dr. G. T. Moody shows that these attempts to prevent iron from rusting were unsucessful owing to the extreme difficulty of completely excluding traces of carbon dioxide. When very special precautions are taken to eliminate this substance iron may be left in contact with pure oxygen and water for many weeks without undergoing change. In one experiment thirty times the quantity of oxygen necessary to convert the whole of the iron into oxide was passed during the course of five weeks, but not even a speck of rust appeared. On the other hand, by removing the scrubbing arrangement by which the air was freed from carbon dioxide, so as to permit the ingress of this gas with the air, rusting commenced almost immediately, and in seventy-two hours the whole of the surface of the metal was seen to be corroded, and a considerable quantity of red rust was formed. Specimens of iron which had been exposed for several weeks to the action of pure oxygen and water without rusting were exhibited by Dr. Moody at the recent conversazione of the Royal Society.

It is also shown by Dr. Moody that while rust is being formed from iron under natural conditions a large proportion of ferrous carbonate is produced; the composition of rust in the course of formation is thus altogether out of harmony with the hydrogen peroxide theory, since this theory postulates that twice as much hydrogen peroxide is produced by the interaction of iron, oxygen, and water as is necessary completely to oxidise the ferrous oxide to the ferric state. The fact that certain compounds such as the alkalis, sodium nitrite, and potassium ferrocyanide prevent rusting is due, not to their power of decomposing hydrogen peroxide, but of interacting with carbon dioxide. Some substances, such as potassium iodide, which destroy hydrogen peroxide do not inhibit, but actually accelerate, the rusting of iron.

The facts recorded thus afford no basis for the assumption that iron can be caused to rust by pure water and pure oxygen alone, and give a satisfactory explanation of phenomena which were considered as being explicable only in the light of the hydrogen peroxide hypothesis.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The Herbert Spencer lecture will be delivered in the examination schools on Thursday, June 7, at 3 p.m., by the Hon. Auberon E. W. M. Herbert, St. John's College.

Dr. G. C. Bourne, fellow of New College, has been nominated to the office of public examiner in zoology for 1906 in succession to the late Prof. Weldon.

At a meeting of the Junior Scientific Club on May 25 some experiments on "liquid crystals" were shown by Messrs. H. B. Hartley (Balliol) and H. L. Bowman (New College).

The following is the text of the speech delivered by Prof. Love in presenting Captain H. G. Lyons for the degree of D.Sc. *honoris causa* on May 29:—

Magnas profecto gratias hodie debemus Aegypto fluvioque Nilo, quo quotannis campos inundante, orta est ex necessitatibus hominum agellos suos summa cura dimetientium, Geometria, subtilissimae cuiusque scientiae parens. Debitum pro portione solvit Magna Britannia, cum moribus institutisque Europaeis in Aegyptum inducendis, tum viris ingenio et scientia pollentibus eo missis, qui ipsis rei publicae rectoribus quasi moderatores et gubernatores sint. In hoc numero locum insignem obtinet Henricus Georgius Lyons, qui cum decem abhinc annos omnia quae ad agrorum dimetiendorum, ad astrorum observandorum rationem pertinent, intermissa invenisset, non solum operam instauravit, sed etiam ipse nova quaedam commentus est, cum de harenae solique aevo et materia, de varia camporum planitie, de imbrium diversitatibus diligentissime quaereret: quod genus cognitionis quam late pateat nemo non videt. Agrorum quidem irrigandorum causa hoc opus noster suscepit, neque praeclarissimos fructus in hac re non assecutus est: nunc agit ut, custodibus et speculatoribus in ripis Nili tanquam in statione dispositis, his nuntiis fretus fluminis incrementum quantum anno proximo futurum sit ante praedicat: qua de re voce non incerta iam loquitur augur optimus. Neque tamen huic viro satis est scientiae et rei publicae inservire: quin vetustissimis illis monumentis quibus abundat Aegyptus magno opere delectatur. Veluti cum Nili regendi causa maximus ille prope Philas agger aedificaretur verebantur homines ne amplificata fluminis vis templis nobilissimis damnum adferret, huius viri laus est fanorum fundamentis confirmatis stabilitisque ita civium commodis consuluisse ut antiquitati venerandae parceretur.

Cambridge.—The voting on the proposals of the studies and examinations syndicate, which took place last Friday and Saturday, is likely to be misunderstood. The proposals put forward were those suggested by the Bishops of Bristol and Ely and by Mr. S. H. Butcher when the previous recommendations of the syndicate had been rejected. The committee presided over by Dr. Henry Jackson, which exists for the support of the movement in favour of the abolition of compulsory Greek, took no part in the recent agitation; indeed, many of its members voted against the proposals of the syndicate. The committee made no effort to bring up its supporters from the country, and regarded, in fact, the proposals of the syndicate as hardly worth accepting. The studies and examinations syndicate will probably now cease to exist. It has sat for three years and has produced two reports, both of which have been rejected in the main by the clerical vote. It is a well-known fact that in the first contest over compulsory Greek there was a majority of residents in the University and a majority of laymen in favour of its abolition. It now seems as if nothing but a Royal Commission can remove what to many is an absolute bar to their entrance to the University.

The Hopkins prize of the Cambridge Philosophical Society for the period 1897–1900 has been adjudged to Mr. S. S. Hough, F.R.S., of St. John's College, for his papers on the dynamical theory of the tides, published in the Philosophical Transactions of the Royal Society.

The professor of chemistry gives notice that the chemical laboratory of the University will be open for the use of students in the Long Vacation during July and August. Dr. Fenton will give a course of fifteen lectures on general chemistry on Tuesdays, Thursdays, and Saturdays, beginning on July 5. Mr. J. E. Purvis will give a course of lectures and practical demonstrations in pharmaceutical chemistry for the first part of the third examination for the degree of M.B. on Mondays, Wednesdays, and Fridays, beginning on July 4; and also a revision practical course in the chemistry and physics of hygiene.

The Board of Agricultural Studies announces that an examination will be held for one "Surveyors' Institution scholarship" on July 24–27. The scholarship is tenable for three years, and is of the value of 80*l.* per annum.

Prof. F. Franz Martens, privat docent for physics in the University of Berlin, who, on Prof. Matthiessens's resignation of the physics chair of the University of Rostock was temporarily appointed as his substitute, has been appointed professor of physics in the Berlin Handelshochschule.

At the May meeting of the Columbia University trustees, Mr. J. K. Rees, Rutherfurd professor of astronomy and head of the astronomical department, was made a professor emeritus. Mr. Harold Jacoby succeeds Prof. Rees; Dr. C. Lane Poor will be associated with him as a professor in the department, and Dr. S. A. Mitchell has been promoted to an instructorship in astronomy.

It is reported, says *Science*, that the University of California will lose 12,000*l.* yearly by the destruction of buildings owned by it in San Francisco, and that it will lose a further sum of 10,000*l.* yearly by the reduction in value of assessable property in the State. Our contemporary hopes, however, that the loss of income on the San Francisco property is only temporary, and that the State will not permit the University to suffer from the decrease in the taxes.

The Society for the Advancement of Mathematical Scientific Instruction will hold an annual general meeting in Erlangen during next week. Among the papers of general interest will be:—the investigations of glaciers, by Prof. Hess, of Ausbach; the experiment in ancient times and in the Middle Ages, by Prof. Wiedemann, of Erlangen; the proposals of the education commission of the Naturforschergesellschaft (p. 92), by Prof. Pietzker, of Nordheim; and the conception of number and quantity in teaching, by Prof. Wieleitner, of Speyer. Excursions will be made to Nürnberg and the French Switzerland.

An agreement for the mutual recognition of certificates has been arrived at between the Universities of Manchester, Liverpool, Leeds, and Sheffield Joint Matriculation Board and the Universities of Oxford and Cambridge. This Joint Matriculation Board will grant exemption from its matriculation examination to persons who have passed Responsions at Oxford with one additional subject, or have passed parts i. and ii. of the Previous Examination at Cambridge with one of the additional subjects. Under certain conditions as to the subjects taken, exemption will also be granted to holders of higher certificates of the Oxford and Cambridge Senior Local examinations. It will be remembered that a similar arrangement between the Universities of Oxford, Cambridge, and London has been announced already. Holders of Oxford and Cambridge Local certificates or higher certificates of the Oxford and Cambridge Joint Board are, if they have taken certain subjects, given exemption from the London Matriculation. Similarly, the Matriculation examination, in certain circumstances, gives exemption from Oxford Responsions and the Cambridge Previous examination.

An important advance in the development of the forestry branch of Armstrong College has been made by an agreement effected between H.M. Office of Woods and the college authorities, by which the latter take over the local management of Chopwell Woods, in the county of Durham. These woods are within a few miles of the college, extend over an area of nearly 900 acres, and carry crops of larch, spruce, Scotch pine, oak, ash, and other trees, most of which were planted about fifty years ago. The woods will be gradually brought under a proper rotation of cropping by the clearing and replanting of the more mature portions from time to time, and the carrying out of this work will afford favourable opportunities for demonstrating the various operations relating to practical forestry. H.M. Commissioner of Woods, Mr. J. F. F. Horner, has obtained the consent of the Treasury to a house being provided in the woods as a residence for the college lecturer in forestry, Mr. A. C. Forbes, and to continue to pay as heretofore the ordinary working expenses of the woods. The arrangement will facilitate the holding of short courses for practical foresters and others desirous of acquiring a knowledge of the subject, while as a practical demonstration area for the students attending the college forestry class the woods will be invaluable, and should render Newcastle one of the most favourable centres for forestry instruction in the United Kingdom.

In a paper on social conditions in Australia, read at a meeting of the Society of Arts on May 1, the Hon. J. G. Jenkins, Agent-General for South Australia, dealt with the educational advantages of the country. "Generally speaking," he said, "the system of public education is free, compulsory, and secular, the whole expense being met out of the general revenue. The greatest care is taken to provide schools in every part of the country as well as in the thickly populated cities, and in some of the thinly settled districts schools of from ten to fifteen children are established. Fortunately, Australia's educational advancement has not been delayed by sectarian interference. There it is generally considered that a country's advancement rests on the education of its people, and that as national education is a national gain, the nation's treasury should meet the bill. Efforts have been made from time to time by zealous propounders of sectarian beliefs to incorporate religious instruction with the Education Acts of the different States, but the majority of the people are strongly opposed to any form of State aid to religion. They feel that in the bitter strife for sectarian supremacy the efficiency of the schools would become impaired and the practical education of the children neglected. The parents generally take advantage of the public schools for their children, but for those who object, either from class prejudice or religious scruples, good private schools are available."

Prof. J. F. Sellers, of Mercer University, recently sent out a number of inquiries to forty-four teachers of chemistry in the southern States of the American union; the answers made by forty of the teachers form a symposium on chemical requirements which was presented to a meeting of the American Chemical Society. The paper is printed in *Science* of May 11. In reply to a question asking if chemistry should be taught in preparatory schools, a majority of five thought it should. Answers to a second question showed that in a small majority of colleges only does chemistry follow a course of physics. Prof. Sellers found that about equal time is given to lectures and to laboratory work, and most teachers consider that individual laboratory work should always form part of a chemistry course. Similarly, there is a consensus of opinion that qualitative analysis should follow general chemistry. The majority of the institutions represented offer graduate work in chemistry. The paper shows that few southern chemistry teachers carry on research themselves, and this is because they are overloaded with instruction or executive duties, and are not supplied with adequate library or laboratory facilities for advanced students. The majority of southern colleges give technical courses, and these are controlled by local demands and natural supplies. The sting of the paper, so far as our universities are concerned, lies in the tail, which is as follows:—"Once the American universities were replicas of the British system, but now the German university sets the standard. It is this shifting of method and manner that affords us of to-day, in the matter of the practical virtue of our courses in science, an assured guarantee of commercial and industrial progress."

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 1.—"The Specificity of the Opsonic Substances in the Blood Serum." By Dr. William **Bulloch** and G. T. **Western**. Communicated by Leonard Hill, F.R.S.

Conclusions.—(1) When staphylococci are brought into contact with normal human serum, and are subsequently removed by centrifugalisation, the serum loses its opsonic power for Staphylococcus, although the opsonic power of *Bacterium pyocyaneum* is preserved.

(2) Contact of normal human serum with tubercle bacilli leaves the opsonic power of that serum for staphylococcus almost intact, while the opsonic power for tubercle bacillus is completely removed.

(3) Contact of normal human serum with staphylococcus leaves the opsonic power of that serum for tubercle bacillus almost intact, while the opsonic power for staphylococcus is completely removed.

(4) Inoculation of a human being with tuberculin causes quantitative increase in the tuberculo-opsonin, whereas the quantity of staphylococcus opsonin is unaltered.

(5) Inoculation of a human being with staphylococcus vaccine causes a quantitative increase in the staphylococcus opsonin, whereas the quantity of tuberculo-opsonin is unaltered.

March 8.—"On the Relationship between Hæmolysis and the Phagocytosis of Red Blood Cells." By Dr. R. D. **Keith.**

The conclusion come to is that the phagocytosis of red blood cells does not depend on the presence of the hæmolytic amboceptor, since:—

(1) The substance which induces phagocytosis is partially destroyed by heat, while the hæmolytic amboceptor is entirely thermostable.

(2) The hæmolytic amboceptor may be present in considerable amount in a hæmolytic serum without inducing phagocytosis, notwithstanding prolonged contact of the amboceptor with the red blood cells.

Dean has suggested that phagocytosis may be caused by a complement acting through an amboceptor, and that the partial destruction, of the property in the serum inducing phagocytosis, by heat may be due to the destruction of the complement, while the amboceptor, even in the absence of the complement, may still be capable of inducing phagocytosis. This theory, while it is difficult to disprove directly owing to the complement being destroyed at the same temperature as the thermolabile part of the substance inducing phagocytosis, seems to be an improbable one for the following reasons:—

(1) That it is not an action analogous to that of other amboceptors, *e.g.* that concerned in hæmolysis. If one destroy the complement of a hæmolytic serum by heat, no hæmolysis takes place, notwithstanding the presence of the amboceptor in large amount.

(2) The hæmolytic amboceptor may be present in large amount in a diluted serum, without that serum having the power of inducing phagocytosis even when Dean's method of testing is employed.

(3) In the dilution experiments recorded in the paper it is shown that one may dilute the complement to such an extent as to abolish hæmolysis, and yet such a serum has a greater "opsonic" power in these dilutions than has the same serum when heated and employed in corresponding dilutions.

"Upon the Properties of an Antityphoid Serum obtained from the Goat." By Dr. Allan **Macfadyen.** Communicated by Dr. C. J. Martin, F.R.S.

Conclusions.—(1) The intravenous injection of the goat with the toxic cell juices of the *B. typhosus* (obtained under the conditions described) in small and carefully regulated doses resulted in the production of an antiendotoxin.

(2) The antiendotoxin value, as so far tested, reached a point at which 1/50 c.c. of the serum neutralised thirty lethal doses of the toxic typhoid cell juice. This action was not demonstrable in 3 c.c. of normal goat's serum, and was obtained after about four months' treatment of the goat. The results, after a more rapid method of immunisation, are better *qua* goat and rabbit than those obtained by Dr. Besredka in the course of two years with dead and living bacilli *qua* horse and guinea-pig.

(3) The serum was also agglutinative for the *B. typhosus*, the titrate rising to 1/1,000,000.

(4) The serum was also bacteriolytic, 1/10,000 c.c. neutralising ten lethal doses of the *B. typhosus*.

(5) The serum did not give a precipitin reaction with typhoid cell juices.

(6) The serum, whilst neutralising the typhoid, did not neutralise the cholera endotoxin.

Entomological Society, May 2.—Mr. F. Merrifield, president, in the chair.—Fourteen examples of both sexes of *Hystrichopsylla talpae*, Curtis, the largest British flea, taken in the nest of a field-mouse in a tuft of grass at Grange, near Gosport, Hants, on March 28: Commander J. J. **Walker**.—Living specimens of *Apate capucina*, *Deilus fugax*, a *Cryptocephalus* (*rugicollis*), two species of Anthaxia, &c., forwarded by Dr. T. A. Chapman from Ste. Maxime, South France: G. C. **Champion**.—An example of the weevil *Procas armillatus*, F., taken near Dartford, Kent, on April 13: F. B. **Jennings**. This species appears to be extremely scarce in Britain, and, with the exception of a single specimen taken near Chatham by Commander Walker in 1896, has not been recorded from this country for a considerable period.—Beetles from New Guinea, including *Aesernia mecki*, Jac., *A. costata*, Jac., *A. gestroi*, Jac., and Cetoniadæ and Lucanidæ from South Africa and Borneo: M. **Jacoby**.—Specimen of *Hydrochus nitidicollis*, Muls., a beetle not hitherto recorded in Britain, taken at Yelverton, in the River Meavy, in April: H. St. J. **Donisthorpe**.—Lantern-slide photographs (from nature) of the ♀ calcaria postica in Hymenoptera belonging to divers groups, mostly Aculeate, but including also representatives of chrysids, ichneumonids, and sawflies: Rev. F. D. **Morice**. Mr. Morice submitted that, in all the examples shown, the structure of the calcaria themselves (and also of the parts adjacent to them) clearly indicated that their main function was that of an elaborately constructed instrument for toilet purposes.—Specimens of *Mylothris agathina*, Cram., and of *Belenois thysa*, Hopff.: Dr. F. A. **Dixey**. The close resemblance between these species obtained chiefly in the dry-season form of the latter, and not in the wet. Dr. Dixey considered this to be a fresh illustration of the special liability to the attacks of enemies experienced under dry-season conditions, leading in some cases to the adoption of a cryptic coloration, and in others, as here, to mimicry of a protected form such as *M. agathina*.—A criticism of the late Prof. Packard's paper on the markings of organisms: H. **Eltringham**.—The genus Imma, Walk. (=Tortricomorpha, Feld.): E. **Meyrick**.

Royal Astronomical Society, May 11.—Mr. W. H. Maw, president, in the chair.—Some points arising out of a discussion of the double stars in Struve's "Mensuræ Micrometricæ": T. **Lewis**. A memoir upon the subject had just been completed, and was about to be published by the society. Questions concerning the distribution of double stars, and the relation between those relatively fixed and those in motion, were considered. The facts appeared to point to the conclusion that the sun is situated in a cluster, but not centrally.—The orbit and mass of 85 Pegasi: W. **Bowyer** and H. H. **Furner**.—Some considerations concerning the number of the stars: Miss W. **Gibson**. The conclusions were derived from a discussion of seventy-two stars, and the relations between parallax, magnitude, and proper motion were considered.—Observations of Jupiter's sixth and seventh satellites, from photographs taken at the Royal Observatory, Greenwich: **Astronomer Royal**. A large number of plates had been taken for the positions of the satellites with exposures of five minutes to nearly three hours. Photographs of Jupiter had also been taken, which showed that the tabular errors are very small. The results were confirmed by meridian observations.—Prints from negatives of the solar eclipse of August, 1905: **Astronomer Royal**. Seismographic records taken at the Royal Observatory, Edinburgh: Prof. F. W. **Dyson**. The records showed that the trace of the San Francisco earthquake reached Edinburgh in about seven minutes.—Observations of the magnitude and position of Nova Geminorum: E. E. **Barnard**. Photographs of the Milky Way taken at Mount Wilson, California, during the spring and summer of 1905: E. E. **Barnard**.—The president announced that news had been received that no injury had been caused to the Lick Observatory by the recent earthquake.

PARIS.

Academy of Sciences, May 14.—M. H. Poincaré in the chair.—A singular effect of friction: E. **Guyou**. An explanation of an experiment of M. de Saintignon. A spherical glass globe, filled with water and containing a fine powder, is rotated with a high velocity round one of its diameters as axis. The powder, if lighter than water, collects along the axis of rotation, but if heavier than water the sphere is divided into three zones, separated by two parallels of latitude equidistant from the equator. The upper and lower segments are clear, the powder being distributed in the central zone and mainly on the two boundary lines. A simple explanation is given of this paradoxical effect.—The influence of velocity on the law of deformation of metals: P. **Vieille** and R. **Liouville**.—Low temperatures and chemical analysis: MM. **d'Arsonval** and **Bordas**. An arrangement is described permitting of the direct determination of water in aqueous solutions by distillation at the ordinary temperatures, the receiver being kept at −80° C. The method is very rapid compared to those in ordinary use.—New researches on diastatic saccharification: L. **Maquenne** and Eug. **Roux**. The action of malt on starch has been studied under varying conditions of time, acidity, and nature of the starch, and the experimental results tabulated.—Three toxins of human trypanosomiasis of different origin: A. **Laveran**. The cases studied came from Gambia, Uganda, and Ubanghi. From the morphological point of view, no difference could be noted between them. Experiments with guinea-pigs, rats, and mice showed slight differences only. All the observations support the view that the three trypanosomes from the different localities belong to the same species.—The centres of gravity of discontinuous systems: Haton **de la Goupillière**.—A new octane, hexamethylethane: Louis **Henry**. This hydrocarbon is formed as a bye-product in the action between the magnesium compound of tertiary butyl bromide and acetaldehyde, probably by the action of some unchanged butyl bromide upon the magnesium compound. It is a solid, volatile at the ordinary temperature, and possessing a penetrating odour. It boils at 106° C. to 107° C. under 765 mm.—An account of an earthquake at Bogota on January 31 last: M. **Souhart**.—A new arrangement for the spectroscopy of phosphorescent substances: C. **de Watteville**. The phosphorescent substance under examination is illuminated by an electric spark about eighty-two times per second, the interval of time elapsing between the exposure to the spark and exposure to the photographic plate being about 1/3000th of a second. The period of the spark is governed by a rotating disc, and is independent of the speed of the contact breaker of the coil. The phosphorescence of bodies examined with this apparatus is very bright, and in the spectra obtained, which are rich in ultra-violet lines, none of the lines corresponding to the metal of the electrodes are visible.—The measurement of very short intervals of time by means of a condenser: M. **Devaux-Charbonnel**. The method is based on the measurement of the charge of a condenser through a variable resistance, first during the short interval of time to be measured, and then completely. Experimental results are given showing the accuracy obtainable to be of the order of 0·0001 sec.—The conductivity of ammonium sulphate in mixtures of sulphuric acid and water: G. **Boizard**.—The complete synthesis of some camphor derivatives. Isolaurolene and isolauronolic acid: G. **Blanc.** The starting point of these syntheses is αα-dimethyladipic acid, the synthesis of which has been described in a previous note. The anhydride of this acid by slow distillation at the ordinary pressure gives 2 : 2-dimethylcyclopentanone. The tertiary alcohol obtained from this by Grignard's reaction on distillation at ordinary atmospheric pressure splits up into water and isolaurolene.—α-Chlorocyclohexanone and its derivatives: L. **Bouveault** and F. **Chereau.** This substance is obtained by chlorinating either cyclohexanone or cyclohexanol in the presence of calcium carbonate. The chlorine in this derivative is reactive, potassium carbonate solution giving α-oxycyclohexanone. Substituted homologues of cyclohexanone are obtained without difficulty by the action of alkyl-magnesium compounds on chlorocyclohexanone; the methyl, ethyl, and isopropyl derivatives are described.—Stereoisomerism in the group of unsaturated αβ-acyclic compounds: E. F. **Blaise** and P. **Bagard.**—The genus Mascarenhasia: Marcel **Dubard.**—A case of a green organ deprived of assimilating power: Jean **Friedel.** The ovary of *Ornithogalum arabicum* is green and contains chlorophyll, but is devoid of assimilating power, although the ovary of *Ornithogalum umbellatum*, which is also green, has a well-developed assimilating power. The difference is possibly due to a superficial alteration of the chlorophyll grains.—The diseases of the coffee plant in the Congo Free State: E. **De Wildeman.**—The replacement of the vibrating muscles of the wing by adipocyte columns in ants after the nuptial flight: Charles **Janet.**—A new myxosporidium of the common tench: Louis **Léger.** This species was discovered in looking for the cause of a heavy mortality of the tench, and is named by the author *Chl. cristatum*. The disease of the fish was due to other causes.—Culture of the spirillum of recurrent African fever in man (tick fever): C. **Levaditi.** Details of the method of culture are given. The virulence of the spirillum was maintained through a long series of cultures.—The pathogeny of tuberculosis: H. **Vallée.**—The terraces of the Rhone valley below Lyons: M. **de Lamothe.**—The tectonic and stratigraphical relations of Sicily and Tunis: Émile **Haug.**—The geology of Calabria: Maurice **Lugeon** and Émile **Argand.**—A method of taking samples of sea-water for bacteriological studies: P. **Portier** and J. **Richard.** The construction and use of the apparatus are made clear by four diagrams.—The increase in the flow due to the cold season in the Seine and Loire basins: Edmond **Maillet.**—The mineralisation of subterranean waters and the causes of its variation: F. **Dienert.**—The Ahannets of Nimes, Belgium: E. A. **Martel** and E. Van den **Broeck.**

DIARY OF SOCIETIES.

THURSDAY, May 31.

THE ROTHAMSTED EXPERIMENTS.

The Book of the Rothamsted Experiments. By A. D. Hall. Pp. xl+294. (London: John Murray, 1905.) Price 10s. 6d. net.

ALTHOUGH the Rothamsted experiments have formed the subject of over 200 papers and reports, no book describing them has hitherto been published in this country. The present volume, by Dr. Gilbert's successor, is therefore a welcome addition to agricultural literature. We do not forget that two works entitled "The Rothamsted Experiments" were published respectively in 1888 and in 1897, but the former was an account of a few experiments only, and the latter discussed the practical results rather than the experiments themselves.

Mr. Hall's book has been written chiefly for the general reader who may be interested in agricultural experiments, but it is also intended for the student and the teacher. It opens with biographical notices of the two remarkable men who have made the name of Rothamsted familiar. Then follow three introductory chapters—the first mainly historical, the second dealing with meteorological observations, and the third describing the soils of the experimental fields. At the end of the book there are three appendices, the most important being a list of Rothamsted publications. These sections of the work, with the index, occupy some 90 out of a total of 334 pages. The remainder of the book consists of ten chapters, each dealing with one experiment, or with groups of similar experiments. The text is illustrated by fourteen full-page plates, and by a large number of diagrams, while figures obtained in the experiments occupy ninety-two tables.

Those who conduct field experiments will read with some surprise the account given of the soil of Rothamsted. The estate was recently surveyed by Mr. H. B. Woodward, of the Geological Survey, and he described the experimental fields as resting on a very mixed deposit of clay-with-flints overlying chalk. The chalk is extensively piped, and appears occasionally in irregular pinnacles near the surface. The soil is a grey, flinty, or pebbly loam, ten inches or more in thickness, and varying in character according to the number of stones in it. From this description the soil would appear to be anything but an ideal one for agricultural experiments, but we know that on the whole it has been satisfactory. It would seem, therefore, that where the soil is of moderate depth, variations in the subsoil may not interfere seriously with field plots.

Lawes and Gilbert had wide interests, and at one time or another they touched upon almost every important subject dealt with by the agriculturist. Their main work was on what may be described as the balance-sheet of the soil, and most of the crop and feeding experiments were planned to throw light upon the soil's losses and gains; but they found time for investigations on many other subjects, such as the source of fat in the animal body, the economic feeding of live-stock, ensilage and sewage farming.

The experiments upon field crops at Rothamsted were chiefly of one type. The land was divided up into plots, usually of from one-eighth to one-half of an acre in size; the plots received different manures such as farmyard manure, superphosphate, nitrate of soda, and the sulphates of ammonia, potash, soda, and magnesia. The artificial manures were employed in various combinations. With few exceptions, plots received the same manures year after year, and the field was occupied by the same crop either permanently, as in the case of the wheat and barley experiments, or so long as the crop could be got to grow, as in the case of clover and potatoes. The primary object of these experiments was to ascertain how crops grow, and more especially to discover what capacity the important farm crops have of obtaining nourishment from unmanured soil, and what class of manure is most necessary for the healthy development of each. As the work progressed, other points were brought to light—thus, for example, in connection with the wheat experiments it was shown (1) that the fertility of ordinary soils was of two types—one quickly exhausted (condition), the other of a very enduring character (inherent fertility); (2) that high farming is not a remedy for low prices in the case of wheat; (3) that superphosphate and the sulphates of potash and ammonia do not occur in appreciable quantities in the drainage waters from corn-fields, but that nitrates readily pass through the soil and are lost. In the experiments on meadow herbage, as with wheat, it was soon shown what classes of manure were required, but after a time it became apparent that different species in the meadow were differently affected by the treatment the plots received, and for many years the interest has centred in the varying fortunes of the combatants in this "battle of the meadow." There is an excellent account of these changes, and the diagrams in this section of the book are particularly striking—not so striking, however, as the plots themselves now are. There are no field experiments so full of interest to the naturalist as the plots in the park at Rothamsted.

Mr. Hall gives a very good summary of the Rothamsted work, and his book forms a complete guide to the experiments. It contains just the information which the visitor wants, and it is also well adapted for the agricultural student. But in the interests of the visitor and the student we hope that a new edition of smaller size may be published before long. A royal octavo page, "English" type, and thick paper make the book in its present form an admirable library edition, but the student wants something more compact and less expensive.

We venture to make a further suggestion. It is that in subsequent editions the "Practical Conclusions" which are appended to most of the chapters should be omitted. They do not harmonise with the rest of the work—in a good many cases, indeed, they seem to be based on general agricultural principles rather than on results obtained in the Rothamsted experiments—and in their present form they are more likely to cause readers to underestimate than to appreciate the great value of the work of Lawes and Gilbert. Take, for example, the "Practical Conclusions" which follow Chapter IV.—"Experiments upon Wheat." The chapter extends to thirty-eight pages, and deals with some of the most important work done at Rothamsted. The conclusions are three in number, and in effect are as follow:—(1) Wheat is in less need of direct manuring than most other crops of the farm, and "can usually be grown with the residues in the soil, especially if it follows a clover crop." (2) Manures for wheat should be mainly nitrogenous, and nitrate of soda is generally better than sulphate of ammonia. (3) "When wheat is grown two or three times in succession, about 1 cwt. per acre of some slow-acting nitrogenous manure and 2 cwt. of superphosphate should be ploughed before seeding, and a top-dressing of 1 to 2 cwt. per acre of nitrate of soda should be applied in February. Only on the lightest sandy and gravelly soils will any return be obtained for the use of kainit and other potash salts with wheat."

These conclusions do not represent the "practical" teaching of Lawes and Gilbert, and although it is admitted that they are conclusions which may be fairly drawn from the Rothamsted experiments on wheat, we think the book would be improved by their absence.

Rothamsted has exercised a great influence on practical agriculture, but in perusing Mr. Hall's book we have been impressed by the fact that the experiments, important as they are, do not in themselves account for the estimation in which Rothamsted has been held by agriculturists. If, however, the reader turns to the list of papers in appendix i. he will there find the explanation of much of Lawes and Gilbert's influence. They began their experiments as students of nature, and with the one object of adding to the existing knowledge of agriculturists. As their work progressed they not only came to possess an unrivalled acquaintance with the general facts of agricultural science, but they gained a very close knowledge of the business of the practical farmer. They were thus able to find in their experiments much that explained the farmer's difficulties, and, as they were always careful to place their results before farmers, their papers in the agricultural journals soon attracted the notice of practical men. As long ago as 1856 a writer on Rothamsted says: "These lessons the English farmers have learnt from Mr. Lawes. They have accepted them with becoming gratitude. They are practising them with increasing confidence day by day to their great and proved advantage."

It was not the habit of Lawes and Gilbert to confine themselves to Rothamsted data; they drew freely on other sources of information in compiling their papers; and they wrote upon subjects rather than upon experiments; to quote Mr. Hall, "The papers on specific investigations often tend to be less accounts of the experiment as a whole than discussion of such of its results as bear upon the dominant idea with which Lawes and Gilbert were then engrossed." This habit, possibly undesirable in a scientific report, was most valuable to the readers of their general papers. To the agriculturist, Lawes and Gilbert were known as teachers rather than as experimenters, and while the accuracy and extent of their experiments brought them scientific fame, it was as interpreters of science, as men who thoroughly appreciated both the scientific and the practical aspects of their subject, that they became leaders in the agricultural world, and for close on two generations continued to be the trusted advisers of the British farmer.

T. H. Middleton.

EVOLUTION AND PHILOSOPHY.

Evolution the Master-key. By Dr. C. W. Saleeby. Pp. viii + 364. (London: Harper and Brothers, 1906.) Price 7*s.* 6*d.*

Dr. Saleeby has written a very interesting book. The grand range and sweep of his reasoning is remarkable. He deals, and generally very ably though very briefly, with most of the profoundest problems of science and philosophy. As the title of his book proclaims, his object is to apply the doctrine of evolution to all problems and to show that, though some entirely baffle human thought and reasoning, yet to most there is a key, and one key only. They must be studied from the evolutionary standpoint. Each train of thought is pursued till its logical conclusion is reached. There is no stopping half-way. When great principles are expounded, Dr. Saleeby does not leave them in barren solitude, but boldly faces the inferences that inevitably follow. He is, in fact, very thoroughgoing. Dr. Saleeby's science and philosophy are always alive and human, for he always traces new thoughts and new discoveries to their originators. In his admirations he is very hearty and genuine. His heroes are the men who have advanced human knowledge and helped to emancipate the human intellect. Occasionally he rises to eloquence.

After part i., which is preliminary and general, our author proceeds to inorganic evolution. The evolution of sun and planets from a nebula, the gradual dissipation of the sun's heat, and the possible return to the nebula state through collision with another celestial body—all this is excellently described. After this, radium and the architecture of the atom come up for investigation. Part iii. deals with organic evolution, beginning with a discussion of the origin of life, and not omitting the practical question of eugenics. The subject of part iv. is superorganic evolution—the evolution of mind, the human will, the origin of ideas, the evolution of religion, evolution and marriage, evolution and education, and so forth. In part v. we have evolution and optimism. In part vi. Dr. Saleeby tackles the difficult subject of dissolution. Though energy never disappears, yet it is dissipated, and so becomes unavailable. Is the death of the whole universe in prospect? Are there alternate periods of evolution and dissolution? Part vii. is occupied with evolution and the religion of the future.

In a book covering so wide a field it is inevitable that there should be a good deal to criticise. Part i., which deals with preliminary questions, is too long. The chapter on the philosophic temper is quite unnecessary. Dr. Saleeby's overpowering admiration for Herbert Spencer occasionally leads him astray. Herbert Spencer attributed organic evolution mainly to the inheritance of acquired characters, tracing even the stag's antlers to this principle. Though a large majority of biologists think otherwise, our author maintains that time has vindicated Spencer. The evidence he himself produces is worth little or nothing. Pathogenic bacteria, he says, quoting Haeckel, when they "are passed through the body of a highly susceptible animal become possessed of a much greater degree of virulence than formerly." "The progeny of such bacteria, often after tens and hundreds of generations, are possessed of a character which was acquired by their ancestors during their passage through the body of the susceptible animal." Grant that this is so, still the unicellular organisms are in quite a different category from the higher animals.

Dr. Saleeby's optimism sometimes affects his judgment. Natural selection, he maintains, is still making for the improvement of the human breed. Is this really so among civilised races? And, if so, what need of Mr. Galton's eugenics, which he highly commends? Again, Dr. Saleeby denies the freedom of the will. Like nearly all modern psychologists, he is a determinist. Like a true optimist, he finds a satisfaction in the fact that we cannot act without motive—in other words, that we are automata. He tells us that we have will, but this turns out only to mean that the brain can inhibit the working of the lower nerve-ganglia. If a slave is allowed to keep a slave, he does not thereby cease to be a slave himself. After all, what we want is a working belief in free will, and this is the inalienable property of every healthy man. When it comes to action a healthy determinist throws aside his theories and his philosophic temper, and has as strong a sense of freedom as any barbarian. In conclusion, we must congratulate Dr. Saleeby on having produced so readable and so able a book.

F. W. H.

THE UNIVERSITY IDEA.

The Launching of a University, and Other Papers. A Sheaf of Remembrances. By Dr. J. D. C. Gilman. Pp. 386. (New York: Dodd, Mead and Co., 1906.) Price 2.50 dollars net.

THE launching of the Johns Hopkins University could not be more fitly or more intimately described than by one who has "the advantage of knowing more than anyone else of an unwritten chapter of history." Such a record could hardly fail to throw interesting sidelights on the growth of the idea of the University in its modern conception. It is interesting to notice that the launchers of the Johns Hopkins University were largely influenced, not only by the evidence of University Commissions in Great Britain, but also by the writings of Newman and Matthew Arnold, of Pattison and Appleton. The actual founder was as liberal in his ideas as he was in his gifts, and the administrators of his gift made the fullest use of their discretion. President Gilman himself had a roving commission to pick the brains of the older Universities in England, France, and Germany. The main problem was to disengage the University from the college idea, and to give to the University point of view all the distinctness of which it was capable. The selection of the original faculty was sufficient to secure this result. It included such men as Sylvester, Martin, Rowland, Morris (from Oriel College), Gildersleeve, and Remsen, who succeeded Dr. Gilman as president in 1902. We are given interesting glimpses of these and other noteworthy teachers, as also of other famous English and American savants who were at different times and in different degrees associated with the Johns Hopkins University—such as Freeman and Huxley, Cayley and Kelvin—and of such celebrities as Dean Stanley, Lowell, Child, and Lanier, the poet. The interest of these chapters is, in fact, largely personal and local, interspersed with general reflections on the advancement of science, the conflict of studies, and the idea of research. Brief notices are also given of what are perhaps the two most distinguished features of the Johns Hopkins University—its publications and its medical school.

The "addresses on various occasions, historical and educational," are of somewhat unequal interest. For the most part they are too occasional, as well as too topical in character, to be of very general interest. Some of them are fitly characterised as "a sheaf of remembrances"; some touch, without going very deeply into, University problems; while others, again, are of the nature of social and ethical homilies. Here, as elsewhere, the author dwells on the progress which has been made towards the recognition of "the true significance of University work, as distinguished from collegiate discipline," and at the same time indicates that the development of graduate study has not been without its influence upon the organisation of collegiate work. "Two gains are doubtless permanent"—elective courses or an option between "groups" of undergraduate studies, and the "rapidly increasing" recognition of the value of "liberal education"—not only as the preliminary antecedent to higher and special studies, but also as a preparation for business and politics. We are not sure, however, how far Dr. Gilman's estimate of the value of the "elective" system is representative of opinion among home or foreign observers. In another place he describes the system as "a triumph of the last thirty years." With regard to liberal culture, Dr. Gilman observes that "a liberal education is not now complete unless it includes a knowledge of French and German." Both these points deserve the consideration of University reformers in other places.

Perhaps the most striking note of Dr. Gilman's addresses on University subjects is his strenuous plea for "research." To the term itself he takes not unreasonable exception; for the thing he has nothing but enthusiasm; and in this connection what he has to say about the magnificent promise of the Carnegie Institution, with which he has been prominently associated, will be read with interest. Among the gevelopments of University activity in America which Dr. Gilman selects for commendation are the growth of scientific laboratories (including observatories and surveys), the expansion of libraries, the adjustment of the claims of science and letters, the "clarification" of the idea of the University, the admission of women to the advantages of higher education, and the advancement of professional schools, especially schools of medicine and law. Dr. Gilman also notes with satisfaction the mutual growth of "sweet reasonableness" among the leaders of religious and of scientific thought. The remaining addresses on such miscellaneous subjects as "Hand-craft and Redecraft," "Greek Art in a Manufacturing Town," "Civil Service Reform and Education in Philanthropy," do not seem to call for special notice. They are all, however, animated by the same lofty enthusiasm and the same large outlook that characterise the author's "idea of the University," and of the future which it has before it in the general life of the nation.

A RAMBLE IN THE WEST.

Highways and Byways in Oxford and the Cotswolds. By Herbert A. Evans. Illustrated by Frederick L. Griggs. Pp. viii+407. (London: Macmillan and Co., Ltd., 1905.) Price 6s.

OXFORD and its colleges are always before the world. Early Oxford, Mediæval Oxford, Stuart Oxford, Modern Oxford, it has been described over and over again in all its phases and all its moods. It has furnished the artist with unfailing inspiration, it has been the excuse for endless reminiscences, we have seen it approach "the cross-roads," and recently it has been held to account in the columns of *The Westminster Gazette*.

The author of this volume may well be pardoned if he does not write of the city at length. The few pages which he spares to it are given up for the most part to the archæology of the less visited portion to the west of the north and south artery, the quarter which centred round the castle still in existence, and the magnificent foundations of Osney and Rewley long since levelled with the dust. He does not attempt anything in the nature of a general survey. If Oxford has a place in his book it is mainly because, situated as it is, at a point where the hills from east and west most nearly meet, it is, as it were, the gate into the country whither he would lead us, the country that is bounded by the fringe of the Cotswold on the west and the Cherwell on the east, in other words the northern half of the basin of the Upper Thames. He does not claim to have described this exhaustively—he has merely tried to point out what struck him as attractive in its history and scenery, in the hope of making it seem attractive to others. That he has succeeded in so doing is certain. Whether he takes us in thought to the Cotswolds proper, to Painswick or Winchcombe or Stow on the Wold, whether he writes ot the escarpment of Edgehill, or the Vale of Evesham, of the Forest of Wychwood, or of regions still nearer the city, he inspires us with the same feeling of interest, the same desire to set out and see for ourselves.

If we have any complaint to make it is that the author has not told us more about the natural features of the district. To the fauna and flora we find only scattered allusions, *e.g.*, to the Arion and the Acis on the hills near Barton, or the Salvia Pratensis in the Forest of Wychwood. Of the geology and hydrography he writes as little as possible. Like most other nations, the British are surprisingly ill acquainted with the land in which they live, but it does not follow that they are past educating.

For our own part we should have liked more than a mention of the botany of Tadmarton Heath, we should have been glad to have a general idea of the course of the Upper Thames, or the formation and lie of the Cotswolds, the more westerly portion of the great oolite sheet, which starts from the borders of Dorset and runs north-east across England to find its termination in the Yorkshire moors. On the other hand the author is generous with historical and antiquarian details. His pages are full of memories of the Civil War, of which this region was one of the chief theatres; the battles, Edgehill, Cropredy, &c., are brought clearly before our minds. He is a good raconteur, and his notes on the old families and local worthies are very good reading. The great houses (Broughton, Sudeley, Compton Wynyatts, &c.) receive full justice at his hands, while his descriptions of the churches, not only of the great wool-churches of Cirencester, Chipping Campden, &c., but of the humbler village types, are instructive, and all things considered wonderfully free from monotony.

We have no hesitation in recommending the book. It is not only attractive, but taking it as a whole it is accurate and valuable; between its covers is store both of pleasure and of profit. Like others of this series it has been illustrated by Mr. Frederick L. Griggs.

OUR BOOK SHELF.

A Manual of Geometry. By W. D. Eggar. Pp. xxiii+325. (London: Macmillan and Co., Ltd., 1906.) Price 3*s*. 6*d*.

A NEW text-book of elementary geometry by the author of the well-known "Practical Exercises in Geometry" will be eagerly welcomed. The "Manual of Geometry" is based on the earlier treatise, but the subject has been extended by the introduction of theorems side by side with the practical work. In deciding on the ground to be covered the author has been largely guided by the revised syllabuses of various examining bodies, and the manual will be found specially suited to students preparing for the Oxford and Cambridge Locals, London Matriculation, Littlego, Army and Navy Qualifying, and similar examinations.

After a short preliminary course of practical and experimental work, practice and theory proceed together. The experimental method is always prominent, being continually used in leading up inductively to the theorems. As each theorem is reached a strict deductive proof is informally and partially outlined, and the student keeps a note-book in which the theorems are entered, accompanied by a complete formal proof written out in his own words. Sets of problems and exercises are likewise provided. The style of the author is attractive, and the course as a whole has great educational value; in fact, we know of no text-book which presents the subject in a way more suited to the natural capacities of the youthful reader, or which is better adapted to impart a thorough knowledge of concrete geometry, and at the same time to develop the reasoning faculties in a legitimate manner.

There is a chapter describing the vernier, spherometer, callipers, and the micrometer screw gauge, and also treating briefly of the mensuration of the simpler geometrical solids. There are selections of recent examination papers, four-figure logarithms and trigonometrical ratios, answers to numerical problems, and a very useful general index.

If a draughtsman were to criticise the book he would probably say that in measuring and setting off lengths the scale should be directly applied without the intervention of dividers; that a line to be accurately measured should have its ends clearly defined by short cross-lines; and that diagonal scales, being of little or no practical use, are made rather too much of in the chapter devoted to them. But these are very minor matters, and do not detract from the general excellence of the work. We know of no text-book of elementary geometry which can be more confidently recommended to teachers, and none from which students are likely to derive more profit.

Les Procédés de Commande à Distance au Moyen de l'Électricité. By Captain Régis Frilley. Pp. vii + 190. (Paris: Gauthier-Villars, 1906.) Price 3.50 francs.

THE problem considered in this volume is that of communicating to a distant mechanism a movement the magnitude, direction, and sense of which are definite functions of those of a transmitting mechanism. The character of the movements which it is desired to transmit varies very much in degree from the simplest of all (traction), in which the three "commands"—*forwards, backwards, stop*—are alone the orders to be obeyed. The author classifies the different mechanisms employed, not according to their complication, but according to the methods that are characteristic of them. These form seven groups—(1) direct action apparatus, (2) apparatus using relays, (3) apparatus employing rotating fields, (4) Wheatstone's bridge devices, (5) apparatus based on the use of induction sparks, (6) escapements, (7) Hertzian waves. The various devices that have been used from time to time are very clearly described under these headings with the aid of diagrams. In chapter viii. an account is given of the commutating device of Lieutenant-Colonel Rivals, by which the sending and receiving instruments can be used as either in turn. Altogether the book forms a very useful and suggestive summary of this very important branch of modern military practice.

Das Radium und die radioactiven Stoffe. By Karl Frhr. von Papius. Pp. viii + 90. (Berlin: Gustav Schmidt.) Price 2 marks.

THIS book contains a semi-popular account of radioactive phenomena. The leading experimental facts and the conclusions of their discoverers are described clearly enough, but with little in the way of suggestive comment. The printing and illustrations are good, but we notice a serious error in Fig. 10, which suggests that the β-rays of radium, when deflected by magnetic force, lie in the same plane as the poles of the deflecting magnet. The contrary is, of course, the fact, and such a mistake cannot but suggest serious doubts as to the competence of the author's general scientific knowledge. R. J. S.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Ionisation and Temperature.

THE discourse by Prof. J. J. Thomson, published in NATURE of March 22 (vol. lxxiii., p. 495), was of importance from several points of view. The explanation of the method of ionisation which he suggests was of especial interest to myself, and I should be pleased if I might be allowed to raise one query concerning it.

Prof. Thomson does not regard the temperature of the gas as having any effect upon the ionisation. It has, indeed, never been shown that high temperature alone would produce ionisation. On the other hand, is there any reason for supposing that ionisation by impact may not take place much more easily at high temperature than at low, and that this is the explanation of the discharge observed by Prof. Thomson? That the gas in this case must have a very high temperature would seem exceedingly probable, for the amount of electrical energy lost in the discharge is very great when compared with the thermal capacity of the gas through which the discharge occurs. Thus in one case when the discharge became luminous the current was 0·045 ampere, the potential difference 50 volts, the distance between the electrodes 5 mm., and the pressure of the gas 0·01 mm. The dimensions of the tube are not given, but if we assume the volume of the gas to be 2 c.c., the residual gas to be atmospheric gas, and that the whole electrical energy is used in heating the gas, we should conclude that it would raise it $7 \cdot 4 \times 10^7$ degrees. It is, of course, not to be supposed that the temperature does reach any such value, but we have reason to believe that it reaches a very high temperature, and may it not be that this has a very great effect upon the production of the ions? C. D. CHILD.

Colgate University, Hamilton, N.Y., May 11.

THE average temperature of the gas when the discharge first became luminous was comparatively low; for example, a fine platinum wire immersed in it did not become hot enough to be visible. The figures quoted by Prof. Child refer to the current after the luminous discharge had been well established; the current when the transition from dark to luminous discharge took place was very much smaller, generally less than 10^{-5} ampere.

J. J. THOMSON.

A Horizontal Rainbow.

J'AI étudié récemment un arc-en-ciel horizontal qui se montrait à la surface d'un petit étang dans les premières heures de la matinée. On l'observait, comme celui dont Mr. W. R. M. Church a envoyé la description à NATURE (April 26, p. 608), en tournant le dos au soleil; et il disparaissait quand la hauteur du soleil était de 44° environ. Il avait la forme d'un arc d'ellipse dont un foyer se serait trouvé à peu près dans l'ombre de la tête de l'observateur. Ses caractéristiques étaient les mêmes que celles de l'arc-en-ciel ordinaire: ouverture angulaire de 42° sur le bord rouge, largeur de 2°, apparition à 53° (plus rare) d'un second arc plus faible et plus large avec les couleurs disposées dans l'ordre inverse, obscurité de l'espace compris entre les deux arcs.

Tout invitait donc à chercher l'origine du phénomène dans des sphérules d'eau, qui ne pouvaient être que répandues sur la surface calme. C'est effectivement ce qu'une étude attentive m'a fait découvrir. Les sphérules en question ont généralement quelques dixièmes de millimètre de diamètre. Elles sont très nettement visibles quand on se penche sur l'étang, mais la moindre agitation les fait disparaître. Je les attribue à la rosée déposée à la surface de la nappe tranquille, laquelle est un peu grasse par suite de l'existence de nombreuses colonies d'animalcules et de végétaux dans ses eaux stagnantes. L'arc-en-ciel observé par Mr. Church me semble dû à la même cause: dépôt du brouillard à l'état sphéroïdal sur la surface calme du lac. V. SCHAFFERS.

Louvain (Belgium), rue des Récollets, 11.

NOTES ON SOME CORNISH CIRCLES.[1]

III.

Boscawen-un, N. lat. 50° 5′ 20″.

MY wife and I visited Boscawen-un on a pouring day, when it was impossible to make any observations. Mr. Horton Bolitho, who was with us, introduced us to the tenant of Boscawen-noon—Mr. Hannibal Rowe—who very kindly, in spite of the bad weather, took us to the circle and the stone cross to the N.E. of it.

Lukis thus described this monument[2] :—

"The enclosed ground on which this circle stands is uncultivated and heathy, and slopes gently to the south. Twenty years ago a hedge ran across it and bisected the circle.

monolith enclosed within it was inclined, it is possible that it was upright at that time.

"Dr. Stukeley's supposition was that it originally stood upright, and that 'somebody digging by it to find treasure disturbed it.'

"On the north-east side there are two fallen stones which Dr. Borlase, in 1749, imagined to have formed part of a cromlech. It is more probable that they are the fragments of a second pillar which was placed to the north-east of the centre, and as far from it as the existing one is. There are instances, I believe, of two pillars occupying similar positions within a circle. One of the stones, that marked C in my plan, on the eastern side of the ring was prostrate in the doctor's time.

"At a short distance to the south-east and south-west there are cairns, which have been explored."

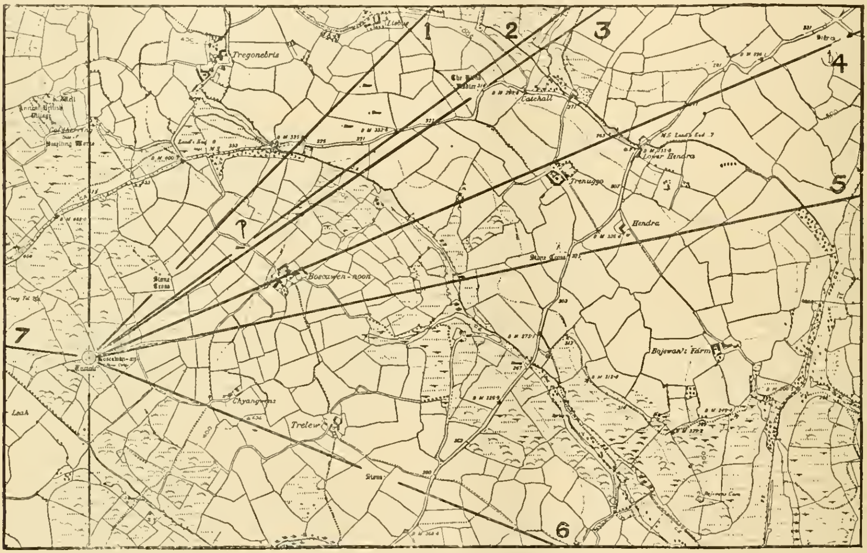

FIG. 8.—Photograph of the Ordnance Map showing sight-lines.

"This monument is composed of nineteen standing stones, and is of an oval form, the longer diameter being 80 feet and the shorter 71 feet 6 inches. One of the stones is a block of quartz 4 feet high, and the rest, which are of granite, vary from 2 feet 9 inches to 4 feet 7 inches in height. On the west side there is a gap, whence it is probable that a stone has been removed. Within the area, 9 feet to the south-west from the centre, is a tall monolith, 8 feet out of the ground, which inclines to the north-east, and is 3 feet 3 inches out of the perpendicular.

"In 1594 Camden describes this monument as consisting of nineteen stones, 12 feet from each other, with one much larger than the rest in the centre. It must have been much in the same condition then as now. As he does not say that the

For this monument I have used the 6-inch map, as the circle lies nearly at the centre, and all the outstanding stones are within its limits. The heights of the sky-line were measured by Mr. H. Bolitho at a subsequent visit with a miner's dial; the resulting declinations have been calculated by Mr. Rolston. A theodolite survey will doubtless revise some of them :—

Marks	Az.	Hills	Dec.	Star	Date

7. Stone	N. 83 30 W. ...	1 0 (?)	+ 4 36	Pleiades (September)	2120

I gather from a report which Mr. H. Bolitho has been good enough to send me that modern hedges

[1] Continued from vol. lxxiii., p. 563.

[2] "Prehistoric Stone Monuments of the British Isles : Cornwall," W. C. Lukis, p. 1.

and farming operations have changed the conditions of the sight-lines, so that 1 and 3 are just invisible from the circle. This is by no means the only case in which the sighting stone has just been hidden over the brow of a hill and in which signals from an observer on the brow itself have been suggested, or a *via sacra* to the brow from the circle; there are many monoliths in this direction which certainly never belonged to the circle. From menhir P (No. 2) a fine view is obtained from N. to S. through E., so that the Blind Fiddler and the two large menhirs, and almost the circle, are visible. The curious shapes of 1 and 2 are noted, the east face vertical and the west boundary curved, like several sighting stones on Dartmoor.

The circle itself has several peculiarities. In the first place, as shown by Lukis, it is not circular, the diameters being about 85 and 65 feet; the minor axis runs through the pillar stone in the centre and the "fallen stones" of Dr. Borlase towards the "stone cross" (which is no cross but a fine menhir) in Az. N. 43° 15′ E. This would suggest that this was the original alignment in 2250 B.C., but against this is the fact that the two stones of the circle between which the "fallen stones" lie are more carefully squared than the rest. It is true, however, that this might have been done afterwards, and this seems probable, for they are closer together than the other circle stones.

The one quartz stone occupies an azimuth S. 66° W. It was obviously placed in a post of honour. As a matter of fact, from it the May sun was seen to rise over the centre of the circle.

As there are both at Tregaseal and Boscawen-un alignments suggesting the observation of the summer solstice sunrise, it is desirable here to refer to the azimuths as calculated. For this purpose Fig. 9 has been prepared, which shows these for lat. 50° both at the present day and at the date of the restoration at Stonehenge.

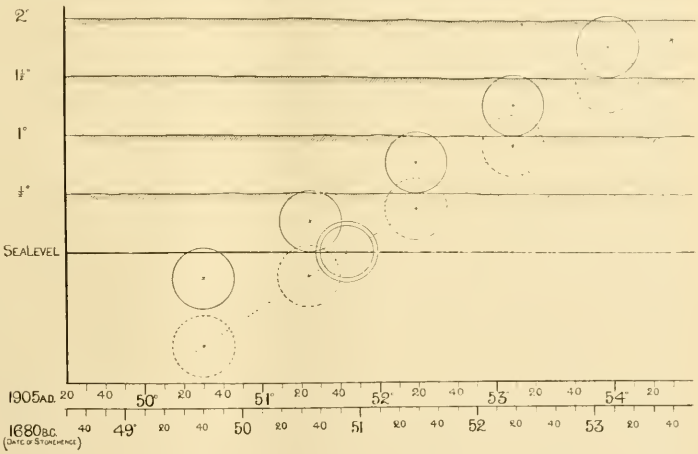

FIG. 9.—Showing the azimuths at the present time and in 1680 B.C. at which the sun rose in Cornwall at the solstice, with different elevations of the sky-line. These are shown at the side.

My readers should compare this with the table on p. 33, vol. lxxii., which gives the solstice sunrise conditions of Stenness in lat. N. 59°. Such a comparison will show how useless it is to pursue these inquiries without taking the latitude and the height of the sky-line into account.

The "Stripple Stones" (lat. 50° 32′ 50″ N., long. 4° 37′ W.)

This is a very remarkable circle consisting of 5 erect and 11 prostrate stones situated on a circular level platform 175 feet in diameter on the boggy south slope of Hawk's Tor on Hawkstor Downs in the parish of Blisland. The circle itself is about 148 feet in diameter, and the whole monument is, in Lukis's opinion, the most interesting and remarkable in the country. Surrounding the platform there is a ditch 11 feet wide, and beyond that a penannular vallum about 10 feet in width. The peculiarity of the vallum is that it has three bastions situate on the north-east, north-west, and east sides. It is to the north-east bastion that I wish to refer.

Sighting from the huge monolith, which is now prostrate but originally marked the centre of the circle along a line bisecting the arc of this bastion, we find that the azimuth of the sight-line is N. 25° E.; the angular elevation of the horizon from the 1-inch Ordnance map appears to be about 0° 22′. Thus we get in the same form as before:—

Alignment	Dec.	Star	Date
Centre of circle to centre of bastion ...	35° 1′ N. ...	Capella	1250 B.C.

indicating that this alignment was formed for the same purpose as that which dominated the erection of "The Pipers."

The "Nine Maidens" (lat. 50° 28′ 20″ N., long. 4° 54′ 35″ W.)

In this monument we find a very different type from those considered previously.

The Nine Maidens are simply 9 stones in a straight line 262 feet in length at the present day; possibly, as suggested by Lukis, it may have extended originally to the monolith known as "The Fiddler," situated some 800 yards away in a north-easterly direction. Measuring the azimuth of the alignment on Lukis's plan, and finding the horizon elevations from the 1-inch Ordnance map, we have the following:—

Az	Hills	Dec.	Star	Date
N. 28° E. ...	0° 0′ ...	33° 47′ N. ...	Capella ...	1480 B.C.

It may be remarked that here we have a date for the use of Capella intermediate between those obtained for "The Pipers" and the "Stripple Stones" respectively.

NORMAN LOCKYER.

THE STABILITY OF SUBMARINES.

THE construction of submarines for the Royal Navy began about five years ago. On March 31, twenty-five vessels of the class had been completed, fifteen were building, and twelve more were projected in the Navy Estimates for 1906–7. France at the same date had thirty-nine submarines completed, and fifty building or projected. Russia had thirteen vessels completed and fifteen building. The United States had eight vessels completed and four building, while Congress has recently sanctioned a special vote of 200,000*l.* for further work on submarines. Germany, Italy, and Japan as yet have done but little, but they are moving in the same direction. An American engineer, Mr. Holland, has exercised the greatest influence on recent submarine design, having worked at the problem for thirty years, and proved himself a worthy successor of his fellow-countrymen Bushnell and Fulton, who were pioneers in submarine construction in the closing years of the eighteenth century and the commencement of the nineteenth. The first five British submarines, ordered in 1900, were repetitions of a type designed by Mr. Holland, tried and approved by the United States Navy Department. Great developments have taken place in later British submarines. Those first built had displacements of 120 tons, surface speeds of eight to nine knots, and gasoline engines of 160 horse-power. Vessels now building have displacements exceeding 300 tons, a surface speed of thirteen knots, and gasoline engines of 850 horse-power. The cost of the earlier vessels was about 35,000*l.*; that of the later vessels must be twice as great. Other countries have taken similar action, and some are building still larger vessels.

British submarines are kept continuously at work, and this experience has yielded valuable information leading to successive improvements. The vessels chiefly used for experimental purposes up to date belong to the "A" class 200 tons in displacement and ten knots surface speed. Vessels of this class consequently have been most before the public. Their active employment has not been free from accidents, but, having regard to novelty of type and special risks which unavoidably accompany the power of submergence, it is a matter for congratulation that these accidents have not been more numerous and serious in their consequences. Official inquiries have been made into the causes of accidents, and reports have been published. In the opinion of the writer these proceedings showed a tendency to minimise risks necessarily encountered in working submarines. He consequently undertook a lengthy series of calculations for typical submarines of different dimensions, in order to ascertain their conditions of stability in various conditions which occur on service. The results for one class are embodied in a paper presented to the Royal Society on May 3, which paper contains also the results of similar calculations made for a cruiser of ordinary form. The distinctive conditions of submarines were emphasised by comparing these results, and the editor of NATURE has suggested that an explanation in popular language of the principal conclusions, based on the investigations, may be of general interest.

Submarines are generally "cigar-shaped," with circular or nearly circular cross-sections. This form is adopted in order to provide, with a minimum expenditure of weight, structural strength sufficient to meet severe external fluid pressures which may come upon the hulls if submarines sink to considerable depths. Such depths are not reached intentionally, but experience shows that they may be attained accidentally, and that very quickly.

In ordinary vessels the freeboard is considerable, and the sides are approximately vertical between the lightest draught reached on service and the deepest (load) draught; consequently, within these limits of draught, horizontal sections of the vessels coincident with the water-surface—known as *planes of flotation*—remain practically constant in form, area, and moments of inertia. In cigar-shaped submarines, with circular cross-sections, the freeboard is small, and the lightest draught of water bears a large proportion to the diameter of the largest circular cross-section. For the typical submarine dealt with in the Royal Society paper, the extreme breadth (diameter of largest cross-section) is a little more than twelve feet, and the lightest draught of water is about ten feet. The circular form of cross-section involves rapid diminution in lengths, breadths, areas, and moments of inertia of successive planes of flotation as the draught of water is increased from light to load. These changes are accompanied by rapid and considerable losses in the stability, and the conditions differ radically from those of ordinary ships. For the typical submarine the extreme length is 150 feet, and breadth extreme 12.2 feet; but the length of water-line at the lightest draught is only 94 feet, and breadth 8.2 feet. When the draught of water is increased eighteen inches (by admitting water-ballast) and the vessel is prepared for diving, the length at the water-line falls to 41 feet, and the breadth to 3.6 feet. In the cruiser of ordinary form an equal change of draught produces small change in length, breadth, and area of the planes of flotation, and these dimensions are practically equal to the extreme length and breadth of the vessel. For the cruiser the moments of inertia of successive planes of flotation about their principal axes remain nearly constant within these limits of variation in draught; whereas for the submarine moments of inertia diminish rapidly as the draught of water is increased. In the cruiser the extreme length is 260 feet, and the metacentre for longitudinal inclinations is 352 feet above the centre of buoyancy at light draught, and 328 feet when the draught is increased by eighteen inches. In the submarine the extreme length is 150 feet, but the corresponding height of longitudinal metacentre above centre of buoyancy is only 37 feet at lightest draught, and falls to $1\frac{1}{4}$ feet when the vessel is prepared for diving. At the lightest draught the power of the submarine to resist longitudinal inclinations (changes of trim) is relatively small; in the diving condition it is diminished almost to vanishing point. It will be understood, therefore, that when a submarine is prepared for diving every man has to remain at his station, and no weights must be moved; every opening into the interior must be closed hermetically. The reserve of buoyancy is extremely small in the diving condition. A submarine of more than 200 tons weight may have only 400 to 800 pounds reserve—representing 40 to 80 gallons of water.

Even at their lightest draughts the reserve of buoyancy of submarines is very small as compared with that in other vessels. In good examples it is 6 per cent. of the corresponding displacement—little more than half the lowest percentage accepted for low-freeboard monitors when fully laden, and about one-fourth the corresponding percentage for the deepest laden cargo steamers. Openings into the interior are placed at the tops of conning towers at a considerable height above water, and Admiralty regulations provide that all openings shall be closed before water-ballast is admitted to bring a vessel into the diving condition. Further, it is now provided that before proceeding at full speed at the surface, the maximum reserve of buoyancy shall be secured by emptying ballast tanks. One of the most serious accidents that have occurred to British submarines—that to A 8—was unquestionably due in great measure to proceeding at full speed with about half the maximum reserve of buoyancy, certain tanks containing water-ballast. The vessel was driven under water as she gathered speed, dipped her bow suddenly, brought the open top of the conning tower to the water-level, was partly filled, and foundered.

Maintenance of the full reserve of buoyancy and lightest draught of water when proceeding at the surface increases safety in two directions. It secures much greater longitudinal stability, and diminishes the tendency to plunge produced by the relative motions of the water surrounding the vessel, especially at the bow. These motions are largely discontinuous, broken water being piled upon the bow, and the phenomena being of such a character that only direct experiment on models or vessels can give accurate information. Such experiments have been made both in this country and abroad, and they indicate the occurrence of a tendency to plunge at certain critical speeds. The problems are still only partially solved, but it is certain that the maximum reserve of buoyancy should be maintained. It also appears desirable to keep the vessels on an even keel, since a cigar-shaped form has then its maximum longitudinal stability for a given mean-draught of water. In the Royal Society paper calculations are recorded showing the diminution of stability accompanying changes of trim in submarines.

In modern submarines of large size the operation of diving is performed when the vessels have headway. Horizontal rudders, controlled by skilled men, are employed as the active means of depressing the bow. The pressures on the upper surface of the vessel resulting from the relative movement of the surrounding water develop a vertical component acting downwards which overcomes the small reserve of buoyancy and the vertical component of the pressures on the rudder. The submarine then moves obliquely downwards. When the desired depth below the surface has been reached the steersman operates the horizontal rudders in such a manner that the vessel shall advance on a practically horizontal course, although it really is an undulating one. Watchfulness and skill are necessary to achieve this result, and there must be no movements of men or weights which would vary the position of the centre of gravity. If such movements become necessary—as, for example, when torpedoes are discharged—compensation must be arranged to take effect at once. Failures to comply with these conditions may involve serious consequences, and have caused submarines to dive to great depths. With trained and disciplined crews such accidents are rare. Plans for automatic maintenance of any desired depth—similar to those used in locomotive torpedoes—have been brought forward and tried; but for large submarines manual control has been found preferable. In small submarines it has been found possible to dive without headway by varying the volume of displacement, admitting water into suitable chambers from which it can be readily expelled when the desired depth has been reached, and a balance restored between weight and buoyancy. Such methods involve the necessity for minute and rapid adjustments, which can be secured on a small scale much more readily and certainly than on a large scale. As a consequence, horizontal rudders and headway have been generally adopted for large submarines, and have answered well on the whole. One great advantage of the plan is that when headway ceases the horizontal rudders become inoperative, the small reserve of buoyancy reasserts itself, and the submarine comes to the surface. The other system—varying the volume of displacement especially when applied to large vessels, involves risks of reaching great depths in a short time before buoyancy can be restored. This is recognised in vessels which work on that system, and detachable external weights are fitted, so as to restore buoyancy in cases of emergency.

There has been a considerable increase in the speed of submarines, both at the surface and when submerged. Our latest types are said to have surface speeds of thirteen knots and a radius of action of 500 miles with their gasoline engines, while the underwater speed is nine knots and radius of action 90 miles. These higher speeds are attainable, no doubt, but they necessarily involve greater risks, especially in the diving condition. Pressures on horizontal rudders increase as the *squares* of the speeds, and the extreme sensitiveness of submarines when submerged to the action of external forces tending to produce changes of trim must demand much greater watchfulness, skill, and promptness of action on the part of steersmen than are now required, if greater speeds are to be attained under water. The risks of attaining rapidly excessive depths of submergence must increase as speeds are raised, and they are now far from negligible. At the lightest draughts increase of speed would also involve greater risks of accidental plunging. Exhaustive experiments are necessary, therefore, before designers of submarines commit themselves to the production of vessels having much greater surface speeds, and still more of vessels having much greater under-water speeds. Submarine design is not a task to be lightly undertaken by amateurs; it requires thorough experimental and scientific treatment by competent naval architects, who should be furnished by naval officers with the strategical and tactical conditions to be fulfilled in the completed vessels, and should ascertain what is involved in the fulfilment of these conditions.

W. H. White.

THE RISE AND PROGRESS OF THE ZOOLOGICAL SOCIETY.[1]

It was a happy thought on Mr. Scherren's part to tell the story of the Zoological Society of London, and he is to be congratulated on the success with which he has accomplished his evidently congenial task. The history of a development is always interesting, especially when it is still progressing, and there is, moreover, a strong personal interest in the book, since many eminent workers, whose names and deeds are familiar, have cooperated in various ways in furthering the welfare of the society since its inception in 1826. Mr. Scherren's book is not only a careful contribution to the history of zoology in Britain during the last eighty years, but is at the same time good reading for its revelation of what goes on behind the scenes in a scientific society, and for its record of many interesting events in what is familiarly called the "Zoo."

On November 29, 1822, John Ray's birthday, a bud from the Linnean Society formed itself into a "Zoological Club," which four years afterwards took shape as the Zoological Society. There were 342 members at the close of the year, and there are now ten times as many. In 1828, when the gardens were opened to the public, there were about 600 specimens, and there is now a specimen for each F.Z.S. A farm for breeding purposes and experimental work (from which nothing very noteworthy ever resulted) was established in 1829 at Kingston Hill, and scientific meetings began to be held in 1830. Such were the

[1] "The Zoological Society of London: a Sketch of its Foundation and Development, and the Story of its Farm, Museum, Gardens, Menagerie and Library." By Henry Scherren, F.Z.S. Pp. xii+252; 12 coloured plates, 50 uncoloured plates, 9 plans. (London: Cassell and Co., Ltd., 1906.) Price 30s. net.

beginnings of the Zoological Society. How it grew from more to more Mr. Scherren tells us with no lack of circumstantial detail. We see the long procession into the scientific ark, we hear the quaint comments made when conspicuously new creatures arrived, we can realise from the abundant plates how the "houses" increased in number, size, and efficiency, and we are reminded how men like Owen, Yarrell, Waterhouse, Gould, Huxley, Flower, Sclater, Murie, and Wolf helped the Society forwards in varied ways. From time to time there were new departures, such as the publication of Proceedings and Transactions, the institution of aquarium and insect-house, the formation of a library, the experiment of the Davis lectures. As in many a development there were periods of rapid growth and of temporary arrest, of crisis and metamorphosis, and there was quite recently a general reorganisation. The author gives expression to the view forced upon him by the history "that before the Zoological Society was half a century old its bionomical work practically ceased owing to the increasing influence of morphographers and systematists in its councils. The election of the Duke of Bedford as president, the recommendations of the Reorganisation Committee, and subsequent changes, mark a return to lines laid down by the charter." We fervently hope that this policy will be adhered to, and that the "Zoo" will gradually become a recognised centre of bionomical research and evolutionist experiment.

FIG. 1.—Rocky Mountain Goat. From "The Zoological Society of London."

No naturalist can read this well-told history without having his gratitude to the Zoological Society revived, not only for what it has directly accomplished through the gardens and the workers there, through the scientific meetings and the publication of what has been submitted there, but also for the way in which the society has given aid and encouragement to bibliography (notably through the Zoological Record), to institutions such as the biological stations of Naples and Plymouth, as also to travellers, collectors, and, indeed, zoologists at large. The excellence of the plates which adorn Mr. Scherren's volume reminds us also of the important part the society has played in sustaining and raising the standard of zoological illustration.

THE INTERNATIONAL FISHERIES INVESTIGATIONS.

THE latest publications of the International Fisheries Organisation consist of the part of the *Bulletin des Resultats* containing the results of the quarterly cruises carried out in May, 1905, the fourth volume of *Rapports et Procès-Verbaux*, and Nos. 28 to 32 of the *Publications de Circonstance*. The bulletin contains the usual data—hydrographical and plankton observations obtained in the course of the obligatory voyages made by the exploring vessels. At first the west coast of England and the coasts of Ireland were not included in the area to be investigated, but for the last year the Irish Board of Agriculture and Technical Instruction have allowed their steamer to make the necessary quarterly cruises, and a report on these is now made to the International Council by Mr. E. Holt.

The *Publications de Circonstance* include an account of an investigation of the fisheries for salmon and sea-trout in the rivers and neighbouring waters of the Baltic, with special reference to measures of artificial culture, being the report of an international commission appointed by the International Council for Fishery Investigations, and two papers by Dr. R. J. Witting, of a very technical nature, dealing with the measurement of ocean currents, one of them describing a new electrically registering current meter. The two remaining reports are by Dr. C. Kofoid and Dr. L. Gough, the former dealing with a means of studying plankton from deep water layers, and the latter describing the migrations of an oceanic species of Siphonophore.

In the former paper Dr. Kofoid describes the construction of a bucket for obtaining samples of water from considerable depths. Plankton from deep water has hitherto been obtained chiefly by means of self-closing nets, or by bringing up water from the requisite depth by a pump and hose-pipe, both methods of some uncertainty in their results. The apparatus described consists of a bucket of considerable dimensions which is lowered down to the depth required, where it fills with water, and is then closed by means of a specially constructed catch and "messenger." The samples of sea-water obtained by making a number of hauls with this apparatus are then filtered in the ordinary way, and the organisms present are so obtained. It is claimed that the apparatus is simple and certain in its results, and that it can also be used for obtaining temperatures from the depths to which it is lowered.

Dr. Gough describes the distribution of the Monophyidan genus *Muggiaea atlantica*, Cunn., in the waters of the English Channel, the Irish Sea, and off the south and west coasts of Ireland during the year 1904. It is shown that a shoal of Muggiæa entered the Channel in May, and that the shoal was introduced into this area by the current of Atlantic water which, just before this time, had set into the Channel as a stream flowing north past Ushant from the Bay of Biscay. The shoal entered the English Channel and reached as far as Plymouth, from which region it disappeared at the end of the year. After entering the Channel the shoal divided, and, rounding Land's

End, one portion entered the Irish Sea, and by September had reached as far north as the Cardigan Bay and south Arklow light-ships. The other part of the shoal passed along the south coast of Ireland, and was observed in November as far along the west coast of Ireland as Galway Bay. The disappearance of the shoal from the Irish Sea in September is attributed to the southerly flow of water from that area into the Channel blocking its further northerly migration. It is shown that the shoal must have entered the Irish Sea from the south, for plankton collections taken from the Bahama light-ship in the north of that area did not contain the organism, which could not, therefore, have passed through the north channel. The paper is illustrated by charts which show the distribution of Muggiæa from month to month during the year 1904.

The volume of *Rapports* is noteworthy only because of a statement made by Mr. Archer, the English Chief Inspector of Fisheries, at one of the "reunions," that it is the wish of the British Government "that no tasks should be undertaken or interests created the conclusion of which could not be reasonably looked for by July, 1907," since it is not the intention of the Government to continue the large expenditure involved beyond the five years originally contemplated. It is very probable, then, that the British share of the work will cease in the course of another year, and that with the withdrawal of this country the international investigations will come to a close.

It has, indeed, been apparent for some time past that the International Organisation, as at present constituted, could not continue on a permanent basis. For the last five years it has been necessary to maintain, at a very great expense, the Bureau at Copenhagen, the Central Laboratory at Christiania; and a complex system of "reunions" of the council, the "commissions," the "special commissions," and "sections." All this organisation was no doubt necessary, in the first instance, to bring together those engaged in the work, and to secure the necessary coordination in the hydrographical investigations. But since this preliminary organisation must now have been completed, it is desirable in any case that some simpler and less expensive means of coordination should have been evolved. It should be remembered that the international scheme of investigations originally included fishery research proper, hydrographical investigations, and, though this has never been stated in so many words, the promotion of international agreement with respect to the observance of "closed areas," such as the Moray Firth, and the regulation of fishing on the high seas. With regard to the latter point one cannot speak at present, but it may be pointed out that fishery legislation on an international scale has been notoriously difficult to obtain in the past, and that the chances of securing this at the present time ought not to be jeopardised by the unconditional withdrawal of Great Britain from the scheme of international work. Purely fishery investigations need not be imperilled by any such action. There does not appear to be any real advantage in the prosecution of these on an international scale. No amount of research carried out in another area than our own will relieve us of the necessity of investigating fishery questions locally with respect to the special economic and legislative problems involved. Fishery research with regard to such issues as the protection of immature fishes, closed areas and closed seasons, the regulation of fishing methods, and the like, must be carried on if fishery restrictions are ever to be more than an expensive and vexatious interference with the legitimate operations of our fishermen. If a fair proportion of the annual grant at present made to the International Organisation is in the future made to supplement the efforts of existing fishery research institutions, with, of course, proper Government inspection, then the withdrawal of our Government from the international scheme need cause no apprehensions.

It is different with regard to the hydrographical investigations. If these are to be carried on at all it must be on an international scale, and with proper coordination as regards methods and publication of results. Quite apart from the assistance which such research is likely to afford meteorological science, it seems now to be certain that it is sure to throw light on the ultimate causes which affect the shoaling movements and migrations of food fishes. There is really no good reason why, even if the fishery investigations of the International Organisation be dropped, the hydrographical work should not go on. The present hydrographical cruises could be continued by the national staffs; and methods having already been worked out, the coordination of the work and the publication, in a uniform style, of the results need entail no great expense. The international conferences which have become so marked a feature of fishery affairs, both on the administrative and scientific sides, might be dispensed with, and no really useful object would be sacrificed.

NOTES.

THE council of the Society of Arts has awarded the Albert medal for the present year to Sir Joseph W. Swan, F.R.S., "for the important part he took in the invention of the incandescent electric lamp, and for his invention of the carbon process of photographic printing."

A LARGE physical laboratory is, the *Pioneer Mail* states, to be built by the Punjab Education Department in Lahore on the present camping-ground of the Public Works Department, as soon as the new Public Works offices are constructed.

THE *British Medical Journal* states that a general institute of psychology specially intended for the study of the phenomena of subconsciousness, the investigation of the causes of criminality, and the discovery of means of curing social evils will shortly be formally constituted in Paris. Among those to whom the initiation of the scheme is mainly due are Profs. Brouardel, d'Arsonval, and Gariel, and MM. Boutroux, Giard, and A. Picard.

WE notice with regret the announcement of the death, at eighty-three years of age, of M. Raphael Bischoffsheim, honorary member of the Paris Academy of Sciences. M. Bischoffsheim was a generous benefactor to science. He contributed largely to the Pic du Midi Observatory, bore the expense of the great equatorial at Paris Observatory, gave largely to the Montsouris Observatory, and founded the fine observatory at Nice. He was elected a member of the Institut de France in 1890 in succession to M. Cosson.

A COMMITTEE has been formed with the object of establishing a memorial of the late Sir William Wharton, K.C.B., F.R.S., whose death at Cape Town in September last was a sad incident of the British Association meeting in South Africa. For a long period Sir William Wharton filled with distinguished ability the important post of hydrographer to the Navy, and the committee has decided that the most appropriate testimonial would be such as would follow the same lines and exist for the same purpose as the Beaufort testimonial, which is awarded as a prize to the officer who has distinguished himself as having passed the best examination in mathematics and nautical astronomy for lieutenant in his year. This Sir William Wharton won in the year 1865. By the proposed arrangement two awards for the same object would be given under the names of "The Beaufort Testimonial" and "The Wharton Testimonial," thus associating the names of the two eminent hydrographers who have served for the longest periods in that capacity. It is proposed in addition, if the funds admit, to present a medal, having on the obverse a bust of the late Sir William Wharton, and on the reverse a suitable inscription. The committee includes Vice-Admiral Sir Charles Drury, K.C.B., K.C.S.I.; Captain A. Mostyn Field, F.R.S.; Vice-Admiral Swinton C. Holland; Admiral of the Fleet Sir F. Richards, G.C.B.; and Captain T. H. Tizzard, C.B., F.R.S. Messrs. Coutts and Company, Bankers, 440 Strand, London, have arranged to receive contributions to the fund.

ON May 25 Lord Avebury presided at the annual conversazione of the Selborne Society and delivered his presidential address. He spoke of the coming of age of the society, of the interest which many members were taking in the forthcoming "Country in Town" Exhibition, and of the bird sanctuary maintained by the Ealing branch. He also alluded to the destruction of roadside beauty, to the way in which ladies prefer the authority of shopkeepers to that of ornithologists with regard to "artificial ospreys" so called, and to the injury to birds, which gamekeepers still continue to do. In the latter part of his remarks Lord Avebury dwelt upon the manner in which the study of nature adds to the happiness of life. Nearly 700 guests were present, and there was a large number of interesting exhibits, including some fifty microscopes exhibited by members of the Royal Microscopical Society, the Quekett Club, and other institutions.

MESSRS. R. B. Woosnam, D. Carruthers, and A. F. R. Wollaston, three members of the zoological expedition sent to Africa under the auspices of the Natural History Museum, South Kensington, have made the following ascents in the Ruwenzori range. On April 1 they ascended Duwoni, the peak rising to the north-east of the Mubuku Glacier. This peak has two tops of apparently equal altitude; the southern top, which was reached, was found to be 15,893 feet. On April 3 they ascended Kiyanja, the peak at the western end of the Mubuku group of peaks. The altitude was found to be 16,379 feet. (The altitudes were taken by aneroid and by the boiling-point thermometer.) Both these peaks have been thought by different explorers to be the highest points in Ruwenzori, but from the summit of Kiyanja a still higher peak with two tops was seen in a north-westerly direction. The weather at this season of the year is very unfavourable, the mountains being almost constantly buried in clouds with frequent snowstorms, which prevented the party from making further explorations.

ON Friday last, June 1, the Secretary for Scotland received a deputation of the Royal Scottish Geographical Society, laying before him the claims of the society in connection with the proposed National Galleries Bill (see p. 137). The deputation was introduced by Mr. C. E. Price, M.P., and the society's position and claims were explained by Prof. Geikie (president), Mr. W. B. Blaikie, Dr. George Smith, Mr. W. C. Smith, K.C., and Mr. Ralph Richardson. The national character of the society was touched upon, as also the important work it did in fostering the study of geography, in providing lectures by eminent travellers in the four great centres of population, and in giving facilities for the inspection of maps and valuable geographical works. It was claimed that the society should be recognised officially as one of the scientific societies of Scotland, to be provided with premises free of rent (at present 120*l*. is paid in rent), to have a grant from State funds, and to be represented on the new Board of Trustees. Reference was also made to the present endeavour to found a chair of geography in the University of Edinburgh. The Secretary for Scotland in reply thanked the members of the deputation for their presence, and pointed out that their memorial went further than the recommendation of the departmental committee which recommended the remission of the rent of 120*l*. which the society pays for its accommodation in the National Portrait Gallery. He was not sure that this was a convenient time to urge the Government to further expenditure, but he would not fail to take into serious consideration all that had been urged in the interests of the society.

WE regret to announce the death on May 29 of Dr. William Fream, who since 1894 acted as the agricultural correspondent of the *Times*, and was formerly a frequent contributor to our columns. Born in 1854, Dr. Fream was educated at the Royal College of Science, Dublin, and became professor of natural history at the Royal Agricultural College at Cirencester. After lecturing for a time on botany at the Guy's Hospital Medical School he became professor at the Downton College of Agriculture. Later he was chiefly engaged in writing, and for ten years acted as editor of the Journal of the Royal Agricultural Society. His best-known books were one on the Rothamsted experiments and his "Elements of Agriculture," written for the Royal Agricultural Society, which reached its seventh edition last year. Dr. Fream will be remembered for the part he took in a controversy as to the merits of perennial rye grass in pastures, a controversy which cannot yet be regarded as settled. Mr. Faunce de Laune, and with him Mr. Carruthers, maintained that rye grass was neglected by stock, and should be excluded from any mixture used for sowing down land to grass. Dr. Fream, however, by growing pieces of turf selected from the most famous pastures in the country, demonstrated that rye grass was a large constituent of such good grass land, and in consequence argued strongly in favour of the high opinion in which this grass has always been held by practical farmers.

PRELIMINARY arrangements have been made for the establishment of a great marine museum in New York with an astronomical museum as an adjunct to it. The New York Observatory and Nautical Museum will, according to *Science*, have an endowment of not less than 100,000*l*., and, in addition to this, it is expected that the city of New York will provide a site in Bronx Park adjacent to the botanical garden and zoological park, and will also erect the museum building and the domes and smaller buildings for the observatory. In the nautical museum will be collected and exhibited models of all types of vessels, safety and signal devices, nautical instruments and methods of determining position, charts, marine engines and motors, and historic instruments and relics. The museum and collections will be arranged so that properly qualified persons can avail themselves of the facilities there offered for investigation and research. The observatory will be provided with a great telescope, for photographic and visual work, astrophysical instruments for the investigation of solar problems, magnetometers, seismographs, and other necessary instruments. A time service will be instituted so that chronometers may be rated, marine instruments will be tested, and tidal investigations will be inaugurated.

Commenting upon Mr. Southerden's letter on "Carbon Dioxide in the Breath," published in Nature for May 24 (p. 21), Mr. E. A. Parkyn writes to direct attention to the well-recognised fact that the presence of 0·06 per cent. of carbon dioxide in the atmosphere need not be injurious, but that the gas is generally found in bad company, for an increase of carbon dioxide is almost invariably accompanied by a corresponding increase of organic impurity. In other words, the importance attaching to the rise of carbon dioxide to 0·06 per cent. is a true indication of the vitiation of the air by organic matter given out during respiration.

A communication from the Zi-ka-wei Observatory, near Shanghai, informs us that the great San Francisco earthquake was registered by the seismographs there. The shocks were fairly strong, and they lasted a little more than 1h. 34m. The first preliminary tremors, transmitted through the mass of the globe, began at 9h. 35m. 0s. p.m. Chinese coast time. The first large waves, travelling along the crust, on an arc of a great circle, were felt at 9h. 55m. 54s. The last waves of decreasing amplitude left their trace at 10h. 31m. 35s. p.m., and the last slight movements of the ground died away at 11h. 9m. 44s. p.m. April 18. These records should be of service in determining the velocity of propagation of the seismic undulations by connecting them with observations of the exact minute and second of the occurrence at San Francisco.

Mr. Charles Van Norden, writing from East Auburn, California, U.S.A., says that he was on the fourth floor of the Palace Hotel, San Francisco, on April 18, when the disastrous earthquake occurred. The movement seemed from south to north, and the rocking of the massive walls of the hotel was so violent that its continuance even for a few seconds seemed impossible. To Mr. Norden, who was in bed, the motion seemed like that of a small rowing boat on a choppy sea. The shock occurred at 5.13 a.m., and at 6 a.m. Mr. Norden had left San Francisco by the ferry boat for Oakland. While sitting on the deck of the ferry boat, looking at the many fires gathering together in a great conflagration, he noticed a thunder-cloud—a white, cumulous mass, dark at the bottom—hanging over the city. The morning was clear and mild for San Francisco, and no other cloud was in sight. None of the descriptions of the catastrophe mentions this feature, and Mr. Norden is curious to know if other observations were made of it.

An excellent little *résumé*, by Mr. D. J. Scourfield, of the leading features and possible developments of Mendel's law of heredity appears in the Proceedings of the South London Entomological and Natural History Society for 1905–6. Other articles are devoted to the British plume-moths, the lengthened pupa-stage of certain Lepidoptera, and notes on Hawaiian entomology.

The contents of the *Sitzungsberichte und Abhandlungen* of the Dresden Isis for the second half of 1905 include an article by Prof. O. Drude on the meaning and scope of the term œcology (ökologie), or the manifestations of plant and animal life in regard to the struggle for space (or existence) in connection with climate and other external influences. Mr. H. Engelhardt contributes an illustrated article on the Tertiary flora of Chili.

A striking instance of increased patronage due to the adoption of "popular prices" is recorded by Captain Stanley Flower in his report of the Giza Zoological Gardens for the past year. By the reduction of the gate-money the number of visitors to the garden leaped up from 64,711 in the previous year to 177,587, an excess of 112,876 over any other year. The receipts showed, however, but a comparatively small increase £E.1402 against £E.1388 in 1904. The stock of animals has been largely increased, and a notable new feature in the gardens is the formation of an extensive enclosure, where a number of the larger birds of the Nile Valley are allowed to roam at comparative liberty.

Old churchwardens' accounts of various Bedfordshire parishes have been utilised by Mr. J. Steele-Elliott, for an article which appears in the May number of the *Zoologist*, to afford information with regard to the fauna of the county during the last two and a half centuries. The entries cited refer to sums paid for the destruction of "vermin." The absence of mention of birds of prey is noticeable, as is the infrequent occurrence of rats, but special interest attaches to certain entries referring to martens. Polecats were evidently once abundant, and it is curious to note the persistent war waged against the hedgehog probably on account of its supposed milk-sucking propensities. Mr. Heneage Cocks refers, in the same issue, to an artificial cave at Park Place, Remenham, Berks, which forms the abode of a number of bats, some belonging to rare species, including *Myotis bechsteini*.

We have received seven parts (Nos. 1448, 1449, and 1452 to 1456) of the Proceedings of the U.S. National Museum, which include descriptions of Japanese Hymenoptera and of South American geometrid moths and grasshoppers, as well as of two American river-mussels; fully illustrated notes on molluscs of the family Pyramidellidæ from Japan, America, and the intermediate areas; a synopsis of Japanese sturgeons; and an account of the osteology of the creodont carnivorous mammals of the genus Sinopa. The latter genus, which occurs in the Lower and Middle Eocene of North America, according to Mr. W. D. Matthew, may be regarded as an extremely primitive form, with cheek-teeth of the opossum-type, from which have been evolved the more specialised Cynohyænodon, Pterodon, and Hyænodon of the Oligocene. Japanese sturgeons are, it appears, represented only by two species. Of the Pyramidellidæ, Messrs. Dall and Bartsch name a number of new species, and also figure others.

The application of De Vries's mutation-theory to molluscs forms the subject of an article by Mr. F. C. Baker in the May number of the *American Naturalist*. The shells selected for observation are fresh-water snails, more especially Limnæa and Valvata, the former of which is well known to be an exceedingly variable or "unstable" type. Series of specimens of Limnæa from particular localities are figured to exhibit the range of variation, which is so great that the extreme forms, if isolated, would be allowed specific rank. Special attention is directed to the sudden development of an apparently new species in a newly-formed pond in the United States. While the mutation-theory seems to account more satisfactorily than any other for these variations, the author deprecates haste in applying a hypothesis founded upon plant-variation to animal life. In the same issue Dr. E. A. Andrews discusses the mode in which American crayfish of the genus Cambarus lay their eggs. The first process is the careful cleansing of the lower surface of the body preparatory to the extrusion of a glairy substance from the "cement-glands" in which the eggs are afterwards laid. During oviposition the female lies supine and externally inert, but after this occurs a long, rhythmic alternation of poses connected with the fastening of the eggs to the abdominal appendages.

THE *Haslemere Museum Gazette* is the title of a new serial published by the institution the name of which it bears, and to be issued in monthly parts at the price of sixpence. The Haslemere Museum specially devotes itself to education at first-hand, that is to say, by inculcating familiarity with actual specimens rather than the cultivation of mere book-knowledge. One of the objects of the new journal is to assist and amplify this excellent conception. It is proposed to refer in turn to the chief museums in London (including those devoted to art), the Zoological Society's Gardens, &c., and to direct the attention of readers to some of the most noteworthy objects in each. By this means—without in any way usurping the function of a "guide"—it is urged that the educational value of such establishments will be largely increased. Nor will nature itself be neglected, as is demonstrated by the frontispiece, representing two oaks growing under similar conditions, but one with and the other without leaves. Excellent "lecturettes" on prehistoric times and the severance of Britain form part of the contents of the first number. Giraffes in the British Museum, with a (not absolutely accurate) transcript of the accompanying label, form the subject of another section.

IN connection with the study of the occurrence of glycogen and paraglycogen in fungi, the late Prof. Errera compiled a bibliography of the subject. The list of papers with his abstracts on their contents is published in *Recueil de l'Institut botanique*, Brussels, vol. i., 1905.

IN the *Bulletin du Jardin impérial botanique*, vol. vi., part ii., Madame O. Fedtschenko writes a note on species of Eremurus in which she refers the species *Eremurus Aucherianus* and *Eremurus Korolkowi* from Turkestan to *Eremurus anisopterus* and other species. Mr. V. Arcichovskij discusses the size of plants as a specific character.

To replace the list of ferns and fern-allies cultivated in the Royal Gardens, Kew, issued in 1895 and now out of print, a second edition compiled by Mr. C. H. Wright has been published. The plants are enumerated under the three groups of ferns, fern-allies, and cultivated forms of British ferns. The table of fern-distribution throughout the world, drawn up by Mr. J. G. Baker for the previous edition, has been revised, showing a considerably increased percentage for temperate Asia.

A DETAILED account of the distribution of the forest flora of the Bombay Presidency and Sind has been contributed by Mr. W. A. Talbot to the *Indian Forester* (January to March). Mr. Talbot distinguishes an evergreen forest flora of Malabar showing a decided Malayan affinity, a Deccan dry deciduous flora in which African elements predominate, and the flora of the Western Ghats and Konkan, in which there is a mixture of high deciduous and evergreen forests. The dry Deccan flora includes such typical species as *Zizyphus jujuba*, *Acacia catechu*, *Sterculia urens*, and *Bombax malabaricum*. Myristicas, Dipterocarpeæ, laurels, and palms are characteristic of the tropical evergreens.

THE Bulletin of the Johns Hopkins Hospital for May (xvii., No. 182) is mainly devoted to medical subjects. Dr. Cushing contributes an interesting article on a course of instruction in operative medicine, and Dr. Pratt one on the home sanatorium treatment of consumption, in which the problem of applying the open-air treatment of tuberculosis in the homes of the poor is dealt with. The proceedings of the Johns Hopkins Historical Club are devoted to a "symposium" of the "gold-headed" cane, a stick or cane, now in the possession of the Royal College of Physicians of London, which made its appearance in medical circles about the year 1689, and for one hundred and thirty-six years was carried by a leading London practitioner, including John Radcliffe, Richard Mead, Anthony Askew, William Pitcairn, and Matthew Baillie, all well-known names in medical history.

WE have received from Mr. Herbert Kynaston, director of the Transvaal Geological Survey, a copy of his memoir on the geology of the Komati Poort coalfield (Pretoria, 1906, price 7s. 6d.). It covers 55 pages, and constitutes the second of the series of descriptive memoirs which it is the intention of the Geological Survey to issue from time to time. It is an admirable piece of work, giving a connected account of the character, behaviour, and distribution of the coal-bearing strata of the Komati Poort district. A description is also given of the associated sedimentary and igneous rocks. Apart from the prevalence of intrusive sheets and dykes of igneous rock throughout the coal-bearing strata, the conditions are favourable, and no evidence was observed of the beds having been disturbed by faulting in a manner that would be discouraging to mining operations. The actual Coal-measure series occupy 150 square miles, and the great thickness of the coal-bearing strata, and the favourable situation of the better portion of the field, render the prospects eminently satisfactory. The memoir is accompanied by two coloured geological maps and six sections, and six photographic views giving an excellent idea of the character of the scenery on the Crocodile and Komati rivers.

SOME valuable results of an experimental investigation on the effect of fire on building stones were described by Mr. W. R. Baldwin-Wiseman at a meeting of the Surveyors' Institution on May 14. The purpose of the research was not so much to determine the design of a building for fire resistance as to estimate the ultimate stability of an edifice after subjection to a severe conflagration, and to afford some small assistance to those who may be called upon to decide whether demolition or reconstruction shall succeed the wrecking influences of a big conflagration. The points of primary importance in determining the most efficient design for fire resistance are summarised as follows:—(1) That the edifice should in no wise be flimsy; (2) that it should be constructed of stone possessing a uniform or fairly uniform coefficient of expansion, and retaining a considerable strength after subjection to high temperatures; (3) that all combinations of different stones should be avoided as much as possible; (4) that combinations of stone and metal should be avoided, especially when the former rests directly upon the latter, even when the metal is entirely enshrouded in stone, for stone acts as a fairly good conductor of heat; (5) that stair wells and lift wells should open as little as possible on to the main building, and should preferably be enclosed and glazed with wired glass from basement to roof; (6) that floor areas should not be unduly large or corridors unduly long.

THE first parts of two serial publications, issued by Messrs. Cassell and Co., Ltd., have been received. A new edition of Prof. G. S. Boulger's "Familiar Trees" is to be completed in twenty-nine fortnightly parts, and will contain 114 coloured plates and 114 illustrations from photographs. Mr. W. F. Kirby's "Butterflies and Moths of Europe" will be published in thirty-two instalments at fortnightly intervals; and the completed volume, with its large pages and fifty-four coloured plates, will form an attractive addition to the naturalist's reference library.

Mr. T. Fisher Unwin has published a second edition of "Methods in Plant Histology," by Dr. C. J. Chamberlain, of the University of Chicago. The first edition of the book appeared in 1901, and was reviewed in our issue of November 28, 1901 (vol. lxv., p. 75). It is only necessary to say of the present edition that more attention has been given to the collection of materials. Prof. Kleb's methods for securing various reproductive phases in the algæ and fungi have been outlined, and methods for growing other laboratory material are more complete. New chapters dealing with microchemical tests, free-hand sections, special methods, and the use of the microscope are included.

OUR ASTRONOMICAL COLUMN.

Sun-spot and Chromospheric Spectra.—A paper of exceptional interest to workers in solar physics was read by Prof. A. Fowler at the April meeting of the Royal Astronomical Society.

Whilst observing the bright lines in the spectra of metallic prominences on the sun's limb, Prof. Fowler has been able to classify them into "long" and "short" lines, a fact which points to their origin being in the higher and the lower chromosphere respectively; he also states the fact that the lines emitted by the upper chromosphere, the "long" lines, are those which, speaking generally, are enhanced when passing from the arc to the spark in terrestrial spectroscopy.

Further, Prof. Fowler found that these long lines are generally *weakened* in sun-spot spectra, whilst the short lines are generally widened, or *strengthened*. The evidence for this differential treatment of "enhanced" and "arc" lines in the solar atmosphere is most conclusive for the elements iron, titanium, and chromium (the *Observatory*, No. 370).

Proposed Daily Photographs of Chromospheric Radiations.—A paper by M. Deslandres, which is published in the *Comptes rendus* for May 7, discusses in detail the possibility of obtaining daily photographs of the radiations emitted by the solid and liquid particles of the chromosphere, without waiting for the rare occasions afforded by total eclipses of the sun.

In order to do this M. Deslandres proposes to employ an apparatus similar to that used by him for the same purpose during the last eclipse, and to obtain a concentrated image of the chromosphere, without the photosphere, by a special arrangement of mirrors and lenses.

If the coloured screens are insufficient, it is suggested that the spectroheliograph might be employed. By obtaining the ordinary spectroheliograms with K_1 and K_2, and then another in which the bright interspaces, *i.e.* the continuous spectrum, were projected on to the primary slit, it would be possible to separate the parts due to the particles from those parts of the chromospheric radiations due to permanent gases.

M. Deslandres further suggests that the same methods, if successful in this instance, might be employed for the analysis of the structure of other celestial bodies such as nebulæ and comets.

Stars with Variable Radial Velocities.—A list of four stars the radial velocities of which have been found to be variable is published by Mr. J. H. Moore in No. 3, vol. xxiii., of the *Astrophysical Journal*.

The radial velocity of τ Ursæ Majoris has been found to vary between -1 km. and -10 km., that of λ Hydræ between $+15$ km. and $+24$ km., and that of μ Ursæ Majoris between -16 km. and $+27.4$ km. In the case of Y Ophiuchi, discovered to be a spectroscopic binary by Mr. S. Albrecht, the variation of the velocity is found to agree, in point of time, with the light variation, both having the period 17·12 days.

Four other spectroscopic binaries with variable velocities are announced by Prof. Frost in the same journal. The first two, B.D. $-1°.1004$ and 29 Canis Majoris, are remarkable for the long range of their velocities and their short periods. In the former of these two, the radial velocity changed from $+132$ km. on February 12 to -34 km. on February 16, whilst that of the second star changed as follows:—1906 January 26, -164 km.; January 29, -3 km.; February 12, -243 km.; February 16, -92 km. Owing to under-exposure, these results are, however, slightly uncertain.

The stars μ Orionis and T Monocerotis have also been shown to have variable velocities in the line of sight.

Observations of Nova Persei No. 2.—No. 96 of the Lick Observatory Bulletins is devoted to the publication of the results obtained by Messrs. Townley and Maddrill from magnitude observations of Nova Persei No. 2.

The observations extended over the period February 24, 1901, to July 5, 1902, the magnitude on the latter date being 9·4.

The table given contains the weighted, mean magnitudes of the Nova on more than one hundred nights, with notes on the observing conditions and the comparison stars and instruments employed.

Observations of Shadow Bands.—In No. 4086 of the *Astronomische Nachrichten* Dr. M. Roso de Luna, of Madrid, briefly describes a new arrangement of screens for the observation of the shadow bands during total eclipses of the sun. Altogether he proposes to employ six screens, one horizontal, two vertical (N. and S. and E. and W.), one oriented to the azimuth of the sun at the moment of totality and another perpendicular to it, and one placed in the direction of the wind.

Such an arrangement was employed at Soria (Spain) during the last eclipse, and the following results obtained:—breadth of bands, 2 cm.; distance from one band to the next, 6 cm.; velocity of the movement of the bands, 30 metres per minute.

The Radial Motion of β Arietis.—In No. 4090 of the *Astronomische Nachrichten* Herr H. Ludendorff publishes the results obtained from an investigation of the radial velocities of β Arietis during the period October 21, 1902, to December 16, 1904.

Thirty-seven spectrograms were obtained with the spectrograph No. iv. (three prisms) of the Potsdam Observatory attached to the 32·5 cm. refractor, and the range of the velocities determined was from $+60$ km. (on January 19, 1903) to -17 km. (on December 25, 1903).

From an analysis of the results, Herr Ludendorff concludes that the period of β Arietis is $321/n$ days, where n is equal to or less than 5.

Publications of the Nicolas Observatory, St. Petersburg.—We have just received vols. iii. and xiv. (series ii.) of the "Publications de l'Observatoire central Nicolas, St. Petersburg."

The former contains a catalogue of right-ascensions of the principal stars contained in the Pulkowa catalogue for the epoch 1885·0, the results being based on observations made between September, 1880, and November, 1887, with the meridian telescope. The catalogue is published in the same form as those which appeared in 1845 and 1865.

Vol. xiv. contains a part of the results of the observations made with the vertical circle of the observatory between May 1, 1896, and May 19, 1899. The remaining part of the results and the discussion of the whole are reserved for the next volume (xv.) of the publications.

THE ROYAL OBSERVATORY, GREENWICH.

The annual inspection of the Royal Observatory, Greenwich by the Board of Visitors took place on Wednesday, May 30, when the Astronomer Royal submitted a report of the work accomplished during the twelve months May 11, 1905, to May 10, 1906. A brief summary of this report is given below.

The new working catalogue of stars of the ninth magnitude and brighter, situated between declinations $+24°$ and $+32°$, is now complete, and includes more than 12,000 stars; the star-places have all been accurately brought up to 1910 from the Astronomische Gesellschaft catalogues.

A new determination of the pivot errors of the transit instrument, made during November, showed that the errors in the form of the pivots are insensible. The determination of the co-latitude for 1905 has been delayed by the necessity of applying the corrections to the star-places due to the variation of latitude. The value found for 1904, with Bessel's refractions, is 38° 31′ 21″·74.

The second nine-year catalogue, for epoch 1900, which was completed last year, will be divided into two sections, one containing the fundamental and zodiacal stars, the other the astrographic reference stars. For the second section the places (for 1900) of the stars within 10° of the pole have already been determined, and a comparison of these with the places given in Carrington's Redhill catalogue should discover a number of proper motions hitherto undetermined, thereby providing new material for the discussion of the solar motion.

Mr. Cowell has completed the discussion of the Greenwich meridian observations of the moon from 1750 to the present time, and has found the necessity of introducing three empirical terms, of which the third has a period of about 300 years. Because the introduction of this term renders the determination of the secular acceleration of the moon from modern observations impossible, Mr. Cowell has worked up the conditions for six ancient eclipses of which the historical records seem to be fairly authentic. By introducing accelerations of eleven seconds per century for the moon and four seconds for the sun, he found it possible to bring the conditions of every one of these eclipses into agreement with the historical records of the phenomena attending them. By treating ten of the lunar eclipses recorded in the Almagest in the same way, additional evidence for the existence of these accelerations was obtained. At first glance the acceleration for the sun was difficult to account for, and Mr. Cowell hypothecated a resisting medium through which the earth travels; but more recently he has found that a lengthening of the day by the two-hundredth part of a second per century would account for the quantity required for this acceleration. As one of the principal features of Mr. Cowell's discussion was the employment of the day as the unit of time, the lengthening of that unit would produce the apparent acceleration.

Owing to the re-mounting and re-polishing of the object glass the altazimuth was out of use from July 12 to August 30, but for the remainder of the year it was employed for observations of the sun, moon, planets, and fundamental stars. The lunar crater Mösting A was observed whenever the conditions were favourable, and, as the same kind of observations are being made at the Cape Observatory, the results will serve to determine anew the parallax of our satellite. The value obtained from the discussion of the two sets of observations should be more trustworthy than that previously obtained, which depended solely upon observations of the moon's limb, a much more difficult feature to "set on" than the crater. Mösting A was also observed with the transit circle whenever possible, and the mutual agreement of the two sets of results was very satisfactory.

Eight hundred and twenty-three double and twenty-four single observations of various stars were made with the reflex zenith tube, and the results have been reduced up to March 31.

The weather was not favourable during the year for observations of difficult double stars with the 28-inch refractor, but the time was utilised in completing the measures of neglected doubles in Struve's "Mensuræ Micrometricæ"; the total number observed was 606, of which 158 have their components separated by less than 1″·0, and seventy by less than 0″·5. The diameters of Jupiter and his satellites were also measured with this instrument. Both the polar and equatorial diameters of Jupiter were observed, first with the filar micrometer and then with the double-image micrometer, on each night, and it was found that the mean of the results of the two methods produced a very good value for the diameter. The error caused by irradiation in the filar micrometer observation is apparently exactly corrected by the error introduced in the second method by the fact that when the two images are apparently in contact they actually overlap to a slight extent.

The 26-inch refractor was employed on twenty-eight nights in obtaining seventy-two photographs of Neptune and its satellite, using the occulting shutter as in previous years. These photographs are now being measured.

A number of photographs of Jupiter's newly-discovered satellites vi. and vii. were obtained with the 30-inch reflector. This success is remarkable because it was the expressed opinion of the discoverer of the satellites that vii. was too faint to be photographed through our British atmosphere. Yet nineteen photographs of this object were secured at Greenwich on fifteen nights, and eighty-six negatives of satellite vi. were taken on thirty-six nights. The 30-inch reflector was also employed for obtaining photographs of twenty-three minor planets, five comets Nova Aquilæ, and several nebulæ.

The reduction of the Eros plates is complete, and the results have been communicated to M. Lœwy.

At the date of last year's report the measurement of the Greenwich plates for the Astrographic Catalogue was complete, but a number of the measures have been repeated, and the press copy has been prepared for the seven zones 80° to 86°. The measures of the eight zones 77° to 84° have been printed during the year, and include 46,329 separate stars covering an area of 450 square degrees of sky. The remaining 78·5 square degrees between 85° and the pole will include about 6000 stars. An interesting table given in the report shows the number of stars which have been measured, and will be contained in the Greenwich section of the catalogue, and compares it with the number shown in each of the corresponding zones of the Bonn Durchmusterung and the Astronomische Gesellschaft catalogues. Thus it is shown that the total in the Greenwich section will be about 178,380, whilst for the same region the B.D. contains only 25,184 stars. A similar table compares the number of stars shown on the Greenwich chart plates in several zones with those contained in the corresponding zones of the B.D. In the total area of 558·3 square degrees the latter contains 2259 stars of magnitude 9·0 and brighter, and 6542 altogether, whilst for the different exposures given for the Greenwich plates the following numbers are shown:—

Exposure	20 secs. ...	3m. ..	6m. ...	40m.
Number of stars...	12,019 ...	56,921 ...	58,393 ...	170,180

Thus on the plates taken at Greenwich with forty minutes' exposure there are 304·8 stars per square degree, and about twenty-six times as many stars as are given in the corresponding region in the B.D. The second Greenwich volume of the Astrographic Catalogue is printed up to the end of 84°, and will soon be ready for publication. Twelve thousand photographic prints, reproducing on double scale 191 plates in zones 65° to 70°, have been made during the year, bringing the total number of plates reproduced since the work began up to 401, or rather more than one-third of those contained in the Greenwich section. During the year under report the astrographic telescope has been used to obtain duplicate plates for the chart to replace previous ones which are not entirely satisfactory for reproduction purposes.

Heliographic observations were carried out as usual, the sun being photographed on 210 days. The solar activity was very pronounced during 1905, the record for that year being about double that for 1904.

The magnetic observations were made as in former years, and the principal results for the magnetic elements for 1905 were as follow:—

Mean declination	16° 9′·9 West
Mean horizontal force	4·0173 (in British units) 1·8523 (in metric units)
Mean dip (with 3-inch needle)...	66° 55′ 55″

There were no days of "great" magnetic disturbance, and only twelve days of lesser disturbance in 1905.

The various meteorological observations were continuously maintained throughout the year, the mean temperature being 0°·2 above, and the rainfall 1·21 inches below, their respective averages for the fifty years 1841–1890.

In the chronometer and time-service department the report follows the usual lines, but the Astronomer Royal remarks on the inferiority of the box chronometers and the superiority of the watches submitted for tests during the period covered by the report. Of fifty-nine chronometers sent in, thirty-three were rejected because they failed to attain the minimum standard of constancy. This is a larger number of rejections than in any previous year, although the number submitted was smaller than usual.

In concluding the report, the Astronomer Royal directs attention to the serious menace to the continued efficiency of the observatory on its present site involved in the establishment in the immediate neighbourhood of large generating stations for the supply of electric power to distant districts. The most serious danger at present arises from the new power station erected by the London County Council, which is situated directly north of the observatory. Not only will the high chimneys actually prevent stars from being seen when near the northern horizon, but the heated gases arising from the buildings may seriously affect the accuracy of any results obtained. Again, the new station is but half a mile from the observatory, and the running of the engines, although their number is not yet complete, produces serious tremors on the mercury reflecting surface, on the steadiness of which the accuracy of the astronomical results is critically dependent. At present the instruments employed in the magnetic pavilion have shown no disturbance, but it is greatly to be feared that the contemplated increase of the electrical plant will also have a serious effect on the work of this department.

THE ROYAL SOCIETY OF EDINBURGH AND THE NATIONAL GALLERIES OF SCOTLAND BILL.

On Friday last, June 1, the Secretary for Scotland received an important deputation of the Royal Society of Edinburgh regarding the claims of science in the readjustment of grants in aid and allocation of national buildings as contemplated in the National Galleries of Scotland Bill recently introduced in Parliament.

The chief point discussed was the position of the society in regard to its present occupancy of part of the Royal Institution, Princes Street. The deputation, which was very representative of science in Scotland, was introduced by Sir J. Batty Tuke, M.P. The claims of the society were presented by Lord M'Laren, vice-president; Mr. J. W. Gulland, M.P.; Principal Sir William Turner, of Edinburgh University; Principal Mackay, Dundee; Prof. Cash, Aberdeen; Prof. Gray, Glasgow; and Prof. Chrystal, secretary of the society. It was pointed out that in the National Galleries Bill, which contemplates devoting the Royal Institution, as well as the present National Gallery building, entirely to art, no provision is made for the Royal Society, which has occupied the west wing of the Royal Institution since that building was constructed seventy years ago, and for which, indeed, the building was originally designed. The deputation suggested the introduction of a clause safeguarding the position of the society, so that it shall not be dispossessed until equally good and convenient rooms have been obtained elsewhere out of public money. It will be impossible to carry on the important work of the society, especially as regards the publication of valuable and expensive memoirs, without this guarantee. Not only so, but it was urged that the Royal Society of Edinburgh should be placed on the same footing as the Royal Society of London and the Royal Irish Academy, both of which sit rent free in Government buildings, and receive grants to the extent of 1000*l.* and 1600*l.* respectively. The Royal Society of Edinburgh receives a grant of 300*l.*, which, however, is nearly all paid back to the Board of Manufactures in the form of rent. The Royal Society of London and five other scientific societies are accommodated in Burlington House next door to the Royal Academy, and it is hoped that a similar principle will be applied in Edinburgh.

The Secretary for Scotland expressed his hearty sympathy with all that had been said as to the importance of scientific work and the national character of the work done by the Royal Society. The National Galleries Bill introduced by the present Government is practically the Bill of last session with some minor alterations. The whole question has been gone into very carefully, and the conclusion is to put the National Gallery into the south building, and give to the Royal Academy the Royal Institution, part of which is at present occupied by the Royal Society. The accommodation for the National Gallery and for the Academy will thus be doubled, and ample scope will be given for future development. It is not possible to house the Royal Society and the Royal Academy in the same building. The decision has been come to after review of all the circumstances, and it carries with it the obligation to find accommodation consistent with the necessities and prestige of the Royal Society. It is the desire and intention of the Government to meet the reasonable demands of the Royal Society in a liberal spirit; and the Secretary for Scotland suggested that the Royal Society should consider the new situation which has been created, and should formulate some scheme for the consideration of the Government.

THE DISCOVERY OF MAGNETIC DECLINATION.

The *Meteorologische Zeitschrift* for April contains an interesting article by Prof. G. Hellmann on the knowledge of the magnetic declination before the time of Christopher Columbus. Some years ago Prof. Hellmann pointed out that, independently of the discovery by Columbus, the variation must have been known on the Continent, from the construction of many pocket sundials provided with magnetic needles for adjusting the instruments to the astronomical meridian, and showing the declination by a line on the floor of the compass-box.

Dr. A. Wolkenhauer recently discovered three such sundials dating from before the time of Columbus. One of these, which is in the Ferdinand Museum at Innsbruck, and

Fig. 1.—Pocket sun-dial with compass and variation line. Date, about A.D. 1451.

was probably made at Nuremberg, is shown in the accompanying photographs by Hofrath von Wieser. The glass shade and magnetic needle have been removed so that the lines on the bottom of the box might be more plainly shown. The lid or flap, which has also been removed, and which adjusts the gnomon when opened, shows the date of construction, viz. 1451, the figures 4 and 5 being in the old form (see also the hour numbers of the dial).

The rim of the compass-box shows the four cardinal points:—M. (Meridies), Oc. (Occidens), S. (Septentrio), Or. (Oriens). On the floor of the compass-box is cut the northerly-pointing bifurcated line of deviation of the magnet, showing about 11° easterly variation. This line is of the same depth and thickness as the hour lines, and a careful examination of the instrument shows that it must have been originally done by the maker. It can easily be recognised, however, that the three other marks west of the original line (two of which have arrow-heads) were roughly inserted at a later time, when probably the declination had become westerly. The short, thick stroke lying 4°–5° west of the N.-S. direction has been scratched the deepest. The magnetic variation was apparently probably known before the beginning of the fifteenth century, but by whom and where it was discovered still remain an open question.

IRISH CAVE EXPLORATIONS.

OUR knowledge of the Irish fauna in Neolithic and early historic times has been greatly extended by recent researches into the cave remains of Ireland. These have been carried out during the past few years by a committee, under the auspices of the British Association and of the Royal Irish Academy. Two reports on these investigations have been published in the Transactions of the latter. The first dealt with the exploration of the caves of Kesh, in the county Sligo, and the second, which has just been issued, with that of the county Clare caves. The committee is now at work further south, in the county Cork.

The Clare caves, which are situated about thirty miles from the sea coast, among beautiful surroundings, in a district of crags and lakes, lie in the lands of Edenvale and Newhall. Our illustration shows the entrance to two of these caves (marked A and B) in a steep ridge of rock overlooking an ancient track, known as the Pilgrims' Road, which leads from Ennis to Killone Abbey and the Holy Well. The others lie barely a mile to the west of these. All the caves have been formed by the solvent action of water on the limestone in which they occur. Several of them are of great extent, with complicated ramifications. They are mostly about 100 feet above sea-level. They differ from many of the great English caves in the absence of a well-marked stalagmite floor, and of their early cave-fauna, including the rhinoceros, hippopotamus, cave-bear, hyæna, &c. The deposits are composed, as a rule, of two easily distinguishable strata. The upper one, generally consisting of brown earth, contains charcoal associated with the bones of domestic animals, while the second is often of a very tenacious nature, and includes many remains of the bear and reindeer, Irish elk, and Arctic lemming.

Photo.] [*R. Welch.*

FIG. 1.—View showing entrances of Bat's Cave (A) and Elder-Bush Cave (B), Newhall.

Of particular interest is the occurrence of the Arctic fox and of the wild cat. The former of these is exceedingly rare in England, and had not been known to occur in Ireland, while as to the latter, it has been held as doubtful whether it ever inhabited Ireland. Several jaws and teeth were found, however, which agreed, not with the Scottish wild cat, but with that commonly met with throughout the African continent, and popularly known as the Caffer cat.

More than 2000 bones of birds were obtained, comprising fifty-eight species, the most noteworthy of which is the crane. The Welsh traveller, Giraldus Cambrensis, stated that when he visited Ireland in the twelfth century cranes were to be met with in flocks, and it is of interest that this account of their presence has been verified by the discovery of these remains.

The occurrence of a shed antler of the Irish elk, and of long bones of this species and of the reindeer, which seemed to show signs of having been artificially fractured, indicate the possible contemporaneousness of man with these deer, but the evidence in this case is not conclusive. The bear, however, was clearly coexistent with man, and probably lingered on in Ireland long after the Irish elk and the reindeer had become extinct. A knee-cap of a large bear, showing the incisions of a knife, was found in one of the caves, and other bear bones were obtained from the upper layer along with charcoal and the remains of domestic animals. Unfortunately all the cave deposits had been greatly disturbed by burrowing animals, such as badgers and foxes, which inhabited them chiefly in recent times.

Some of the caves show traces of human occupation of long continuance in early times, while others may have been used as shelters for short periods. Scrapers and flint flakes, bone pins, and stone implements occurred, while a gold bracelet, and another, richly decorated, of bronze, were found. Of bronze, also, was a buckle engraved with an interlaced pattern and plated with silver. One of the most remarkable of the objects discovered was a lamp, the receptacle being hollowed out of a round stone, not carved in any pattern, but with deep grooves round the sides. Of these and other objects the plates illustrating the report give a good idea. Together with the implements, numbers of human bones were found, although there is no evidence that the caves had ever been used as places of burial. The bones revealed nothing which might lead us to suppose that they belonged to a different race from that inhabiting Ireland at the present time; but their study elicited the fact that some of them belonged to individuals who habitually assumed the squatting position common to all primitive peoples.

R. F. SCHARFF.

NEW PILOT CHARTS.

IN these days of perpetual and feverish haste, which is characteristic of life at sea as well as on shore, the desirability has been realised of introducing modifications in the method of conveying practical information for the use of seamen. Formerly, men had more leisure to wade through the bulky volumes known as sailing directions when they wished to clear up any point in doubt. Now, with less time to spare, the demand is for the concentrated essence rather than the minute details of the facts, and this is one of the objects in view in the production of the several pilot charts originated on both sides of the Atlantic within recent years. Many subjects have to be dealt with, and the space is strictly limited, so that the mariner has before him on his chart-room table all the essential features of the particular subjects.

Two pilot charts are published by the Deutsche Seewarte at Hamburg, one for the North Atlantic and Mediterranean area, issued monthly, the other for the North Sea and Baltic region, issued quarterly. They are elaborately and excellently got up, and in the quality of their varied contents afford further evidence of that thoroughness characteristic of German investigators. The face of each Atlantic chart (36 inches by 27 inches) is covered with information of immediate concern in navigating a ship—the mean direction and force of the prevailing winds in every 5° square; the northern and southern limits of the trade winds; the paths and the intensity of storm systems; the regions of mist and fog; the dust atmosphere off Africa; the tropical rain area; the set and velocity of ocean currents; ice; derelicts; steamship and sailing-ship routes and great circle tracks; copious remarks bearing on all these subjects; variation curves; and illustrations of the storm-warning signals adopted by countries on both sides of the ocean. The whole of the back is devoted to articles, with or without illustrations, discussing subjects of general interest to the navigator, and not necessarily limited to the North Atlantic area. A special investigation of the winds, currents, and air and sea temperatures experienced along the Mediterranean steamship routes is being carried out at the Seewarte, and the results are now appearing month by month on the pilot chart.

The issue for last February contains a very complete work on the handling of ships in tropical hurricanes Atlantic, Indian and Pacific Oceans, the Arabian and China Seas. The April number gives an account of a very severe Atlantic storm, the maximum violence occurring on the rise of the barometer; a still longer article deals with water-spouts. The May chart gives the true bearing and the compass bearing at about three hundred positions round the coasts of the British Isles. The North Sea-Baltic publication is equally complete, each quarterly issue containing one general chart for the region and others for the several months of the quarter, together with an abundance of letterpress dealing with a great variety of subjects, such as the investigation of the fisheries and the physical condition of the waters of the region, the surface currents of the Kattegat and Sound, ice, and tidal streams.

With five years' experience in the preparation of the monthly North Atlantic pilot charts, our Meteorological Office has now commenced the publication of a similar series of "Monthly Meteorological Charts of the Indian Ocean North of 15° South Latitude, and Red Sea." The area covered by the map extends from 30° N. to 15° S., between the meridians of 30° and 100° E. The first number, issued in London on May 9, is for the month of May. Presumably future issues will be well in advance of the month to which they relate, so as to be in the hands of mariners navigating the Indian Ocean during the month. Generally, the chart presents the same features as the North Atlantic one. For each ocean space of 5° of latitude by 5° of longitude the frequency of winds of light, moderate, or gale force is shown for the sixteen even points of the compass, the observations upon which the results are based covering a period of fifty years. Apparently through inadvertence a pecked line intended to indicate the northern limit of the south-east trade has been omitted. Tracks of some cyclonic storms are given in red. It is left to the sailor to assume whether the date given is at the commencement or end of the tracks, there being no directing arrow heads. The set and velocity of the ocean currents are shown in blue, and in a lighter blue the variation curves for 1907. Use is made of the land spaces for supplying a variety of information by means of letterpress and inset charts.

A small chart of the whole area gives, for the month, the average distribution of barometric pressure over the sea, and the mean temperature of the air and of the water. An enlarged map of the Guardafui and Ras Hafún district shows the currents, sea temperatures, and misty weather in this dangerous locality, and suitable notes accompany the map. Over Arabia appear remarks on the various air and water elements of the Red Sea and Gulf of Aden. On the back of the sheet are given complete summaries of the elaborate storm and weather signals of the Bay of Bengal and of the Húgli River storm signals, which are far more precise than those in use in any other part of the world. A map of the southern Indian Ocean, from the equator to 40° S., and 30° to 120° E., is used for reproducing the late Dr. Meldrum's monthly tracks of cyclones between 1848 and 1885. There are notices to captains relating to the collection of meteorological observations, to the necessity for accurate determination of the errors of barometers in use, and to the compass adjustment marks at Kalpi anchorage.

Altogether the new publication gives promise of supplying a much-needed want in a simple and easily accessible form for a part of the ocean about which there has hitherto been but little information. The monthly variations in the circulation of the waters of the Arabian Sea and of the Bay of Bengal will alone well repay careful study, while a more accurate knowledge of the different winds of the region covered by the chart cannot fail to be of the greatest practical benefit to shipmasters and their officers.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Oxford.—The electors to the Linacre professorship of comparative anatomy will proceed to an election next month. Candidates are desired to send in their names so as to reach the registrar's office not later than Saturday, July 7. The Linacre professor is by virtue of his office a fellow of Merton College. He is entitled to receive from the college a stipend of 700*l*. a year in addition to the emoluments of a fellowship, which amount at present to 200*l*. a year.

Cambridge.—Mr. E. S. Roberts, Master of Gonville and Caius College, has been elected Vice-Chancellor for the ensuing academical year.

Mr. L. Noon, Trinity College, has been elected to a John Lucas Walker studentship in pathology.

The assessment to be paid by the colleges to the University in the present year has been fixed at 30,038*l*., or 13*l*. per cent. on the college incomes.

The Chancellor, His Grace the Duke of Devonshire, has made a gift of 500*l*. to the special fund now being raised on behalf of the University library.

Mr. C. L. Boulenger, King's, has been nominated to the University table at the Naples Zoological Station; and Mr. K. Lucas, Trinity, to the table at the Plymouth Marine Biological Laboratory.

The special board for mathematics has made some minor alterations in the proposals for the re-modelling of the Mathematical Tripos, parts i. and ii., but it is proposed to submit unchanged to the Senate the principles of the original report.

Ten candidates have been successful in the special examination in agricultural science and the first examination for the University's diploma in agriculture.

Mr. W. A. Cunnington, Christ's, for a dissertation on "Tanganyika," and Mr. C. Shearer, Trinity, for a dissertation on "The Development of Larval Nephridia," have been approved as advanced students for the certificate of research.

Prof. Bradbury, Prof. Osler, Dr. S. West, and Prof. Rose Bradford have been appointed examiners in medicine; Dr. Rivers Pollock and Prof. Spencer, examiners in midwifery; and Dr. Kellock, Prof. Barling, Mr. Stanley Boyd, and Mr. Dunn, examiners in surgery for the ensuing academical year.

A sum of 6000*l*. from the benefaction fund, raised by the University Association, has, with the approval of the Chancellor, been contributed to the cost of the botany and medical school buildings.

The name of "Frederick James Quick, of Trinity Hall," founder of the Quick professorship of biology, has been added to the list of benefactors in the Commemoration Service.

A Royal Commission has been appointed for the purpose of holding an inquiry into Trinity College, Dublin, and the University of Dublin. The terms of reference of the commission are as follows:—"To inquire into and report upon the present state of Trinity College, Dublin, and of the University of Dublin, including the revenues of the College and of any of its officers and their application, the method of government of the University and of the College, the system of instruction in the College and the teachers by whom it is conducted, the system of University examinations, and the provision made for post-graduate study and the encouragement of research; and also to inquire and report upon the place which Trinity College, Dublin, and the University of Dublin now hold as organs of the higher education in Ireland, and the steps proper to be taken to increase their usefulness to the country." Among the commissioners are Sir Edward Fry (chairman), Sir A. W. Rücker, F.R.S., and Prof. D. J. Coffey.

According to the *Reichsanzeiger*, the number of students who took the "Doktor-Ingenieur" degree of the technical Hochschulen at Berlin, Hanover, and Aachen during the last winter semester was seven in Berlin, five in Hanover, and four in Aachen, while the number who took this degree during the two semesters from March, 1905, to

March, 1906, at the Dresden Technische Hochschule was seventeen; of these thirty-three we find that eight passed the *viva voce* examination with distinction, whilst the ages of the candidates varied from twenty-three to thirty-nine years. As a reason for this small number of the students who eventually take the degree, it is said that the great majority of the students, after having passed through their eight semesters of stiff study and obtained the coveted diploma, qualifying them to style themselves "Dipl. Ing.," have frequently neither the desire nor the means for the extra semester's study and research necessary for the doctor's degree.

THERE is no diminution in the generosity shown by American citizens towards higher education. *Science* announces that Columbia University has received 100*l*. for a mathematical prize, given by Mrs. Louise T. Hoyt. Mr. Edward S. Harkness has given 540*l*. to the morphological museum at the College of Physicians and Surgeons, and Mr. Archer M. Huntington 200*l*. to support a lectureship in geography. In April, 1905, Mr. Andrew Carnegie offered Morningside College, Sioux City, Iowa, 10,000*l*. on condition that they raised 30,000*l*. On April 3, 1906, his conditions for the gift were satisfied, and Mr. Carnegie's cheque has been received. Mr. Carnegie has also given the sum of 10,000*l*. to Drury College, at Springfield, Missouri, on condition that the college increases its resources by the sum of 40,000*l*. About one-third of this sum has been raised since January 1. Mr. R. Y. Cummings has given 4000*l*. to the Field Museum of Natural History to defray the expenses of an ethnological study of the native tribes of the Philippine Islands.

ALBION COLLEGE is now building a new biological laboratory, which is expected, we learn from *Science*, to be completed in time for the opening of the college year in September. Mr. Andrew Carnegie has promised 4000*l*. to the endowment fund of the college on condition that 16,000*l*. additional is raised for the purpose. Mr. Carnegie has also given Kenyon College 5000*l*. to aid poor students. A new scholarship of 1000*l*. has been given to Barnard College, Columbia University, by Mrs. George W. Collord in memory of her brother. By the will of Roland Hayward, of Milton, Mass., the museum of comparative zoology of Harvard University will receive the testator's collection of Coleoptera.

A CLAUSE in the Education Bill before Parliament will, if it eventually become part of the Act, abolish the Teachers' Register. There is a strong feeling among teachers in secondary schools and others that such a course would be very prejudicial to the progress of secondary and higher education, inasmuch as it would discourage the movement to secure adequate training for secondary-school teachers. A meeting of the heads of training colleges for secondary-school masters and mistresses in all parts of the country was held at Bedford College, London, on May 26, to consider the proposals of the Government, and after discussion numerous resolutions were adopted unanimously. These resolutions declared that, as a result of the proposal, public confidence in the stability of the Board of Education has been shaken seriously; that a part of the present register fulfils a purpose that is useful and not otherwise provided for; that grants and other administrative aids to the training of secondary-school teachers, as promised by the Board of Education, do not form a substitute for a register. The recognition of a profession, one resolution insists, with powers over entrance to its ranks, is an essential element in creating a respected and permanent profession; and another lays it down that in view of the difference of conditions at the various centres of training and of the necessity for experiments in the training of teachers, the Board of Education should give as much liberty as possible in the regulations under which the preparation for diplomas is conducted.

THE current number of the *University Review* contains a vigorous article by Mr. H. P. Biggar on the establishment of a graduate school at Oxford. One of the chief aims of a university should be, the article insists, the extension of the bounds of knowledge in each department of learning by masters who are capable of making fresh discoveries therein. This object is constantly before the minds of the authorities of German and French universities. In both these countries the graduation of students is dependent upon their success in prosecuting research, and from France and Germany instruction in research has spread to the United States. Since 1876, Princeton, Columbia, Chicago, Cornell, and other American universities have found themselves bound to establish graduate schools where training may be obtained in research, and from the United States post-graduate studies have spread to Canada. With us, however, graduate studies are practically unknown. At Oxford, for instance, which Mr. Biggar takes as an example, because it is there alone that Rhodes scholars may study, the University ceases to enforce any test of proficiency beyond the degree of Bachelor of Arts. The B.A. has but to continue to pay certain fees to his college for about three and a half years after taking his degree, when he may come up, pay some 20*l*., receive the degree of Master of Arts, and become a member of Convocation. What is wanted, Mr. Biggar maintains, is to establish at Oxford a proper graduate school, that is merely the reinforcement of a thesis, either for the M.A. or for the doctor's degree. The important part is that the increase of knowledge should be looked upon as one of the main ends to be kept in view. Then, perhaps, the Rhodes scholars will discontinue to experience the disillusionment which awaits many of them, who come hoping to find themselves among *the makers of new knowledge*! and participating in the glorious work.

THE distinguished representatives of the University of Paris and the Collège de France, together with guests from nine other French universities, arrived in London on June 4, and have during the week been entertained by the University of London and the Modern Language Association. The visitors were met at Victoria Station by Sir Edward Busk, Vice-Chancellor of the University of London; Sir Arthur Rücker, principal of the University; and many members of different faculties of the University and of the Modern Language Association. In the evening of June 4 the French guests were entertained at an informal dinner. Sir Walter Palmer, chairman of the London University organisation committee, in proposing in French the toast of "Our Guests," said that the visit is a unique fact in the annals of university life, which will long remain imprinted on our hearts as a new phase in the scientific and literary development of the two nations represented. What could be of happier augury than so distinguished an assembly of men of letters and of science leaving their country and paying a visit to their colleagues in order to draw closer still the bonds existing between the arts and the sciences of the two countries? M. Bayet, director of higher education at the Ministry of Public Instruction, responding in French, remarked that if there is a domain in which the *entente cordiale* has its place it is the domain of letters, science, and art. It has long had its place there, for if we reascend the current of the centuries we find that this *entente cordiale* has existed almost always between England and France. We are creditors and debtors of each other. Frenchmen, he said, salute the profound influence which England has exerted upon them in the domain of letters, science, and art. They know the English writers, poets, and philosophers, they love them, they have drawn inspiration from them, and in their hearts they associate themselves with the cult of great writers and thinkers. M. Lippmann, who responded for the faculty of science of the University of Paris, spoke in English, and said science is not bounded by the Channel nor has it a local habitation. There is but one geometry throughout the world. The laws of nature reach beyond the stars. For that reason the guests feel at home in any place among the brotherhood of scientific men. He continued, it is a happy dispensation that a university should have been founded within the precincts of this huge city. London is gigantic in size, wealth, and might; its shipping is unrivalled, its commercial activity unexampled; but the greater the pressure of business, the heavier the load of accumulated wealth, the more needful it is to augment the power of the priceless element which is the soul of a university, the more so as the experimental work done in laboratories and in experimental research of any kind is the prime source of industrial progress, as well as an antidote to fortune.—On Tuesday the visitors were received at the Foreign Office in order that Lord Fitzmaurice and Mr. Lough, M.P., might welcome them officially on behalf of the Government. At the conclusion of the reception they were driven to the University of London, where luncheon was served. Addresses were afterwards delivered by the Vice-Chancellor (Sir Edward Busk), M. Liard, Sir Arthur Rücker, and Prof. M. E. Sadler, and a visit was made to the new physical and chemical laboratories of the Royal College of Science. In the evening several receptions were held in honour of the guests.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, May 9.—Mr. Aubrey Strahan, F.R.S., vice-president, in the chair.—The eruption of Vesuvius in April, 1906: Prof. Giuseppe **de Lorenzo.** After the great eruption of 1872 Vesuvius lapsed into repose, marked by merely solfataric phenomena, for three years. Strombolian activity followed, varied by lateral outpourings of lava in 1885, 1889, 1891, 1895, &c., and by outbursts from the principal crater in 1900 and 1904. Fissuring of the cone and slight outpourings of lava began in May, 1905, and continued until April 4, 1906, when the first great outburst from the principal crater occurred, accompanied by the formation of deeper and larger fissures in the southern wall of the cone, from which a great mass of fluid and scoriaceous lava was erupted. After a pause the maximum outburst took place during the night of April 7 and 8, and blew 3000 feet into the air scoriæ and lapilli of lava, as well as fragments derived from the wreckage of the cone. The south-westerly wind carried this ash to Ottajano and San Giuseppe, which were buried under 3 feet of it, and even swept it on to the Adriatic and Montenegro. At this time the lava which reached Torre Annunziata was erupted. The decrescent phase began on April 8, but the collapse of the cone of the principal crater was accompanied by the ejection of steam and dust to a height of from 22,000 feet to 26,000 feet. On April 9 and 10 the wind was north-easterly, and the dust was carried over Torre del Greco and as far as Spain; but on April 11 the cloud was again impelled northward. The ash in the earlier eruptions was dark in colour, and made of materials derived directly from the usual type of leucotephritic magma; but later it became greyer, and mixed with weathered clastic material from the cone. The great cone had an almost horizontal rim on April 13, very little higher than Monte Somma, and with a crater which possibly exceeds 1000 feet in diameter; this cone was almost snow-white from the deposit of sublimates. Many deaths were due to asphyxia, but the collapse of roofs weighted with dust was a source of much danger, as was the case at Pompeii in A.D. 79. The lava-streams surrounded trees, many of which still stood in the hot lava with their leaves and blossoms apparently uninjured. The sea-level during April 7 and 8 was lowered 6 inches near Pozzuoli and as much as 12 inches near Portici, and had not returned to its previous level on April 18. The maximum activity coincided almost exactly with the full moon, and at the time the volcanoes of the Phlegræan Fields and of the islands remained in their normal condition. The author believes that this eruption of Vesuvius is greater than any of those recorded in history, with two exceptions—those of A.D. 79 and of A.D. 1631.—The Ordovician rocks of western Caermarthenshire: D. C. **Evans.** The ground dealt with is practically identical with that examined by the late Thomas Roberts, whose notes were published in 1893. It extends from the River Cywyn on the east to the Tave on the west, and from the base of the Old Red Sandstone on the south to the top of the Dicranograptus-Shales on the north.

Zoological Society, May 15.—Dr. J. Rose Bradford, F.R.S., vice-president, in the chair.—Descriptions of the two species of water-mites (Hydrachnidæ) collected by Mr. W. A. Cunnington in Lake Nyasa during the third Tanganyika expedition, 1904–5: J. N. **Halbert.**—A collection of mammals made by Mr. W. Stalker in the northern territory of South Australia, and presented to the National Museum by Sir William Ingram, Bart., and the Hon. John Forrest: O. **Thomas.** The collection included sixteen species, of which the two following were of special interest: *Mus forresti*, sp.n. Size, medium. Colour, drab-grey above, white below. Teeth with their laminæ peculiarly twisted, the first molars with large cingular ledges. Head and body, 104 mm.; tail, 72 mm.; hind foot, 19 mm. Type, B.M. No. 6.3.9.39. *Phascogale ingrami*, sp.n. Size, minute; the teeth and feet smaller than in any known Australian marsupial. Head peculiarly flattened. Head and body, 80 mm.; tail, 60 mm.; hind foot, 10 mm. Type, B.M. No. 6.3.9.77.—The skull of a young ribbon-fish (Regalecus): Prof. W. B. **Benham** and W. J. **Dunbar.**—Descriptions of two species—one of them new—of hair-worms of the family Gordiidæ: Dr. von **Linstow.** The specimens were obtained in Korea by Mr. Malcolm Anderson, who was making collections of the fauna of eastern Asia for the Duke of Bedford.—Descriptions of a new lizard, a new snake, and a new toad collected in Uganda by Mr. E. Degen: G. A. **Boulenger.**—The gestation and parturition of certain monkeys that had bred in the society's menagerie in the spring of the present year: R. I. **Pocock.**

Faraday Society, M y 15.—Dr. F. Mollwo Perkin, treasurer, in the chair.—Behaviour of platinised electrodes: H. D. **Law.** The author desired to find an electrode on which the reduction of the aromatic aldehydes and similar easily reducible compounds could not be effected. Platinised platinum, as being the metal from which hydrogen is liberated at the lowest potential, was tried as the kathode in an acidified alcoholic solution of benzaldehyde. At first energetic reduction took place; the activity of this, however, diminished in successive experiments, and was extremely small after twelve hours' polarisation.—The electrolysis of fused zinc chloride in cells heated externally: Julius L. F. **Vogel.** The dehydration of zinc chloride by evaporating under reduced pressure, and the electrolysis of the salt in a fused state in externally heated cells were investigated by Dr. O. J. Steinhart and the author jointly on behalf of the Smelting Corporation, Ltd. Further investigations were made after the United Alkali Company had joined the Smelting Corporation in testing the process, and details are given in the paper of the work as carried out under the joint supervision of the author's firm and the chemical staff of the United Alkali Company. The author describes how the process was carried successfully to a stage when continuous electrolysis was carried on for eleven days and nights, and three cwt. of pure zinc was produced. On the failure of the Smelting Corporation the work was suspended, and finally abandoned, although further elaborate investigations were undertaken by the United Alkali Company utilising cells heated internally by the current.

Royal Microscopical Society, May 16.—Dr. D. H. Scott, F.R.S., president, in the chair.—Some observations recently made on the parasites of malaria and the phagocytic action of the polymorphonuclear leucocytes: Dr. **Bernstein.** The subject was illustrated by drawings showing the results of observations made during the examination of blood taken from a patient suffering from malarial fever. The observations were made at intervals of a few minutes during a period of five hours. A crescent form of the parasite was seen to become engulphed by a leucocyte, in which it was soon surrounded by vacuoles and was ultimately destroyed, only the pigment granules remaining; other leucocytes afterwards approached and absorbed some of the granules. The blood film was stained, and the preparation, showing the pigment granules in the polymorphonuclear leucocytes, was exhibited under a microscope at the meeting.

Chemical Society, May 17.—Prof. R. Meldola, F.R.S., president, in the chair.—The relation between absorption spectra and chemical constitution, part vi., the phenylhydrazones of simple aldehydes and ketones: E. C. C. **Baly** and W. B. **Tuck.** A spectroscopic investigation of the phenylhydrazones of formaldehyde, acetaldehyde, propylaldehyde, acetone, and diethylketone shows that these exist in two forms, an unstable true hydrazone and a stable azo-form. The absorption spectra of the hydrazones of the three nitrobenzaldehydes show that the colour of these substances is not due to their existence in the azo-form.—The rusting of iron: J. T. **Nance.** The "rusting" of iron in solutions of ammonium chloride is probably due to the action of hydrogen ions formed by hydrolysis of the salt.—Aromatic compounds obtained from the hydroaromatic series, part ii., the action of phosphorus pentachloride on trimethyldihydroresorcin: A. W. **Crossley** and J. S. **Hills.**—Studies of dynamic isomerism, part v., isomeric sulphonic derivatives of camphor: T. M. **Lowry** and E. H. **Magson.**—The densities of liquid nitrogen and liquid oxygen and of their mixtures: J. K. H. **Inglis** and J. E. **Coates.** The results showed that a slight contraction took place on mixing the two liquids. It was found that the solubility of nitrogen in oxygen obeys Henry's law, but that the solubility of oxygen in nitrogen does not obey the simple form of that law, since oxygen dissolved in nitrogen is associated to the extent of about 9 per cent.—Glutaconic and aconitic acids: H. **Rogerson** and J. F. **Thorpe.**—The chemistry of organic acid "thiocyanates" and their derivatives: A. E. **Dixon.**—The molybdilactate and the tungstilactate of ammonium: G. G. **Henderson.** Molybdic and tungstic anhydrides are dissolved, the latter with some difficulty, when heated on the water-bath with solutions of ammonium lactate, the products being ammonium molybdilactate, $MoO_2(C_3H_4O_3NH_4)_2$, and ammonium tungstilactate, $WO_2(C_3H_4O_3NH_4)_2$, respectively. Descriptions of these salts are given.

Society of Chemical Industry (London Section), May 21.—Mr. A. Gordon Salamon in the chair.—The electrochemical problem of the fixation of nitrogen: Prof. Philippe A. **Guye.** Among the many investigations undertaken to solve this problem, two directions have led to industrial methods, the one, calcium cyanamide, the other, electrochemical nitric acid. The principal technical details of the manufacture of calcium cyanamide are given, and it is pointed out that its cost price depends upon that of calcium carbide. From this it is concluded that a kilogram of nitrogen fixed as calcium cyanamide will cost a little more than ammonia salts and Chili saltpetre, if the excess of calcium carbide obtained in carbide works not available for the development of acetylene is used. This conclusion seems confirmed by some agricultural tests made with this new compound of nitrogen of which the value, relative to Chili saltpetre, is not definitely fixed. Passing to electrochemical nitric acid, the author summarises the principles of its preparation, and although these are very simple, the application has presented serious difficulties, which, however, now appear to be solved by the experiments carried out in Norway. The absorption of the nitric acid by sulphuric acid is insisted on, as this allows concentrated nitric acid to be directly obtained, which is of greater commercial value than nitrate of lime, and consequently of more interest to a new industry. Analysis of the cost of electrochemical nitric acid leads to the conclusion that a kilogram of nitrogen is fixed slightly cheaper as nitric acid than as calcium cyanamide. In concluding, the author discusses the exterior economic factors which may hasten the development of the nitrogen industries. Among these the direct synthesis of ammonia from nitrogen and hydrogen, and the recovery of the nitrogen of coal in the ammoniacal form by the methods of L. Mond are mentioned. These processes, combined with the production of electrochemical nitric acid, will in all probability solve the problem of obtaining electric energy cheaply by motors utilising the power of coal.

Dublin.

Royal Dublin Society, April 24.—Prof. J. A. McClelland in the chair.—Entoptic vision, part iv., Haidinger's brushes and other entoptic phenomena: Prof. W. F. **Barrett,** F.R.S. The term entoptic vision may be employed to include the observation of all those phenomena the cause of which is situated within the eyeball. In previous papers on this subject the author has shown how obscurities in the path of a homocentric pencil of rays within the eye may be self-detected, delineated, and measured with great ease by means of the entoptiscope, a simple instrument devised by the author. Obscurities due to incipient cataract can be detected, and its progress watched and the effect of any possible remedy examined. In the present paper the entoptic phenomena are studied, delineated, and submitted to exact measurement, such as (1) the so-called Haidinger's brushes, or coloured polarised fasciculi seen when a brightly illuminated surface is looked at through a Nicol's prism, and the seat of which has been the subject of considerable discussion; (2) the moving corpuscles, like darting fire-flies, seen when a bright sky is looked at through a cobalt blue glass. These are depicted and measured in the paper, and the result leaves little doubt that they are really due to the movement of blood corpuscles in the vessels of the retina, the curved streaks of light they leave behind being due to the retention of the image of a quickly-moving body. Other entoptic phenomena are also discussed.—The absorption of β radiation by matter: Prof. J. A. **McClelland** and J. E. **Hackett.** It is important to know the true coefficient of absorption of β rays for different substances. There are really no data on the subject, as the coefficient usually measured depends to a large extent upon the power of the substance to emit secondary β rays. This coefficient gives, therefore, little information as to the actual stopping power of different forms of atoms. The present paper describes a method of determining the *true* absorption coefficient.

Royal Irish Academy, April 23.—Dr. F. A. Tarleton, president, in the chair.—Magneto-optic rotation: F. E. **Hackett.** The author examines the two dispersion formulæ deduced by Drude for the magneto-optic rotation, and brings forward a method to decide between them. The analysis consists in deducing from the constants of the formula, based on the hypothesis of rotating ions, the quotient of the area of the ionic orbit by the period of the ion for the absorption bands of carbon disulphide and creosote. The radii of the ionic orbits thus obtained are 100 times the ordinary molecular radii. From this result it is argued that the theory of rotating ions cannot account for more than one-thousandth of the rotation observed in these substances. A similar analysis applied to the constants of the Hall effect formula leads to values of ϵ/m of the same order as are obtained for electrons. Similar results are shown to hold in general for diamagnetic substances. It is then concluded that the theory based on the Hall effect gives a sufficient explanation of the rotation in diamagnetic substances.—The total solar eclipse of August 30, 1905: A. L. **Cortie.** The observations recorded in this paper were made at Vinaroz, on the Mediterranean coast of Spain. The results were:—(1) the corona was of the maximum type; (2) there were numerous prominences, especially one great group on the east limb of the sun; (3) the lower corona was much disturbed over this group, with a marked structure of arches and interlacing rings; (4) a well-marked vortex-ring with a white centre was connected with the prominences; (5) a ray, of presumably dark matter, and a group of plumes, marked the south-east quadrant; (6) the dark ray and plumes coincided in position with the sun-spot regions, and were possibly connected with the area disturbed by the great February spot; (7) some straight bright rays marked the south-west quadrant, also in the region of the spot-zones; (8) the general trend of the streamers was north and south, the largest streamers being placed almost at the south pole; (9) the inner corona was a ring of intense brilliancy, comparable to the full moon; (10) the streamers seemed in general to mark the regions of prominences more than those of spots.—Sixteen years' observations on the relation of temperature and rainfall to the spread of scarlatina, measles, and typhoid fever: R. Sydney **Marsden.** Weekly returns of cases of these diseases and the corresponding weekly variations of temperature and rainfall had been recorded for the years 1890–1905 at Birkenhead, and curve diagrams had been worked out to show the relation of the diseases to amount of rainfall and temperature as these varied above or below their average normal amount. Atmospheric temperature was found to have no effect on the spread of these diseases. As regards rainfall, this was shown to have no influence whatever as regards measles, but in the case of scarlatina the number of cases increased after deficient rainfall and decreased after rain; the number of *cases* increases after a series of dry years.

Newsholme has shown diphtheria to be affected in a similar manner. Dr. Marsden asks: Is it possible that scarlatina and diphtheria are "allotropic" forms of the same disease? In the case of typhoid, the number of cases occurring seems to be independent of whether it is a wet or dry year, but there seems to be a slight tendency for the number of cases to fall after rain.

PARIS.

Academy of Sciences, May 21.—M. H. Poincaré in the chair.—The president announced the loss by death of M. Bischoffsheim.—The discontinuity of the specific heats at saturation and Thomson's curves: E. H. **Amagat.** Simple relations between the dynamical reactions of muscle and the energy which produces them: A. **Chauveau.** Geometrical loci of centres of gravity: Haton **de la Goupillière.**—The intestinal origin of tuberculous tracheo-bronchial adenopathy: A. **Calmette**, C. **Guérin**, and A. **Déléarde.** The work communicated in the present paper has an important bearing on the question of the spread of tuberculosis by milk. It has been shown experimentally in the case of animals, and clinically in twenty-four cases of children, that whenever tuberculous infection is manifested by tracheo-bronchial adenopathy, tuberculous bacilli exist in the mesenteric ganglions, even when the latter appear to be healthy. These bacilli make their way into the system by the intestine.—Geodesic and magnetic work in the neighbourhood of Tananarive: Ed. El. **Colin.** The magnetic elements are given in tabular form for forty-nine stations round Tananarive.—A magnetic collimator which transforms a binocular into an instrument for taking bearings: A. **Berget.** A compass with a collimating lens and a system of totally reflecting prisms is fitted to one of the telescopes of the binocular, allowing the position of the needle of the compass to be read off to about 0·25 of a degree if held in the hand, or more closely if a support is used. The right-hand telescope is directed at the object the position of which is to be examined; the magnetic azimuth is read off directly at the same time in the left limb of the binocular.—The correlation between the variations of the absorption bands of crystals in a magnetic field and the magnetic rotatory polarisation: Jean **Becquerel.**—The sulphides, selenides, and tellurides of tin: H. **Pélabon.** The effect of the gradual addition of sulphur to tin on the melting point has been studied, and the relation between the percentage of added sulphur and the melting point given in the form of a curve. The corresponding curves for selenium and tellurium are also given.—The direct oxidation of cæsium and some properties of the peroxide of cæsium: E. **Rengade.** Oxygen, even when well dried, attacks cæsium energetically at the ordinary temperature. At $-40°$ C. the metal blackens, but there is no incandescence; at $-80°$ C. the action is very slow, and it is only after some minutes that the metal commences to tarnish. The action of an excess of oxygen gives cæsium peroxide, Cs_2O_4, a yellow oxide, easily dissociated at high temperatures. Water acts on it at ordinary temperatures, giving the hydroxide CsOH, oxygen, and hydrogen peroxide. Gently heated in carbon dioxide, cæsium carbonate and oxygen are produced. Dry hydrogen commences to reduce the peroxide at about 300° C.—New methods of preparing some organic compounds of arsenic: V. **Auger.** Methylarsinic and cacodylic acids can now be obtained commercially at a moderate price, and with these substances as starting points the author shows how various arsenic compounds can be readily prepared, including methylarsine iodide, CH_3AsI_2; methylarsine oxide, CH_3AsO; methylarsine chloride, CH_3AsCl_2; cacodyl chloride, $(CH_3)_2AsCl$; cacodyl, $As_2(CH_3)_4$; and tetramethylarsonium iodide, $(CH_3)_4AsI$.—Researches on diazo-compounds. The transformation of azo-orthocarboxylates into c-oxyindazylic compounds: P. **Freundler.**—The gases from thermal springs. The determination of the rare gases: general presence of argon and helium: Charles **Moureu.** Analyses are given of the gases from forty-three springs of mineral waters. Argon has been recognised in the whole of the forty-three samples examined, and helium in thirty-nine. It is possible that helium is also present in the remaining four, but in proportions so small that its presence is masked by the argon spectrum.—The elasticity of organic tissues: Ad. **Goy.** The apparatus described allows of six determinations being carried out nearly simultaneously on separate samples of muscle, the latter being surrounded by a fluid appropriate to its preservation. Drying in the course of the measurements is thus avoided.—The regenerator of fibrin and comparative estimations of this substance in different vascular territories of the dog after defibrination: M. **Doyon**, A. **Morel**, and N. **Kareff.**—A reaction of the oxydase type presented by the halogen compounds of the rare earths: E. **Fouard.** The oxidation of hydroquinone was determined in the presence of equimolecular solutions of the chlorides of thorium, cerium, lanthanum, neodymium, praseodymium, and samarium. The presence of the salts increased the rate of oxidation, samarium being the most active in this respect. The action is comparable to an oxydase.—The effect of adrenalin on the amount of glycogen in muscle: Mme. Z. **Gatin-Gruzewska.** The injection into a rabbit of a solution of adrenalin (containing 1 mg.) caused the total disappearance of the glycogen both in the liver and muscles. When the effect of the injection has passed off, the animal, if fed, has not lost the power of producing glycogen.—The identity of *Hemipygus tuberculosis* and *Hemicidadis crenularis*: M. **Seguin.**

CALCUTTA.

Asiatic Society of Bengal, May 2.—The relative proportion of the sexes in *Helopeltis theivora*: H. H. **Mann.** Hitherto no careful investigations have been made as to the relative number of males and females in any species of Heteropteron, but the fact that *Helopeltis theivora* is a serious pest of tea has given the chance for ascertaining details in its case. The paper summarises the result of daily catching of the insects for three years, and it is concluded that (1) the females are always much more numerous than the males; (2) the proportion of males increases as the conditions of life become more difficult.—Notes on the freshwater fauna of India, No. 5, some animals found associated with *Spongilla carteri* in Calcutta: Dr. N. **Annandale.** Several animals have been observed to use the dead skeleton of the sponge as a shelter for themselves or for their eggs, while an Oligochæte worm (*Chaetogaster spongillae*, sp.nov.), two chironomid larvæ, a coleopterous larva, and a larva of the neuropterous genus Sisyra appear to have a more intimate connection with the living organism. The advantage of this connection is in some cases reciprocal.—The life-history of an aquatic weevil: Dr. N. **Annandale** and C. A. **Paiva.** A general account of the mode of life and metamorphosis of a weevil which feeds on and lays its eggs in the submerged parts of the water-plant Limnanthemum.—A new goby from fresh and brackish water in Lower Bengal: Dr. N. **Annandale.** An account of a minute fish of the genus Gobius, which appears to have escaped notice owing to its retention of juvenile characters.—Preliminary note on the rats of Calcutta: Dr. W. C. **Hossack.** The author shows that the subject of rats has become of practical importance owing to the part they play in the propagation of plague. He names and gives chief characters of the four varieties found in Calcutta. He shows that colour is very variable and not a trustworthy distinction, and gives a table of the principal measurements of the four varieties found.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part i. for 1906, contains the following memoirs communicated to the society:—

December 23, 1905.—The calculation of chemical equilibrium from thermal measurements: W. **Nernst.**—Determination of the velocity of propagation and absorption of earthquake waves which have traversed the antipoint of the original focus: G. **Angenheister.**—Comparison of the seismic diagrams, from Upsala and Göttingen, of earthquake waves which have encircled the globe: F. **Akerblom.**

January 13.—The equilibrium of the sun's atmosphere: W. **Schwarzschild.**

February 3.—The number and dimensions of the taste-buds in the circumvallate papillæ of man at various periods of life: F. **Heiderich.** The action of luminous rays upon living cells: E. **Hertel.**—Electric phenomena accompanying the disintegration of ammonium: A. **Coehn.** (March 3.—A second communication on the same subject.)

February 17. Researches from the Göttingen University Chemical Laboratory, xv.:—(1) The process of isomerisation in oximes; (2) isomeric forms of cyclodimethylhexylamine; (3) the simplest methene-hydrocarbons of the various ring-systems and their transformation into alicyclic aldehydes: O. **Wallach.**—Contributions to the theory of vortex-rings: J. **Weingarten.**

DIARY OF SOCIETIES.

THURSDAY, JUNE 7.

ROYAL SOCIETY, at 4.30.—On the Osmotic Pressures of some Concentrated Solutions: Earl of Berkeley and E. G. J. Hartley—On the Regeneration of Bone: Sir William MacEwen, F.R.S.—The Effects of Self-induction in an Iron Cylinder: Prof. E. Wilson.—An Account of the Pendulum Observations connecting Kew and Greenwich Observatories, made in 1903: Major G. P. Lenox-Conyngham.

ROYAL INSTITUTION, at 5.—Man and the Glacial Period: Prof. W. J. Sollas, F.R.S.

LINNEAN SOCIETY, at 8.—On Two New Species of Populus from Darjeeling: H. H. Haines.—Biscayan Plankton, part viii., The Cephalopoda: W. E. Hoyle.—Part ix., The Medusæ: E. T. Browne.

CHEMICAL SOCIETY, at 8.30.—Ammonium Selenate and the Question of Isodimorphism in the Alkali Series: A. E. H. Tutton.—An Improved Beckman Apparatus for Molecular Weight Determination: J. M. Sanders.—Resolution of Lactic Acid by Morphine: J. C. Irvine.—The Vapour Pressures of Binary Mixtures, part i., The Possible Types of Vapour-pressure Curves: A. Marshall.—Action of Sodium on αα-Dichlorpropylene: I. Smedley.—Thiocarbamide as a Solvent for Gold: J. Moir.—The Action of Sulphur Dioxide and Aluminium Chloride on Aromatic Compounds: S. Smiles and R. Le Rossignol.

FRIDAY, JUNE 8.

ROYAL INSTITUTION, at 9.—Studies on Charcoal and Liquid Air: Sir James Dewar, F.R.S.

PHYSICAL SOCIETY, at 8.—On the Solution of Problems in Diffraction by the Aid of Contour Integration: H. Davies.—The Effect of Radium in Facilitating the Visible Electric Discharge *in vacuo*: A. A. Campbell Swinton.—Mr. J. Goold's Experiments with a Vibrating Steel Plate, exhibited by Messrs. Newton and Co.—Fluid (liquid) resistance: Col. de Villamil.

ROYAL ASTRONOMICAL SOCIETY, at 5.—The New Reduction of the Meridian Observations of Groombridge: Lewis Boss.—On Mr. Cowell's Discussion of Ancient Eclipses of the Sun: Simon Newcomb.—The Physical Condition of Mars: R. Crawford.—*Promised Papers:* Results of Micrometer Measures of Double Stars made with the 28-inch Refractor in the Year 1905: Royal Observatory, Greenwich.—Errors of Jupiter from Photographic and Transit Circle Observations: Royal Observatory, Greenwich.—A Simple Method of obtaining an Approximate Solution of Kepler's Problem (an Instrument will be shown by which the Solution is Effected): A. A. Rambaut.—Solar Parallax Papers, No. 4; the Magnitude Equation in Meridian Circle Right Ascensions of the "Étoiles de Repère": A. R. Hinks.—Spherical Slide Rule: W. B. Blaikie.—Discussion on some of the Results of Observations of the Solar Eclipse of 1905 August 30.—Contributions are promised by Prof. H. H. Turner and Mr. H. F. Newall.—Mr. Newall promises a Paper, Notes on Polarisation Phenomena in the Solar Corona.

GEOLOGISTS' ASSOCIATION, at 8.—The Higher Zones of the Upper Chalk in the Western Part of the London Basin: H. J. Osborne White and Ll. Treacher.

MALACOLOGICAL SOCIETY, at 8.—Mollusca of the *Porcupine* Expeditions, 1869-70, Supplemental Notes, part iii.: E. R. Sykes.—Notes on the Dates of Publication of the "Mineral Conchology" and "Genera Rec. Foss. Shells": E. R. Sykes.—Description of *Oliva ispidula*, L., var. *longispira*: F. G. Bridgman.—On *Chloritis heteromphalus*: H. A. Pilsbry.

MONDAY, JUNE 11.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Geography of the Indian Ocean: J. Stanley Gardiner.

SOCIETY OF CHEMICAL INDUSTRY, at 8.—Recent Progress in the Cement Industry: Bertram Blount.—On Purifying and Stabilising Guncotton: Dr. R. Robertson.

INSTITUTE OF ACTUARIES, at 5.—Fifty-ninth Annual General Meeting.

TUESDAY, JUNE 12.

ANTHROPOLOGICAL INSTITUTE, at 8.15.—Two Years among the Akikuyu of British East Africa: W. Scoresby Routledge.

MINERALOGICAL SOCIETY, at 8.—On the Occurrence of Axinite in the Area South of Bodmin, in Cornwall: G. Barrow.—Cassiterite Pseudomorphs from Bolivia: R. Pearce.—Notes on Skiodromes and Isogyres: Dr. J. W. Evans.

WEDNESDAY, JUNE 13.

GEOLOGICAL SOCIETY, at 8.—Recumbent Folds produced as a Result of Flow: Prof. W. J. Sollas, F.R.S.—The Crag of Iceland—an Intercalation in the Basalt-Formation: Dr. Helgi Pjetursson.

VICTORIA INSTITUTE, at 4.—Wonders and Romance of Insect Life: Frederick Enock.

THURSDAY, JUNE 14.

ROYAL SOCIETY, at 4.30.—*Probable papers:* The Experimental Analysis of the Growth of Cancer: Dr. E. F. Bashford, J. A. Murray, and W. H. Bowen.—On the Electrical and Photographic Phenomena manifested by certain Substances that are commonly supposed to be Ætiologically Associated with Carcinoma: Dr. W. S. Lazarus-Barlow.—The Bone Marrow; a Cytological Study forming an Introduction to the Normal and Pathological Histology of the Tissue: Dr. W. E. Carnegie Dickson.—On the Relation of the Liver Cells to the Blood Vessels and Lymphatics: P. T. Herring and S. Simpson.—(1) Note on Lipase; (2) The Hydrolytic Action of Acids in Presence of Salts: Prof. H. E. Armstrong, F.R.S.

MATHEMATICAL SOCIETY, at 5.30.—Exhibition of Models of Space-filling Solids: W. Bailey.—The Algebra of Apolar Linear Complexes: Dr. H. F. Baker.

INSTITUTION OF MINING ENGINEERS, at 11 a.m.—Address by the President.—The Commercial Possibilities of Electric Winding for Main Shafts and Auxiliary Work: W. C. Mountain.—Electrically-driven Air-compressors, combined with the working of the Ingersoll-Sergeant Heading-machines, and the subsequent working of the Busty Seam: A. Thompson.—Practical Problems of Machine-mining: Sam Mavor.—The Strength of Brazed Joints in Steel Wires: Prof. Henry Louis.—Bye-product Coke and the Huessener Bye-product Coke Ovens: J. A. Roelofsen.—Considerations on Deep Mining: George Farmer.

FRIDAY, JUNE 15.

INSTITUTION OF MINING ENGINEERS, at 10.30 a.m.—Rescue Apparatus and the Experience made therewith at the Courrières Collieries by the German Rescue Party: G. A. Meyer.—A New Apparatus for Rescue-work in Mines: W. E. Garforth.—A Rateau Exhaust-steam-driven Three-phase Haulage Plant: William Maurice.—Development of Placer Gold-mining in the Klondike District, Canada: J. B. Tyrrell.—Mining Education: Prof. J. W. Gregory.—The Capacity-current and its Effect on Leakage Indications on Three-phase Electrical Power-service: Sydney F. Walker.—Petroleum Occurrences in the Orange River Colony: A. R. Sawyer.

NATIONAL ASSOCIATION FOR THE PROMOTION OF TECHNICAL AND SECONDARY EDUCATION, at 3.—Annual General Meeting.

THURSDAY, JUNE 14, 1906.

THE RESPIRATORY SYSTEM OF VERTEBRATES.

Lehrbuch der vergleichenden mikroskopischen Anatomie der Wirbeltiere. Edited by Dr. Albert Oppel. Part v., Parietal Organ. By Dr. F. K. Studnička. Pp. vi+254. Price 8 marks. Part vi., Atmungsapparat. By Dr. Albert Oppel. Pp. x+824. (Jena: Gustav Fischer, 1905.) Price 24 marks.

If any interruption should overtake the present rapid growth of scientific knowledge it will not be in the acquisition of new facts that the breakdown will occur, but in the systematisation of facts already acquired by present and past generations of workers. The task of systematisation, so necessary for further progress, is in the hands of the writers of text-books, but, unfortunately, the fate which presides over that world wherein men of science live and move has ordained that the financial success of a text-book is in inverse proportion to its scientific value. The general student can command with ease both author and publisher, but the specialists, for whom a text-book is a first necessity, find it almost impossible to obtain either author or publisher. It is the good fortune of those specialists who are actively investigating the finer structure of the vertebrate body to find that, thanks to the untiring industry of Prof. Oppel and the enterprise of Herr Gustav Fischer, the text-book they so much needed has now been provided for them. In bringing to a conclusion the sixth part or volume of this great task, Prof. Oppel modestly consoles himself with the hope that the work, to which he has devoted twelve years of his life without reward or fee, may prove of use to others. It is in no niggardly spirit that we in England must acknowledge the service he has rendered us.

Within the sixth volume Prof. Oppel has compressed the results of two centuries of inquiry into the minute structure of the breathing organs of vertebrate animals. The facts are drawn from more than 900 separate publications as well as from his own researches, and deal with the respiratory system of more than 500 species of vertebrate animals. A close examination of the great mass of evidence which has been thus brought together leaves one convinced that, however unlike they may seem, the gill of the fish and the lung of the mammal serve not only the same functional purpose, but are, indeed, but modifications of the self-same organ. It is now clear that in the evolution of the vertebrates there has been no development of a completely new organ of respiration. By a process which we understand but imperfectly at present, the same organ has been modified to serve the same purpose in fishes, amphibians, reptiles, birds, and mammals. The embryological investigations into the origin of the lungs of the frog by Goette, of the fowl by Kastschenko, of the human embryo by Fol, and the later researches of Weber and Buvignier, leave no room to doubt the truth of that generalisation.

Perhaps no two structures have engaged the speculative fancy of naturalists so much as the swim-bladder of fishes and the air-sacs of birds. As to the first, it cannot be said that the great number of observations which Prof. Oppel has succeeded in massing in his pages takes us perceptibly nearer a conception of the true nature and origin of the swim-bladder and its relationship to the vertebrate lung than were the naturalists of fifty years ago. A theory which regards it simply as a hydrostatic organ for permitting a fish to accommodate itself to any depth of water gives only a very incomplete explanation of its presence and structure. On the other hand, the nature of the air-sacs of birds is now almost completely understood. When the facts grouped together by Prof. Oppel are considered it becomes evident that in the vertebrate lung, be it of a frog, of a lizard, of a bird, or of a mammal, there are three distinct parts which differ in structure and in function. In no vertebrate form have these three parts become so highly specialised and distinctly separated as in birds. The three parts are:—(1) a vascular membrane covered by peculiar epithelium and puckered so as to form alveoli (the respiratory part); (2) an elastic chamber or series of chambers, capable of being enlarged and diminished on inspiration and expiration (the bellows part); (3) a series of non-collapsible tubes for conveying the air to and from the air chambers (the conducting part). In the avian lung the bellows part has become completely separated from the respiratory portion, and forms the air-sacs. Intermediate stages in the process of separation are to be seen in the lungs of reptiles. In the mammalian lung the bellows part is broken up into a series of small chambers throughout the whole organ, which form what we in England have been in the habit of calling infundibula, but which, in the more elaborate terminology of Dr. W. S. Miller, are now demarcated into vestibule, atrium, and air-sac.

The progress of our knowledge of the minute structure of the mammalian lung has been peculiarly slow. In part this has been due to the elaborate nomenclature employed. The same term has been used to designate totally different parts, and the same part has been called by several different names. Prof. Oppel has done us a great service in coordinating the terminology used by different investigators. It is clear from the manner in which Prof. Oppel discusses the question as to the nature of the epithelial covering of the gills that he finds it difficult to break away from the tradition which has come down to us from the older embryologists—that there is a profound morphological distinction between the ectodermal and endodermal layers of the embryo. From the minute manner in which he relates the matter it is evident that he quite enjoyed the prolonged scholastic discussion which was first raised by Aeby—as to whether the branching of the bronchial tree was by a process of dichotomy or monopody.

The fifth volume, which deals with our knowledge of the pineal body, and the pineal eye or parietal organ, was entrusted by Prof. Oppel to the safe hands of Dr. F. K. Studnička. That authority has not only coordinated the results contained in some three hundred papers dealing with this structure, but has added much new and valuable work of his own.

The study of structure by itself and for itself is a most unprofitable occupation, and Prof. Oppel, by including a free reference to function and development, has not only added greatly to the interest, but also to the value of these two volumes.

A. K.

A TEXT-BOOK OF GENETICS.

Vorlesungen uber Deszendenztheorien mit besonderer Berücksichtigung der Botanischen Seite der Frage gehalten an der Reichsuniversität zu Leiden. By Dr. J. P. Lotsy. Erster Teil. Pp. xii+384. (Jena: Gustav Fischer, 1906.) Price 8 marks.

AS the moment is favourable, may it be suggested that the branch of science the rapid growth of which forms the occasion of Prof. Lotsy's book should now receive a distinctive name? Studies in "Experimental Evolution" or in the "Theory of Descent," strike a wrong note; for, theory apart, the physiology of heredity and variation is a definite branch of science, and if we knew nothing of evolution that science would still exist. To avoid further periphrasis, then, let us say genetics.

Prof. Lotsy's lectures are a welcome contribution to genetics. They are expository and critical rather than creative, but there is plenty of room for such a work. Since it must be admitted that to most of us facts appeal "first when we see them painted," such a presentation as this book provides should attract many who would find little to detain them in original records.

There are twenty lectures in this first part, and a second part is promised. After a philosophical introduction, which must be left to the judgment of those versed in such matters, the author proceeds to a careful discussion of the evidence for direct adaptation. Though no Lamarckian in the usual sense, he has a high respect for Lamarck's penetration and breadth of view. In this revindication of a great name, naturalists of the younger generation who have studied Lamarck's writings at first hand will probably sympathise with Prof. Lotsy. In a limited sense the modification produced by environment—biaiometamorphosis, as Prof. Lotsy calls it—is important. No botanist doubts that the forms of plants can be profoundly changed by the conditions to which they are exposed. The normal or habitual form in which we know a species is only one of these modifications. Consequently each experimental proof of the dependence of form on environment has a direct bearing on the genesis of type. But the question of *purposeful* or adaptative modification is quite distinct, and of any transmission of purposeful modification in descent there is no evidence.

The section of the book which gives it its chief value is that in which an account is provided of the new developments in genetics, especially Mendelian analysis and the experiments of de Vries. The consequences of Mendelian segregation are described with great clearness, and are illustrated by some excellent diagrams, of which one (p. 101) is striking and novel. The members of the various generations are shown in a perspective view, drawn approximately to scale, in a way which should do something to remove the supposed obscurity of these phenomena. Both the description of the facts and the critical discussion of the bearing of Mendel's discovery on the earlier or Galtonian method of calculating inheritance are especially lucid and to the point.

The weaker features of this section are such as are almost inevitable in attempts to confine a rapidly growing study within text-book limits. The relative importance of the various elements is continually changing. For example, though due stress is laid on Tschermak's fine series of cases illustrating the influence of hidden factors, or cryptomeres, Cuénot's useful exposition of the part played by double factors in the case of mice seems to have been left out. Having regard to the remarkable developments which have followed, this omission is unlucky. In the same connection it is a matter of special regret to myself that the revised and simplified account of the "walnut" combs in fowls did not reach Prof. Lotsy in time to prevent a reproduction of my former and erroneous idea in his text-book.

By all who are working at genetics the discussion of de Vries' mutations will be read with interest. Till now those remarkable observations have been regarded either with indiscriminate enthusiasm, or with still more unreasoning suspicion. But on those who know that the mutations of Œnothera are not errors of observation, and hesitate to accept them as the single key to the final mysteries of evolution, the question begins to press: What *are* those mutations? Upon this point the teaching of genetic research is clear. Before we can form a definite view as to the nature of any given mutation we must know its gametic relations to the type from which it sprang, and to the sister-mutations. So far, these relations, as expressed by the ratios in which the forms appear, seem to be almost always irregular in the Œnothera cases. Experience, however, has shown that such irregularities, as in the case of Miss Saunders' *Matthiola*, may conceal an underlying regularity which fuller analysis can reveal. For instance, we know that various individuals of a form A may give respectively an F_2 ratio 9A : 7B; or 3A : 1B; or all A; or 27A, 9C, 28B, and so on, and the causation or meaning of these several ratios is clear. May not such complexities be the source of the confusion which apparently besets the Œnothera cases? That is the opinion to which Prof. Lotsy inclines, and the position is for the most part unassailable as yet. All that can be positively asserted is that these mutations are forms arising discontinuously, and that their distinctions are exactly comparable with those that often appear to characterise species. But now that we understand what a medley of phenomena is included in the term "specific difference" it becomes necessary to go further and to ascertain which phenomenon is exemplified in each case. That genetic analysis can alone answer that question everyone now perceives. De Vries' own discussion of his results contains manifest traces of an attempt to incorporate the Mendelian ideas into earlier and pre-Mendelian conceptions, and the result is not always harmonious or convincing. We look to de Vries and the many observers who are now at work on Œnothera to bring the various possibilities to a strict test, case by case, and so complete what has been begun with such astonishing success.

Meanwhile, however, it must be conceded that there are serious difficulties in the way of a purely Mendelian account of the Œnotheras—more perhaps than Prof. Lotsy indicates. Of these one of the most formidable is the behaviour of the form *nanella*, for which other cases afford no parallel. There are, further, the objections de Vries himself has urged in the passages contributed to Moll's exposition of his work—particularly, that no indication of a hybrid origin of his original stock is forthcoming. Again, though the sterile pollen grains are suspicious, I may mention that in a collection of wild Œnotheras (? species) made near Baltimore, I found none which had not some bad pollen grains. Were all these hybrids? it may well be asked. If so, hybrids of what? Our Rubi hybridise freely, but, as Focke showed, there are pure forms with perfect pollen, and hybrid forms with an admixture of bad grains. This test should be made in America on a large scale, to discover whether any Œnothera is "pure" by that criterion.

But again, we know that the production of analytical varieties by a hybrid, and the production of novel forms by a mutating species, must be exceedingly similar and perhaps indistinguishable phenomena. Hybridisation cannot be regarded as the sole source of analytical variation—witness the case of *Primula sinensis* and the sweet pea, where analytical variation is rife, though no hybridisation has taken place. The interrelationship of the two sets of occurrences is still obscure; but by experimental breeding it can in great measure be elucidated, and in the course of that inquiry the meaning of mutation will probably be discovered.

Only salient features of the book have been mentioned; many others must be passed over. *Capsella* has provided (p. 180), as might be expected, good examples of the constancy of *petites espèces*. Time brings revenges, and we must hope that Jordan would have felt satisfaction in the recognition now accorded to his once discredited work, though, by the perversity of things, that work is used to complete and support those views he most detested. Strange, too, would it seem to his opponents to see Jordan's microspecies received as a valuable element in the general doctrine of mutability!

In several minor points the book is open to criticism. The Artemia-Branchipus story should not be repeated even incidentally without words of caution. The pictures even in these half-tone days are below the mark, and such pictures as those of peloric Linaria make one long for decent woodcuts again. The figure of the Norwich canary would surprise the fanciers of that city, and it suggests that the crest is a Norwich character. Lastly there is a profusion of most distracting misprints.

W. BATESON.

TEXT-BOOKS OF PHYSICS.

(1) *Muller-Pouillets Lehrbuch der Physik und Meteorologie.* Edited by Leopold Pfaundler. Tenth edition. First vol. (in two parts). Pp. xiv+801. Illustrations. (Brunswick: F. Vieweg und Sohn, 1905 and 1906.) Price 7 marks and 3 marks 50.

(2) *Cours de Physique de l'École Polytechnique.* By J. Jamin. Troisième supplément. Radiations, Électricité, Ionisation. E. Bouty. Pp. vi+420. (Paris: Gauthier-Villars, 1906.) Price 8 francs.

(3) *Lehrbuch der Physik.* By H. A. Lorentz. Translated into German by G. Siebert. Erster Band. Pp. vi+482. (Leipzig: Johann A. Barth, 1906.) Price 8 marks.

(1) THE preparation of this tenth edition of a well-known text-book has been undertaken by Dr. Pfaundler, in succession to Dr. Wild, whose death occurred soon after the publishers had put the revision in hand. For the present instalment on mechanics and acoustics Dr. Pfaundler is responsible; but for other parts of the four volumes in which the work will be completed the co-operation has been secured of Dr. Lummer (optics and heat), Dr. Kaufmann (magnetism and electricity), Prof. J. M. Pernter (meteorology), Dr. Nippoldt (terrestrial magnetism), Dr. Drucker (physical chemistry), and Dr. Wassmuth (heat conductivity and thermodynamics).

It is intended to maintain the characteristics of the book as being essentially non-mathematical. This plan, of course, very much restricts the treatment of most of the problems dealt with, and in many cases prevents any proof being given of formulæ which are discussed. There is room, however, for a text-book of this kind, as is amply testified by the success of the previous editions. In spite of the limitation in the treatment, the author has succeeded in giving a very comprehensive account of his subject. He is very clear, and takes special pains to be so in cases where difficulties are commonly met with. For example, in connection with *mass* and *weight* he is very precise. The kilogram is a mass, and not a weight; one can only say *it has a weight*, and can call this the kilogram-weight. In stating this he is in agreement with the International Committee of Weights and Measures (Paris, 1901), whose decisions may be considered as representing the common-sense of the scientific world.

The intention is to bring out the remaining volumes quickly. It is expressly hoped that owing to the large number of collaborators, the treatise may be completed before the first volume is out of date.

(2) The second of the volumes under notice is the third supplement to the treatise on physics, commonly known as "Jamin et Bouty." The subject-matters embraced are radiations, électricité, ionisation. It is

more than six years since the second supplement appeared, and in the interval the study of the kathode stream, the phenomena of radio-activity, and in general of everything concerned with the propagation of electricity in gases has given rise to a new conception of electrical conductivity, and of the ultimate constitution of what were once called the "electrical fluids." The faith of scientific men in the non-transmutability of matter has been shaken; even the notion of material mass tends to be absorbed in that of electromagnetic inertia.

This is the state of things as set forth in the preface to this supplement; no surprise need be felt, then, at its large size compared with that of the preceding numbers. The portion dealing with radiations includes amongst other things an account of recent work on the energy of a block body, the pressure of radiation, the laws of dispersion (normal and anomalous), remainder rays, and N-rays. In regard to the last-named subject, we have no wish to be dogmatic; there is certainly some evidence that M. Blondlot has been experimenting with objective, and not entirely with subjective, phenomena, and if this is so, experiments should not cease until the *exact* nature of these phenomena has been established. But when M. Bouty devotes nearly two pages to this subject, and does not even hint that there is doubt, amounting to disbelief, in the minds of most of the leading physicists of the world in regard to this matter, we think that he is hardly doing justice to it.

In electricity, leading sections deal with wireless telegraphy, polyphase currents, the ionic theory, and the work of Nernst. Under the head of ionisation are taken the phenomena of ionisation in gases and radio-activity. The volume concludes with some miscellaneous practical applications of electricity.

Any who are familiar with the main treatise and the previous appendices will know that M. Bouty is a master of lucid exposition; there is no need to commend this volume to them. Those who are desirous of learning, in brief but clear summary, the present state of knowledge in regard to the above supremely important subjects may be recommended to read this appendix.

(3) The third of the above books is the first volume of a course of elementary physics based on lectures delivered to classes consisting largely of medical students. As the reader is assumed to be attending experimental lectures and, if possible, performing experimental work himself in a laboratory, small space is given here to descriptions of experiments and of methods of observation.

The subjects dealt with are mechanics, and the properties of bodies in the solid, liquid, and gaseous states. The sixth chapter consists of thermodynamical considerations in respect to gases. This chapter is undoubtedly very lucid, but we think that its proper place is later on—after calorimetry. The mathematics employed is simple, and the treatment very clear. The name of the author is, of course, a sufficient guarantee of the nature of the book. We look forward to seeing the German translation of the remainder.

REDUCTION OF GEODETIC MEASURES.

The Adjustment of Observations by the Method of Least Squares, with Applications to Geodetic Work. By T. W. Wright, with the cooperation of J. F. Hayford. Second edition. (New York: D. Van Nostrand Co.; London: A. Constable and Co., Ltd., 1906.) Price 3 dollars net, or 12*s*. 6*d*. net.

THIS is a book which in its original form grew out of the experience and requirements of the U.S. Coast and Geodetic Survey. As points of novelty or difficulty arose in the course of the work and were solved by the staff, Mr. Wright collected the decisions and the methods as guides for the treatment of similar cases in the future. The systematic arrangement of these cases, and the discussion of the principles which furnished the solution, provided a mass of materia which has been of great service to the department An opportunity has now arisen for the revision o, this work, and in the belief that the information would be of advantage in many operations connected with scientific engineering, the original author, in collaboration with Mr. J. F. Hayford, chief of the computing division and inspector of geodetic work, has given to this material the form of a treatise.

The book is eminently practical. The authors do not enter into the question whether the principle of least squares suggests the best or the only method for deriving from a mass of imperfect data a result that will command general confidence. They recognise the fact that the method has secured an impregnable place in all inquiries to which it is applicable, and proceed at once to discuss the law of error on the ordinary Gauss-Chauvenet lines. The subject necessarily does not lend itself to any novelty of treatment. The value of the earlier chapters at least lies in the fact that the authors place before us the results of a wide and profound experience. Everywhere they keep in sight the practical treatment, insisting on the importance of arithmetical checks and processes of abbreviation. In this connection one is glad to see Doolittle's system of solution set out in a complete scheme, as well as other processes which have a practical application.

The question of the rejection of discordant observations will always occasion a computer some anxiety The authors have evidently suffered, and the practical rule given here may not be generally accepted, but is valuable as showing, presumably, what is the practice in the U.S. Geodetic Survey. The authors advise that no observation should be retained for which the residual exceeds five times the probable error of a single observation, and that all observations the residuals of which exceed three and a half times the probable error of a single observation should be examined, and rejected, if any of the conditions under which the observation was made were such as to produce any lack of confidence. The conviction is also expressed that an observer's best observations are poorer than he believes them to be, and his poorest better. As a consequence of this the range of weights that observers attach to their observations is too large.

Actual geodetic measures necessarily introduce the problem of conditioned observations, in which no set of values can be assumed to satisfy approximately the observation equations which does not exactly satisfy some *a priori* conditions. This problem may not necessitate any fresh method of treatment, but the applications are somewhat unusual, and, again, it is of very great importance to know what is done in actual practice. The authors have given us a valuable treatise, prepared with care, and generally free from errors. There is some confusion in the numbering of the figures after p. 193, but this, if annoying, is of less importance than any error in the formulæ.

OUR BOOK SHELF.

Modern Milling Machines. By Joseph G. Horner. Pp. ix+304. (London: Crosby Lockwood and Son, 1906.) 12*s.* 6*d.* net.

A MODERN machine shop in any large works would be very incomplete indeed without a full complement of milling machines. The proportion of this class of machinery very largely depends upon the class of work dealt with. For instance, in a sewing-machine, cycle, or motor-car factory the milling machine would predominate, being in many specialised forms, each machine designed for some particular function. On the other hand, in a general engineering establishment any milling machines installed would be of the universal type, and capable of dealing with many different operations, such as the universal machines made by Brown and Sharpe, of U.S.A., and many others.

It is only during recent years that milling machinery has come prominently to the front, principally due to the fact that designers of such machines have grasped the fact that they must be made of ample weight with large bearing and wearing surfaces, so as to ensure steady running without spring of the machine and consequent vibration. Another very important consideration is the possibility of obtaining suitable material for the cutters used. The cost of making a milling cutter is infinitely more than the value of the cast steel used. It is evident, therefore, that when once completed the cutter should have a long life. This desideratum has been rendered possible by the introduction of high-speed tool steel, the results obtained being of a most satisfactory nature, particularly those from the "Air-hardened" steel manufactured by Edgar Allen and Co., of Sheffield. The cost of the material, therefore, is a secondary consideration.

In the volume under notice the author describes very fully many different types of machines, and probably one of the best chapters is that dealing with the design and manufacture of the cutters. The power required very largely depends on the design of cutter used, other things being equal; to use a cutter in any degree dull is also poor economy.

Another valuable assistant to the milling machine and its cutters is the introduction of special cutter grinding machines, which, I believe, emanated from the Brown and Sharpe Manufacturing Company. Many of these machines are described and illustrated, the author having gone very fully into the subject. This is as it should be, since a good cutter is of the utmost importance in milling work.

Chapter xi. is too short, though very interesting; it deals with the subject of feeds and speeds. On these constant worries of a machine-shop manager our author has much to say, and sensible advice to give, and we cordially agree with him where he points out how easy it is to get wonderful results by means of a sharp tool running for short periods by comparison with work done under ordinary shop conditions. Such work, as a rule, does not pay.

We can recommend this volume to all interested in machine-shop practice. The machines dealt with are of the latest type, and much useful information will be found scattered through its pages.

Lectures on the Method of Science. Edited by T. B. Strong, Dean of Christ Church. Pp. viii+249. (Oxford: Clarendon Press, 1906.) Price 7*s.* 6*d.* net.

THESE lectures formed part of a course on scientific method delivered at the University Extension summer meeting at Oxford last August. The discourses are intended to illustrate the forms taken by scientific method in various departments of research. Prof. Case deals with scientific method as a mental operation; Prof. Francis Gotch, F.R.S., treats of various aspects of the method; Prof. C. S. Sherrington, F.R.S., describes the scope and method of physiology; the lecture by the late Prof. Weldon discusses inheritance in animals and plants; Dr. W. McDougall explains the psychophysical method; Dr. A. H. Fison applies the method to the question of double stars, Sir Richard Temple to the evolution of currency and coinage, Prof. W. M. Flinders Petrie, F.R.S., to archæological evidence, and the Rev. Dr. Strong to history.

From the nature of the case, the arguments are such as to appeal to persons of general culture rather than to specialists. If Oxford were as energetic in the prosecution of scientific research as she is in popularising knowledge by means of extension lectures, men of science would probably be disposed to think her activities better and more suitably directed. The omission of an index can never be justified in the case of a scientific book, but that a work devoted to scientific method should be deficient in this respect is an irony which cannot be overlooked.

The Secrets of Dog-Feeding. By "Great Dane." Pp. ix+58. (Southampton: Toogood and Sons, 1906.)

THE mere fact that this little work has reached its second edition within less than a year of the date of its first appearance may be taken as a sufficient guarantee that it has obtained the verdict of approval from dog-owners, and is therefore a success. The author is of opinion that the nature of the food is a matter of prime importance in the case of valuable, highly-bred dogs, and one which too often receives but insufficient attention on the part of their masters. While advocating a mixed diet, he deprecates the use of green vegetables, which has of late years come much into fashion among many dog-owners; and he adds that to a dog which has been kept largely upon farinaceous food the change to a meat diet in later years will often produce highly satisfactory results. The constituents of nearly all the foods referred to are given, so that readers can judge for themselves as to their nutritious value.

R. L.

In My Garden. A Little Summer Book for Nature Lovers. Pp. 72. (Wellingborough: The Lavender Press; London: Philip and Tacey, Ltd., 1906.) Price 1*s.* net.

THIS dainty little memorandum book, with its blank pages for notes on experiments in gardening and other observations of natural objects, will please all students of country life. The well-selected quotations and the hints on table decoration should appeal to a wide circle of readers.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Inheritance of an Abnormality.

A CASE of the heredity of an abnormality of the hand may be of interest to some of your readers.

A father and a mother with normal hands had a family of three sons and seven daughters. The eldest son had an abnormality of each hand, the second and third fingers being apparently jointed to the same bone, and the third daughter has a different abnormality, both hands being affected. The accompanying skiagram, kindly taken for me by Mr. J. J. Blake, of Onslow Road, Richmond, will show the character of this abnormality. All the remaining children had normal hands.

FIG. 1.—Abnormal hand of third daughter.

The eldest son had two children without abnormalities, and the second son three children that were normal. The eldest daughter had one son and two daughters normal; the son has two normal children, the first daughter one child abnormal, and the second daughter two children normal.

Returning to the third daughter with the abnormal hands, all her eight children are normal; the fourth daughter has two normal children; the fifth daughter has two children abnormal and five normal; the sixth has three normal, and the seventh five normal children.

There is no tradition of abnormalities in any of the relations of the father or mother. It may be mentioned that the husbands of the eldest and fifth daughters, some of whose descendants are abnormal, are first cousins (not first cousins of their wives).

The following scheme may make the relationship more clear (N signifies normal; A, abnormal; and *c*, children):—

Father and Mother, both N.

Sons			Daughters						
1 A.	2	3	1	2	3 A.	4	5	6	7
2*c*. N.	3*c*. N.		son, 1*, 2*		8*c*. N.	2*c*. N.	2*c*. A. 5*c*. N.	3*c*. N.	5*c*. N.
			2*c*. N., 1*c*. A., 2*c*. N.						

* Daughters.

May 30. HERBERT MCLEOD.

Thermometer Scales.

A DECIDED disadvantage of the centigrade scale in meteorology is the use of negative numbers for temperatures below freezing point. In taking out means of months where negative numbers occur the labour is doubled, and other additional sources of error have to be avoided.

The Fahrenheit scale is not so liable to this trouble, but there are other objections to its use. Both of these scales might be superseded by a scale starting from absolute zero, on which the temperature of melting ice is 350°. Such a scale is compared in the following table:—

	° C.	° F.	° Positive
Absolute zero	−273 ...	−459 ...	0
Mercury melts	− 39 ...	− 38 ...	300
Ice melts	+ 0 ...	+ 32 ...	350
Very hot weather ...	+ 39 ...	+102 ...	400
Water boils	+100 ...	+212 ...	478

The great advantage of this positive scale in meteorology is that temperatures, except the most unusual, fall between 300° and 400°, so that temperature columns might be headed "300° plus." On this scale water, under a pressure of 31·3 inches, boils at 480°, so that the most important temperatures in physics are easy to remember.

Solar and Lunar Halos.

AN interesting halo round the sun was seen a few miles from here, on Dartmoor, from 7.30 p.m. to sunset on June 7. The halo consisted of a double circle, the inner one having an angular radius of about fifteen to twenty degrees, with concentrations of light at the top and at the right extremity—the bottom of the ring was below the horizon, and the left extremity hidden by clouds—and a concentrated ray from the sun to the top of the circle. The outer circle was double the diameter of the inner one, and much fainter. A similar halo round the moon (with the exception of the outer circle) was observed the same evening. ROWLAND A. EARP.

The Laboratory, Buckfastleigh, Devon, June 12.

THE ROYAL SOCIETY OF EDINBURGH AND THE GOVERNMENT.

THE great deputation on behalf of the Royal Society of Edinburgh, which waited on the Secretary for Scotland at the Scottish Office in Parliament Square in Edinburgh on June 1, stated a strong case in favour of more liberal treatment of the society by the Government. As one speaker expressed it, they were met there on Scottish soil, indeed at the very heart of the ancient metropolis of the kingdom of Scotland, to confer with their own Secretary of State, and to urge the claim of a society which has been identified with scientific progress in Scotland during the nineteenth century to remain in its old home, and receive some small assistance in producing its Transactions and Proceedings. It must be admitted that this appeal met with only a very disappointing response.

The Royal Society was the heir and successor of a previous society which was established in 1731, and therefore has been practically contemporary with the great scientific illumination which had its beginning in Newton's "Principia." After an existence of about half a century the society was established, in 1826, in the Royal Institution on the Mound in Princes Street, the building in the form of a classic Greek temple, which with the unfinished national monument on the Calton Hill—the Edinburgh Parthenon—and some other public buildings on classic models, affords the outward and visible part of the claim of Edinburgh to be called the Modern Athens. Of the real distinction of the city, its eminence in the arts, science, and letters, the Royal Society has undoubtedly contributed a very considerable part. Never a scientific society only in the purely technical sense of the present day, and never imposing any arbitrary restriction on its fellowship, it has had on its roll and among its presidents and office bearers all the authors, jurists, philosophers, mathematicians, and physical investigators whom Scotland has produced during the eventful period of the society's existence.

Though, like others that might be cited, the Royal Society of Edinburgh has been from time to time perhaps a little too closely identified with the city in which it has had its headquarters, it has always been a national institution. Its library, which is rich in scientific periodicals, has been consulted by men from all parts of Scotland, and its rooms have been a rallying place for Scottish workers, especially in later years for the younger generation of biologists, mathematicians, and physicists. It was never more active than at present, and is in danger of being ruined by its very success, for the problem of providing for the expense of the publication of the many excellent memoirs which have been received of late for its Transactions has seriously embarrassed the council. This point should be carefully borne in mind in considering the reply of the Scottish Secretary to the deputation. The demand made was not merely that the society should not be dispossessed of its rooms without full compensation (though this was the immediate reason for the deputation), but that it should be treated with regard to publications in a small degree at least as the Royal Society of London and the Royal Irish Academy are treated.

As was explained in our last week's issue, the proposal of the Government is to provide the Royal Scottish Academy with a separate house in which, like the Royal Academy at Burlington House, it may annually exhibit its pictures and sculpture to the general public, and—incidentally, of course—to the patrons of Art. Hitherto this Academy has shared the rooms provided for artistic purposes in the National Gallery building also on the Mound; and competent judges, even within the Academy itself, have deemed the provision sufficient. Some of their chief men have even dared to suggest that what was wanted was not so much an extension of space as an elevation of the standard of selection! Nevertheless, the bitter cry of the artists for some time has been for a house of their own; and this the Government has now determined to provide, not by erecting a suitable new building from public funds, but by the cheaper method of evicting the Royal Society of Edinburgh from the rooms which were arranged for it in a building erected mainly for its accommodation. When the decision was announced to the Royal Society it was accompanied by a statement of the willingness of the Government to do something to "help" the Society in the difficulty thus created for it by no fault of its own. Though Mr. Sinclair has now gone a good deal further, and admitted that the Government will be under an obligation to do something substantial, he still merely speaks of "help," and urges the Society to trust to the "liberal spirit" in which the Government is sure to view its necessities!

Now this is all very well, but, as Mr. Sinclair knows, it is not exactly business. The Government of the day has always been lavish of assurances of its high consideration to the men of science who have applied to it in the past, whether for the Royal Society of Edinburgh, the Ben Nevis Observatory, or anything else, but for science in Scotland at least it has consistently refused to do anything whatever beyond continuing the small dole it has hitherto given. The society is not justified, therefore, in being too trustful. It is being dispossessed, and its claim for compensation should either be recognised by a clause in the Bill now before Parliament or acknowledged by being made the subject of a definite pledge by the responsible Minister.

Another assurance asked for by the society and no less essential remains to be given. Time is needed in which to find the best possible premises, to fit them up, remove the library, and arrange for the meetings, without interruption of the society's work. At present the council has only a legal right to two years' notice, and a definite promise that this much too narrow limit of time will not be insisted on is most important. As it is, the insistence of the Scottish Secretary on the necessity for promptitude of decision and action by the society is ominous.

With regard to the promise of "help" towards the erection, or provision otherwise, of new rooms, it is to be observed that the society has no funds to contribute to the erection or purchase of a building. Every penny left after providing for a very modest budget of ordinary expenses goes to the publication of scientific papers. The dole of 300*l.* made by Government is actually paid back to the Board of Manufactures as rent for the rooms in the Royal Institution. For publications the Royal Society of Edinburgh receives nothing; the Royal Society of London receives 1000*l.* per annum for publications; the corresponding body in Ireland—the Royal Irish Academy—lives in its own house, which was given it by the Government, and enjoys a grant of 1500*l.* a year. [Moreover, the houses in London and Dublin are maintained by the Board of Works, which means a further yearly contribution not made to the Edinburgh society.] The request of the deputation that some small annual grant should be made for publications was ignored in the Secretary's answer. That answer, it is to be observed, was written out beforehand, and read as soon as Prof. Chrystal had summed up for the Society, so that even the usual form of taking the representations made into consideration was omitted. In fact, except as regards the admission of the claim of the society to some compensation for disturbance, the statements and claims of the deputation went the way of most representations made to Scottish Secretaries, whether at home at Parliament Square or on the alien soil of Dover House.

The British Science Guild has not been established too soon. The Government and Mr. Sinclair may have as generous intentions as the friends of the artists in the Edinburgh Press urge the Royal Society to believe—and we may say that nobody doubts that the intentions of both are good—but it will be the duty of the council to obtain the necessary guarantees for the continued usefulness, if not for the existence, of the society. If necessary the British Science Guild will no doubt lend its powerful aid.

ARCHÆOLOGY IN THE ISLE OF MAN.[1]

THESE notes form a useful handbook to the geology and antiquities of the Isle of Man, and those responsible for persuading the authors to reprint and amplify their scattered notices have conferred a benefit on the public. Although the little volume runs to little more than 100 pages, it includes a good survey of both branches of the subject, and emphasises the interest of the island in the two aspects of its remoteness in some respects from its neighbours and as a meeting place of the arts of the Celt and the Northman. The evidences of man's presence in the island naturally begin with the Neolithic period, the climatic conditions of the Pleistocene age effectually preventing him from reaching so far north; but from Neolithic times onwards the story of the island can be traced by its archæology. Flint appears only to exist in the form of nodules washed from the Boulder-clay, and the "factories" of flint implements are always on actual deposits of Boulder-clay. Some of the implements figured are, as the authors admit, of very rude make, as well as of very curious types (Fig. 4).

It is perhaps hardly surprising that signs of dwellings are not found near these Neolithic "floors" or factories. Stone-age man, here as elsewhere, chose his dwelling for reasons of security or shelter from the weather rather than from the proximity of a good store of flint nodules. Dwellings in the form of hut circles have, however, been found in fair numbers, and though it is by no means improbable that they date from Neolithic times, the authors are justly cautious in dogmatising on their age. No type of exploration is more difficult than that presented by the ordinary hut circle, and often the principal evidence is that of analogy. Such remains, moreover, share with stone circles the danger of having been disturbed by treasure seekers, with the result that stratigraphical deductions cease to be of value. It cannot be too often insisted upon that the class of exploration that produces the fewest objects of intrinsic value, viz. those of prehistoric times, should be excavated with most care and attention to detail. The reason is a simple one. The elucidation of the problems of early man depends solely upon such explorations, for no other documents can possibly exist to help in the solution of the puzzle. In later historic times the helps to knowledge are endless. Both Mr. Kermode and Dr. Herdman clearly recognise the importance of careful work, but, like most students of the earlier periods, they will doubtless admit the need of this warning to the unwary or careless explorer.

Apart from the interest to those who study the Manks antiquities as part of the general archæological scheme, this little book can scarcely fail to have a good effect in the island itself. It is to be hoped that all the relics that may come to light in future will be deposited in Castle Rushen, where they will be available for comparison and study. It is sad to read of such things going astray when a little tact or trouble might have preserved them.

[1] "Illustrated Notes on Manks Antiquities." By P. M. C. Kermode and W. A. Herdman. Pp. 108. (Liverpool: Tinling and Co., Ltd., 1904.)

The Bronze age in the Isle of Man was evidently a time of considerable communication with the mainland. The types of urns, as well as the fact that all the stone axes are of foreign material, show that trade must have been fairly brisk. The urn shown in Fig. 23 is, for instance, nearly related to the Scottish urns of the same time. This fact has, of course, an important bearing on the relative date of this and other periods when such communication existed. If the same types of funeral furniture are found here as on the mainland, it not only shows intercommunication, but also, as a necessary consequence, proves the contemporary existence of the same burial customs in the two places. Thus although it may well be that the remoteness of the island prevented its inhabitants from being quite as advanced as the continental dwellers, yet the difference in time can only have been slight. The authors seem to lay rather more stress than the facts justify upon the retarding effect of the inaccessibility of the island. It is probable that the civilisation was relatively further behind the rest of England during the eighteenth century, for instance, than it was in the Bronze age. The similarity of stone implements in parts of the world widely separated is not always easy to explain, though the similarity of need has a good deal to do with it. But an elaborated and more complex object, such as an ornamented pottery vase, can scarcely be reproduced in all its details without some relations between the two makers. Commonplace though such an observation may be, it is very necessary to bear such facts in mind in discussing an island civilisation like that of the Isle of Man, or even of Britain.

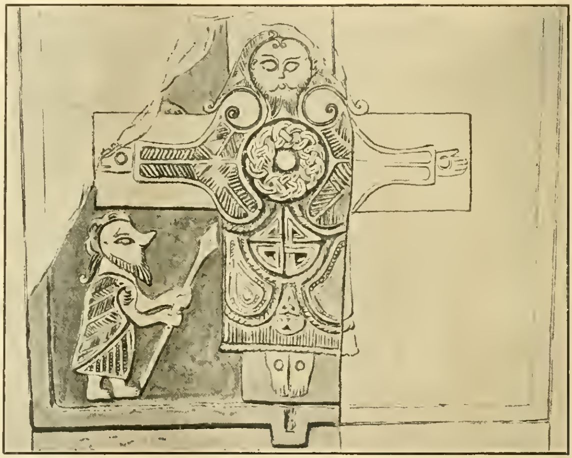

FIG. 1.—Cross from Calf of Man. From "Illustrated Notes on Manks Antiquities."

The most characteristic, and in some respects the most interesting, antiquities of the island are the Scandinavian and Celtic carved stones of Christian times. It is very useful to note how the Northmen appreciated the delightful complicated designs of their Celtic forerunners. The respective shares of Scandinavian and Celt in the motives of these curious monuments, and even in the finest Celtic manuscripts, have never been adequately elucidated. The genius of the two races in the treatment of ornament differed so widely that in some pages of the "Book of Kells," for example, the two can be separated as easily as if they were of different colours. It is odd to find that Mr. Kermode describes the interesting crucifixion shown on p. 72 and here reproduced as "an example of pure Byzantine art." To our eyes it is nearly pure Celtic, and has no relation, artistically, to any Byzantine crucifixion we have ever seen. The statements, however, throughout the "Notes" are in general accurate and restrained, and there is an entire absence of the wild local enthusiasm so often found in books of this particular character. The "Notes" may be commended as likely to be of great use to anyone visiting the island or studying its antiquities.

MOLLUSCAN MORPHOLOGY.[1]

THIS fifth volume of the important "Treatise," edited by Prof. Ray Lankester, deals with the Mollusca, and is the work of the one biologist capable of doing this group most justice, namely, Dr. Paul Pelseneer. Like its predecessors in the series it treats of the subject almost exclusively from the morphological standpoint, just such a sufficiency of systematic matter being added as to justify the title, while it is, of course, very far from being, and indeed does not pretend to be, a manual on the phylum.

Some delay has occurred in its appearance, owing to the need of translation and revision for the press, which has been carried out by Dr. Gilbert Bourne.

FIG. 1.—*Stenogyra mamillata*, left side view, with four embryos in the oviduct. *em*, embryo. From "A Treatise on Zoology."

The work itself is an expansion of Dr. Pelseneer's similar contribution to Blanchard's "Traité de Zoologie." The translation is remarkably well done, and save in some of the opening sentences it is hard to realise that it was not written in English. Not but that there are small slips such as "biannual" for "biennial." The revision, we suspect, has largely consisted in the importation of new terms, so dearly beloved of a certain school of biologists, that do not altogether make for clearness, and are foreign to the lucid style customary in the author's other writings. The opening paragraph on the "general description and external characters" of the Mollusca (p. 3) is a case in point. While the statement (p. 20), "It has been shown that in the Cephalopoda hyperpolygyny is the rule, and in certain Atlantæ and American Unionidæ, hyperpolyandry," inspires the not hypercritical comment that, without hyperbole, it is hypertechnical. Certainly a glossary will be indispensable to the work.

One is glad to observe that that mythical monster, the "Archi-" or "Schematic Mollusc" has dwindled to a shadow of its former self, and now survives solely in a diagrammatic figure as a "scheme of a primitive mollusc" (Fig. 19). For, as Verril pointed out in 1896 (*Amer. Journ. Sci.*, series iv., vol. ii., pp. 91–92), the primitive mollusc is rather to be sought in the early larval stages, such as the Veliger form. Even now one is tempted to think that the "primitive" has been introduced by the translator, since the author in his previous work, to which reference has already been made, simply labels his figure "Schème d'un Mollusque," which is rather a different thing.

Dr. Pelseneer's explanation of the torsion of the gastropod body evidently now meets with Prof. Lankester's approval, for it is the only one advanced and is reinforced by an additional diagram.

A good deal more attention is paid, and rightly, to the shell than in the author's previous writings, and it is interesting to see Sharp's theory of the progressive disappearance of the anterior adductor muscle in certain successive forms of Lamellibranchs (which was first illustrated by specimens in the Index Hall of the Natural History Museum) made the subject of illustration, though in the text this disappearance is made the cause, instead of the consequence, of the alteration of the body-axis.

One or two other points need further attention. Allusion might advantageously have been made to the origination of the gill in Cyclas, Teredo, and Scioberetia by perforation of a continuous membrane: also to the discovery by Dall that Philobrya passes through a glochidium stage, which is therefore not confined to the Unionidæ.

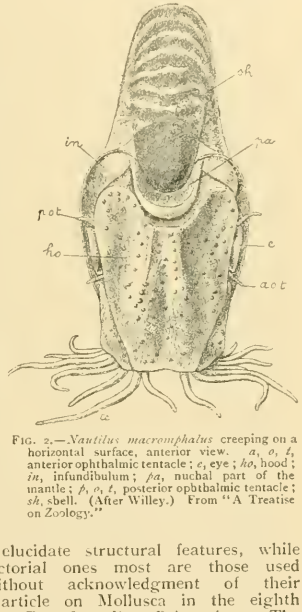

FIG. 2.—*Nautilus macromphalus* creeping on a horizontal surface, anterior view. *a, o, t*, anterior ophthalmic tentacle; *e*, eye; *ho*, hood; *in*, infundibulum; *pa*, nuchal part of the mantle; *p, o, t*, posterior ophthalmic tentacle; *sh*, shell. (After Willey.) From "A Treatise on Zoology."

The systematic portion is open to much criticism. It does not differ materially from that given in Dr. Pelseneer's previous works, though there is, so to speak, some shuffling of the cards. It is a great pity, however, that the nomenclature has not been brought up-to-date. This would have prevented such an error as recording *Zonites* as British.

The majority of the illustrations, which are all clear and well printed, are diagrammatic, or elucidate structural features, while of the few pictorial ones most are those used by Owen, without acknowledgment of their source, in his article on Mollusca in the eighth edition of the *Encyclopædia Britannica*. The greater number of these are now, very properly, attributed to their rightful authors, but of those still labelled "From Lankester after Owen" it has escaped observation that Nos. 71, 134, and 136 are after Adams, No. 158 after Philippi, and Nos. 66 and 135 are from S. P. Woodward's "Manual," while the well-known figure of *Sepia officinalis* (No. 299) is from Férussac and D'Orbigny's "Histoire."

The index would have been more useful had references to the genera cited elsewhere than in the systematic parts been included.

All these are, however, minor points, and the fact remains that malacologists now possess one of the best-written treatises yet produced in the English language on the morphology of the Mollusca.

(B V)².

[1] "A Treatise on Zoology." Edited by Dr. E. Ray Lankester, F.R.S. Part v., Mollusca, by Dr. Paul Pelseneer. Pp. 305; 301 text illustrations. (London: A. and C. Black, 1906.) Price 15*s*. net.

CYCLES IN CHRONOLOGY.[1]

THAT the 1260 years understood to be expressed by the "time, times, and a half" (taking "time" to indicate a prophetic year of 360 days each) of Dan. xii. 7, and repeated in Rev. xii. 6 and in Rev. xi. 2 and xiii. 5 under its equivalent term "forty and two months" (taking a month as thirty days), was in fact an astronomical cycle, was first suggested by Loys de Chéseaux in a work published at Paris in 1754, three years after the author's death. But it did not meet with much attention in England until a small work on the subject was published by Mr. W. Cuninghame in 1834, and it was subsequently more fully explained by Mr. H. Grattan Guinness in his "Approaching End of the Age," which appeared in 1878.

Dr. Bell Dawson however, in a pamphlet now before us, goes into the matter much more elaborately, using the most recent knowledge of the lengths of the solar and lunar years (by lunar year he means twelve lunar synodic months or lunations), and finds a remarkable correspondence between multiples of these which coincide with those of the number in Daniel. As seven is a perfect number in Scripture, and Daniel mentions three and a half prophetic years ("time, times, and a half"), he thinks that the 1260 must be doubled, which makes 2520 lunar years. Now a lunation contains, according to the most modern determinations, 29·530589 days; 504 of these are equal to 178,601 days and 2520 to 893,005 days within about four minutes. An eclipse-cycle is also pointed out, *i.e.*, that 649 solar years are almost exactly equal to 8028 (223×36) lunations (the former amounting to 237042·1853, and the latter to 237042·0355 days), which is much more accurate than the Metonic cycle.

Dr. Bell Dawson carefully notes the different values which have been found (observationally and theoretically) for the secular acceleration of the moon's mean motion; but he seems to have forgotten that though probably constant or nearly so in amount, its effect, when long periods of time are taken into account, varies like the accelerating force of gravity, as was pointed out by Halley, its discoverer, according to the square of the number of centuries. As Chéseaux had done before him, he shows the astronomical significance of the cycle 2300 years in Dan. viii. 14, as well as that of the 1260 years before spoken of; but he treats it somewhat differently. Chéseaux (whose scheme, we may mention, is explained in the second volume of Mr. Chambers's "Handbook of Astronomy") took the difference between 1260 and 2300 (*i.e.* 1040) years, and showed that 1040 solar years form a period almost exactly equal to 12,863 lunations, the former amounting to 379851·8839 and the latter to 379851·9624 days. But Dr. Bell Dawson takes them as lunar years (or periods of twelve lunations) and shows that 1780 (the mean between 2300 and 1260) lunar years is almost precisely equal to 1727 solar years, each exceeding 630773 days by only 0·27 and 0·37 respectively, and therefore differing from each other by only 0·10 of a day in that time or about 0·006 in a century. It does not appear that any reference is made to the 1290 and 1335 days of Dan. xii. 11 and 12. No attempt is made to discuss the *terminus à quo* (or therefore *ad quem*) of Daniel's periods, being beyond the scope of the paper before us, which treats only of the numbers themselves and their accordance with astronomical epochs.

Dr. Bell Dawson inserts a reflection on the inferior accuracy of the Roman calendar arrangements to those of the Chaldeans and other Oriental nations. It is probable, however, that when Julius Cæsar reformed the calendar he decreed that each fourth year should be an intercalary year, not because he was not aware that the actual length of the year was somewhat less than $365\frac{1}{4}$ days (a question which had been discussed by Sosigenes, who assisted him), but because he thought it would be a convenient rule and sufficient for all practical purposes. In this a distinguished astronomer of our own day (Prof. Newcomb) agrees with him; and indeed the chief object of the introduction of the Gregorian calendar was to bring back the date of the vernal equinox to that which it had at the epoch of the Council of Nicæa. W. T. L.

[1] "Solar and Lunar Cycles implied in the Prophetic Numbers in the Book of Daniel." By Dr. W. Bell Dawson. Pp. 20. (From the Transactions of the Royal Society of Canada, vol. xi., Section 3.)

PREVENTABLE DISEASE AND MILITARY STRENGTH.

IN a letter to the *Times* (June 6), Mr. St. John Brodrick directs attention to the serious diminution in the military strength of an army, not to say the terrible loss of life, which ensues in campaigns from diseases which are largely preventable. It is a truism, well recognised by medical men, that the soldier has much more to fear from the ravages of disease than from the bullets of the enemy. Mr. Brodrick points out that

"In South Africa the deaths per 1000 were 69 from disease and 42 from wounds, but the admissions to hospital were 746 per 1000 from disease and 34 from wounds. In other words, about 450,000 were passed through the hospitals for disease during the war, and 14,800 deaths occurred, while the admissions for injuries in action were only 22,000."

Dysentery and enteric fever are the great scourges of an army in the field, and, as was pointed out in an article in NATURE (lxxii., p. 431), are largely preventable. That this is the case is proved by the records of the Russo-Japanese War, in which the Japanese had a total of some 221,000 killed and wounded and 236,000 cases of sickness, a ratio very different from that which obtained in our own army in the Boer War. The Japanese have realised to the full the importance of hygienic measures in the field; sanitary corps went on ahead of the main army and chose the camping grounds, supervised the water supplies, and exercised a rigid sanitary control in all matters, with the above result.

Mr. Brodrick suggests one simple remedy:—

"Why should not the admirable body of Army Medical officers who have made sanitary conditions a study educate combatant officers in the elements of military hygiene? Every cadet at Sandhurst or Woolwich should be examined on passing out in a problem which he should grasp as easily as tactics or strategy, since upon it the fighting strength by which he is to win his battles depends. A captain before promotion to major might be encouraged to get a special certificate which would excuse him from all such training at the Staff College."

Sir Frederick Treves, in a letter to the *Times*, cordially supports this suggestion, and goes further, advocating that a like knowledge of a more elementary character should be possessed by the private soldier.

In addition it may be added that the formation of a sanitary corps seems desirable to aid the medical staff, to guard and control the water supplies, and the like. At present the Army Medical officer is powerless to enforce sanitary measures; although responsible, he can give no orders, and can only act through a commanding officer, often junior to himself, who has no technical knowledge. Moreover, through the Esher Committee, the Director-General, who formerly had direct access to the Secretary of State and had a seat on the Army Council, has been deprived of those privileges, the Adjutant-General at present being practically head of the Medical Department. Now that a former Secretary for War has directed public attention to the matter, it is to be hoped that those in authority will recognise that medical science is a vital part of military strength, a dictum which has for years been preached by the medical profession.

NOTES.

At the meeting of the council of the Royal Astronomical Society, held on Friday last, June 8, the following resolution was unanimously agreed to:—"That the council learn with deep concern of the danger threatened to the Royal Observatory, Greenwich, from the erection of a large electric generating station near the observatory; and desire to represent to the Admiralty at the earliest opportunity their conviction of the paramount importance of maintaining the integrity and efficiency of Greenwich Observatory, which has been adopted as the reference point for the whole world." It was further resolved that a copy of this resolution be forwarded to the First Lord of the Admiralty.

Mr. Haldane, M.P., Secretary of State for War, will open the electrical laboratory of the National Physical Laboratory on Monday, June 25, at 2.45 p.m.

At the twenty-fifth annual meeting of the Royal Society of Canada, recently held at Ottawa, Dr. William Saunders, the director of the Dominion Government's system of experimental farms, was elected president for the ensuing year, with Dr. S. E. Dawson vice-president.

Invitations have been issued by the Institution of Electrical Engineers for a conversazione at the Natural History Museum on Tuesday, June 26, to meet the visiting delegates from kindred institutions.

Prof. K. Birkeland, of Christiania, the inventor of the only successful commercial process for obtaining nitric acid by the direct oxidation of atmospheric nitrogen, will read a paper before the Faraday Society about June 26 entitled "Oxidation of Atmospheric Nitrogen by Means of the Electric Arc."

Much interest was aroused in India some time ago in the attempt to introduce the permanganate treatment of snake-bite. In the Central Provinces a large number of Sir Lauder Brunton's lancets were distributed last October for use by vaccinators and selected landholders. Several cases of successful treatment have been reported to Government, but unfortunately, says the *Pioneer Mail*, none of the reports gives sufficient detail to prove that the bites were really those of poisonous snakes, and it is therefore not possible to form any conclusions as to the value of the treatment.

A party of Birkbeck College zoological students spent Whitsuntide at West Mersea, near Colchester, collecting marine specimens. Owing to the low temperature of the surface waters the tow-netting expeditions were not very productive, but many and varied forms of life were brought up by the trawl and the dredge.

The annual conversazione of the Royal Geographical Society will be held at the Natural History Museum to-morrow evening, June 15.

A telegram from Reggio di Calabria states that fairly strong earthquake shocks were felt there on June 10 at 2.30 a.m. and 9.45 a.m. At Monteleone, Calabria, two strong shocks were felt at 2.45 a.m.

Prof. W. F. Kohlrausch, of Hanover, will be the president of the Verband deutscher Electrotechniker for 1906–8.

Dr. Bernhard Mohr, of London, recently presented to the museum of the German Chemical Society 100 letters written by the famous Liebig to Dr. Mohr's father, the late Prof. Friedrich Mohr, of Bonn, during the years 1834 to 1869.

Dr. Stutzer, assistant in the geological institute of the Freiburg (Saxony) Mining School, has been awarded a grant of 2000 marks by the committee of the Carnegie fund to enable him to continue his investigations on iron deposits in Lapland.

Prof. Ludwig Boltzmann, the well-known professor of theoretical physics in the University of Vienna, has been awarded the prize of the Peter Wilhelm Muller fund of Frankfurt a.M. The award consists of an appropriately worded gold medal and 9000 marks, and is made to the most brilliant workers in pure science.

At the seventy-eighth meeting of the Deutscher Naturforscher und Aerzte, which will be held this year on September 16–22 in Stuttgart, there will be an exhibition of scientific and medical appliances and subjects as in previous years. The König Karls Hall of the Königlicher Landesgewerbemuseum has been set apart for the purpose. All announcements and communications may be addressed to the president of the exhibition committee, Dr. Lampert, Archivstrasse 3, Stuttgart, from whom further particulars may be obtained.

Prof. Walter Nernst, professor of physical chemistry in Berlin, has declined the opportunity of proceeding to Leipzig as the successor of Prof. Ostwald, whose resignation will take place on September 30. Prof. Nernst was formerly a privatdocent at Leipzig from 1889 to 1891, when he accepted a professorship in Göttingen University. According to the *Physikalische Zeitschrift*, Prof. Ostwald's successor is to be Dr. K. Haussermann, professor of technological chemistry and director of the applied chemistry laboratory of the Technical High School, Stuttgart.

A special meeting was held in the Great Hall of the University of Athens on May 20 to celebrate the fortieth anniversary of Dr. A. C. Christomanos's appointment as professor of chemistry in the University. A large audience, including the Greek Minister of Education, the University professors and students, and many of the general public, was present. Dr. A. C. Dambergis, the professor of pharmaceutical chemistry, referring to the great work which Prof. Christomanos has done in the forty years, asserted that the greatest has been the pioneer work in the introduction of scientific chemistry into Greece with the provision for laboratory work in chemistry and the other sciences, and more particularly in organising so successfully the large chemical department of the University with its laboratory accommodation for 130 students. Prof. Christomanos was the recipient of numerous honours, including several from foreign countries.

Dr. Rudolf Knietsch, the director of the Badische Anilin- und Soda-Fabrik, died on May 28 at the early age of fifty-two. From the *éloge* dedicated to Dr. Knietsch's memory by the Badische Anilin- und Soda-Fabrik, we learn that Dr. Knietsch was born in 1854 in Oppeln, in Schlesien. From 1876–1880 he studied at the Technical High School in Berlin, and graduated in 1881 at Jena University. He was for a short time an assistant in Dr. Emil Jacobsen's private laboratory, and in 1882 entered the Farbenfabrik von Bindschedler und Busch in Basle, where he worked at the nitration of dichlorobenzaldehyde and the preparation of chloroindigo. In 1884 he joined the Anilin- und Soda-Fabrik. He founded in 1888 the industry of liquid chlorine, and devoted himself with zeal to the task of modifying the Winkler process of preparing sulphuric anhydride. Knietsch read an important communication on the results of this work before the German Chemical Society in 1901. For the solution of the problem of the commercial preparation of synthetic indigo Dr. Knietsch proved himself to be the right man in the right place. In company with a number of earnest colleagues he worked out and developed the present manufacturing processes for the preparation of the materials necessary for the synthesis of indigo and other dyes. Always broad-minded, he was ready at any time to replace existing plant and methods by improvements. In 1904 Knietsch was placed at the head of the firm. The Verein deutscher Chemiker, at the annual general meeting in Mannheim in 1904, awarded the Liebig gold medal to Dr. Knietsch, and at the opening of the new Technological Mechanical Institute of the Dresden Technical High School in 1905 the honorary degree of Dr. Ing. was conferred on him.

THE weekly weather report issued by the Meteorological Office for the period ending June 9 shows that the present month has opened with typical summer weather. The major portion of the United Kingdom was entirely rainless, the only rains reported occurring in parts of Scotland and Ireland, and amounting only to few hundredths of an inch. Bright sunshine was for the most part greatly in excess of the average, 80 per cent. of the possible duration occurring in the Channel Islands and 71 per cent. in the south of England. The temperature averages were generally rather low, and in the south of England the sheltered thermometer at night fell below the freezing point.

WE learn from the Journal of the Society of Arts that what can be done by sanitation to stamp out malaria is shown by Mr. Consul Morgan in his reference (No. 3565, Annual Series) to the work of the Italian Red Cross Society during late years to stamp out malaria in the Roman Campagna. The first attempt was made in 1900, when the returns showed that not less than 31 per cent. of the inhabitants of the "Agro Romano" had been fever-stricken. In 1901 the figure was returned at 26 per cent., 20 per cent. in 1902, 11 per cent. in 1903, 10 per cent. in 1904, and 5·1 per cent. during last year. These results were obtained by strict sanitary measures, use of wire nets so as to prevent access of mosquitoes to cottages, and free distribution of quinine among the peasantry.

THE annual dinner of the London section of the Society of Dyers and Colourists was held on May 23, when a representative company was presided over by Sir Thomas Wardle, president of the society. In proposing the toast of the London section of the society, the president expressed his astonishment at the beautiful work being done in the dyeing industry in Italy, and how much pure chemistry is being made use of in that work. London, he continued, is taking an interest in chemical development, and he suggested that the Dyers' Company might associate itself in some way with such a body as the Society of Dyers. Sir Thomas Wardle concluded his address by appealing to the younger men to take advantage of the splendid scientific training now available, and to induce others to do the same, for by such methods many of our lost industries would be won back. Responding to the toast of the "Allied Industries," Dr. J. C. Cain said no doubt to some extent our patent laws, the lack of cheap alcohol, and other causes have had a certain amount of influence in the downfall of the English aniline dye industry, but in his opinion the only real cause has been the lack of a man of commanding genius, like Perkin or Nicholson, who could discover a colour, make it, and sell it. Prof. R. Meldola, F.R.S., in proposing "The Visitors," remarked that we have lost tone in our supremacy in this branch of manufacture, but the blame is not on the shoulders of the dyers, who have always been on the *qui vive* to utilise new discoveries It was the English and Scotch dyers who first took up chemical dyes and encouraged the manufacturers to proceed. Mr. F. Robinson proposed "The Chairman," and directed attention to the fact that present-day results and modern methods could never have been attained but for the research chemists and their work. At one time dyeing was more an art than a science; now our chemists have made it practically a science. The old dyestuffs such as indigo and madder are gradually and surely disappearing, and are being supplanted by synthetic products. The English dyeing and colouring industry is moving with the times, and will eventually hold its own against all rivals.

WE have received a copy of No. 12 of the fifteenth volume of the *Zeitschrift für Oologie und Ornithologie*, said to be the only serial in the world specially devoted to the interest of the egg-collector. The present part contains notes on the eggs of two African birds previously unknown to collectors, general observations and suggestions on subjects intimately connected with oology, and descriptions of certain eggs from Turkestan.

IN the report for the year 1905, the committee of the Albany Museum, while referring with satisfaction to the general progress of that institution and the present state of the collections, directs attention to the congested state of the buildings, and the urgent need for more space and for additional funds, if the work is to be carried on in an effective manner. The appointments of Profs. Duerden and Schwarz to the zoological section are stated to have been followed by most satisfactory results.

IT has been stated by those who have investigated the subject in the selachian group that fishes lack lymphatic vessels other than those of the visceral system, the superficial and deep-seated vessels of the heart and trunk being regarded as veins, and their sinuses as venous sinuses. However this may be in the case of sharks, Mr. W. F. Allen, in a paper on the lymphatics of the loricate fish Scorpænichthys, published in the Proceedings of the Washington Academy (vol. viii., pp. 41–90), shows that it is not so in the case of the group to which the latter belongs. On the contrary, Scorpænichthys has as fully developed a lymphatic system as any vertebrate, so that it may be said that in general wherever connective tissue exists there lymphatics will be found.

THE February and March issues of the Proceedings of the Philadelphia Academy contain a paper by Mr. J. A. G. Rehn on tropical American grasshoppers of the group Acridinæ, with descriptions of several new forms, and likewise the commencement of one by Dr. R. Smith on the phylogeny of the races of a species of gastropod of the Eocene genus Volutilithes. In the case of the genus Fulgar, it has been supposed that certain Miocene forms represented the ancestral stock of the living American species. According to the author this is not so, the fossil forms being decadent senile offshoots from the original line, which appear, however, to be dominant. A very similar state of affairs is shown to exist in the case of Volutilithes, with the important exception that the main ancestral line is the one which is dominant.

The Ostracoda of the San Diego region (No. 1), the California shore-anemone, *Bunodactis xanthogramma*, and sexual dimorphism in the hydroid polyps of the genus Aglaophenia, form the subjects of articles nine, ten, and eleven of Contributions from the San Diego Marine Laboratory issued in vol. iii. of the Zoological Publications of the University of California. In the article on dimorphism (by Mr. H. B. Torrey and Miss Martin) it is shown that in the genus mentioned, not only are the gonophores dimorphic, but an analogous dissimilarity also obtains in the jointed plumose structures known as corbulæ, of which numerous examples are figured. The plate intended to illustrate Mr. Torrey's paper on the sea-anemone was destroyed in the San Francisco fire, but a new one will be supplied later.

The April issue of *Spolia Zeylanica* is of more than usual interest. It opens with a translation of an article by Dr. F. Doflein, of Munich, entitled "Termite Truffles," being the description of certain remarkably nodular masses of fungus cultivated in their nests by white ants in Ceylon. The hillocks of these termites were found by the author to contain a number of large chambers, each approximately the size of a cocoanut, and each containing one or more large friable masses, looking somewhat like small bath-sponges. These cakes were occupied by thousands of termites, ensconced in the cells and connecting passages. The framework of each was beset with numerous white nodules of the size of pins' heads, which proved to be fungus-growths. These nodules are eaten by the larvæ of the workers and soldiers and by the sexual forms at all ages, the adult soldiers and workers having, however, other food. That the funguses are introduced and cultivated by the termites seems undoubted. In the same publication Dr. A. Willey records a singular instance of symbiosis in a crab, originally described from Mauritius under the name of *Melia tessellata*. When first described its habit of holding sea-anemones in its two front claws was not noticed, but although this was observed later on in Mauritius, it has been generally overlooked. According to Dr. Willey's account and figure, the crab holds in each claw a small white anemone, which it presents, with the tentacles fully expanded, to every intruder, in "true boxing attitude." The ground-colour of the crab is whitish with a rosy flush on the front of the shell, which has also a pattern of black lines. "Probably both crab and actinians benefit by the association, the actinians enjoying increased mobility, and the crab sheltering and defending itself with the living gloves with which it is provided." In the author's opinion, the stinging threads of the anemone are the active means of defence and offence.

A leaflet, No. 16, published by the Department of Agriculture in British East Africa, contains the reports on various samples of cotton grown at Golbanti and Malindi. The cotton was produced from Egyptian Afifi seed, except for one sample of Sea Island and one of American upland. The soils on which the crops were grown were a heavy alluvium or a lighter red soil, the latter yielding much better results, owing probably to its requiring less cultivation. The values, except for the Sea Island, ranged between fivepence and sixpence per pound. There is a striking difference between the yield from Egyptian seed on the red soil and the other crops obtained.

The green colour of plants is such an ever-present reality that the explanation is apt to be overlooked. The absorption spectra of chlorophyll and the curves of absorption and assimilation do not directly furnish a solution, and it is only from the consideration of these, together with the effects produced by the absorption and dispersion of light rays in the atmosphere, that a satisfactory explanation is obtained. The subject is ably discussed by Prof. E. Stahl in *Naturwissenschaftliche Wochenschrift* for May 6, where he points out that the two pigments contained in chlorophyll are suited to the sun's rays as modified by reflection, the colours being complementary to those of the chlorophyll-absorbing rays that predominate in diffused light, and that certain rays, *e.g.* the ultra-red, are excluded wholly or in part owing to the danger of too great absorption in direct sunlight.

The fungus *Phycomyces nitens* is well adapted to physiological investigation owing to the rapidity of its growth and its sensibility to stimuli. Proceeding out of investigations by Elfving wherein curvature of the sporangiophores was attributed to physiological action through space, Prof. L. Errera was led to experiment on the curvatures caused by the presence of various substances such as rough and polished metals, porcelain, glass, deliquescent salts, marble, mica, &c. The results so obtained, and the notes relative to them, had been sufficiently fully drafted before Prof. Errera's death to allow of publication, and they appear in *Recueil de l'Institut botanique*, Brussels, vol. vi., 1905. It was found that Phycomyces curves towards bodies that absorb moisture and away from those that give off vapour. Thus the sporophores curve towards an unpolished rod of iron, but not towards a piece that is perfectly polished. A number of photographs accompany the paper, of which one of the most striking is reproduced. A dry, porous pot is suspended over the Phycomyces growing on bread in a moist atmosphere. The pot absorbs moisture, and the sporophores have curved right over the surface of the pot, some of them ultimately turning upwards owing to the stimulus of gravity.

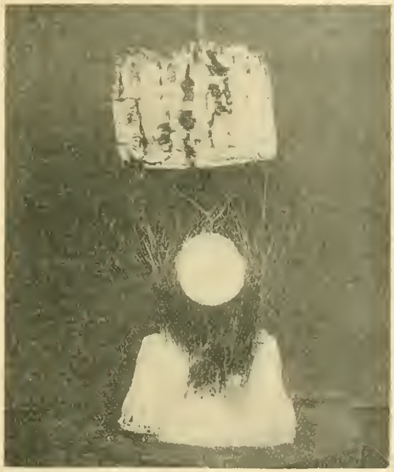

Fig. 1.—*Phycomyces nitens* stimulated to grow towards and over the surface of a porous pot.

THE report for 1905 of the Botanical Exchange Club of the British Isles, prepared by Mr. J. W. White, has been received. Besides being the official organ for the publication of notes by the collectors or special authorities on the correct determination of the plants, the report provides a record of new or rare species with the localities in which they have been found. The new records include *Caltha radicans* for Perthshire, *Ulex Gallii*, var. *humilis*, for Cornwall, the aliens *Hibiscus Trionum* and *Bromus unolioides* collected in Salop, *Lotus tenuis* from near Cardiff, and *Epipactis atrorubens* from Banff. The specific determination of the large-flowered Œnothera so plentiful on the Lancashire coast having been questioned, Mr. C. Bailey sent specimens to Dr. O. Focke, of Bremen, who considers that it is probably a form of the famous variable *Œnothera Lamarckiana.*

THE Home Office has issued for 1905 statistics of the persons employed, output, and accidents at mines and quarries in the United Kingdom, arranged according to the inspection districts. The total number of persons employed was 887,524, of whom 858,373 worked at the 3252 mines under the Coal Mines Act and 29,151 at the 688 mines under the Metalliferous Mines Act. At the quarries under the Quarries Act there were 94,819 persons employed. The death-rate from accidents was 1·49 per 1000 persons employed for coal miners and 2·49 per 1000 for metal miners.

WE have received the two latest additions to the valuable series of bulletins issued by the Peruvian Corps of Mining Engineers. In *Boletin* No. 30 Mr. Carlos E. Velarde gives a detailed account of the means adopted to obviate accidents in the mines of the Cerro de Pasco. *Boletin* No. 31 is a monograph on the mineral resources of the province of Cajamarca, by Mr. F. Malaga Santolalla. The work covers eighty-three pages, and is well illustrated and furnished with maps and sections. The coalfields of the province are of considerable importance, bituminous coal being worked at Yanacancha and anthracite at Punre. Descriptions are also given of mines of silver-lead ores, of copper, antimony, and sulphur. In fact, the province is one of exceptional mineral wealth.

MESSRS. SWAN SONNENSCHEIN AND CO., LTD., have published a second edition of Mr. C. H. Hinton's book on the fourth dimension. The first edition was reviewed in the issue of NATURE for July 21, 1904 (vol. lxx., p. 269), and it is only necessary to say that the new edition differs chiefly by the addition of a new chapter of twenty-three pages on a language of space. The new chapter is also published separately.

OUR ASTRONOMICAL COLUMN.

PHOTOGRAPHING THE CORONA WITHOUT A TOTAL ECLIPSE.—A communication from MM. Millochau and Stefanik referring to a recent note in these columns (May 31, p. 112) on their proposed method of photographing the corona without a total eclipse of the sun points out that the meaning of part of their note in the *Comptes rendus* was misinterpreted.

The successful experiments at Meudon dealt with the feasibility of photographing the line at λ 5303 with a *spectrograph*; and others, performed since their communication to the academy was published, have clearly affirmed the possibility of observing the green coronal line when the atmosphere is sufficiently pure and suitable screens are employed. It is this study of the *spectrum* of the corona that they hope to complete on the summit of Mont Blanc.

OBSERVATIONS OF NOVA GEMINORUM.—The results of some interesting observations of Nova Geminorum, which were made by Prof. Barnard between the date of the Nova's discovery (March, 1903) and February 27, 1906, appear in No. 6, vol. lxvi., of the Monthly Notices (R.A.S.).

At the time of discovery the magnitude of the Nova was 8·0, but it steadily decreased until at the present time the object is but very little brighter than the fifteenth-magnitude star which slightly precedes it.

The observations made in order to discover any possible difference of focus between the Nova and the surrounding stars indicated no such difference at first, but on September 21, 1903, it was found that the focus for the Nova was 0·29 inch further from the object-glass than that of a tenth-magnitude preceding white star. In connection with these observations a curious feature was noted on March 30, 1903. The Nova appeared to have two distinct foci, both of which gave sharp images. The one image was of about 8·5 magnitude, of reddish-yellow colour, and at the ordinary stellar focus, whilst the second was of the tenth magnitude, about 0·39 inch further out, and of a beautiful crimson colour. On April 6 the crimson image was still present, though not so strong or definite, and on April 27 it had entirely disappeared. This image was probably due to the strong Hα line in the spectrum of the Nova.

Measures of the distances between the Nova and the surrounding comparison stars, of which Prof. Barnard gives a chart, indicate a decrease of distance between one of the latter and the Nova. From this it would appear that the Nova is in motion, but that cannot be stated as a fact until further measures have been made. The measures of the position of the Nova gave no indication of a parallax.

PERSONAL EQUATION IN PHOTOMETRIC OBSERVATIONS.—In No. 4089 of the *Astronomische Nachrichten* Prof. Ceraski directs attention to the fact that in recording the results of observations made with the Zöllner photometer it very often happens that no mention is made of the relative positions of the real and the artificial stars during the observation, and asks that this should always be carefully recorded by the observer.

There is often an effective personal equation introduced into the results, depending upon whether the real star is to the right or to the left of the artificial star when the observation is made, and as this equation varies with the instrument employed and the magnitude of the variable star at the moment of observation, it becomes important that the conditions should be carefully recorded and the resulting corrections applied when the final values are computed.

COMET 1906*b* (KOPFF).—In No. 4087 of the *Astronomische Nachrichten* Herr M. Ebell publishes a newly derived set of elements and an ephemeris for comet 1906*b*. The following are the elements:—

$$T = 1905 \text{ Oct. } 18{\cdot}6620 \text{ (Berlin M.T.)}$$
$$\left.\begin{aligned} \omega &= 158^\circ\ 42'\ 11''{\cdot}4 \\ \Omega &= 342^\circ\ 13'\ 35''{\cdot}1 \\ i &= \ \ 4^\circ\ 14'\ 32''{\cdot}4 \end{aligned}\right\} 1906{\cdot}0$$
$$\log q = 0{\cdot}522130$$

The ephemeris shows that the comet has just passed from the constellation Leo, wherein it was discovered on March 13, into Virgo, and is situated about one-third of the distance between υ Leonis and β Virginis, reckoning from the former.

A note in the *Observatory* (No. 371) points out that the perihelion distance of this comet is greater than any previously recorded, with the exception of that of the comet of 1729. Prof. Wolf has found an image of the comet on a plate secured on January 14, 1905, more than a year before the discovery, an event which is unique in the history of cometary observations. At that time the magnitude of the object was about 0·4 that at the time of discovery, and approximately equal to the present magnitude.

OBSERVATIONS OF VARIABLE STARS.—Twenty-two newly discovered variable stars in Carina are announced in Circular No. 115 of the Harvard College Observatory. The variability of these stars was discovered by Miss Leavitt from the examination of six plates taken with the Bruce telescope, the total number of variables discovered from these plates being now thirty-nine. The star H 1232 is found to be an Algol variable, and a number of the observations made near minima, together with an ephemeris for May, June, and July, are given in the circular.

A plan proposed by Prof. Bailey for the construction of a variable star Durchmusterung, in which the cooperation of amateur and other astronomers is sought, is described in No. 116 of the same publications.

The results of a number of variable-star observations made by Mr. S. D. Townley at the Lick Observatory during the summer of 1902 are published in No. 95 of the Lick Observatory Bulletins. Most of the stars observed were taken from the "Catalogue of Stars recognised as Variable since the Appearance of Chandler's Third Catalogue," which appeared in the *Astronomical Journal* (vol. xxii.) in 1902.

VISIT OF REPRESENTATIVES OF FRENCH UNIVERSITY EDUCATION.

THE French visitors have come and gone. To describe in detail the events of a crowded programme would be impossible. We can here only give a brief sketch. From the first meeting on Whit Monday, at the informal dinner given at the Empress Rooms of the Royal Palace Hotel, it was obvious that the *entente* between the French savants and their English hosts was sincere and cordial, and that it was of much older standing than the political agreement. The Vice-Chancellor, Sir Edward Busk, speaking in French, struck the right note at the outset, and Sir Walter Palmer, the chairman of the reception committee, and Mr. P. J. Hartog, the academic registrar of the university (who acted with Mr. W. K. Hill as secretary), both former students of the Sorbonne, welcomed, in the French guests, old teachers and fellow-students.

To the toast of "Our Guests," proposed by Sir Walter Palmer, responses were made by M. Bayet (for the Ministry of Public Instruction), M. Boutroux (for the Faculty of Letters of Paris), M. Lippmann (for the Faculty of Sciences of Paris), M. Chavannes (for the Collège de France), M. Thamin and M. Angellier (for the French provincial universities), M. Morel (for the Société des Professeurs de Langues vivantes), and M. Gautier (for the Guilde Internationale), several of whom, including MM. Lippmann and Angellier, spoke in excellent English.

On the following morning the official proceedings began with a reception by Lord Fitzmaurice and Mr. Lough, Parliamentary Secretary of the Board of Education, in the large room of the Foreign Office, followed by luncheon for 300 guests in the East Gallery of the University.

The gallery, which is nearly 200 feet long, was decorated with French and English bunting, and with red, blue, and white flowers; and the French robes of crimson silk (science) and yellow silk (arts), with the ermine-barred *epitoga*, the scarlet gowns and many-coloured hoods of the Englishmen, and the light summer dresses of the ladies, formed a gorgeous display. It was a surprise to the Frenchmen, who had been somewhat loth to don academic costume, very rarely worn in France, and only on solemn official occasions, to discover its value in a pageant. One of the most distinguished of them prophesied that the English fashion would before long be followed in France.

Official distinction was given to the reception by the presence of M. Cambon, the French Ambassador, who responded to the toast of the President of the French Republic; and the connection of the University with London was emphasised by the toast "Welcome to London" proposed by Mr. Evan Spicer, chairman of the London County Council, and responded to by M. E. Hovelaque, the French Inspector-General, who has of late years transformed the teaching of English in French schools, and who spoke with an ease and distinction that Englishmen might well envy. After lunch came addresses in the Great Hall to an audience of about 1800 persons. The Vice-Chancellor gave a brief but interesting sketch of the relation between the University of Paris and the older English universities; M. Liard, the Vice-Rector of the University of Paris, gave an account of the great and fruitful reforms in French secondary and university education, on which, as Sir Edward Busk justly said, he has for many years exerted "a commanding and beneficent influence"; Sir Arthur Rücker, principal of the University, showed how the ideal of Adam Smith of free and competitive teaching, and the ideal of Dr. Johnson of an endowed and privileged university were united in the University of London with its external and internal sides, and he amused his audience greatly by pointing out that while the test of "residence" at the Inns of Court was eating, and at Oxford and Cambridge was sleeping, that test in London had been divorced *a mensâ et thoro*; Prof. Sadler, as past-president of the Modern Languages Association, a number of the French guests of which were entertained by the University, gave an interesting and suggestive sketch of French influences on English education. After the addresses tea was served in the new, and still unfinished, chemical and physical laboratories of the Royal College of Science, over which the visitors were conducted by Sir Arthur Rücker, Prof. Tilden, Prof. Callendar, and the staff of the college. In the evening the guests were invited to meet fellow-specialists informally at parties given by Sir Edward Busk (modern languages and literature), Prof. and Mrs. E. A. Gardner (classics, archæology, and philosophy), Sir William and Lady Ramsay (mathematics and physical sciences), Mr. Mackinder (history and geography), and Dr. Waller, Dr. Farmer, Dr. Halliburton, and Dr. Starling (biological sciences).

On Wednesday morning, June 6, and afternoon, the County Council took charge of the visitors; they were driven in thirty-five carriages, headed by two mounted policemen, from the Royal Palace Hotel to Westminster, where they inspected the Abbey and school, then to the excellent Camberwell School of Arts and Crafts and the Oliver Goldsmith School, and so to Belair, the beautiful park of Mr. Evan Spicer, where lunch was served in an open marquee. The guests returned *viâ* Dulwich College and Picture Gallery, and drove through the Dulwich Common Park, now maintained by the County Council, in which there is a magnificent show of rhododendrons and azaleas. In the evening private dinners were given by the Vice-Chancellor and Lady Busk, the Principal and Lady Rücker, Dr. and Mrs. Bradford, Sir William Collins, M.P., Dr. Headlam, principal of King's College, Mrs. J. R. Green, Sir Philip Magnus, M.P., and Lady Magnus, Dr. and Mrs. T. L. Mears, Sir Walter and Lady Palmer, Dr. and Mrs. Pye-Smith, and the principal, professors, and lecturers of University College.

The evening concluded with a brilliant and crowded reception at the French Embassy.

On Thursday morning, June 7, a series of eight addresses was given in the Great Hall of the University of a singularly varied and interesting character, in which it may fairly be said that the English speakers, Prof. Gardner, Dean of the Faculty of Arts, who spoke in Latin, Dr. Waller, Dean of the Faculty of Sciences, and Sir William Ramsay, who spoke in French, did not fall short of the high literary level characteristic of French eloquence. M. Croiset and M. Appell, the Deans of the Faculties of Arts and Sciences of Paris, M. Léger, professor at the Collège de France, M. Benoist, Rector of Montpellier, and M. Morel, vice-president of the Société des Professeurs de Langues vivantes, gave addresses on which it is impossible to comment adequately. It is understood that they will be published later, when we hope to have occasion to describe them.

On the afternoon of Thursday, June 7, the French guests journeyed by special train to Windsor, where they were introduced by Lord Rosebery, Chancellor of the University, and by the Vice-Chancellor, to the King and Queen, and were afterwards entertained at tea in the Castle; and in the evening the proceedings, so far as London was concerned, concluded with a brilliant conversazione at the University.

On June 8 half the guests of the University and of the Modern Language Association were entertained at Oxford and half at Cambridge. The majority left London on Saturday and Sunday, June 9 and 10.

In these festivities there has been much brilliancy, much pomp and circumstance. But behind the show there has been real and solid work accomplished or begun. Lessons are learnt better from men than from books, and the lessons to be derived from French education, to which (with the Army) France has devoted the best part of her energies since 1871, have been sadly neglected by England. We have still to learn that solid secondary education is a necessary preliminary to fruitful university education; that it is possible to combine literary and scientific training; that both in secondary and in higher teaching, if the teachers are to stimulate individuality in their pupils, they must be given time and opportunity to cultivate and develop their own; that examinations may be used to test the power of taking general views, as well as of remembering an infinity of details; and many other things, which France can teach us. But apart from intellectual profit, there is a moral profit in a meeting of this kind. Blessed are the peace-makers; and the discovery of unsuspected and deep human sympathies between workers in the same intellectual fields, between men and women whose business it is to train up the young minds of their own people, makes for the peace of Europe.

ECONOMIC ENTOMOLOGY.[1]

(1) SINCE 1867 the State entomologists of Illinois have constantly issued very able reports on noxious and beneficial insects. The first were by Walsh and Le Baron; the last twelve have been by Prof. Forbes, the writer of the present work. In 1894 he issued the first part of "A Monograph of Insect Injuries to Corn." This extended to some 170 pages, with fifteen plates, and dealt only with those insects that attack the planted seed and the roots of corn of various kinds. This dealt mainly with wire-worm, white-grubs or chafer larvæ, ants, aphis, their natural enemies and means of prevention. The second part that has just appeared is very much better than that issued nearly twelve years ago. It treats of the insect injuries to those parts of the corn plant above ground, including stalk, leaves, and ear.

A very excellent plan we do not remember having seen before is adopted in the text, namely, that of grouping the insects under the following three headings:—(1) the more important pests; (2) the less important pests; and (3) the unimportant species.

In dealing with the first it is pleasing to note that the insects are dealt with in a strictly practical manner. Such reports as these can well be made to serve a double purpose if properly drawn up as this one is, namely, as a reference book for practical men and also for those who are studying the subject from a student's point of view. The coloured plates, of which there are eight, include the army-worm, corn bill-bugs, the chinch bug, the corn-worm, white-grub, the seed-corn maggot, and other well-known corn pests. The plates are good, and show in some cases, not merely the perfect insect, but the whole life-history and the damage produced on the growing plant.

Among the more interesting sections we find a good account of the damage caused by the chinch bug (*Blissus leucopterus*, Say) and the means of preventing it, of the army-worm (*Leucania unipunctata*, Haw.), and of the corn-leaf louse (*Aphis maidis*, Fitch). In regard to the latter some interesting new observations are recorded, although nothing very definite has been arrived at in regard to the life-history of this corn pest. The author (p. 133) refers to "the failure of all attempts to find or produce a bisexual generation or an alternative food plant of *Aphis maidis* or to learn how and where it passes the winter."

Some interesting notes are given on several species of Crambus, called popularly in the States "sod web-worms" or "root web-worms" (Figs. 1 and 2). Although we have many species of Crambus in Europe, no very material damage has been recorded. In America we learn that "not infrequently these 'web-worms' become so abundant as to cause brown and deadened spots in a lawn or meadow, sometimes, indeed, deadening the turf as thoroughly as white-grubs or cut-worms can do." Corn seems to be very heavily injured and even completely destroyed over considerable areas in early spring. This is an attack we must be prepared for in many localities in this country when grass land is broken up, an unlikely proceeding, however, at the present day with the low price of corn. Probably a good deal of damage is done here now, but has been attributed to other causes. The figures given by Forbes are thus reproduced to give an idea of the larval stage, during which the damage is done.

FIG. 1.—The Sod Web-worm (Crambus) web (*a*) containing larva, at base of young corn plant; *b*, *c*, injuries to leaf and stem.

In this country, again, we have not observed any injurious Syrphidæ or hover flies, but we find recorded by Forbes (p. 162) that *Mesogramma politum*, Say, feed, not on Aphides, but on the pollen and juices of corn and cotton (Ashmead). The whole work is full of interesting and sound material alike to the practical man and student. One point we notice; the corn-worm or cotton-worm is still called *Heliothis armiger*, Hübner, instead of *Heliothis obsoleta*, Fabricius, which antedates it.

A key to the discussion of insect injuries to corn is given which will prove very useful to those studying the subject in America, and even elsewhere, for where species differ genera often agree in various parts of the world. A very complete bibliography and a copious index complete the work, which is useful to us in many regions other than America.

(2) This work contains a good deal of useful information and a lot of what appear scrappy notes, which will, however, serve a useful purpose later on. The great difficulty of working at such a subject as the one Mr. Stebbing is engaged upon can only be estimated by those who have attempted the like.

The economic entomologist is often too apt to jump at specific and even generic determinations, or is loth to publish his observations unless the scientific name can be given. Some groups of insects are almost impossible to name specifically, and many others should only be treated by specialists, who have not always time or inclination to deal with the material sent them.

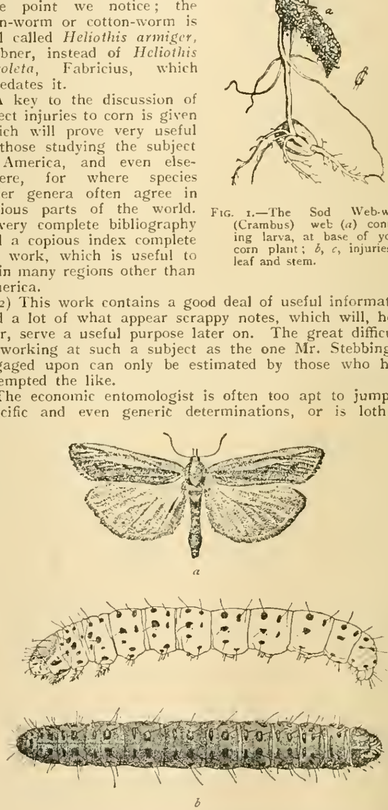

FIG. 2.—The Common Sod Web-worm (*Crambus trisectus*): *a*, adult slightly enlarged; *b*, back and side views of larva (much enlarged)

[1] (1) "A Monograph of the Insect Injuries to Indian Corn." Part i. By S. A. Forbes. Twenty-third Report of the State Entomologist on the Noxious and Beneficial Insects of the State of Illinois. Pp. 273+xxxiii; 238 Figures and 8 Coloured Plates. (Chicago, 1905.)

(2) "Departmental Notes on the Insects that affect Forestry." By E. P. Stebbing, F.L.S., F.Z.S., F.E.S. No. 3, with Preface and Index to vol. i. Pp. 335-469+8 plates. (Calcutta: Government Printing Office, 1906.) Price 2s.

Nevertheless, it is very necessary that we should record the bionomics of arthropods of economic importance, even though we have to leave to some future date the scientific nomenclature, which in many cases is quite as diverse as the sometimes derided popular one! It is thus pleasing to find in this work valuable information recorded without waiting for even the definite generic status of the pest in question.

From p. 379 to p. 385 is detailed in a most able manner the life-history and workings of a cerambycid beetle, probably a Stromatium, which attacks the sandal-wood tree.

This "borer" is well known to be one of the most assiduous pests in the sandal-wood area of North Coimbatore, and yet Mr. Stebbing tells us that he is as yet unable to obtain any beetles and that he is not even sure of its generic position. So much is recorded, however, that one has only to find and name the beetle and fill in a few details and the account is complete. The sandal-wood borer will remain the same to the Indian forester, who is indebted to Mr. Stebbing for that work of special value, its life-history, whatever technical name it appears under later on. Other forest enemies are recorded in similar manner; sometimes the genus is doubtful, sometimes the species.

The most interesting part of this work deals with the bamboo beetle or shot-borer (*Dinoderus minutus*, Fabricius). This and allied species are often very destructive to bamboos.

It is shown that this species is the chief pest to bamboos in Calcutta and in the hotter, damper parts of the country, apparently taking the place of the *pilifrons* in Upper India.

In the account of this pest we find recorded some real practical work with regard to protecting bamboos from the ravages of this insect. The conclusions arrived at show that soaking the rods for five days in water, then drying them and soaking them for forty-eight hours in common Rangoon oil, is the best method of treatment. Other interesting wood-borers are also dealt with, including a goat-moth (*Duomitus leuconotus*, Walker) found in Calcutta, Sikhim, and Ceylon, which attacks the Cassia trees just as our goat-moth attacks the ash and oak; and there is also a very full account of the Casuarina bark-eating caterpillar (*Arbela tetraonis*, Moore), a widespread pest in Casuarina plantations, where it often does much damage.

An unusual, yet useful, diversion we note in this report is that at the end of each subject are mentioned the "points in the life-history requiring further investigation."

The plates are for the most part rather crude, but serve their purpose. The photogravure of bamboos tunnelled into by the bamboo-borer is, however, an exception. A great foundation is being prepared in such a work as this; it is only a foundation, but, judging from what we have seen of this and others, it is one upon which we need not be afraid to continue building. FRED. V. THEOBALD.

THE SOUTH-EASTERN UNION OF SCIENTIFIC SOCIETIES.

THE eleventh annual congress of the South-Eastern Union of Scientific Societies was held at Eastbourne on June 6–9 at the invitation of the local natural history society. On Wednesday evening, June 6, the retiring president, Prof. Flinders Petrie, opened the proceedings and gave up his chair to Dr. Francis Darwin, who delivered the presidential address. The title of the latter was "Periodicity," and in it Dr. Darwin pointed out that one of the most striking features of living things is their periodic or rhythmic character. Life itself may be described as a rhythm made up of alternate destruction and reconstruction. Protoplasm—"the physical basis of life"—is alternately falling to pieces by a degradation into simpler compounds and rebuilding itself from the food materials supplied.

In the address simpler instances were mentioned, such as are seen in the process of reproduction, for instance in the case of a plant, which produces a seed that gives rise to another plant, and so on. Again, allusion was made to the seasonal appearance and disappearance of the leaves of deciduous trees. Attention was turned to the time limits between the earliest and latest unfolding of the leaves in various trees and to the attempts which have been made by phænologists to explain these periodic phenomena as being strictly regulated by temperature.

In the end, however, Dr. Darwin was able to show that the plant is really master of the situation, and not the temperature, for among other things buds in ordinary circumstances will not develop at the end of summer, and at this time it is much milder than in the spring, when they begin to unfold and grow into shoots. The plant is, in fact, guided by internal rather than external conditions, for the bud has to go through certain invisible changes during its winter's rest before it is ready for its normal growth, and these invisible changes are part of the plant's automatic rhythmic capacity which enables it to be independent, to a large extent, of external changes. The same arguments were found to apply to the daily movements of plants. Increase of temperature may cause flowers to open in the morning, but it has no effect at night. Again, leaves that show sleep movements by falling at evening from a horizontal position to one which is, roughly speaking, vertical, will, even if kept in the dark, return to their original station in the morning. At nightfall the sleep movements again occur, though as the plant becomes more and more unhealthy owing to the absence of light they are gradually lessened. Dr. Darwin described a very interesting case of habit in a sleeping plant, namely, the scarlet runner, which he recently demonstrated. Like other plants, the one in question adapts itself to one-sided illumination by placing its leaves obliquely so that they are at right-angles to the line of illumination, and get the full advantage of the light. If a scarlet runner which has assumed this oblique position is allowed to go to sleep at night as usual, and is then placed in a dark cupboard, it will in the morning assume the diurnal position as already mentioned in the case of other sleeping plants. Most remarkably, however, it does not return to its normal day position, that is, with horizontal leaves, but takes up the oblique position already described. This looks like a reminiscence of its former position, and is interesting psychologically since it might almost be described as an instance of a plant taking advantage of its individual experience.

Another experiment showing how a periodic movement had been induced, and pointing to a kind of memory on the part of a plant, was described by Dr. Darwin, who finally touched upon circumnutation, which he looked upon as the raw material out of which movement in response to stimuli has been developed.

During the congress several papers were read which showed, not only that the neighbourhood of Eastbourne is very rich in plants, birds, and insects, but that there are many keen naturalists in the county of Sussex. For instance, Mr. J. H. A. Jenner dealt generally with nature near Eastbourne, a communication by the late Dr. Whitney and Miss Milner treated upon the flora of the Eastbourne district, while Mr. Ruskin Butterfield compared the birds of Sussex with the list for Great Britain, showing that from the county in question there is a greater number of birds recorded than from any other.

On Thursday evening, June 7, Dr. Jonathan Hutchinson gave a powerful discourse on the educational value of museums. He emphasised the need for large and inexpensive buildings, and showed the great importance of museums now that it has been recognised that things, and not words, must be studied if the memory is to be of any real use. He dwelt on a graphic method of teaching history adopted in Haslemere Educational Museum, which he founded, and also alluded at length to the moral effect of proper education.

Two papers dealt with geology, namely, that on sea erosion and coast defence, by Mr. E. A. Martin, and the geology of the Upper Ravensbourne Valley, with notes on the flora, by Mr. W. H. Griffin. The former contribution summed up the present situation, and was particularly suggestive, while the latter showed how much useful work a naturalist can do who devotes his time ungrudgingly to a particular district.

At the reception given by the Mayor of Eastbourne, Mr. Edward J. Bedford gave a most successful lecturette on bird architecture. The photographic lantern-slides which illustrated it were particularly good, which, seeing that Mr. Bedford began his work in this direction so long ago as 1890, is not, perhaps, to be wondered at.

The last lecture, on Saturday morning, June 9, to which the teachers of the district were invited, was given by Mr. Wilfred Mark Webb, on nature-study. As two years ago Mr. Webb presented a formal paper to the union, he contented himself, after a few brief remarks, with showing by means of lantern-slides what directions the pursuit in question has taken or might take.

A number of interesting specimens were brought together to form the usual congress museum under the direction of Mr. E. W. Swanton, and the photographic surveys of Surrey, Kent, and Sussex contributed a selection of photographs.

The business done included the election of Prof. Silvanus Thompson as president for 1907, and the acceptance of an invitation to visit Woolwich for the twelfth congress in that year. Dr. Abbott, the founder of the union, its first secretary and late treasurer, was added to the list of vice-presidents, of whom besides Dr. Hutchinson, Mr. F. Merrifield, Mr. F. W. Rudler, the Rev. T. R. R. Stebbing, Dr. Treutler, and Mr. W. Whitaker attended the congress.

The perfect weather made the four excursions to Mickleham Priory and elsewhere a complete success, and a pleasing feature of the meeting was the votes of thanks to local secretaries, Mr. J. J. Hollway and Mr. Sparks, and their coadjutors, as well as that to the general secretary, the Rev. R. Ashington Bullen, which was emphasised by the whole company rising in their seats.

THE SURFACE TRAJECTORIES OF MOVING AIR.[1]

THE Meteorological Office has just published the results of an investigation into the movements of the air during storms and periods of barometric depression affecting the North Atlantic and western Europe. The authors deal, not so much with the discussion of theories about cyclones as with the results of direct observations on the direction and force of the winds as recorded at as many stations and as often as possible. Apart from ships' logs, the records from about 200 stations have been utilised.

The attempt has been made to trace the path of any body of air from the point where it descended from the upper regions of the atmosphere along the surface of the earth to the place where it ascended again, and the method used is briefly as follows:—Using hourly observations whenever possible, arrows have been drawn on a map through the position of the recording station showing the direction of the wind, and the length of the arrow is equal to the distance which the recorded velocity suggests as being the journey of the air during the half-hour preceding and the half-hour following the time of observation. By this method the trajectories are made up step by step through station after station as the hourly maps are made up. Anemometer records are consulted to decide where the velocity of the wind has been sufficiently constant to carry the trajectory properly from one hour to the next.

In the discussion of certain circular storms and barometric depressions which have passed over the British Isles, and which have been selected as typical examples, 162 trajectories were examined, and also the changes in the meteorological conditions along them. Naturally many of these trajectories do not represent the full course of the particular current considered, only the beginning, the middle or the end coming within the region under observation.

These trajectories have been divided into five classes. Class i.—Final-stage trajectories terminating generally, but not always, near the centre or the trough of the depression. These are marked by diminishing pressure, increasing velocity, and falling temperature. These currents end under cloudy skies and with rainfall. In some cases the end is caused by the meeting with a cross-current. The conclusion is that this air has fed the ascending current, and that the rain has been caused by the expansion and consequent cooling. These trajectories are always from almost due south, and show very little curvature.

Class ii.—Initial-stage trajectories, commencing in regions of fairly still air which may be quite near to the centre of the depression. The meteorological conditions and changes which characterise this class are the reverse of those for class i., even to this extent, that they flow from low pressure to high. There are many cases of this class shown; too many to suggest a mistake.

Class iii.—Looped trajectories generally cross the track of the depression twice, once in front of the storm and once behind, and may be taken as a continuation of classes i. and ii.

Class iv.—Spiral trajectories generally represent cold currents blowing from the east or north round the west of the centre of the depression to replace the southerly currents of class i.

Class v. has three subsections:—(*a*) trajectories from a point in front of the trough; (*b*) from a point in the rear; and (*c*) in the line of the trough. The meteorological conditions accompanying (*a*) and (*b*) are similar to those for classes i. and ii. Trajectories in the line of the trough are remarkable for the strength of the wind and for the small and irregular changes of pressure. The accompanying weather is generally cloudy, but without rain.

The trajectories over the Atlantic are obtained from observations made between August, 1882, and September, 1883, and, as only daily records are used, the investigation is on a much coarser scale. Moreover, they are more open to criticism, for there may be many changes in the meteorological elements in twenty-four hours. Some of the trajectories traced are remarkable for their length; for example, between December 23 and 30, 1882, one is traced from West Africa to North Russia, and another from Florida to the British Isles, and between November 13 and 17 one is followed from Hudson's Bay to the Adriatic.

In seeking to locate the positions of ascending and descending currents and the connection between these and the distribution of rainfall, it has been taken as proved that an ascending current of air is necessary for the production of measurable rainfall, and we are reminded that it is not necessary or usual for these ascending or descending currents to be vertical. They are generally very oblique. The approximate positions of ascending currents are located by noting the convergence of air to such places, divergence denoting descension.

Convergence may be produced by the trajectories being directed towards one point, or by air overtaking air which is preceding it in the same direction, or by the wind blowing towards a persistent cross-current. These are obvious and typical cases.

If two sets of isochronous points or trajectories be joined by lines, then the ratios of the enclosed areas will indicate convergence or divergence according to whether the second area is smaller or larger than the first.

The greater convergence takes place almost always in front of the centre of the depression, and this agrees with the area of greatest rainfall. As, however, the rain is generally brought by southerly winds, the rainy district is somewhat to the north of the area of convergence, the current evidently having continued its onward course whilst rising.

Some of the general conclusions deduced during the investigation may be given:—

(1) In the front portion of travelling storms there is air moving from high pressure to low and to lower temperature and rainfall, while in the rear, even quite close to the centre, there is movement from low pressure to high and towards improving weather conditions.

(2) Fast-travelling storms receive air from the right hand (south) of the path in front of the storm, and lose an equivalent amount from the rear at the same side. Slow-travelling storms receive air from the south direct to

[1] "The Life-history of Surface Air-currents; a Study of the Surface Trajectories of Moving Air." By Dr. W. N. Shaw, F.R.S., and R. G. K. Lempfert. (London: Published by the Authority of the Meteorological Committee, Wyman and Sons, Ltd.) Price 7*s.* 6*d.*

the centre, whilst air from the north flows round the rear.

(3) Southerly winds are generally short-lived as surface currents. Other currents last longer. They may persist until they reach the trade winds, or they may turn and join the depression from the south, or may disappear in some depression over the Atlantic.

(4) The central areas of well-marked anticyclones have not shown themselves to be the usual birthplace of descending currents. These generally originate in the "col" or shoulder of an anticyclone, or the areas of comparatively low pressure between two anticyclonic or two cyclonic areas. Only very rarely has a trajectory been traced back to the centre of an anticyclone.

(5) Surface observations have not indicated the conditions which mark out the track of a barometric minimum.

The publication contains some twenty-six valuable plates of weather charts with the trajectories plotted, and accompanied by full notes and selected observations along the trajectories. The trajectories have also been drawn having regard to the centre of the storm as a fixed point. There are also some mathematical notes by Mr. G. T. Bennett with reference to looped trajectories and the calculation of dilatation of areas in travelling storms.

W. M.

NEW ARCTIC EXPEDITIONS.

THE present season promises to be one of unusual importance in the annals of Arctic exploration, both in the way of scientific investigation of specific problems such as those stated in the paper by Sir Clements Markham published in the January number of the *Geographical Journal*, and in what may be more correctly described as "attacks on the Pole."

According to a note in the current number of the *Geographical Journal*, Mr. A. H. Harrison's expedition reached Herschel Island, near the mouth of the Mackenzie, in February last, where Mr. Harrison found Lieut. Hansen and the members of the *Gjöa* expedition. Writing on March 1, Mr. Harrison expressed the intention of making his way during April to Bailie Island, and thence to Banks Land, where he proposes to spend next winter.

The general scheme of the expedition—now formally designated the "Anglo-American" Polar Expedition—undertaken by Mr. Einar Mikkelsen and Mr. Leffingwell, has already been outlined in these columns (January 25, vol. lxxiii., p. 302). Since his arrival in the United States the American Geographical Society has voted Mr. Mikkelsen a sum of 3000 dollars, the largest grant ever given to an explorer by the society, and the council of the Royal Geographical Society has made a second grant of 100*l.* Mr. Mikkelsen has purchased a schooner of 66 tons burden, which he has named the *Duchess of Bedford*, and has now been able to elaborate his plans in considerable detail on the lines already announced (see the *Times*, April 21, and the *Geographical Journal*, vol. xxvii., p. 507). The programme is an extensive and extremely hazardous one, but if even a part of it is successfully carried out scientific results of great value will certainly be obtained.

The Danish or "Danmark" expedition, for which funds amounting to about 250,000 kr. have been raised by means of a Government grant and private subscriptions, will leave Copenhagen on July 1 under the leadership of Mr. L. Mylius-Erichsen, and make its way so far north as possible along the east coast of Greenland. There a landing will be effected, and the party will proceed along the east coast, wintering *en route*, to the most northerly point of Greenland, which is, in the leader's opinion, the most favourable place from which to make an attempt to reach the Pole. A sledge expedition will set out for the Pole from here, and return in time to winter on the ship the second year. In March, 1908, Mylius-Erichsen, accompanied by one of his staff and two Greenlanders, hopes to set out on the second part of his journey, and realise the daring plan of traversing the inland ice of Greenland on the broadest portion of the continent. The crossing is to be effected partly by motor-car, partly by dog sledges, and partly on ski, and is expected to occupy about two months and a half.

Mr. Walter Wellman has formed a project for reaching the North Pole by means of an airship. The vessel is to start from a base in Spitsbergen, and it is estimated that the return voyage of 1200 miles may be accomplished in from five to fifteen days. This expedition is being financed by Mr. Victor Lawson, chief proprietor of the *Chicago-Record Herald*, and a very full description of the airship —which is of a quite novel type—is given by Mr. Wellman in the April number of the *National Geographic Magazine*. The contract for construction was given to M. Louis Godard, of St. Ouen. According to a Reuter correspondent in the *Times* of June 5, the ship will leave Paris for Spitsbergen in a few days.

A CATALOGUE OF FOSSIL INVERTEBRATES.[1]

THIS catalogue of fossil invertebrates, compiled by Mr. Charles Schuchert, assisted by Messrs. W. H. Dall, T. W. Stanton, and R. S. Bassler, is arranged alphabetically, and gives the catalogue number of the department registers, the name of the species as written in the work cited, the kind of type (for instance, holotype, cotype), the formation, locality, author, and place of publication, with remarks on the present name if different from the one cited, or a cross reference when the same species appears in the list under more than one name. Remarks, together with sources of such, are added in brackets where necessary.

The list itself is preceded by an admirably clear and carefully written introduction by Mr. C. Schuchert, dealing mainly with type terms. Use is made of the contributions of Schuchert, Buckman, Cossmann, Oldfield Thomas, Bather, and others to the discussion of the terminology of type specimens, thus furnishing a valuable and concise summary of definitions, the understanding of which is necessary for the proper appreciation of the catalogue. In addition to terms already in use are others which are introduced here for the first time, and consequently call for brief notice. Primary types or proterotypes are divided into holotypes, cotypes (or syntypes), paratypes, lectotypes, and chirotypes, the last two terms being new. The term "chirotype" is proposed for "the material upon which a published manuscript name is based." In cases "where the original diagnosis is without illustrations or is accompanied by figures based on two or more specimens, the first subsequent author is at liberty to select from these cotypes a type for the old species, adhering, as far as can be ascertained, to the intention of the original author." Such a type specimen is designated a "lectotype." Supplementary types are divided into plesiotypes, neotypes, and heautotypes. "Heautotype" is a new term proposed by Buckman for "a specimen figured by an author as an illustration of his own already founded species, such not being a proterotype." Typical specimens are divided into "topotypes," "metatypes," "homœotypes," and "ideotypes" (new). The term "ideotype" is used by Buckman for specimens which come from places other than the original locality, and named by an author of a species after publication. The term "protograph" (suggested by Buckman for the original figure or figures illustrating a holotype) and "synthetograph" (a drawing which is a composite figure based upon several specimens of the new species) are also introduced here for the first time. For any artificial specimen moulded directly from a primary type Schuchert proposes the term "plastotype." For types of genera or genotypes the word "geno" is prefixed to the primary type terms, thus giving the corresponding terms "genoholotype," "genosyntype," and "genolectotype."

We cannot but feel grateful to Mr. Schuchert for his clear correlation of type terms. Although distinctly opposed to a multiplicity of terms in itself, we feel certain that such as are introduced in this volume justify their usage in the interest of scientific method.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—Dr. William Somerville has been elected to the Sibthorpian professorship of rural economy.

The following have been nominated to examine in the final honour schools:—in physics, Mr. W. C. D. Whetham; in chemistry, Prof. Arthur Smithells; in physiology, Mr. W. M. Bayliss.

An examination for a geographical scholarship of the value of 60*l.* will be held on October 11. Candidates, who must have taken honours in one of the final schools of the University, should send in their names to the reader in Geography, Old Ashmolean Building, Oxford, by October 1.

An appointment to the Oxford biological scholarship at Naples will be made next Michaelmas term. Candidates should send their names to the professor of comparative anatomy, the professor of physiology, or the professor of botany, by October 15.

CAMBRIDGE.—Dr. Nuttall, F.R.S., has been appointed reader in hygiene; Dr. L. Humphry has been re-appointed university lecturer in medicine, and assessor to the regius professor of physic.

The degree of LL.D. *honoris causa* will, on June 16, be conferred on His Excellency Paul Cambon, G.C.V.O., the French Ambassador.

A prize of 50*l.* from the Gordon-Wigan fund will be awarded in next Easter term for a research in chemistry to be carried out in Cambridge by a member of the University under the standing of Master of Arts.

A course of lectures and demonstrations in crystallography will be given during the long vacation by Mr. Hutchinson, beginning on July 7.

In the Mathematical Tripos, part i., two candidates are bracketed as senior wranglers, namely, Mr. A. T. Rajan and Mr. C. J. T. Sewell, both of Trinity. There are thirty-three wranglers. In part ii. all seven candidates are placed in the first class.

The diploma in agriculture has been awarded to six candidates, who have passed both parts of the examination.

The certificate of research has been awarded to two advanced students, Mr. P. Phillips and Mr. E. F. Burton, both of Emmanuel College, for researches in experimental physics.

Prof. Sims Woodhead will represent the University at the dedication of the new buildings of the Harvard Medical School on September 25 and 26.

The inaugural address of the local lectures summer meeting will be given by the Hon. Whitelaw Reid, American Ambassador, on August 2.

MR. HALDANE, M.P., Secretary of State for War, has consented to distribute the prizes at the London Hospital Medical College on Friday, July 13.

PROF. LECOMTE has been appointed professor of the botany of the phanerogams in the Paris Museum of Natural History, and Dr. Trouessart professor of zoology.

HERR ADOLF HALLICHS, managing director of the Friedrich Wilhelms metallurgical works, Mülheim, has been appointed a professor of the Technical High School at Aachen.

DR. R. SCHENCK, privatdocent for chemistry in the chemical institute of Marburg University, has been chosen for the professorship of physical chemistry in the Technical High School in Aachen.

DR. FRANZ ARTHUR SCHULZE, privatdocent and senior assistant in the physics institute in Danzig, has been appointed professor of physics in the Technical High School as successor to Prof. Zenneck, now in Brunswick.

MR. J. D. DALY, of the Department of Agriculture and Technical Instruction, Ireland, has been appointed secretary of the Royal Commission upon Trinity College, Dublin, and the University of Dublin.

DR. OTTO DIELS, senior assistant in the chemical institute of the University of Berlin, whose brilliant discovery of carbon suboxide was only recently made known, has been granted the title of professor. Dr. Karl Neuberg, assistant in the pathological institute of the same University, has also received the same honour.

AT the meeting of the Glasgow University Court on June 7 a letter of resignation was received from Prof. McKendrick, the professor of physiology. Prof. McKendrick has held the chair of physiology for thirty years, and has decided to retire at this time in order that his successor may have a considerable share in the equipment, and an opportunity of arranging the details of apparatus, both for teaching and research, of the physiological laboratories, which have been designed according to specifications supplied by Prof. McKendrick, and are now approaching completion.

IT is announced in *Science* that Yale University has received an anonymous gift of 1000*l.* to the forestry school, the income of which is to be used for the publication of works on forestry by graduates and members of the faculty.

THE council of the University of Paris has definitely approved of the scheme for the extension of the University. This will include, according to the *Lancet*, the construction of an institute of chemistry covering an area of 9000 square metres. Here will be established the various departments of chemistry belonging to the faculty of science and the department of applied chemistry which, since its creation, have been provisionally installed in some sheds. The cost of this will be 3,000,000 francs, which will be divided between the City of Paris and the State. The extension scheme also includes the acquisition by the University, in view of future necessities, of a plot of land of 14,000 square metres. Towards the cost of this land the University will pay 1,900,000 francs and the city 700,000 francs, to which will be added the donation from the Prince of Monaco. On a portion of this area will be erected the Institute of Oceanography, founded by the Prince of Monaco.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 15.—"On the Specific Heat of, Heat Flow from, and other Phenomena of the Working Fluid in the Cylinder of the Internal Combustion Engine." By Dugald **Clerk**. Communicated by the Hon. C. A. Parsons, C.B., F.R.S.

This paper describes experiments made with a gas-engine of sixty brake horse-power, devised to obtain data necessary for a more complete theory of the internal combustion motor, and also to discriminate between the effects of continued combustion in a gaseous explosion, and specific heat change, at temperatures between 200° C. and 1500° C. The new method of experiment consists in alternately compressing and expanding the highly heated gases within the engine cylinder while cooling proceeds, and observing by the indicator the successive pressure falls and compression and expansion curves from revolution to revolution.

From some two hundred indicator cards taken under varying conditions have been calculated:—(1) a curve of apparent specific heat of the gaseous contents at constant volume between 200° C. and 1500° C.; (2) curves of heat loss to the enclosing walls; and (3) distribution of heat in the working cycle calculated from diagrams only. The apparent specific heat at constant volume is proved to increase from 22 foot-pounds per cubic foot at 200° C. to 27·4 foot-pounds at 1500° C., and an examination of expansion curves and specific heat determinations made at different engine speeds and jacket temperatures shows that combustion is proceeding, and accounts for a part of the apparent increase of specific heat. Tables I. and II. show the apparent instantaneous specific heats and the mean specific heats in foot-pounds per cubic foot of working fluid at 0° C. and 760 mm.

Table I.—*Table of Apparent Specific Heats (Instantaneous) in foot-pounds per cubic foot of Working Fluid at* 0° *C. and* 760 *mm.*

Temperature °C.	Specific heat at constant volume ft.-lbs.	Temperature °C.	Specific heat at constant volume ft.-lbs.
0	19·6	800	26·2
100	20·9	900	26·6
200	22·0	1000	26·8
300	23·0	1100	27·0
400	23·9	1200	27·2
500	24·8	1300	27·3
600	25·2	1400	27·35
700	25·7	1500	27·45

Table II.—*Table of Mean Apparent Specific Heats in foot-pounds per cubic foot of Working Fluid at* 0° *C. and* 760 mm.

Temperature C.	Specific heat at constant volume ft.-lbs.	Temperature °C.	Specific heat at constant volume ft.-lbs.
0—100	20·3	0—900	23·9
0—200	20·9	0—1000	24·1
0—300	21·4	0—1100	24·4
0—400	21·9	0—1200	24·6
0—500	22·4	0—1300	24·8
0—600	22·8	0—1400	25·0
0—700	23·2	0—1500	25·2
0—800	23·6		

The curves of heat loss show that for equal temperature differences heat loss per unit surface exposed increases with density, and values are given of the heat losses for various temperatures. From these curves mean temperatures of the cylinder walls have been calculated, and shown to vary at full load from 190° C. for the whole stroke to 400° C. for the three-tenths stroke.

Calculations are made of heat distribution in the working cycle of the fluid which show that the total heat present in the form of combustible gas can be accurately calculated from the indicator diagram alone, by means of the new data obtained in the investigation.

It is pointed out that with a sufficiently sensitive indicating instrument the rate of continued combustion can be determined, and the true change of specific heat obtained from experiments made by the new method. The determination of the specific heat of gases heated by high compressions, such as one and a half tons to the square inch, is suggested, to avoid the complications introduced by combustion. It is shown that in these experiments the rate of loss of a mass of flame at 1000° C. to the comparatively cold walls of the cylinder was less than the rate of addition of heat by work performed by the piston, so that the flame temperature in the first compression rose from 1000° C. to about 1300° C., that is, compression in 0·25 second enabled a mass of flame to be handled in such a manner as to obtain accurate results. In these experiments, with maximum pressures of four hundred pounds per square inch, nearly twenty-eight tons total pressure was applied from 120 to 160 times per minute.

Mallard and Le Chatelier's experiments are discussed, and it is shown that no curve of specific heat can be deduced from their observations. It is pointed out that the curve of apparent change of specific heat of certain gases from 0° C. to 1500° C. has been here determined experimentally for the first time. The gases forming the working fluid consist mainly of carbonic acid, steam, nitrogen, and oxygen. The composition and all other details are given in the paper.

Anthropological Institute, May 22.—Prof. W. Gowland, president, in the chair.—(1) A series of slides of stone monuments found in Assam; (2) a paper on the "genna" (tabu) among the tribes of Assam: T. C. **Hodson**. The tabus are of two kinds, general or communal, as contrasted with private or individual tabus. Communal tabus are observed by the whole village, which consists of several exogamous subdivisions, and are automatic, in the sense that they are of regular occurrence or necessarily follow the occurrence of some event. These regular tabus are mostly connected with the crops, and are frequently times of great license. The village is made genna before the crop is sown, at the harvest-home, and sometimes on the appearance of the first blade of the crop. When the village is genna everyone must stay in until the tabu is over, and it sometimes lasts as long as ten days, and no one who is outside is allowed to come in. The village is also genna when a rain-making ceremony is necessary, and, in fact, any magical ceremony for the good of the whole community is necessarily accompanied by a general genna. Gennas are also occasioned by natural phenomena, such as earthquakes, eclipses, &c., and when the annual ceremony of laying the ghosts of those who have died within the year is held. Individual gennas are necessary at all important events in life, such as childbirth or marriage, and are as inevitable as crop gennas. They are also extended to certain foods, especially in the case of the head man of the village, and are also necessary when any person wishes to erect a monolith, usually for self-glorification. Such an individual is genna from the moment he takes the first steps towards erecting a monolith until the stone is finally in position. Slides of these monuments were shown by Mr. Hodson earlier in the evening. Gennas are also occasioned by the birth or death of any animal within the house, and warriors before and after a raid are subject to them.

Geological Society, May 23.—Mr. R. S. Herries, vice-president, in the chair.—The importance of Halimeda as a reef-forming organism, with a description of the Halimeda-Limestones of the New Hebrides: F. **Chapman** and D. **Mawson**. Calcareous algæ, nullipores, Lithothamnion, &c., have been frequently referred to as forming important contributions to the rock of coral-reefs. The material obtained in the great boring, the lagoon borings, and lagoon dredging at Funafuti has yielded a considerable quantity of Halimeda, and Dr. Guppy has described a Halimeda-Limestone in the Solomon Islands. Evidence such as this shows that the important deposits of calcareous plant-remains forming at the present day can scarcely be paralleled by any deposit formed in past geological times except, possibly, the limestones of the Alpine Trias, which owe their origin to the thallophytes Diplopora and Gyroporella. Among other Halimeda-Limestones mentioned by the authors are those of Christmas Island, Fiji and Tonga, and the New Hebrides.—Notes on the genera Omospira, Lophospira, and Turritoma, with descriptions of new species: Miss Jane **Donald**. The new species described in the paper belong to three genera, characterised by the possession of a band on all the whorls formed by the gradual filling up during growth of a sinus, and not a slit, in the outer lip.—Lantern-slide views illustrating the late eruption of Vesuvius and its effects: Prof. H. J. **Johnston-Lavis**. Nearly all the photographs were taken by the exhibitor, who explained the different phenomena portrayed. He considered this eruption to resemble mostly that of 1822, although the present crater was larger, attaining 1500 feet both north-by-south and east-by-west; it was probably 500 feet to 600 feet deep at least. The remarkable character about this eruption was the large amount of fragmentary material ejected, especially in a north-easterly direction, crushing in the roofs of the buildings in the towns of Ottajano, San Giuseppe, and Terzigno. At the first-named locality the depth attained was nearly 0·75 metre, made up as follows:—0·04 m. grey dust, 0·49 m. reddish lapilli, chiefly "supplementary ejecta," 0·20 m. black vesicular scoria, chiefly the "essential ejecta." The material which fell at the observatory and Naples had much the same arrangement, but was, of course, less, and practically only sand and dust. Near the base of the cone the ejecta attain to blocks several tons in weight; and it may be estimated that, at the north-eastern toe of the great cone, in some places, the débris must be 60 feet thick. It is to be seen as much as 30 feet in thickness in the new ravines that have been formed. After careful study, Prof. Johnston-Lavis had come to the conclusion that the remarkably uniform and deep scoring of the cone by very regular "barrancos" was due to the sliding and avalanche-like effect of the rapidly accumulating fragmentary material on the steep slopes, and not due to water-action. The volcano seems to have opened at four, if not five, different places on the south-western, southern, and south-eastern sides, giving rise to at least three important streams of lava. Another rift, to the north-north-east of the cone, emitted lava that forms an apron on that side of the mountain, and must, of course, have been formed early in the eruption, that is, before April 7 to 8. The ejected blocks are chiefly old lavas and scoria, partly re-cooked and metamorphosed, with their cavities filled by tachylytic juice from the fluid magma of the neighbouring chimney. The cavities are also often lined by sublimations of augite, hornblende, leucite, microsommite, hæmatite, halite, and a well-crystallised, yellow, deliquescent mineral which proves to be a new chloride of manganese and potash for which a new mineral name is proposed. A few fragments of limestone, and the various mineral aggregates derived by metamorphism from it, are met with, but they are chiefly re-ejected old ejected blocks. A light green spongy tachylyte is also frequent. The "essential ejecta," either as scoria or lava, does not show any marked difference from the usual products of Vesuvius in such eruptions during the last three centuries. Although much damage has been done, great areas of rugged lava-surfaces that would have required centuries to render cultivable are now available for the growth of woods, vines, and herbaceous plants.

Physical Society, May 25.—Dr. C. Chree, F.R.S., vice-president, in the chair. Colour phenomena in photometry: J. S. **Dow.** The author has found that to compare lights of different colours is chiefly a matter of practice. The central portion of the retina is more sensitive to red, and less sensitive to green, than the surrounding portion. When an attempt to photometer lights of different colour is made, differences are found as the distance of the eye from the photometer-screen is altered, and different results are obtained with different photometers. Differences of 5 per cent. can easily be obtained. The Purkinje phenomenon, generally regarded as a cause of uncertainty in ordinary work, only becomes noticeable at small illuminations and with large fields of view. Experiments are described to show that flicker photometers seem to be affected by colour-phenomena, but to a smaller extent than ordinary ones. Whether flicker or an ordinary photometer is adopted, it is necessary to specify the size of the field, the distance of the eye, and the order of illumination used in order to get consistent results.—Automatic arc-lamp: H. **Tomlinson** and G. T. **Johnston.** A simple form of automatic arc-lamp. A vertical brass tube supported by a wooden framework carries the upper carbon, which can be raised or lowered by hand and clamped in any position in the tube. The lower carbon fits into a hollow brass tube, and into the lower part of the tube is fitted an iron plunger. The plunger is surrounded by a solenoid, consisting of a layer of No. 14 copper wire, the internal diameter of the solenoid being slightly greater than the diameter of the plunger. The plunger dips into a box of mercury, and is made to float upright by means of a brass collar and by the rounded ends of three nails forming an equilateral triangle. The current enters the upper carbon through the brass cylinder, passes through the lower carbon into the mercury, and then through the solenoid. To "strike the arc" the lower carbon is raised to touch the upper one, and the plunger is then permitted to sink into the mercury until the suction of the solenoid balances the buoyancy of the mercury.—The theory of moving coil and other kinds of ballistic galvanometers: Prof. H. A. **Wilson.** The exact formulæ giving the quantity of electricity passed through various types of ballistic galvanometers in common use are obtained. The various types require different formulæ, all of which reduce to the same formula when the angle of deflection is small. In the case of a moving-coil galvanometer with rectangular coil, iron core, and pole-pieces arranged so as to give a radial magnetic field, the formulæ take a simple form. Bifilar galvanometer free from zero creep: A. **Campbell.** For measuring direct currents and voltages of ordinary range moving-coil galvanometers are convenient. The usual instruments are affected by gradual displacement of zero when a deflection is maintained for some time. This difficulty is got over by replacing the torsional suspension by a bifilar system with two wires so far apart that the gravity control swamps that due to the torsion of the wires. The wires are more than 1 cm. apart, and the sensitivity with 40 ohms resistance is 400 mm. at 1 metre for 0·001 ampere. The full deflection may be maintained for hours without causing a zero creep of 1 part in 2000. To attain good damping a powerful magnet is used.

Zoological Society, May 29.—Mr. Frederick Gillett, vice-president, in the chair.—Mammals collected by Mr. C. H. B. Grant in the Zoutpansberg district of the Transvaal, and presented to the National Museum by Mr. C. D. Rudd: H. **Schwann** and O. **Thomas.** The collection was obtained at two localities—Klein Letaba at 1000′ altitude and Woodbush at 4500′—and so gave a good general idea of the fauna of the region. In all it consisted of about 250 specimens belonging to fifty-one species and subspecies, of which several were described as new. In addition, the old genus Macroscelides was broken up into three, the new name Elephantulus being given to the group of which *M. rupestris* was the type, and Nasilio to that typified by *M. brachyrhynchus.*—The vascular system of Heloderma, with notes on that of the monitors and crocodiles: F. E. **Beddard.**—The external characters of an unborn fœtus of a giraffe (*Giraffa camelopardalis antiquorum* ♂ × *G. c. wardi* ♀): F. E. **Beddard.**—The South African diaptosaurian reptile Howesia: Dr. R. **Broom.**

DUBLIN.

Royal Irish Academy, May 14.—Dr. F. A. Tarleton, president, in the chair.—Some applications of Bessel's functions to physics: Prof. F. **Purser.** In this paper the author applies (1) the Besselian forms $K_0(nr)$ sin, cos nz and $J_0(mr)$ (sin h, cos h mz), where $K_0(nr) = J_0(<nr)$, to the solution of problems of electric potential, viz. the finite Leyden jar and equal circular disks fronting one another at different potential, the theory of the condenser formed by a circular disk midway between two large circular plates, and of the guard-ring electrometer. (2) The same functions are applied to some problems in fluid motion. (3) Certain problems in the theory of the elastic equilibrium of a right circular cylinder are discussed by the use of the Besselian forms

$$J_1\left(mr\right)\left(\frac{x}{r},\frac{y}{r}\right)\left(\sin h,\ \cos h,\ mz\right),$$

$$K_1\left(nr\right)\left(\frac{x}{r},\frac{y}{r}\right)\left(\sin,\ \cos nr\right)$$

where

$$J_1(x) = -\frac{d}{dx}J_0(x),\ K_1(x) = \frac{d}{dx}(K_0(x$$

(4) Lastly, the functions $J_0(mr)$, $J_1(mr)$ are applied to some problems of vortical motion of fluids under the influence of viscosity.—A map showing the relative distribution of various types of rock on the sea-floor off the west of Ireland, based on materials dredged by the Fishery Survey of the Department of Agriculture for Ireland: Prof. **Cole.** It is proposed to publish further details in the report of that survey, but meanwhile it is believed that the stones show the actual local distribution of rocks on sunken land, and are not the result of casual drift. The Porcupine Bank undoubtedly consists of a mass of olivine-gabbro, while a Carboniferous area west of co. Galway indicates that Connemara may have risen as an island in the Carboniferous sea.

Royal Dublin Society, May 15.—Prof. J. A McClelland in the chair.—Injurious insects and other animals observed in Ireland during 1905: Prof. G. H. **Carpenter.** In addition to records of several well-known farm and orchard insects, the paper contains an account of the rare "cauliflower" disease of the strawberry, due to the small nematode worm *Aphelenchus fragariae*, J. R. Bos, observed in county Wicklow.—A possible connection between the recent disturbances at Vesuvius and San Francisco: Rev. H. V. **Gill.** This paper contained an account of some experiments with rotating bodies, and an application of the principles involved to certain seismic phenomena. A hollow tee-totum weighted at one point will not spin about its axis of symmetry, but if it contain matter capable of shifting its position, it will automatically tend to steady itself, owing to the symmetrical distribution of the movable matter round its circumference. For example, if three steel balls of equal size be dropped into a smooth, hollow tee-totum they will take up equidistant positions round the edge. These results suggest the possibility of seismic disturbances being related in some such way. The above principles were applied to the disturbances which characterised the month of April—Vesuvius, April 8; Formosa, April 14; San Francisco, April 18. The possibility of this explanation being correct is supported by observed facts in connection with displacement of the poles associated with great earthquakes, and also by the positions of the localities referred to.

PARIS.

Academy of Sciences, May 28.—M. H. Poincaré in the chair.—Remarks on work recently carried out at the Observatory of Besançon: M. **Lœwy**.—Centres of gravity of spiraloid systems: Baton **de la Goupillière**.—An expedition in an aërostat, projected for the exploration of the North Pole: J. **Janssen**. An account of an expedition projected by Mr. Walter Wellman, and supported by the Geographical Society of Washington.—Addition to the note on the use of low temperatures in chemical analyses: MM. **d'Arsonval** and **Bordas**. In the majority of cases the vacuum obtainable by an ordinary pump is sufficient. In certain cases, however, the authors have found it advantageous to use either a mercury pump, or charcoal and liquid air, according to Dewar's method.—Magnetic observations at Tananarivo: Ed. El. **Colin**. Three tables are given showing the results of the absolute measurements of the declination, inclination, and the horizontal component at the Observatory of Tananarivo, taken weekly from May, 1905, to April, 1906.—M. Charles Trépied was elected a correspondant in the section of astronomy in the place of M. Perrotin. The properties which correspond to monogeneity for functions of a hypercomplex variable: Léon **Autonne**.—A particular class of Θ-functions: Henry **Bourget**.—The resistance of electrolytes for high-frequency currents: André **Broca** and S. **Turchini**. The authors showed a year ago that the theory of Lord Kelvin relating to the resistance of cylindrical conductors for currents of high frequency leads, in the case of metals, to results presenting systematic differences from those obtained experimentally. In the experiments in the present paper the conductor is an electrolyte. The resistance was first measured for a low-frequency current (42), and this assumed to be the same as with a continuous current. The resistance of the same solution was then measured with high-frequency currents (190,000 to 3,000,000). For very dilute acid or sulphate of copper solution the ratio of the two resistances thus measured was unity, but for solutions of higher conductivity the heating is less with a high-frequency current than with a low-frequency current, contrary to the result predicted by theory.—X-ray tubes with an automatic regulator: G. **Berlemont**.—The variations in the state of amorphous carbon under the influence of temperature and under the action of oscillations of temperature: O. **Manville**. Amorphous carbon, heated in a current of oxygen, commences at a definite temperature to give carbon dioxide, and at another, higher, temperature, carbon monoxide. These temperatures are a function of the temperature to which the carbon has been previously heated.—The acid phosphites of primary cyclic amines: P. **Lemoult**. The acid phosphites of aniline, *o*-toluidine, and *m*-xylidine are described, together with an advantageous method for preparing them.—The absolute atomic weight of terbium: G. D. **Hinrichs**. If the atomic weights of oxygen, sulphur, and hydrogen used in the determination of the atomic weight of thorium from the analytical figures be taken as the round numbers 16, 32, 1, then the atomic weight of thorium becomes also the round number 159, instead of the 159·22 deduced by M. Urbain.—A contribution to the study of pure ferrotungstens: Em. **Vigouroux**. Using the aluminothermal method, tungsten steels can be obtained containing 46·25 per cent. of tungsten; these, when extracted with dilute hydrochloric acid, yield the whole of the free iron, leaving a substance containing 68·7 per cent. of tungsten, a figure corresponding to Fe_3W_2.—Combinations of mercuric iodide and free methylamine: Maurice **François**.—Some hydro-anthracene derivatives: Marcel **Godchot**. A description of the mode of preparation and properties of octahydro-anthranol and its phenylurethane, β-anthracene hexahydride, γ-anthracene tetrahydride and its dibromo-derivative.—The rapidity of absorption of odours by milk: F. **Bordas** and M. **Touplain**. In an atmosphere containing only 1/100,000 of formaldehyde a few minutes' exposure is sufficient for the milk to show clearly the reaction of the aldehyde. The fresher the milk the more rapidly the absorption appears to take place.—A qualitative reaction of phosphorus: M. **Mauricheau-Beaupré**. The reaction is based on the depolishing of glass by the action of a flame containing small amounts of phosphorous compounds.—A new method for the microscopical analysis of flour and the determination of rice starch in wheat flour: G. **Gastine**. The flour is treated with certain colouring materials in solution, the whole slowly dried on the slide, and mounted in Canada balsam. The differential staining of the hilum is the basis of the method.—Oxydising catalysers and the generalisation of flameless combustion: C. **Matignon** and R. **Trannoy**.—Autocatalysis and the decomposition of a photochemical system: Béla **Szilard**. Details are given of the action of light on a solution of triiodomethane in chloroform.—The study of heterogeneous equilibria under varying pressures: E. **Briner**. The increased pressures are obtained by the use of a cylinder of compressed carbon dioxide, whilst the constancy of temperature during the reaction is ensured by a vapour jacket. A diagram of the apparatus used is given.—The nearly total transformation of the dextrins arising from the saccharification of starch into maltose: A. **Fernbach** and J. **Wolff**. The rate of production of maltose from the dextrins is much slower than the conversion of the starch into the dextrins, so that it is incorrect to assume that the reaction is finished when the liquid no longer gives the iodide of starch reaction. It is proved experimentally that if there exists a dextrin not transformable into maltose, it can represent only a minute fraction of the original starch.—The principles of gutta-percha obtained from *Palaquium Treubi*: E. **Jungfleisch** and H. **Leroux**. From the crude gutta from the leaves of this plant a new substance has been isolated, to which the provisional name of paltreubin is given. It appears to be a mixture of two isomeric alcohols of the formula $C_{30}H_{49}.OH$, the acetates of which were prepared.—The spores of a Streptothrix: MM. **Brocq-Rousseu** and **Piettre**. Under certain conditions of cultivation the spores could be obtained in such abundance that they could be analysed. The analyses given are stated to be the first published on the spores of the lower fungi.—An invasion of algæ (*Colpomenia sinuosa*) on the oysters of the Vannes River: M. **Fabre-Domergue**.—The evolution of some crustacean gregarians: L. **Léger** and O. **Dubosq**.—Researches on the relations between emotional states and infection: M. **Vaschide**. It is known that the leucocytes play an important part in the pathological processes of infection, the state of infection being especially connected with an increase in the proportion of leucocytes with polymorphic nuclei. The author has found that certain profound emotions are followed by an increase in the polynuclear leucocytes. The author cites well-known facts in pathology in support of his results.—Experimental infection by *Trypanosoma brucei*. The destruction of the parasite in the spleen: A. **Rodet** and G. **Vallet**. Experiments on dogs and rats show that in infection by this trypanosome the spleen and the other lymphoid organs are foci for intense destruction of the parasites. The spleen is endowed with an energetic trypanolytic power, and this organ evidently plays an important part in the defence of the body against infection.—The pathogenic importance of bronchial adenopathy: Gabriel **Arthaud**.—The frequency and the probable etiological *rôle* of *Uncinaria americana* in beri-beri: F. **Noc**.—The contradiction of glacial erosion: Jean **Brunhes**.—The degree of mineralisation of subterranean waters: F. **Dienert**.

NEW SOUTH WALES.

Linnean Society, April 25.—Mr. C. Hedley in the chair.—The geology of the volcanic area of the East Moreton and Wide Bay districts, Queensland: H. I. **Jensen**. The district investigated lies between the Pacific Ocean and Moreton Bay on the east, and the beds of the Mary and Stanley Rivers on the west; and between Cooran on the north and North Pine on the south. It is important from a geological point of view on account of the variety of igneous rocks to be found within its borders. The author shows that the low-lying district east of the Blackall and D'Aguilar Ranges, which is composed essentially of Trias-Jura sandstones belonging to the Ipswich Coal-measures and Tertiary alluvials, has been subject to oscillatory movements of elevation and depression in late Tertiary times. At present elevation is going on, as evidenced by raised beaches at Point Arkwright and elsewhere along the coast. The D'Aguilar Range north of Woodford is made up of Trias-Jura sandstone, but to the south of this point it consists of highly interesting plutonic and metamorphic rocks belonging in part to the Gympie beds, in part to much older formations. The country to the west of the D'Aguilar Range forms a peneplain with an average elevation of 500 feet. The Blackall Range is shown to consist of basalt capping rhyolites and rhyolitic tuffs, and Trias-Jura sandstones. The Maroochy district was a centre of great volcanic activity, rhyolites, andesites, dacites and basalts, as well as extensive areas of tuff and breccia, being here found.—The botany of Howell (Bora Creek), N.S.W.: a tin-granite flora: J. H. **Maiden**. Howell is situated nineteen miles to the south-east of Inverell. The tin-granite area under consideration extends in a two- or three-mile radius from the township. It lies on the western New England slope, at an elevation of about 2500 feet, and is included in E.9, New England County, of the botanical map to be found in the society's Proceedings for 1901 (p. 766). A list of the plants found so far, about 150 species referable to forty-two natural orders, is given. The locality is especially rich in Acacias, *A. neriifolia* perhaps being most abundant.

DIARY OF SOCIETIES.

THURSDAY, JUNE 14.

ROYAL SOCIETY, at 4.30.—The Experimental Analysis of the Growth of Cancer: Dr. E. F. Bashford, J. A. Murray, and W. H. Bowen.—On the Electrical and Photographic Phenomena manifested by certain Substances that are commonly supposed to be Ætiologically Associated with Carcinoma: Dr. W. S. Lazarus-Barlow.—The Bone Marrow; a Cytological Study forming an Introduction to the Normal and Pathological Histology of the Tissue: Dr. W. E. Carnegie Dickson.—On the Relation of the Liver Cells to the Blood Vessels and Lymphatics: Dr. P. T Herring and Dr. S. Simpson.—Studies on Enzyme Action, Lipase, II.: Prof. H. E. Armstrong, F.R.S., and Dr. E. Ormerod.—Studies of the Processes operative in Solutions, I., The Sucroclastic Action of Acids as Influenced by Salts and Non-electrolytes: R. J. Caldwell.—The Origin of Osmotic Effects: Prof. H. E. Armstrong, F.R.S.

BRITISH INLAND NAVIGATION.

Our Waterways. A History of Inland Navigation considered as a Branch of Water Conservancy. By Urquhart A. Forbes and W. H. R. Ashford. Pp. xv+336. (London: John Murray, 1906.) Price 12s. net.

IT was originally intended to deal in this volume with the whole subject of water conservancy, which has been defined as "the scientific treatment and regulation of all the water received in these islands, from its first arrival in the form of dew or rain till its final disappearance in the ocean," tracing the evolution and subsequent history of the various branches of water conservancy, which, in addition to inland navigation, comprise fisheries, water-supply, the mitigation of floods, and the prevention of river pollution. Owing, however, to the greatly increased interest displayed in the improvement and utilisation of our inland waterways, this subject has been given precedence of the other branches, and forms the main purport of this book, though the other branches are occasionally referred to.

The appearance of the volume is in any case very opportune, for it has approximately coincided with the appointment of a Royal Commission to inquire into the condition of the inland waterways of the United Kingdom, and to investigate whether it might be possible to devise some scheme by which inland navigation in the British Isles, so long neglected, may be revived and improved, so as to serve profitably for the conveyance of bulky goods, and thereby reduce the cost of carriage, and thus place British manufacturers in a more favourable condition for competing with their foreign rivals, and especially with those for whom a paternal Government has provided the facilities of free and commodious inland waterways.

After a short introductory chapter on "The Objects of Water Conservancy," the rainfall, drainage areas, and principal rivers of the British Isles are referred to in a chapter on "The Water System of the United Kingdom," and certain important changes noted; whilst in the next chapter the legal aspects of water conservancy are dealt with. The authors trace three distinct periods in the history of the navigation of our waterways, namely, the first period, dating from early times up to near the close of the sixteenth century, when the rivers were used for navigation in their natural condition, as described in a chapter on the "Natural Waterways" of England; a second period, from the close of the sixteenth century to the commencement of the Bridgewater Canal in 1759, inaugurating the canal system in England, during which time inland navigation on the rivers was improved and extended by deepening their channels, of which some account is given in chapter v.; and, lastly, the canal era, dating from the construction of the Bridgewater Canal, which, after a chapter on ancient and early British canals, is dealt with in two chapters in regard to England and Wales. A chapter on "The Conservancy of Rivers in England and Wales since the Eighteenth Century" brings the history of English rivers down to the present time; whilst another chapter, on "Rivers and Canals in Ireland and Scotland," where the development of inland waterways was only commenced in the eighteenth century, completes the sketch of river and canal navigations in the United Kingdom. In chapter xi. the decline of inland navigation in the face of railway competition, and by the purchase of important links by the railway companies, is referred to, and statistics as to the total length of canals in the United Kingdom, their traffic and revenues are given; whilst the various causes which have contributed to the very depressed condition of the great majority of the canal companies are explained.

Though the book contains, as indicated by the preceding summary, a considerable amount of information as to the rise, progress, and present condition of the inland waterways of the United Kingdom, as well as the legislative enactments controlling them, which Mr. Forbes, as a barrister, is specially qualified to deal with, the most interesting subject at the present time is undoubtedly the one considered in the last chapter, namely, "The Resuscitation of Our Waterways," to which the previous portion of the book has gradually led up. In dealing, however, with this subject, it is important to draw a very definite distinction between the inland waterways with which the authors are concerned and the maritime waterways of the United Kingdom, such as the tidal estuaries and rivers and the Manchester Ship Canal, which, though referred to amongst inland waterways, are quite outside the scope of the book, and are in no need of resuscitation. The flourishing sea-going trade of Great Britain is, indeed, due to her maritime waterways, many of which have been greatly improved to keep pace with the growth of traffic and the increasing draught of large vessels; whilst the Manchester Ship Canal, though proceeding inland, and having unfavourably affected schemes for the development of inland waterways by its unsatisfactory financial results, is essentially a maritime waterway, and has proved of great value to the sea-going trade of the district by converting the inland city of Manchester into a seaport, independent of Liverpool and the railways.

Whereas, however, the United Kingdom, with its very extensive coast-line and numerous important tidal rivers, is exceptionally well fitted by nature for maritime trade, its restricted area and small river-basins, resulting in small rivers above their tidal limit, separated by high water-partings in proportion to the moderate distance between them requiring to be surmounted by a canal, place this country at a serious disadvantage in regard to inland navigation as compared with the continent of Europe, with its very extensive river-basins draining into large rivers flowing for long distances over comparatively level plains, and capable in some cases of being joined across their water-parting by a canal of requisite size, without having to rise to a considerable elevation, and at a reasonable cost. In spite, nevertheless, of these manifest disadvantages, there is no doubt that the inland waterways of England have been unduly allowed to fall into decay, owing to a surrender in several cases to the railways, the absence of concerted effort to procure uniformity of dimensions in through routes and to effect amalgamations, and the neglect of improvements. Those inland waterways which are under a single control, which possess the requisite traffic in bulky goods, and have been enlarged and improved to provide for the growth of traffic, such as the Aire and Calder Navigation with its coal trade, and the Weaver Navigation with its salt trade, have been able to maintain a very successful competition with the railways; and where waterways connect large centres of commerce and there is a large trade in bulky goods, the old, inadequate waterways have been able to retain a considerable traffic, as exemplified by the Leeds and Liverpool Canal, and the canals clustering round Birmingham and from the Potteries. A careful study of the statistics of Continental waterways proves that, notwithstanding the natural advantages they possess, and the uniformity in size and improvements which have been provided, only those waterways obtain a large traffic which deal with bulky goods and traverse long distances with merely moderate alterations in level.

The value of inland waterways in offering an alternative route to railways for bulky goods, and thus tending to reduce railway rates, as well as relieving railways from being overburdened by the least remunerative portion of their traffic, is obvious; but the points requiring solution are, from what source the funds can be provided for putting the principal waterways in a position to compete with the railways for the conveyance of bulky goods, and what waterways afford a good prospect of a reasonable return on the capital expended in their requisite improvement. The authors, in their final chapter on "The Resuscitation of Our Waterways," after directing attention to the interest aroused in recent years in inland navigation, the steps which have been taken for amalgamating some of the canal companies, the lesser cost of transport and maintenance in the case of canals than with railways, and the possibility of discharging goods at any places on the banks of a canal, indicate three methods by which the necessary improvements, unification of dimensions, amalgamation, and control of inland waterways, might be effected.

The first method is the conferring of additional powers on the Board of Trade to supervise the improvement and development of those waterways which have opportunities of trade in bulky goods, the necessary funds being lent them by Parliament or by local authorities. The second method is "the establishment of a canal trust to acquire, develop, extend, and administer, in the public interest, canals and navigations in England and Wales," which would be empowered to raise the requisite funds by the issue of guaranteed canal stock. The third method is "the nationalisation of waterways" by the purchase of the canals by the Government with funds raised by a loan with this object, which the authors consider is the best method, and one which would speedily repay the cost "by doubling our means of communication" and "by the immense incentive given to commercial enterprise." Unfortunately, this is a very optimistic view of the results of the purchase and improvement of our inland waterways by the Government, and not at all likely to be realised, for their total length in England and Wales is only about a fifth of the length of the railways; and only a few of these waterways could be improved with any prospect of a remunerative expenditure. Considering that many of the French canals have a traffic which could hardly pay the working expenses, as is the case with the Caledonian Canal, which belongs to the Government, it is evident that the purchase and improvement of the English canals as a whole would be a financial mistake; but the connection of Birmingham with a seaport by an adequate waterway, the improvement of some of the antiquated canals in its neighbourhood, and the development of some through routes might be effected with good prospects of satisfactory commercial and financial results.

RECENT BOTANICAL BOOKS.

(1) *Alien Flora of Britain.* By S. T. Dunn. Pp. xvi + 208. (London: West, Newman and Co., 1905.) Price 5*s.* net.

(2) *The Aconites of India.* Annals of the Royal Botanic Garden, Calcutta, vol. x., part ii. By Dr. Otto Stapf. Pp. ii + 115–197; with 25 plates. (Calcutta: Bengal Secretarial Press, 1905.) Price 1*l.* 1*s.*

(3) *An Enumeration of the Vascular Plants from Surinam.* By Dr. A. Pulle. Pp. 555. (Leyden: E. J. Brill, Ltd., 1906.) Price 15*s.*

(4) *Die europäischen Laubmoose.* By Georg Roth. Pp. xxviii + 1331. 2 vols. (Leipzig: W. Engelmann, 1903–1905.)

(1) IT has been pertinently remarked that the British cannot altogether escape the designation of aliens in view of the continual influx of foreigners, whether peacefully or formerly as invaders, but in such cases the descendants are eventually regarded as natives. Plants cannot, at any rate within historic times according to the author of this book, pass from the class of aliens to the class of natives. This is an exclusive view, but from a scientific aspect logical and correct. It is a difficult matter to establish a test for the validity of native species, especially in an insular country that has been extensively cultivated and the inhabitants of which have been the foremost voyagers in the world. The criteria adopted by the author depend mainly upon a consideration of the distribution of each species in Great Britain and adjacent countries. This applies especially to plants that are generally recorded as weeds from artificial habitats, but which may nevertheless be truly indigenous; the author distinguishes a considerable number of these that are readily noted, since their descriptions are placed within brackets. A

noticeable genus is Ribes, for which the author favours the inclusion amongst natives of the species *alpinum, grossularia, nigrum*, and *rubrum*. The compilation of this group has demanded much thought, and whether one agrees or disagrees with the discrimination, it is an extremely valuable expression of opinion, and affords the opportunity to those interested to place on record any apparently natural localities for these species. Less interesting, but forming an integral part of the subject, are the more obvious aliens, including introductions, casuals, and what may be termed drifts. The book fully bears out the expectations that were formed of its original and critical character, and to the author's wife due credit must be given for enabling the book to take shape when the pressure of official duties seemed likely to delay its publication.

(2) The early attempts to classify the Indian aconites were prompted by the desire to trace the source of the poisonous root known as Nepal aconite or Bikh. In 1802, when the East India Company decided to send a mission to Nepal, Dr. F. Hamilton was deputed to join the expedition in a scientific capacity, and he endeavoured without success to identify Bikh. After him Wallich took up the collection of Nepal aconites, but, unfortunately, his plants assigned to *Aconitum ferox* were not the source of Bikh, although such was assumed. The confusion so originated was increased when, later on, the same scientific name was applied to different plants from Kumaon and Garwhal, and these and other misnomers have continued to the present day. To Sir George Watt much credit is due for attempting to clear up the nomenclature. In touring through the localities mentioned he spared no pains to collect plants and to ascertain their vernacular names with any general information, and this has materially helped Dr. Stapf in preparing the present monograph. Most of the species fall into two sections—Lycoctonum, containing perennials, and Napellus, containing biennials. The latter is the important group including *Aconitum spicatum*, the true Bikh, and the allied Nepal species, *Aconitum laciniatum*, termed Bikhoma, also *Aconitum heterophyllum*, which contains a bitter but non-poisonous substance, *atisine*, and a similar species, *Aconitum palmatum*. Dr. Stapf decides against the occurrence of *Aconitum napellus* in India, the nearest congener being the poisonous species *Aconitum soongaricum*, of which the properties are unknown. In addition to the task of discriminating between the names ascribed to herbarium specimens and establishing the identity of vernacular designations, Dr. Stapf works out a classification based upon the anatomical structure of the roots. For the biennial species he distinguishes three types of root, the first, normal, showing one continuous ring of cambium; in the second the cambium is separated into several portions, and the bundles appear as star-shaped masses embedded in uniform tissue; the third is characterised by cambium bands having a circular or horseshoe-shaped cross-section.

(3) The colony of Surinam, or Dutch Guiana, has been visited by a large number of plant-collectors, of whom the most important, all about the middle of the last century, were Hostmann, Kappler, Focke, Splitberger, and Kegel, and quite recently Went and the author. A considerable number of the plants sent to Europe by the earlier collectors had been previously worked out, and a list of some fifty papers dealing with the classification of selected portions from different collections is given under the literature; but this is the first attempt to prepare a complete list of the vascular plants. The author has discovered twelve new species, including two in Podostemaceæ, two in Melastomaceæ, one in Loranthaceæ, and a Vanilla. Looking through the orders, the Leguminosæ are the most abundant, then the Orchidaceæ, Gramineæ, and Melastomaceæ in descending order. The Malpighiaceæ, Sapindaceæ, and Guttiferæ are proportionately well represented, and among the ferns Polypodiaceæ and Hymenophyllaceæ. Some of the more important genera are Miconia, Ipomœa, Piper, Peperomia, Inga, Schizæa, Vanilla, and the tropical American genus Dichæa. A tabulated comparison is made with the floras of British Guiana, French Guiana, and the Amazon district, showing that about 60 per cent. of the plants of Surinam occur in each of these regions, and that about 14 per cent. are endemic.

In the phytogeographical survey reference is made to a typical mangrove vegetation found in the river estuaries that gives place to a littoral alluvial belt. The vegetation of the river banks is extremely rich, mention being made of the araceous *Montrichardia arborescens, Pachira aquatica*, and *Cacoucia coccinea*. Further inland there are plains on higher ground called savannahs, but differing from the true savannahs or from the campos of Brazil, where sedges, grasses, species of Schizæa, Eriocaulaceæ, and Melastomaceæ are abundant. In the primitive forest Selaginellas and hymenophyllaceous ferns find a suitable habitat, while *Tecoma leucoxylon, Mimusops Balata, Eriodendron anfractuosum*, and certain Lecythidaceæ are amongst the important trees.

In addition, a list of vernacular names is given, and a few illustrations of typical plant formations that are excellent; also figures of the new species are provided and a map of the country. As Dr. Pulle has been at considerable pains to consult the principal collections in Holland and elsewhere, the enumeration is complete, and the volume forms a valuable contribution to the botany of tropical South America.

(4) To bryologists in this country Lindberg's system, in which the cleistocarpous mosses are incorporated with stegocarpous forms, is the most familiar, as Braithwaite and Dixon have both followed this arrangement. On the Continent, Brotherus has also adopted Lindberg's system in his classification of the mosses in the "Naturliche Pflanzenfamilien." Mr. Roth has preferred to conform more closely to Schimper's grouping, and in this respect and others his classification is very similar to that of Limpricht in "Rabenhorst's Kryptogamenflora." He retains a large number of independent genera

instead of uniting several as subgenera under one main genus, here again differing from English authorities. A good instance is afforded by a comparison of the species united under Weisia by Dixon with the same species that are referred by Roth to seven different genera; and two of these are quite separated from the others, as they fall under the Cleistocarpi. In his treatment of the Hypnaceæ, to which family one naturally turns, Roth also differs considerably from Schimper. Dixon collects ten of Schimper's genera under his genus Hypnum, but specifies five of them as subgenera. Roth has twelve equivalent genera, but again four genera are placed in a different family, and unnecessarily, although not without reason, the genus or subgenus Harpidium is changed to Drepanocladus. This is one of the names which, it is hoped, will be sustained when the nomenclature of the cryptogams is discussed at the next International Botanical Congress.

The points of difference between this work and Dixon and Braithwaite's books are so numerous that British moss-workers will refer to the "Europäischen Laubmoose" for contrast rather than for comparison. As a practical handbook for naming mosses the work deserves much commendation, and bears ample evidence that the writer has definite opinions to express. It is a great pity that analytical tables for distinguishing genera are not given, but the descriptions are good, and important characters are thrown into bolder type. References to the most recent discoveries of new localities and new varieties will be found. The illustrations are very numerous, but poor in execution.

PHOTOGRAPHY IN SURVEYING OPERATIONS.

An Elementary Treatise on Phototopographic Methods and Instruments. By J. A. Flemer. Pp. xix+438. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1906.) Price 21s. net.

THE assistance that photography can render in the laborious work connected with topographical surveys has been repeatedly insisted upon, and the recognition of the fact is being displayed in the construction of a class of instruments admirably adapted for use in the field. With the more convenient instruments that experience will suggest, and with the shortened methods that familiarity will supply, the employment of photography is likely to be still more general, though doubtless it will have to contend against a certain amount of prejudice in favour of older methods.

Mr. Flemer's book is intended to overcome these prejudices and to determine the exact field which the camera can usefully occupy in surveying operations. The method has its limitations. The accuracy of a map constructed from panoramic views must evidently depend upon the precision with which objects can be identified and measured on a photograph or its enlargement. The use of telephoto-lenses or long-focused cameras would increase the accuracy, but at the expense of convenience. More numerous photographs taken at shorter distances would also have the same effect, but then the labour of collecting and reducing the material would approach that due to the ordinary methods. It is the object of such a book as this to show that photography has distinct advantages peculiar to itself. But in many directions in which extreme accuracy is unnecessary, perspective views can be of essential service. A series of panoramic pictures showing the alteration in the face of the country due to volcanic eruptions, or the recurrent changes in sand dunes caused by winds blowing from certain directions at regular intervals, seem to be peculiarly suitable inquiries for photographic methods. Similarly, the changes in glacier formation and the determination of their motion, alterations in coast-line due to erosion, or the location of rocks and buoys would suggest other applications for the process. In wars and manœuvres, either with or without the use of balloons, the process has a large field of application.

Since the translation of a perspective view or combination of views into maps possessing considerable accuracy of detail is likely to concern many other professions than that of a surveyor, properly so called, it is most desirable to have a treatise in which is set out clearly the methods of construction and of the principles underlying the practice of the process. This want Mr. Flemer's book is intended to supply. That the author is competent to deal with the subject practically we entertain no doubt, but whether he has been successful in conveying his knowledge to others it is very difficult to judge. Surveying is technical work that can hardly be learnt without actual experiment in the field under the eye of a trained teacher. What amount of preliminary information is a pupil supposed to have before tackling the problems the author introduces? Certainly one ought to be accustomed to the use of the plane table and the time-honoured methods of procedure before addressing himself to the study of perspective views. The method should be regarded, not as a substitute, but as an addition, to the recognised processes.

Mr. Flemer's book consists practically of three parts. After a short preliminary historic review to show how the principles have been welcomed in various countries, the author discusses the phototopographic methods that various authorities have recommended. The fact that we have so many varieties of detail shows that the subject has not yet taken that mechanical, stereotyped form which it may be expected to assume when fully developed. The second part opens with a chapter on lenses, which seems hardly necessary to introduce the description of the many photogrammetric instruments now in use. This latter is a really valuable and excellent section. Finally, we have the details of the photographic operations, including the development of the plates and prints. There is not much that is new that can be said here, and the treatment of pinhole photography which is naturally connected with this subject is unfortunately discussed in another place. W. E. P.

CONVERSATIONS ON CHEMISTRY.

Conversations on Chemistry. First Steps in Chemistry. Part ii., Chemistry of the Most Important Elements and Compounds. By W. Ostwald. Authorised translation by Stuart K. Turnbull. Pp. viii+373. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1906.) Price 8s. 6d. net.

THE original German edition of this book has been already noticed in NATURE (March 9, 1905, vol. lxxi., p. 435). The translation into English will make it accessible to a wider range of teachers, and to them it is to be warmly commended. No one can fail to be interested in seeing how one of the most lucid of German expositors, and one of the most ardent of reformers, presents the material of ordinary inorganic chemistry to the elementary student, and there are probably few people engaged in the business of teaching chemistry who will not find Prof. Ostwald's book of chemical dialogue eminently interesting and suggestive.

A book by so trenchant a critic naturally invites a close scrutiny, and particular interest will be felt in the treatment of certain points of difficulty which in a peculiar way beset the teaching of elementary chemistry. We may cite, for example, the definition or characterisation of an acid. Prof. Ostwald meets the case in a very simple way. On p. 16 it is written, "Only those compounds are acids which give off hydrogen with magnesium," and this is re-affirmed as quite correct on p. 17. We appreciate the advantage of a touchstone, but it may fairly be asked if, in the first place, magnesium is such a touchstone, and, secondly, whether this is the right kind of basis for the characterisation of an acid. In regard to the first point we think there is doubt, for although it is explicitly stated that water gives off no hydrogen with magnesium, and is not an acid, it is admitted later on p. 247 that "the metal has only a very slight effect on water," and, of course, it might be urged that at higher temperatures magnesium will actually burn in steam and liberate hydrogen in torrents. We think that Prof. Ostwald's pupil, who in this book is invested with a degree of zeal and adroitness calculated to make other teachers envious, might have been allowed to persecute his master a little more on the subject, until he had elicited the confession that on this question of acids, as on so many others relating to chemistry, the relativity and transition of things altogether preclude absolute definitions.

It is, perhaps, almost captious to make these remarks, for the way in which the teacher is exhibited in this book as anxious to be questioned is truly admirable, and most points are worked out with great ingenuity and address to an entirely logical conclusion. The allusion to things and phenomena of real human interest and the suppression of pedantry are also to be warmly commended.

The actual work of translation has, on the whole, been well done. The nationality of the translator is betrayed by occasional troubles with shall and will, and there are some positive mistakes in sense. Thus, "*Leimwasser in Fäulnis übergegangen*" is rendered "lime-water which has become foul," and on p. 40 the first two lines contain a mistranslation which makes a serious error both in fact and theory.

In conclusion, we may perhaps be permitted to regret that so useful a book has not been issued at a price which would make its wide dissemination among teachers more certain. A. S.

NENCKI'S COLLECTED WORKS.

Marceli Nencki Omnia Opera. Gesammelte Arbeiten von Prof. M. Nencki. Two vols. Erster Band. Pp. xlii+840. Zweiter Band. Pp. xiii+893. (Brunswick: F. Vieweg and Son, 1905.) Price 45 marks.

THE death of Prof. M. Nencki at the comparatively early age of fifty-four was a great blow to science. He attained a world-wide reputation as an investigator of the first order, and his laboratory at St. Petersburg became a busy hive of earnest workers, all fired with the enthusiasm and thoroughness of their master. The most fitting monument for such a man is the collection of his works presented to us in the two volumes which form the subject of this review. The labour of love in preparing this book for the press has fallen upon two of his most attached colleagues, namely, Nadine Sieber and Prof. J. Zaleski, and they have chosen the German language as that in which to publish his collected memoirs. They have written an account of his life in the introductory pages, but have wisely chosen to make this brief; his work was his real life, and this is allowed to speak for itself.

Nencki's name is best known, perhaps, for his researches that deal with the decomposition products of albumin, with the history of urea and its precursors in the body, and with the chemistry of hæmoglobin and other pigments. Probably few had any idea how varied were the investigations he undertook in other branches of biological chemistry, and how enormous was the output from his laboratory. The total number of papers now published amounts to three hundred and forty-six. They were issued from the year 1869 onwards, and include not only those written by Nencki himself, or in conjunction with his colleagues, but also those published by the workers in his laboratory.

It is interesting to note how with the advance in knowledge the subjects treated vary with the march of the years. An organic chemist at heart, Nencki best loved a research in which he could apply his chemical learning to obtain exact results. But he never lost sight of the application of chemical knowledge to the problems of medicine, pathology, and pharmacology, even although in many cases the results lacked that certainty and neatness which form the chemist's aim. As bacteriology, the giant daughter of physiology, became a specialised branch of study, we see how the resources of his laboratory were given over to the elucidation of its chemical relationships; and in more recent years the new subject of immunity equally attracted the diligence of the pupils whose work Nencki controlled and directed.

To attempt even an enumeration, still less a review, of the papers contained within the book would be out of place in a brief appreciation of its value. One can only recommend those interested in such subjects as have been indicated to procure this treasure-house of information for themselves.

W. D. H.

OUR BOOK SHELF.

Essais des Matériaux. By H. Bouasse. Pp. 150. (Grenoble: Gratier and Rey; Paris: Gauthier-Villars, 1905.) Price 5 francs.

THE ordinary mathematical theory of elasticity consists mainly in the examination of the consequences of the general principle involved in the statement of Hooke's law, "ut tensio sic vis," or, in other words, the proportionality of stress to strain. In many cases, however, this assumption is far from being satisfied, and the state of strain in a body at any instant depends not only on the actual stresses, but on the changes which have previously occurred in that body.

Prof. Bouasse's treatise consists in large measure of a classification of the various properties arising from the study of strains and stresses, such as permanent deformations, perfectly elastic deformations, viscosity, hysteresis, reversible and irreversible deformations and limits of elasticity. As the author points out, many of the phenomena are of common occurrence, and he instances the displacement of the zero reading of the galvanometer as a simple example. The various effects are illustrated by curves showing the relations between strain and stress. The ordinary theory of elasticity is of course touched on.

The printing of the preface in italics does not favourably impress the English reader at the outset, but everyone must agree with the conclusions at the end, in which the author points out that the subject has not received the attention it deserves, and this at a time when rapid advances have been made in most branches of physics. There is abundant evidence that Prof. Bouasse has given much careful thought and study to the subjects of which he treats, and even if his book does no more than attract attention to a neglected branch of physics it will fill a useful purpose.

The Scientific Roll and Magazine of Systematised Notes. Conducted by Alexander Ramsay. Bacteria. Vol. i. Pp. 528. (Acton, London, W.: R. T. Sharland.) Price 16s.

IT is difficult to comprehend exactly what place this work is designed to occupy. The author must have expended an enormous amount of time and labour upon it, but we regret to say we cannot help feeling that much of his work is misapplied. For example, the 200 pages or thereabouts occupied by the tables of bacteria, arranged according to size, can be of little or no value, because the size of bacteria is extremely variable, and because the finer measurements must be very rough. Had this space been devoted to a summary of bacterial characters and reactions, abstracted from original papers, a great deal of scattered material would have been gathered together, and the result would have been most valuable. The bibliography in the earlier parts should be useful, but the summary of characters contained in the later ones is too brief and scrappy to be of much value.

LETTERS TO THE EDITOR.

Another New Vesuvian Mineral.

IN NATURE of May 31 I gave a preliminary note on a new mineral species *chlormanganokalite*, in speaking of which I made reference to its association with fine crystals of halite that I suggested were likely to prove rich in potash. The latter crystals occur as beautiful cubes often more than a centimetre in diameter, and of a transparent to a milky, opaline tint. They afford on analysis the following results as to their composition:—

KCl ...	87·57		KCl	87·93
NaCl ...	12·02	equal to	NaCl	12·07
Moisture	0·412			—
	100·002			100·00

If we adopt the formula $(KCl)_6NaCl$, we should theoretically expect the following composition:—KCl 88·5, NaCl 11·5, which is sensibly the composition found by analysis as above, especially when we consider the errors inherent to the estimation of these substances.

I think, therefore, we are justified in considering this mineral as a definite double chloride, which I propose provisionally to call *chlornatrokalite*. It is my intention to submit to analysis a number of similar minerals that I have collected at Vesuvius during the last twenty-six years to see if we have to deal simply with mixtures or definite chemical compounds. Spectrum analysis failed to show even traces of calcium, cæsium, rubidium, or lithium.

The great amount of potassium compared to sodium is not astonishing when we consider that potash is the dominant alkali in the paste from which Vesuvian lava and its other products are derived.

The Discovery of Logarithms.

IN the review of a book, "Letters from the Dead to the Dead," which appeared in your number of May 31, your reviewer says:—"As another example we may take the notes to Henry Briggs's letter, in particular the *supposed* proof (p. 75) that Napier's true base is the reciprocal of *e* and not *e* itself. As the difference depends entirely on whether log sin 45° has a plus or a minus sign attached to it, it is interesting to speculate on how many readers will be *deceived* by what is after all a somewhat clever *hoax*." (The italics in the above extract are mine.)

I take it by the use of the words *supposed*, *deceived*, and *hoax*, your reviewer intends to intimate that the formula on p. 75 of "Letters from the Dead to the Dead" is faked, or made by the author to suit his own purposes. Nothing could be further from the truth. I have had the curiosity to make the calculation *de novo*, and I venture to submit that no fair or genuine criticism can be passed upon it. The expression $\log 1/\sqrt{2}$ must have the minus sign. Indeed, I almost wonder whether your reviewer has read the book he is reviewing, because in that book the author quotes from Macdonald's translation of Napier's "Constructio" the statement that e^{-1} *is the base required by Napier's reasoning.*

I am not concerned whether the book in question is a hoax or not. For my part, I do not believe that it is. On the contrary, I believe it will prove to be one of the great books of history. It raises too many fascinating questions to be non-suited in your summary manner, and the reason why John Napier, knowing in 1614 that logarithms computed to base 10 must supersede all others, went on computing his to the surd 1/2·7182818283 as base, is an historical mystery that demands a solution. It is ridiculous to suppose—nay, it is impossible to suppose—that the inventor of logarithms did not know that they must have a base. CECIL SEYMOUR-BROWNE.

The note under criticism purports to be a "proof" that the base originally used by Napier was the reciprocal of e, and not e itself. In reality, it is nothing of the sort. The arithmetical details are both unnecessary and insufficient for the purpose, and their insertion is unfortunately calculated to deceive many readers by obscuring the real points at issue. The same "proof" might equally well be employed to show that the original base was e instead of its reciprocal, but that the minus sign had been omitted from the logarithms of sines. If your correspondent will read any treatise on the history of mathematics, he will see an account of the train of reasoning which led Napier to the discovery of logarithms before the existence of a base or the connection between logarithms and indices had been suspected. There are doubtless many historical points connected with the discovery of logarithms that deserve closer study than they commonly receive, but the publication of a book of this kind is not likely to advance our knowledge of them. If one could be certain that all readers would take the book for what it is worth, no harm would be done. But there are, unfortunately, many people who possess a "little knowledge" (which is, of course, a "dangerous thing") who will derive a large amount of misinformation from the interpretation they will place on the contents of the book, and this misinformation will be very difficult to eradicate.

The Reviewer.

Distribution of the Forms of Corvus cornix and C. corone.

I should esteem it a favour if the writer of the review of Ralfe's "Birds of the Isle of Man" (Nature, May 31, p. 195) would more clearly explain his reference to the dimorphic forms of *Corvus cornix* and *C. corone*, and the "border-line, *i.e.* along the line from the Firth of Clyde to the Adriatic, &c."

The Firth of Clyde is not the limit of the line where they are known to interbreed. They interbreed north of the Firth of Forth, and as far north as Moray at *least*.

And as regards the Adriatic, the forms are known to interbreed and produce every variation of crosses or diverse plumages in *Siberia*.

No doubt your reviewer will be able to explain his meaning, but, as at present expressed, it is somewhat difficult to understand (*v.* p. 105).

The "carrion crow" (*corone*) seems to me to be the more aggressive of the two, and is slowly but surely pushing north in Britain, as I think references to our series of Scottish faunas will show.

J. A. Harvie-Brown.

Dunipace, Larbert, Stirlingshire, N.B., June 2.

The precise line—if there be one—marking the distribution between the breeding areas of *Corvus cornix* and *C. corone* is of little importance to the "problem" suggested to the readers of Nature in the review mentioned. Its direction, however, was taken from Newton's trustworthy "Dictionary of Birds," p. 117, where it is stated to be "an irregular line drawn diagonally from about the Firth of Clyde to the head of the Adriatic." The reviewer cited that statement as authoritative, since he has had no opportunity of personal observation on the subject. It is further stated on the page last cited, "it has now been incontestably proved that along or near the boundary where these two birds march, they not infrequently interbreed, and it is believed that the hybrids which sometimes *wholly resemble*—italics by the reviewer—one or other of the parents . . . pair indiscriminately among themselves or with the pure stock." If these be established facts, then the hybrid wholly resembling the black variety must, *if it occur in any considerable numbers*, retire to breed "to the south-western part of this quarter of the globe," and the hybrid wholly resembling the "grey neck" "to the north-eastern portion." How has this discrimination been acquired? Two further questions may be asked: Can the wholly black and wholly grey hybrids be recognised after they have left the nest? Can the proportion of pure breeds to hybrids in the general crow-population be determined?

The facts given in Mr. Harvie-Brown's letter seem to indicate that the crows in their nursery arrangements behave less perplexingly than the reviewer had deduced from the statements he has quoted above. The black and the grey crows may really be, therefore, not dimorphic forms of one species, but two distinct species.

The Reviewer.

The Date of Easter.

In your issue of April 5 an empirical formula is given for determining the date on which Easter falls in any year from 1900 to 2100. Having tried the formula for certain years within the limits stated, I find that it fails in the case of 1954. For that year it gives April 25, whereas the correct date is April 18. Perhaps some of your correspondents may be able to explain the cause of the discrepancy.

Alexander D. Ross.

Glasgow, June 1.

Your correspondent is correct in saying that the empirical formula of Gauss for determining the date of Easter gives April 25 for the year 1954, and I must confess my inability to assign a reason for its failure in this particular instance.

Chas. Leigh.

The Victoria University of Manchester, June 12.

Geological Survey of Canada.

In the issue of Nature of April 26, under the heading of "Notes," is a paragraph concerning changes in the organisation of the Geological Survey of Canada. This paragraph is liable to be misleading, and I shall be greatly obliged if you will kindly state the facts as they are. On March 27 last Mr. A. P. Low was appointed deputy head and director of the Geological Survey Department, and, at the same time, Dr. R. Bell simply returned to his former position of assistant-director and chief geologist, to which he had been appointed in 1892.

A. P. Low (Deputy Head and Director).

Geological Survey of Canada, Ottawa, Ontario, May 29.

THE FOSSIL VERTEBRATES OF THE FAYUM.[1]

A few years ago it was the fashion among vertebrate palæontologists to say that, at least so far as the Tertiary period is concerned, the Old World was played out in the matter of their special science, and that the scene of advance was shifted to America, where alone important and epoch-making discoveries were to be expected. All this has been changed by the discovery of the wonderful Lower Tertiary vertebrate fauna—or, rather, series of faunas in the Fayum, or lake-province, of Egypt, which Dr. Andrews (who, we are glad to say, has now the privilege of adding the letters F.R.S. to his name) has so admirably and lucidly described in the handsome quarto volume before us. Indeed, it is not saying too much to assert that these discoveries have practically revolutionised our conceptions of the mutual relationships of several mammalian groups, and also our ideas on many points connected with the past distribution and migrations of the mammals of the Old World. Perhaps the most important problem which Dr. Andrews has succeeded in solving is the origin of the Proboscidea; and if this had been the only result of his labours he would have been well entitled to undying fame. As it is, this discovery is only one of several of the highest importance in regard to mammalian evolution we

[1] "A Descriptive Catalogue of the Tertiary Vertebrata of the Fayûm, Egypt; based on the Collection of the Egyptian Government in the Geological Museum, Cairo, and on the Collection in the British Museum (Natural History), London." By C. W. Andrews. Pp. xxxvii+324; pls. 26, and text-figures. (London: Printed by order of the Trustees of the British Museum, 1906). Price 35s.

owe to him, and in some degree to others who have been working on the extinct Egyptian faunas.

Before proceeding further we may take the opportunity of expressing, on behalf of all palæontologists, our appreciation of the generosity of the Egyptian Government in putting at the disposal of the trustees of the British Museum, for the purpose of this catalogue, the whole of the valuable collection of vertebrate remains from the Fayum preserved in the museum at Cairo. We may likewise respectfully tender to the trustees of the national collection our sense of the benefit they have conferred on science by sanctioning the publication of the work before us. Nor must we omit to mention the name of Mr. W. E. de Winton, who has generously defrayed the expenses connected with some of the visits of Dr. Andrews to Egypt to explore and collect the palæontological treasures of this wonderful district.

It will not be necessary on this occasion to refer in detail to the history of the discovery of fossil vertebrates in Egypt. Suffice it to say that the first discovery was not made by the author of the volume before us, although it appears that he was present when the remains of ancestral proboscideans and other primitive mammals were first brought to light.

With a few unimportant exceptions, the whole of the remains described in the volume were derived from strata of Middle and Upper Eocene age lying on the northern side of Lake Moeris. In the author's opinion it appears that the Fayum strata, as we advance from earlier to later times, were, speaking generally, deposited nearer and nearer to some land-mass.

"In the early Eocene the presence of thick marine beds far to the southward shows that the shores of the Ethiopian continent were still remote from the area now under discussion; and this state of things seems to have continued till the Middle Eocene, as shown by the thick nummulitic beds of the Wadi Rayan series, and the exclusively marine character of the fossils both of those beds, the Ravine beds, and the Birket-el-Qurun series above. In the Qasr-el-Sagha series, on the other hand, there is much evidence that the shore was not far off, the presence of thick beds of clay, often current-bedded and containing numerous impressions of leaves, as well as the occurrence of land-mammals, pointing to this conclusion. In fact, the deposits at this horizon may be regarded as partly marine and partly littoral, there having been many small oscillations of level. In the Fluvio-marine (Upper Eocene) beds above, the near presence of a large land-mass is still more obvious, these deposits being, in fact, almost entirely fluviatile, and probably representing the remains of the delta of a great river which, for various reasons, Mr. Beadnell considers flowed from the south-west. At or near the end of the Eocene period this state of things was interrupted by an outburst of volcanic activity, which gave rise to the interbedded basalt-sheets of the Jebel-el-Qatrani; but after this the fluviatile conditions were again resumed, and appear to have continued with some interruptions throughout the Oligocene, Miocene, and, in part at least, the Pliocene periods. Throughout this vast epoch there seems to have been a general tendency towards a gradual advance of the coast-line northwards, and such interruptions and oscillations as did occur are marked by the presence of interbedded marine, littoral, and perhaps, in a few cases, lacustrine deposits."

Obviously, such a state of things affords just the conditions necessary for the preservation of the remains of a series of faunas, and as a matter of fact such remains have been found in two horizons in addition to those forming the subject of the catalogue.

The mammals may be divided into three groups. First, terrestrial forms, such as ancestral proboscideans, hyracoids, and the remarkable Arsinoitherium which appear to have been endemic to the Ethiopian region, and occur in both the upper and lower beds, and are unknown elsewhere. Secondly, terrestrial types like Ancodon and Hyænodon, represented in other parts of the world, and found only in the upper beds. Thirdly, primitive genera of sirenians and cetaceans, confined to the lower beds, some of which are widely spread, while others are unknown elsewhere and may be endemic. All the genera in the first group are ungulates, and, with one exception, belong to that generalised assemblage frequently known as subungulates.

The most striking of all these wonderful ungulates is undoubtedly the huge and powerfully horned Arsinoitherium (Fig. 2); but interesting as is this creature morphologically it adds but little to our knowledge of mammalian evolution, although there is a possibility that it may prove to be an offshoot from the hyrax-stock. In any case the occurrence of this and several other specialised types at such an early stage is one of the most remarkable features of the Fayum fauna.

Although Arsinoitherium is certainly the most ex-

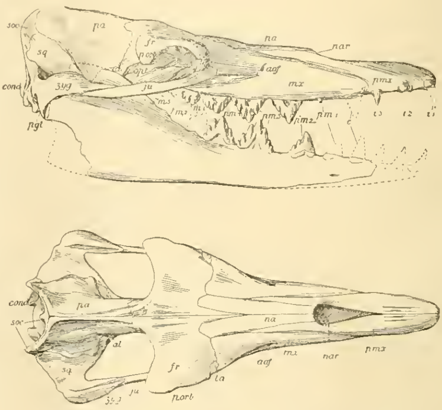

FIG. 1.—Lateral and superior views of the skull of *Prozeuglodon atrox*, a primitive Egyptian Cetacean. The letters refer to the names of the bones; ⅛ natural size. From "The Catalogue of Fayum Vertebrates."

traordinary of the Eocene Egyptian ungulates, it undoubtedly yields place in point of interest to the ancestral proboscideans. The probability that Africa would prove to be the original home of the Proboscidea was suggested, among others, by Prof. H. F. Osborn, who also conjectured that the hyraxes and certain other groups might likewise be of Ethiopian origin. In regard to the two groups mentioned, the truth of this bold prophecy has been fully demonstrated by the discoveries and investigations of Dr. Andrews. Since the evolutionary history of the Proboscidea, as revealed by these discoveries, has already been made familiar to the public in several journals—NATURE among the number—it will be unnecessary to go over the ground again, and it will suffice to mention that in Mœritherium, the earliest known representative of the group, we have an animal but little removed from the generalised common type of primitive ungulates. It may be added that while the Ethiopian origin of the Proboscidea has now been proved, it is nearly as certain that the passage from the mastodons to the elephants took place in south-eastern Asia, or in a lost land between the latter and Africa.

Next, perhaps, in point of interest is the discovery of comparatively giant forms nearly related to the modern hyraxes, which are now as isolated as the elephants. Unfortunately, these Eocene hyraxes—Saghatherium and Megalohyrax—throw little or no light on the ancestry of the group, although serving to show that it was certainly Ethiopian in origin. Whether certain Tertiary South American ungulates are related to the group is left by the author an open question.

Of not less importance are the discoveries and conclusions with regard to the origin and relationships of that isolated aquatic group of mammals now represented by the manatis and dugongs. On this point the author remarks that there seems to be much evidence in favour of the original view of de Blainville that the Sirenia are intimately related to the Proboscidea.

"In the first place, the occurrence of the most primitive Sirenians with which we are acquainted in the same region as the most generalised proboscidean Mœritherium is in favour of such a view, and this is further supported by the similarity of the brain-structure and, to some extent, of the pelvis in the earliest-known members of the two groups. Moreover, in the anatomy of the soft-parts of the recent forms there are a number of remarkable points of resemblance. Among these common characters may be noted the possession of: (1) pectoral mammæ; (2) abdominal testes; (3) a bifid apex of the heart; (4) bilophodont molars with a tendency to the formation of an additional lobe from the posterior part of the cingulum. The peculiar mode of displacement of the teeth from behind forwards in some members of both groups may perhaps indicate a relationship, although in the case of the Sirenia the replacement takes place by means of a succession of similar molars, while in the Proboscidea the molars remain the same numerically, but increase greatly in size and number of transverse ridges."

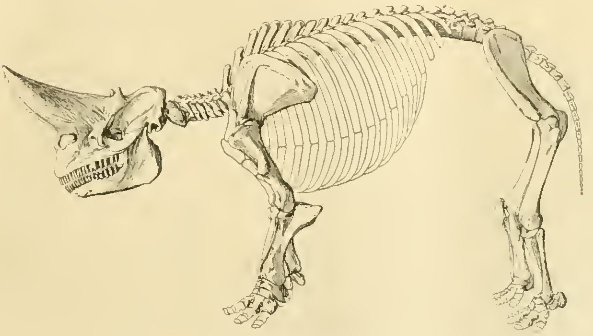

FIG. 2.—Skeleton of *Arsinoitherium zitteli*, $\frac{1}{32}$ nat. size. From "The Catalogue of Fayum Vertebrates"

These and certain other facts referred to by the author in a later paragraph point very strongly to the conclusion that not only are the Sirenia and the Proboscidea derived from a single ancestral stock, but that the Hyracoidea—and so Arsinoitherium—are also derivatives from the same stock, which must necessarily have been Ethiopian.

While thus definitely establishing the herbivorous ancestry of the Sirenia, Dr. Andrews appears to be equally convinced that the Cetacea (as, despite views to the contrary that have been expressed, we should naturally expect) are derivatives from a carnivorous ancestral type. On the evidence of specimens obtained from another part of Egypt, Dr. E. Fraas, of Stuttgart, has demonstrated the derivation of the whale-like Zeuglodon (Fig. 1) from that group of primitive carnivora known as creodonts. Dr. Andrews not only brings forward additional evidence in favour of this most remarkable line of descent, but he is confident—which Prof. Fraas was not—that Zeuglodon itself is an ancestral cetacean, and consequently that whales are the highly modified descendants of creodonts. It must be admitted, however, that the links between Zeuglodon and typical cetaceans are at present unknown; but it may be hoped that these will be eventually brought to light from the deposits of the Mokattam Range.

Of the other classes of vertebrates represented in the Fayum series we can say but little. Reference should, however, be made to the occurrence of a presumed ratite bird, which if rightly identified is the earliest known representative of the group, and suggests the Ethiopian origin of some members at least of the ostrich group in Africa. Such an ancestry, as the author remarks, would explain the resemblance existing between the true ostriches and the extinct Æpyornis of Madagascar, and might likewise serve to connect the former with the South American rheas.

Giant land tortoises are likewise proved by the Fayum discoveries to have occurred in this part of the world at a much earlier date, so far as is known, than elsewhere, and it is noteworthy that the extinct Egyptian species are near akin to the recent Mascarene and Malagasy forms. The association of tortoises belonging to the pleurodiran section, now confined to the southern hemisphere, is another fact of prime importance, as tending to throw light on the dispersal of that group and the former relations of the southern continents.

With regard to the latter point, Dr. Andrews comes to the conclusion that the new facts fully endorse the theory of a former land connection between Africa and South America. "Speaking generally, it appears that (1) probably in Jurassic times Africa and South America formed a continuous land-mass; (2) in the Cretaceous period the sea encroached southwards over this land, forming what is now the South Atlantic. How far this depression had advanced southwards at the end of the Secondary period is not clear, but it appears certain that the final separation of the two continents did not take place till Eocene times, and that there may have been a chain of islands between the northern part of Africa and Brazil which persisted even till the Miocene."

It will thus be apparent that from whatever point of view we regard the Eocene vertebrate fauna of the Fayum—whether from the morphological, the phylogenetic, or the distributional—it is practically impossible to overestimate its extreme importance. When we reflect that what has been discovered can only be the mere fringe of a most extensive Eocene and Upper Cretaceous Ethiopian fauna we shall be in a position to realise what a great part Africa has played in the past as a birthplace and centre of dispersal of mammalian groups, and how profoundly even the present discoveries have modified our conceptions of the past history of the mammalia and of the globe in general.

After a careful study of the volume before us, we have found no occasion for a single word of hostile criticism. The author knows his subject from every possible point of view in a most thorough manner, and has treated it in a thoroughly philosophic way from first to last, while the introduction is written in a style that will appeal to the general reader as well as to the specialist. It is, perhaps, not too much to say that it is the most important contribution to mammalian palæontology that has ever appeared within our own recollection on this side of the Atlantic, and if the twentieth century were to see no other work on mammals—either recent or fossil—it would still have a vast achievement to its credit. R. L.

THE CALIFORNIAN EARTHQUAKE OF APRIL 18.

THE accounts which are reaching this country enable us to form a better idea of the character of the Californian earthquake of April 18 last than could be done from the telegraphic reports of the daily papers, and one of the most striking facts which stand out is the wonderfully small amount of damage done in San Francisco by the earthquake proper. This does not seem to have exceeded the sixth or seventh degree of the Rossi-Forel scale, and the damage to buildings was practically confined to the overthrow of chimneys and of buildings which were either old and badly constructed, or of a design which rendered them especially liable to earthquake damage. The *Scientific American* of May 12 contains a view of the business part of the city, taken after the earthquake, but before the spread of the fire, in which the buildings show little signs of damage, beyond the overthrow of some of the chimney stacks. Where the city was built on made ground settlements and disturbances of ground level led to fractures of the water-mains, but it is not clear from the accounts which have reached us whether there was not also an interruption of the main conduit at some point between the city and the source of supply. Whatever the cause, the consequences of the failure of water were disastrous, and the fire, started by the earthquake, was able to spread unchecked.

FIG. 1.—The Burning of the Business District of San Francisco after the earthquake on April 18. From the *Scientific American*.

Apart from the loss of buildings and lives, San Francisco has lost its most important libraries and scientific collections; the Bancroft library of books and manuscripts relating to the history of the Pacific coast has been saved, as have most of the type-specimens of plants in the collection of the Academy of Sciences, but that is practically all. On the other hand, the Lick Observatory and the University of California have escaped damage, and the working part of the Leland-Stanford University has escaped the complete destruction which has been the fate of the memorial buildings of that institution.

The area over which the earthquake did serious damage was confined to a narrow strip of country extending from the town of Ukiah, on the Russian river, to the town of Salinas, near Monterey Bay. Beyond these limits the country is sparsely settled and may have been vigorously shaken without the fact being reported, but the limits indicated lie about 205 miles apart, or 125 miles north and 80 miles south of San Francisco; within this strip the damage was very capriciously distributed, and died out rapidly to the east and westwards; at Berkeley town many buildings were ruined, but the University of California escaped; San Jose was partly ruined, and most of the buildings of the Stanford University, at Palo Alta, were destroyed, but the Lick Observatory, about fifteen miles to the eastward, was uninjured, nor is any serious injury reported from the towns on the coast. These peculiarities in the distribution of the earthquake damage are explained in an article on the probable cause of the San Francisco earthquake by Mr. Frederick Leslie Ransome, published in the May number of the *National Geographic Magazine*. The article is illustrated by a very clear structural map of the San Francisco peninsula, and an equally clear description of the structural conditions of the region. Probably nowhere in the world have greater displacements taken place in geologically recent times than this district has witnessed; strata of Quaternary age have here been compressed, contorted, and lifted from 1500 to 2000 feet, and right through the peninsula run three nearly parallel faults, two of which, the Pilarcitos and San Andreas faults, are marked by lines of pools and lakes, proving the recent date of the disturbance to which they owe their origin. The third fault, known as the San Bruno fault, is the most important of the three; it has a throw of more than 7000 feet near San Francisco, and has been traced, with more or less certainty, from Point Arenas, 100 miles to the north-west, through Southern California, where it is known as the "earthquake crack," almost to the Gulf of California. A movement along this fault, and others parallel to it, appear to have been the cause of the earthquake, or at any rate of the curious localisation of damage noticed above. The San Bruno fault passes close to the Stanford University and to the city of San Jose, and crosses the main line of water-supply from the Crystal Springs reservoir to the city of San Francisco; it is, presumably, along this fault that the displacement reported in the newspapers took place. There are indications, too, of another fault running along the eastern margin of the bay through Santa Rosa and north-westwards along the valley of the Russian river past Ukiah, which may have been concerned in the violence of the earthquake at those places.

Two other articles in the same magazine deal with the times at which the disturbance was recorded by seismographs. From them we gather that the shock was recorded on a self-registering seismograph in the University of California at 5h. 12m. 38s. a.m. Pacific time, equivalent to 1h. 12m. 38s. p.m. Greenwich time. The seismograph of the United States Weather Bureau at Washington, 2435 miles distant from San Francisco, recorded the commencement at 8h. 19m. 20s. eastern time, corresponding to 1h. 19m. 20s. Greenwich time, and the seismographs of the United States Coast and Geodetic Survey at Sitka, Alaska, and Cheltenham, Maryland, also recorded the shock, commencing at 1h. 16m. 56s. and 1h. 19m. 24s. respectively, the distances from San Francisco being 1455 and 2450 miles. The magnetographs at these two places and at Baldwin, Kansas, were also affected by the passage of the earthquake waves, the times corresponding approximately with those of the arrival of the principal, or third, phase of the disturbance.

FIG. 2.—Map of the San Francisco Peninsula. From the model by Prof. A. C. Lawson. The principal faults are indicated by heavy black lines. From the *National Geographic Magazine*.

THE FORTHCOMING MEETING OF THE BRITISH ASSOCIATION AT YORK.

THE arrangements for this meeting, which will be held from August 1 to August 8, are very well in hand, being at least a month in advance of what they were twenty-five years ago, on the occasion of the jubilee meeting—one of the most successful ever held. The local fund now reaches more than 3000*l.*, and the greater part having been already paid up, the fund has been closed. The various committees are meeting regularly, secure good attendance, and the greatest interest and enthusiasm prevails. One of the local secretaries, Mr. Dale, having died, Mr. Henry Craven, who has succeeded him in the office of town clerk, has been appointed his successor.

The following is an epitome of the general attractions included in the programme:—

Wednesday, August 1.—The Lady Mayoress (Mrs. R. H. Vernon Wragge) will be "At Home" at the Mansion House from 3 p.m. to 6 p.m. to receive foreign visitors, members, associates, and lady ticket-holders. President's address in the exhibition buildings at 8.30 p.m.

Thursday, August 2.—The Sheriff of York and Mrs. Bentley will give a garden-party at their residence, Fulford Grange, to all ticket-holders, from 3 p.m. to 6 p.m. Conversazione in the exhibition buildings, by invitation of the executive committee, at 8 p.m. Music will be provided in the museum gardens, which communicate with the building and will be illuminated.

Friday, August 3.—Messrs. Rowntree and Co. will give a garden-party at their works, Haxby Road, to all ticket-holders, from 3 p.m. to 6 p.m. The works will also be open. Discourse on volcanoes, by Dr. Tempest Anderson, in the exhibition buildings at 8.30 p.m.

Saturday, August 4.—The Archbishop of York and Mrs. MacLagan will give a garden-party at the Palace, Bishopthorpe. Evening lecture to the operative classes by Prof. Silvanus Thompson, F.R.S., on the manufacture of light. The president, Prof. Ray Lankester, will take the chair.

Sunday, August 5.—Special service in the Minster.

Monday, August 6.—The council of the Yorkshire Philosophical Society will give a garden-party in the museum grounds, to all ticket-holders, from 3 p.m. to 6 p.m. They have also intimated that the museum and grounds will be open daily to all members and ticket-holders who wish for a quiet resting-place. The president of the society, Dr. Tempest Anderson, will entertain to tea those who attend each afternoon. Discourse on the electrical signs of life, and their abolition by chloroform, by Dr. A. D. Waller, F.R.S., in the exhibition buildings, at 8.30 p.m.

Tuesday, August 7.—The Dean of York and the Canon in Residence will give a garden-party, to all members and ticket-holders, in the Deanery and residentiary grounds, from 3 p.m. to 6 p.m. Conversazione in the exhibition buildings, by invitation of the executive committee, at 8 p.m. Music will be provided in the museum gardens, which will be illuminated.

Wednesday, August 8.—Meeting of general committee to receive the report of the committee of recommendations, 1 p.m. Concluding general meeting, in the Guildhall, at 2.30 p.m.

It is understood that a large number of important papers has been already promised, and it will be noticed that an unusually attractive series of garden-parties and receptions has been provided. In fact, the number offered has been so large that several very eligible offers of hospitality have had to be reluctantly declined. Practically all the principal residents in York and the neighbourhood have invited members of the association for the time of the meeting, besides a large number of private friends, who will swell the lists of members and associates attending.

The proposed excursion to Norway at the close of the meeting has fallen through, as little interest or support seemed forthcoming. The excursions will therefore be confined to Saturday, August 4, and the following have been definitely fixed:—

Scarborough and Whitby, stopping at Castle Howard.—The Mayor of Scarborough has intimated that he will be "At Home" to a limited number of those taking part in the excursion. Permission has been granted to view the Marine Drive, and the members and associates will be admitted to the Spa on the production of their tickets. It has also been arranged that the train shall stop at Castle Howard to enable any members to pay a visit, but it is understood that only a portion of the house and gardens will be available.

Harrogate, Brimham Rocks, and Pateley Bridge; conductor, Mr. W. Ingham.

Ripon, Studley Park, and Fountains Abbey.—The Marquess of Ripon has kindly promised to entertain a party of about 100 to luncheon, and the Mayor of Ripon will entertain the same party to tea.

Ilkley and Bolton Abbey.

Coxwold, Byland Abbey, Helmsley, Duncombe Park, and Rievaulx Abbey.—It is expected that the party will be entertained at Duncombe Park by the Earl of Feversham; conductor, the Rev. C. N. Gray.

Wensleydale; conductor, Mr. W. Horne.

Mount Grace, Guisborough, and Whorlton Castle.—Admiral Challoner has kindly invited the party to dinner, and it is expected that the Lord-Lieutenant of the North Riding will provide luncheon; conductor, Mr. F. J. Munby.

Driffield, Kirkburn, Wetwang, &c.; conductor, the Rev. E. Maule Cole.

Aldborough and Boroughbridge.—Three steam launches have been engaged to convey the party; conductor, Mr. A. S. Lawson, who will provide luncheon and tea.

A small guide-book will be prepared for each of the above excursions. It is understood that there will be also the usual semi-private excursions arranged in connection with several of the sections.

The exhibition of South African photographs taken by the members last year promises to be of much interest. There is ample accommodation for it at the reception room, and an active committee has the matter in hand.

KEW PUBLICATIONS.

THE "miscellaneous information" supplied from the Royal Gardens at Kew has ever been welcome to botanists and to those concerned in the utilisation of vegetable products. The earlier publications of Sir William Hooker and of his son and successor, Sir Joseph Hooker, are full of interesting matter with which the botanical and horticultural Press of the day was, owing to limitations of space, hardly able to cope.

Of late years such was the pressure of administrative duties that the publication of the Bulletin became very erratic. So much was this the case that we had almost given up the hope of seeing anything but "appendices" to volumes that seemed never destined to appear. In this we were mistaken. Within the last month or two we have received for notice the Kew Bulletin for the years 1900, 1901, 1902, 1903, 1904, and 1905.[1]

Some of these volumes are of exiguous proportions, but there they are, and the troubles of librarians and bibliographers are, in so far, set at rest. Much of the information is, of course, far from being up to date, and in some cases the gentlemen mentioned as having been appointed to fill certain positions have paid the debt of Nature before their nomination has thus been made public.

In spite of these circumstances we can but rejoice that the publication has been resumed, and that the sequence of the volumes is no longer interrupted. The contents are so "miscellaneous" that they do not lend themselves to anything like systematic review. We can only put the books on our reference shelves and welcome the fact, not only that the old gaps are, to some extent, filled up, but that there is now every prospect of the regular issue of that Bulletin to which we look for an official record of the manifold and most important work done at Kew.

A "Catalogue of Portraits of Botanists Exhibited in the Museums of the Royal Botanic Gardens, Kew," by Mr. James D. Milner, clerk and acting assistant-keeper and secretary to the National Portrait Gallery, has also just been published. The catalogue is introduced with a preface by the late director of the Royal Gardens. To botanists it forms a very interesting, but, we must add, a very incomplete list. Kew probably possesses a much larger number of portraits than are here mentioned, so that it is difficult to understand on what principle the selection has been made. The words "exhibited in the museums" do indeed imply that there are other portraits not thus displayed, but unless we are mistaken, or unless some re-arrangement has taken place recently, there are not a few hanging on the walls of the museums which are not included in the list. At any rate, we look in vain for any mention of the Balfours, father and son, of John Ball, of Broome, Babington, B. C. Clarke, Casimir de Candolle, W. T. Thiselton-Dyer, Eichler, Engler, A. Dickson, Farmer, Gardiner, Munro, Miers, Prain, Reichenbach, Seemann, Williamson, and many others whom it would be tedious to enumerate. No doubt many of these are "kept in portfolios," and can be inspected on application, but the absence in the catalogue before us of even the names of these more or less distinguished botanists gives an impression of serious incompleteness which is probably not justified by the facts. This is the more unfortunate as the collection is stated to be "probably unique." If so, the catalogue is very inadequate, as may be seen, not only by the few illustrations we have cited, but also by comparison with Dr. Wittrock's much fuller "Catalogus Stockholmiensis." The text, too, requires revision. In one place we are told of a bust wearing spectacles, and of another bust "in a ruff and fur-lined coat." On another page we are told of a botanist who graduated eighteen years before he was born!

There are other indications of imperfect proof-reading, to which we direct attention in the hope that the defects may be remedied in a subsequent edition. The catalogue, even in its present condition, is of such great interest that we cannot doubt that no long time will elapse before a second edition is called for, and one which can readily be made more representative of the progress of botany, especially in our own country.

[1] "Bulletin of Miscellaneous Information." Royal Botanic Gardens, Kew. (H.M. Stationery Office, 1900–05.)

BARON C. R. VON DER OSTEN SACKEN.

SYSTEMATIC entomology has sustained a great loss by the death of Baron Osten Sacken, as announced in NATURE of May 31.

Baron Osten Sacken was born at St. Petersburg on August 21, 1828, and at the age of eleven his interest in entomology was aroused by his meeting, at Baden-Baden, a young Russian entomologist, Mr. Shatiloff, who gave him his first instructions in collecting Coleoptera. Between 1849 and 1856 he held an appointment in the Imperial Foreign Office, and published papers on the re-classification of the Tipulidæ, as well as a list of the insects of the St. Petersburg district excluding Lepidoptera. His appointment, in 1856, as secretary of the Russian Legation at Washington opened up the second period of his entomological career in the United States. In 1862 he was appointed Russian Consul-General at New York, a post which he resigned in 1871, remaining, however, in America until 1877.

During this period of twenty-one years the main part of Baron Osten Sacken's entomological work consisted in working up the Diptera of North America, in close collaboration with Dr. H. Loew. This work had for its main object the compilation of a catalogue of North American Diptera of which a first edition was published as early as 1858 by the Smithsonian Institution. It was superseded by a far more complete second catalogue published twenty years later. A great deal of further time was taken up with the self-imposed and, at times, somewhat tedious task of editing and translating Loew's monographs, and, in addition, important papers were published on the Tipulidæ, Tabanidæ, Cecidomyidæ, and Cynipidæ. Between 1871 and 1873 some time was spent in Europe, and in 1876 an expedition was made to California the results of which were published under the title "Western Diptera" in the Bulletin of the U.S. Geological and Geographical Survey. Eleven new genera and 137 new species were described.

In 1877 Baron Osten Sacken came to Europe, and took up his abode at Heidelberg The present writer first met him there in the summer of 1877, and, being greatly interested in entomology as a hobby, a close friendship sprang up, which soon became a friendship for life. In the years which followed and which constituted the third period of his entomological career, Baron Osten Sacken published numerous critical papers on Diptera, and increased the number of his published writings from 53 to 179. In 1881 he published "An Essay on Comparative Chætotaxy," in which it was shown for the first time that the arrangement of the bristles on the bodies of Diptera afforded a valuable aid to their classification. In 1892 he published one of his most important papers, on the characteristics of the three divisions of Diptera, *Nemocera vera*, *Nemocera anomala*, and Eremochæta, in which two important innovations were introduced, one referring to the preservation of the distinction between the Brachycera and Nemocera, the other to the grouping of the families of Diptera into larger groups, for which he subsequently adopted Comstock's name of "Superfamilies."

The "Bugonia" superstition of the ancients regarding the production of bees from the carcases of dead animals found a ready explanation at Baron Osten Sacken's hands in the close resemblance to a bee of the common drone-fly, *Eristalis tenax*, the larvæ of which live in putrescent matter. In the paper, first published in commemoration of the twenty-fifth anniversary of the Italian Entomological Society in 1893, and afterwards amplified and printed at Heidelberg, Baron Osten Sacken traces in detail the history of the Bugonia in different ages and nations.

His last important task was to publish a "Record of My Life-work in Entomology," which he concluded in 1904, to quote his own words, "at the age of seventy-six, in good health, and with unimpaired eyesight."

Baron Osten Sacken took great delight in everything connected with mathematics, especially historical points, and the present writer has an early recollection of a question he proposed relating to the conchoid of Nicomedes. In his later years he made a collection of photographs of paintings of the great masters, and it gave him pleasure to arrange and classify them with the same systematic attention to minute detail that he had so successfully brought to bear on the classification of the Diptera. In his manner of living he was equally methodical, and this spirit is shown in the publication of his "Record." His interest in the work of others won for him many friends, who will greatly miss him. He has given us an excellent example of what can be done by a man who cultivates some branch of science for its own sake, and who is not debarred by pressure of professional duties from making the study his life-work. For such workers, biological rather than physical subjects in many cases offer the most promising field.

G. H. Bryan.

NOTES.

Prof. G. von Neumayer, who celebrates his eightieth birthday to-day, will receive the congratulations of many meteorologists and other scientific workers. Nearly a year ago the first part of a third revised edition of instructions and notes on scientific observations for travellers, edited by him under the title "Anleitung zu wissenschaftlichen Beobachtungen auf Reisen," was published, and the last part appeared very opportunely a few days ago. The work has been brought up to date, and is of such a comprehensive nature that justice cannot be done to it in a hurried notice, but we hope to deal with this important contribution to scientific literature in a future issue.

Mr. W. de Fonvielle informs us that Mr. W. Wellman and his balloon—the *United States*—have left Paris for Spitsbergen by way of Antwerp, where the balloon was shipped to Tromsö, and from there to Magdalena Bay, lat. 79° 40′ N. (Danes Island). The last part of the voyage will be executed on board the *Fritjof*, a steamer put at the disposal of the explorer by the American Government. Mr. Wellman hopes to be in Tromsö before June 25, and at Danes Island on July 1. There he will find everything ready for the inflation of his large balloon, measuring 6300 cubic metres, and having a gross lifting power of 7000 kilograms. The necessary preparation will be made by Major Hearsey, of the U.S. Weather Bureau, who left Paris a month ago in order to erect at Danes Island a shelter where the balloon may be housed during the preliminary experiments, which are expected to occupy the whole of July. It is only in August that the departure for the Pole is to take place, if the experiments have proved satisfactory and have been concluded. Mr. Wellman is travelling with Mr. Collardeau, a French chemist, and Mr. Hervieux, a French aëronaut, who is to be the pilot of the polar balloon. In addition to Mr. Wellman, the balloon will have on board Major Hearsey, Mr. Hervieux, and two Norwegian sailors who assisted him in his two previous explorations. A wireless telegraphy system will be established between the two stations of Tromsö and Danes Island. A meteorological station will also be established at the same places, supplied with a captive balloon for obtaining records of the temperature, humidity, direction and force of the wind in the free atmosphere. So for the first time since telegraphy (wire) was utilised in meteorology, American and European meteorologists will have at their disposal observations of the weather in the neighbourhood of the North Pole as well as from tropical stations.

The second of the two annual conversaziones of the Royal Society was held as we went to press last night.

Mr. W. R. Cooper has accepted the position of editor of the *Electrician* in succession to Mr. F. C. Raphael, who will retire on June 30.

It is stated by the *British Medical Journal* that the institute for the experimental investigation of cancer at Heidelberg is now complete. Prof. Czerny is the director; Dr. von Dungern has been appointed head of the scientific department, and Dr. von Wasielewski head of the department of parasitological research.

We learn from *Science* that Mr. George Eastman, of Rochester, N.Y., has subscribed 200*l.* annually for the next three years to enable the continuance of research work in photography at the Yerkes Observatory of the University of Chicago. The investigations will be carried on by Mr. R. James Wallace, photophysicist at the observatory.

The death is announced, in his eightieth year, of M. Edouard Piette, the distinguished archæologist. M. Piette was well known for his discoveries of prehistoric remains, among which may be mentioned those in the caverns of Mas d'Azil (Ariège) and of Brassempouy (Landes). Before his death M. Piette presented his invaluable collections to the Museum of Saint-Germain-en-Laye.

H.M. the Queen has extended her patronage to the "Country in Town" Exhibition which will be opened by H.R.H. Princess Christian in the Whitechapel Art Gallery on July 5. The exhibition will be open until July 19, and as admission will be free, contributions are invited towards the necessary expenses. All communications should be made to the honorary secretary, Mr. Wilfred Mark Webb, at Toynbee Hall, Whitechapel, E.

The *Times* correspondent reports that Dr. Calmette and M. Guérin, of the Pasteur Institute, Lille, have communicated to the Paris Academy of Sciences the results of experiments on protective inoculation against tuberculosis. Having found that dead tubercle bacilli are carried from the digestive tract to distant parts of the body, they made experiments in order to ascertain the immunising effect of dead tubercle bacilli administered in this manner. Young animals, heifers and kids were given by the mouth two doses, with a forty-five days' interval between, of 5 and 25 centigrams of dead tubercle bacilli (or even living bacilli of feeble virulence). A subsequent lethal dose of virulent tubercle bacilli proved innocuous to the animals treated in this way, showing that the dead bacilli had produced an immunity against the living virulent bacilli. Dr. Calmette and M. Guérin conclude that young cattle can be vaccinated by intestinal absorption of bacilli modified by heat, and that this method of vaccination is entirely without danger.

The council of the Society of Arts has awarded the society's silver medal to the following readers of papers during the session just completed:—Mr. W. F. Mitchell, The commerce and industries of Japan; Dr. William Arthur Aikin, Aspects of voice development; Mr. Leon Gaster, Progress in electric lighting; Mr. Walter Garstang, The fisheries of the North Sea; Captain G. S. C. Swinton, London traffic; Mr. Bernard B. Redwood, Motor boats; Mr. J. B. Millett, Submarine signalling; Prof. Thomas Oliver, Bridge building by means of caissons; Mr. Clayton Beadle, Watermarking; Sir James A. Bourdillon, K.C.S.I., The partition of Bengal; Dr. George A. Grierson, The languages of India; Colonel Sir Arthur Henry McMahon, K.C.I.E., Seistan; the Hon. Rodolphe Lemieux, K.C., French Canada; the Hon. J. G. Jenkins, Social conditions in Australia; Mr. Louis N. Parker, Historical pageants; Mr. H. Yates Thompson, Illuminated manuscripts; and Mr. Harry Powell, Cut glass.

The death of Herr Eduard von Hartmann is announced from Berlin. Born in 1842, he was intended for a military career, but retired from service in 1865 owing to a malady of the knee which made him a cripple for life. He received the degree of Doctor of Philosophy from Rostock University in 1867, and two years later published "The Philosophy of the Unconscious," the work on which his reputation chiefly rests. A very voluminous writer—his works contain upwards of 12,000 pages—he published, among other writings, "Phenomenology of Ethical Consciousness" in 1879, "The Religious Consciousness of Mankind in the Stages of its Development" in 1881, and "The Religion of the Spirit" in 1882. About three or four years ago there appeared "Die Weltanschuung der modernen Physik," one of the most important of his later works. His system was an amalgamation of Schopenhauer's doctrine of will with the metaphysic of Hegel, and the "Unconscious" which formed his first principle was but another name of the absolute of the German metaphysicians. "According to von Hartmann," writes one authority, "the Unconscious is the absolute principle active in all things, the force which is operative in the inorganic, organic and mental alike, yet not revealed in consciousness. It is the unity of unconscious presentation and will, of the logical (idea) and the alogical (will). The Unconscious exists independently of space, time and individual existence, timeless before the being of the world. For us it is unconscious, in itself it is super-conscious." The Schopenhauerian side of von Hartmann appealed to the prevailing pessimism of the time, but he himself was no pessimist; full of vigorous ethical feeling, and a strong opponent of the prophets of the *Weltschmerz*, he contributed not a little to the discussion of political and social subjects.

The Society of German Engineers, which with its 20,000 members is now the largest technical society in the world, celebrated on June 11–14 the completion of the fiftieth year of its existence. The opening ceremony was held in the Reichstag building in Berlin, under the presidency of Dr. A. Slaby. Congratulatory addresses were delivered by the Prussian Home Secretary, the Prussian Minister of Education, the Oberbürgermeister of Berlin, and the rector of the Berlin Technical School, as well as by numerous representatives of kindred societies in Germany and other countries, Mr. Bennett Brough (Iron and Steel Institute) speaking for the British societies and Prof. K. E. Hilgard (American Society of Civil Engineers) for the American. The proceedings terminated with a lecture by Dr. W. von Oechelhaeuser on technical work past and present, in which he compared the engineering works of the ancients with those of modern times, and endeavoured to forecast what the future of engineering would be. On June 12 a lecture was given by Dr. A. Riedler, on the development and present importance of the steam turbine; and on June 13 papers were read by Prof. Muthmann, on methods of dealing with atmospheric nitrogen; and by Dr. Hoffmann, on the utilisation of power in mines and metallurgical works. Throughout the week an elaborate programme of visits, excursions, and social functions was arranged for the 1231 members and 464 ladies who took part in the meeting. The German Emperor honoured the society by accepting the Grashof gold medal, and by conferring decorations on the president and other prominent members. An interesting history of the society is given in *Engineering* of June 8. The growth of the society has certainly been remarkable. It was founded in 1856 at Alexisbad, in the Hartz, by twenty-three young engineers. Friedrich Euler was elected the first president, and Franz Grashof the first secretary and editor, the work of the society being carried on in the secretary's private study. The society now has a stately house of its own and a staff of forty-seven officials. Its weekly journal last year cost 26,162*l.* for publishing and 6425*l.* for postage.

THE fourth part of vol. xxvi. of Notes from the Leyden Museum is devoted to invertebrates, more especially crustaceans and insects, Dr. van der Weele contributing three papers on Neuroptera, Mr. C. Ritzema one on a new Sumatran beetle, while Dr. de Man discusses and figures certain crustaceans of the genus Palæmon.

HUNTED for four months in the year over a great part of England, and almost everywhere shot and trapped on every possible occasion, the otter, observes Mr. J. C. Tregarthen in a delightful article in the June number of the *Monthly Review*, yet manages to survive in the British Isles in a manner and in numbers which are truly surprising. The fox, were he not rigorously protected, would disappear from the greater part of England in a very few years, and yet the otter, without the aid of any protection and despite unremitting persecution, continues to flourish in our midst, and this, too, in face of the fact that the female breeds only once a year, and then gives birth to but three or four cubs. The fact that he is here to-day and gone to-morrow—maybe a score of miles away—is, in the author's opinion, the reason of the otter's success in life. It will be news to many of our readers that there are no less than twenty packs of otter-hounds in England and Wales; and now that most of the "methods of barbarism" have been abolished, the author enters a vigorous protest against the attempts of "grandmotherly legislation" to abolish an ancient and exciting sport.

EXTRACTS from two letters written by Mr. T. R. Bell in 1903 and 1904 from India concerning certain butterflies in that country form the most generally interesting portion of the contents of the June number of the *Entomologist's Monthly Magazine*. Special stress is laid by the writer on dimorphism in these insects due to the time of year at which they were developed, the dry-season imagos, owing to what may be described as practical starvation, differing in many cases very markedly from the well-fed wet-season forms. On such differences several nominal species have been founded. Very noteworthy is the fact that in species of the same genus the differences between the dry and the wet forms frequently take quite different lines. "Ocellation" on the under-side of the wings appears, however, to be a distinct character of the wet forms. In breeding certain butterflies, such as some of the "blues," at Kanara it was noticed that males and females came out in equal numbers, whereas in a state of nature the latter are scarcely ever seen, or if observed are found in thick underwood, while the males bask in the open sunshine.

THE *Museums Journal* for May contains the report on the discussion following the papers on the relation of provincial museums to national institutions read at the Museums Association Conference at Worcester last year. The points for discussion ranged themselves under two main headings:—(1) that museums should be taken over by Government, and "run" practically without local assistance; and (2) that all important specimens should go to a national collection. The first proposition met with a direct traverse in one of the papers read, the author of which urged that museums get on much better in proportion as they are independent of Government aid. As regards the second point, which, in the case of zoological museums, related mainly to type-specimens, the question was raised as to the proper places of deposition for such specimens. Should, for example, Indian types go to Calcutta and American to New York, or, on the other hand, should types described in England be placed in the British Museum and those named in America be transferred to New York or Chicago, and so on? Incidentally, it was mentioned that if a national collection received such a valuable augmentation it ought to do something in return, and it was accordingly suggested that the British Museum should start a zoological loan collection. No definite motion was agreed to on any one of these points.

A NEW salamander from North Carolina, remarkable for its brick-red legs, which contrast with the leaden hue of the body, is described in No. 1457 of the Proceedings of the U.S. National Museum by Dr. Stejneger under the name of *Plethodon shermani*. New crickets and leaf-winged grasshoppers, or "katydids," from Costa Rica form the subject of No. 1459 of the same serial, the author being Mr. J. A. G. Rehn. A species of Mimetica has the

FIG. 1.—*Mimetica crenulata*, lateral view of type.

"tegmina," or front wings, of the usual dried-leaf type, and of a form which defies description, although well shown in the accompanying illustration. In part 1458 of the same serial Mr. C. D. Walcott resumes his account of the Cambrian faunas of China, basing his observations on new material. It is anticipated that a fully illustrated report on the subject will be published before the close of the present year.

THE June number of the *Popular Science Monthly* contains several articles of great interest to biologists and geologists. Dr. D. S. Jordan has some suggestive observations on variation in animals and plants. He points out, for instance, that in many cases adaptive characters are older than non-adaptive, as exemplified by the fact that flying-fish flew before the differentiation of the existing genera. Mutation—or saltation, as he prefers to call it—is regarded as only an extreme development of individual fluctuation, the author adding that "while saltation remains as one of the probable sources of specific difference, its actual relation to the process of species-forming in nature remains to be proved." Prof. Carl Eigenmann's article on the fresh-water fishes of South and Central ("Middle") America is worthy of the best attention of all interested in zoological distribution. The leading features brought to notice are:—(1) the variety of the fish-life in tropical South America; (2) the paucity of family-types contributing to this variety; (3) the poverty of the Central American fish-fauna and its essential South American character, except for (4) the isolation of the fauna of the Mexican plateau; (5) the poverty of the Pacific slope fish-fauna and its essentially Atlantic type; (6) the "marine" character of the fishes of Lake Titicaca; (7) the poverty of the Patagonian fauna and its essential distinctness from that of Brazil; and (8) the similarity between the fish-fauna of tropical America and that of tropical Africa. As regards the latter point, the author observes that "a land-connection, whether a land-bridge, intermediate continent, or land-wave, between the two continents is imperative. This land-connection must have existed before the origin of existing genera and before many of the existing families."

As a result of visiting several of the more important herbaria in Europe to study the genus Eupatorium and several allied genera, Mr. B. L. Robinson has published some notes on the Eupatorieæ in the Proceedings of the American Academy of Arts and Sciences, vol. xlii., No. 1. In addition to the diagnoses of new species of Eupatorium and other genera, the pamphlet contains revisions of the genera Piqueria and Ophryosporus, also a discussion of the genus Helogyne.

A SUGAR experiment station was instituted in Jamaica in April, 1904, under the direction of Mr. H. H. Cousins, for investigating problems in connection with the sugar and rum industries. The report for 1905 indicates what is being done in the matter of cultivation experiments to test different manures and varieties and to select new seedling canes. The advantage to be gained by taking new varieties into cultivation is well shown by the results obtained on the Albion Estate, where the Mt. Blanc variety generally grown produces less than any other variety tested, and furnishes less than half the saccharose yield per acre of the seedling B 379.

AN inquiry into the manufacture of Jamaica rums, by Mr. C. Allan, occurring in the above report, deals with fermentation changes, more especially those that give the quality to *flavoured* rums. It appears that the flavour is due mainly to the large amount and nature of the ethers formed. Premising that the characteristics of Jamaica rum are derived from saccharine liquors rich in albuminous matter fermented by yeasts and bacteria, in the case of the high-flavoured rums bacterial action is greatly increased and special bacteria are developed, producing acids that in combination with alcohol form aromatic ethers. It is suggested that higher alcohols, furfurol, and aldehydes may help to give *body* to the spirit.

IN a paper read before the National Academy of Sciences, U.S.A., on April 17, the distinguished seismologist Major C. E. Dutton discusses the possible relationhip between volcanic action and radio-activity. The theory brought forward is that, in limited tracts at depths of less than four miles, rocks are melted by heat due to radio-activity. As the melting proceeds, the water contained in the rocks becomes explosive and an eruption follows. When all the lava is exhausted the reservoir is closed. In due course more heat is generated, rocks are again melted, and a second eruption takes place. This explains, not only the repetitive character of eruptions, but the comparatively shallow depth at which they originate. The horizon of molten rock, if it is dependent on secular cooling of the world, would be at a depth of 30 miles or 40 miles, while if it is due to radio-activity it may possibly be found at a depth of three or four miles.

AN interesting supplement on modern air compressors, covering twenty pages with seventy-three illustrations, is published with the *Engineer* of June 15. It gives an excellent review of the great strides made during the last fifteen years in the use of compressed air. The development of the use of compressed air as a means for transmitting power appears the more remarkable when it is remembered that during the same period the use of electricity for that purpose has grown enormously.

THE Engineering Standards Committee has made arrangements with a firm at Bilston to manufacture commercial sets of standard pipe-flange templates in large quantities. The templates are made, with extreme accuracy, of thin steel plate painted over with aluminium paint, a small piece being cut out at the extremity of each centre line so as to enable the fitter to see that the centre line of the template coincides with the centre line of his flange. The existence of these templates should enable full advantage to be taken of the standardisation that the committee has sought to effect.

IN a note to the *Rendiconti della R. Accademia dei Lincei* (dated April 22 last) Dr. F. Eredia gives the monthly and yearly rainfall values obtained at the Collegio Romano for eighty-one years, 1825–1905. Observations were begun there in 1788, but their continuity and uniformity were not quite satisfactory prior to 1825. The annual mean for this long period is 31·8 inches. The wettest months are October to December; the maximum fall in any month was 14·7 inches, in November, 1878.

THE weather report issued by the Meteorological Office for the week ending Saturday, June 16, shows that the weather for the period was fine and dry generally. The sky was cloudy in the eastern and southern counties of England, and some rain fell in all districts. Thunderstorms occurred in various parts of England on June 12 and 16. Temperature was generally low for the time of year, and in the east of England the mean was 4° below the average. At Dumfries, in the west of Scotland, the thermometer rose to 83°, and in the east of Scotland and in the north-east of England it exceeded 80°. In the north of Scotland the range of temperature for the week amounted to 49°. The winds were mostly from between north and north-east.

AN illustrated price-list of echelon diffraction gratings, just issued by Messrs. Adam Hilger, 75*a* Camden Road, N.W., will be found to be of interest by all practical spectroscopists. The gratings contain from ten to forty plates, the corresponding prices, including suitable mounts, ranging from 13*l.* to 120*l.* The heights of the plates vary from 32 mm. to 40 mm., but can be made higher than this if desired. The standard width of each step is 1 mm., and the thickness of each plate about 10 mm., but this latter dimension may be increased, with a corresponding increase in price, if so desired. The list also contains illustrated descriptions of the more generally used arrangements of the echelon apparatus and of the auxiliary spectroscopes and various accessories employed. Messrs. Hilger make a speciality of the constant deviation spectroscope most usefully employed with echelon gratings, and have just made an important alteration in the adaptation of the telescope and collimator which will greatly increase their rigidity, though the price remains the same.

THE results of a study of the infra-red region of the spectrum, made by M. Milan Stefanik at the Meudon Observatory, appear in the *Comptes rendus* for April 30. While working with the solar eclipse expedition in Spain, M. Stefanik found that, by placing a dark red screen before the slit of his spectroscope, he was able to see to a considerable distance into the infra-red. This led him to continue a research on this matter on his return to Meudon, where he employed a spectroscope having two prisms, containing benzine and carbon bisulphide respectively, and used as the light source an image of the sun projected on to the slit by a lens, after reflection from a silvered plane surface. Screens of various coloured alcoholic solutions were employed, and the best results were obtained when the screen absorbed all the luminous radiations of the spectrum, allowing only the extreme red and infra-red to pass. M. Stefanik has arrived at the conclusion that if only a limited region of the spectrum be allowed to enter the spectroscope this region is seen much better than if the total light were employed, for, despite the large absorption by the numerous pieces of glass included in his apparatus, he was able to observe and to map easily the spectrum down to 1 μ. The group Z was always easily visible, also X, and the lines π, ζ, σ, and τ more rarely. It appears from the variations in the intensities of the lines that some of them are of telluric origin. According to the *Annuaire* of the Bureau des Longitudes the infra-red is visible to 0·795 μ, but by the employment of the screens M. Stefanik has extended the limit to at least 0·900 μ.

THE Oxford University Junior Scientific Club is to be congratulated on the May number of its Transactions. Prof. H. A. Miers gives an interesting account of his recent investigations, in collaboration with Miss Isaacs, of spontaneous crystallisation and the nature of supersaturated solutions, while a paper by Mr. M. H. Godby, on the place of natural science in education, is full of good things, and deserves notice of a larger public.

IN a note in the *Physikalische Zeitschrift* (No. 8, p. 257) Drs. Stefan Meyer and Egon von Schweidler point out that Madame Curie, in a criticism of their work, referred to in NATURE (vol. lxxiii., p. 549), misinterpreted the tenor of their original communication in assuming that they considered polonium to consist of a mixture of radium D, radium E, and radium F. The conclusion they actually formed (Proceedings of the Vienna Academy of Sciences, February 1) was in reality the same as that arrived at by Madame Curie, namely, that polonium is identical with radium F. In another paper (Vienna Academy of Sciences, *Anzeiger*, No. 12) Drs. Meyer and von Schweidler confirm, however, the view that radio-lead is a mixture of radium D, radium E, and radium F, and describe the separation of these substances by electrolysis. Several determinations of the constant of decay of radium E were made as a means of characterising this substance, and the nature of a new radio-active product from actinium is discussed.

THE transformation of oxygen into ozone at high temperatures is the subject of a paper by Messrs. Franz Fischer and Fritz Braehmer in the *Physikalische Zeitschrift* (No. 9). It is shown that when a platinum wire or a Nernst filament is rendered incandescent whilst surrounded by liquid oxygen, or when an arc lamp or hydrogen flame is played upon liquid oxygen, ozone is formed. When the action is prolonged the amount of ozone formed increases; in one experiment 1 per cent. by weight of the oxygen used underwent condensation. Experiments are adduced to prove that the formation of ozone in these cases is solely a thermal phenomenon, and is not to be referred to an ozonising ultra-violet radiation. When any of the methods of heating described are adopted in ordinary air, nitric oxide appears to be the sole product; in such a case the ozone is not cooled and removed from the sphere of action sufficiently quickly to prevent its decomposition. It is well known that when a hydrogen flame burning in oxygen is played upon water or ice hydrogen peroxide is formed in minute quantity; it is interesting to note that when hydrogen is burnt in liquid oxygen no hydrogen peroxide can be detected. In the former case water is oxidised to hydrogen peroxide, in the latter molecular oxygen is converted into ozone.

OUR ASTRONOMICAL COLUMN.

DISCUSSION OF FACULÆ OBSERVATIONS.—An interesting discussion of the observations of faculæ, in which Prof. Mascari compares the frequency and intensity of these phenomena with the solar activity as indicated by sun-spots and the variation of the total luminous radiation from the solar disc, appears in No. 5, vol. xxxv., of the *Memorie della Societa degli Spettroscopisti Italiani*.

Since 1894 the groups of faculæ on the solar disc have been observed, and their number and intensity recorded, on every day that the atmospheric conditions were favourable. The intensities were classified in five groups, viz. brightest (V.V.), bright (V.), ordinary, weak (*d.*), and weakest (*d.d.*).

Analysing the results thus obtained, Prof. Mascari finds that the third class (and possibly the second and third classes) decreased in frequency from that year of sun-spot maximum until 1901, sun-spot minimum, and then increased regularly up to the 1905 maximum. The (*d.*) and (*d.d.*) classes varied in the inverse sense.

Assigning numerical values to these classes, from 5 for the (V.V.) to 1 for the (*d.d.*), and taking the grouped mean for each year as the relative annual brightness of the faculæ, Prof. Mascari finds that this mean brightness also varies with the sun-spot activity, being 2·83 in 1894, 1·88 in 1901, and 2·97 in 1905. Combining, as a product, the mean frequency of the faculæ for each year with their relative mean brightness a similar result is obtained, the respective values being 29·80 in 1894, 4·62 in 1901, and 19·63 in 1905.

These results, combined with those obtained by himself in 1901 and Tacchini in 1878 showing that the chromospheric phenomena were less bright at sun-spot minima than at maxima, led Prof. Mascari to the conclusion that the luminous radiation of the sun is greater at the spot maxima than it is at the epochs of minima.

NEW METHOD FOR THE DISCOVERY OF ASTEROIDS.—In No. 4, vol. xxiii., of the *Astrophysical Journal*, Mr. J. H. Metcalf, of Taunton (Mass.), describes a method which he has employed successfully in the photographic discovery of asteroids.

This method is really an adaptation of that employed in the photography of comets, where the observer, instead of following the guiding star in the usual way, regularly moves the photographic plate during the exposure so that it follows the object which he hopes to photograph, and thus obtains a well-defined single image of that particular object, whilst the surrounding stars are represented on the plate by trails.

By moving his plate in a direction parallel to the ecliptic at a rate previously computed for an ideal asteroid, Mr. Metcalf has obtained some excellent, well-defined circular images of several known faint asteroids, and has also discovered some new ones. For example, one of the reproductions which accompany his paper shows a pair of images of an asteroid of the thirteenth magnitude which he discovered on March 22.

RADIAL VELOCITY OF α DRACONIS.—A brief note by Herr H. Ludendorff, published in No. 4088 of the *Astronomische Nachrichten*, confirms the variability of the radial velocity of α Draconis announced by the Lick observers. According to the latter, the radial velocity on June 16, 1902, was 0 km., and on May 4, 1903, and June 19, 1904, it was -42 km.; values of -43 km. and -40 km. were also obtained.

On two plates secured with the Potsdam spectrograph (iv.) on May 23 and 24, 1903, the displacement of the lines λ 4481 and $H\gamma$ gave the radial velocity of this star as -17 km. and -14 km. respectively.

USEFUL TABLES AND FORMULÆ FOR ASTRONOMICAL COMPUTATIONS.—No. 15 of the Publications of the Groningen Astronomical Laboratory contains a number of tables for photographic parallax-observations, prepared by Dr. W. de Sitter. Each table gives the parallax factors, for each hour of R.A., for every 10° of latitude, and also shows the limiting dates between which a star of the stated R.A. may be observed photographically.

No. 16 of the same publications is given in the same volume, and contains a number of trigonometrical formulæ and a table of goniometrical functions for the four quadrants, compiled by Profs. J. C. and W. Kapteyn; additional formulæ, both for plane and spherical triangles where certain elements are small, are also included.

THE LEEDS ASTRONOMICAL SOCIETY.—We have just received No. 13 of the Journal and Transactions of the Leeds Astronomical Society, which gives a brief *résumé* of the work accomplished by the members of the society during the year 1905.

Eight papers read before the society during the session, dealing with popular astronomical subjects, are reproduced in the journal, together with a number of notes contributed by members to various publications.

From remarks made in the report it appears that this society is greatly in need of increased support, financial and general.

METEOROLOGICAL OBSERVATIONS.

FROM the "Jahrbücher" of the Austrian Meteorological Office for 1904 it appears that changes have recently been made in the comprehensive operations of that important institution. A considerable addition to its labours has been incurred by the transfer to it of the observations of earthquake phenomena originated by the Vienna Academy of Sciences; this organisation embraces a large number of stations. Owing to this transfer the office has adopted the title of Central-Anstalt für Meteorologie und Geodynamik. A considerable increase has been made in the number of weather forecasts sent gratuitously to provincial post-offices; in these telegrams an attempt is made to forecast the weather for two days in advance. On the other hand, it has been found necessary greatly to restrict the amount of data published from stations of the second and third order; this materially lessens the bulk of the year-book. The investigation of the upper air by manned and unmanned balloons is actively continued, and the results are published in the Proceedings of the academy. A separate appendix contains a revision of the yearly means of barometric pressure at various stations since 1886, by Dr. Margueles, and a discussion of thunderstorms and hail, by M. Prohaska.

The results of meteorological and magnetical observations at Stonyhurst College for 1905 have just been issued. This useful observatory possesses photographic recording instruments both for meteorology and terrestrial magnetism, and was one of the seven principal stations included in the scheme of the Meteorological Committee in 1868 for the discussion of the meteorology of the British Isles; its observations extend over the long period of fifty-eight years. The most notable feature of the year appears to us to be the shortage of rainfall, amounting to just upon 8 inches. The total rainfall was 38·84 inches; the least fall in any year was 31·25 inches, in 1887. The prevailing wind was between south and west on 237 days. Drawings of solar spots and faculæ were made on 196 days, and the stellar spectrograph was employed on nearly every available night.

The fourteenth report of the Sonnblick Society for the year 1905 contains statistics of several prominent mountain meteorological stations, including an interesting account of the observatory at the summit of Monte Rosa, at an altitude of about 14,960 feet. The Sonnblick station (Salzburg) is about 10,190 feet above the sea-level, and is far from an agreeable residence for its enthusiastic observers. The mean temperature for the year 1905 was 19°·9 F.; the monthly mean was only above freezing point in July and August, the absolute maxima in those months being 56°·8 and 45°·7 respectively. Rain or snow fell on 230 days, amounting to 68·8 inches, and fog occurred on 274 days. On January 1 the thermometer fell to −35°·3, being the lowest observed since the establishment of the observatory, the next lowest reading being −30°·3, in March, 1890; the wind was north-easterly, with high barometric pressure (30·71 inches) over Scandinavia and low (29·53 inches) over Greece.

The twenty-eighth yearly report of the Deutsche Seewarte, for the year 1905, shows a considerable increase in the useful work of that institution; the number of sets of observations contained in ships' logs exceeded those of the previous year by more than 28,000. These observations are utilised in the publication of monthly charts for the North Atlantic, quarterly charts for the North Sea and Baltic, the preparation of valuable daily synoptic weather charts of the North Atlantic (in conjunction with the Danish Meteorological Institute), and various other investigations. Special mention may be made of the efficiency of the arrangements for the issue of weather forecasts and storm warnings, and of the careful discussion and publication of the observations made at distant stations, including Labrador, the South Seas, the Far East, and German East Africa. The exploration of the upper air by means of kites is actively carried on; 233 ascents were made during the year, the mean of the greatest altitudes being 3910 metres. It has been found necessary to limit the altitudes, except on the days of the international ascents, owing to the frequent loss of the kites; the principal kite (which carries the instruments) broke away on twenty-two occasions, three of which were due to lightning. Unmanned balloons also reached altitudes of 9 to 17 kilometres; the usual inversion of temperature generally occurred between 9 and 11 kilometres. A discussion of the results obtained will be published later on.

The annual summary of the India Weather Review for 1904, which completes the discussion of the meteorology of India for that year, was issued recently. This vast area is, as before, divided into eleven provinces and fifty-seven districts for the purpose of dealing with medical and agricultural statistics respectively. In addition to various tables giving the usual monthly and other values, each element is separately considered under seasons, including the hot, cold, and monsoon periods. We can here only briefly refer to some of the general annual results. The year was characterised by smaller departures from the normal temperature than is frequently the case; the mean of the maxima for the eleven meteorological provinces was 88°·0, of the minima 68°·7, and the mean daily range 19°·4. The Arabian Sea was singularly free from storms; only eleven occurred, and they were all comparatively feeble, and their tracks were less westerly than usual. The rainfall stations now number 2486; the mean amount of rainfall was 57·26 inches, about $1\frac{1}{2}$ inches below the normal. On the Burma coast the fall was 152·65 inches, and in the Indus valley only 7·26 inches. During the year there was a marked increase in the number of sun-spots; the surface of the sun was not free from them on any day. Magnetic disturbances were recorded at Colába on 205 days, but there were only three days on which they were classed as "great."

The report of the Government Observatory, Bombay, for the year 1905 also quotes a remarkable deficit in the rainfall, it being stated as 41·5 inches below the normal of twenty-four years, 1873–1896. The total fall for the year was 33·66 inches only, and the amount for the previous year was 33·42 inches, both of which are record minimum falls, not even excepting that for the famine year, 1899, when 35·9 inches were registered. Milne's seismograph recorded thirty-seven earthquakes during 1905; those on April 4 and 9 and July 23 were very great disturbances. Plague in a severe epidemic form broke out at Alibág, but no cases occurred in the immediate vicinity of the branch magnetic observatory at that place; one case occurred at Colába in the month of April, notwithstanding that all precautions were taken.

The annual report of the Meteorological Department of the Transvaal for the year ended June 30, 1905, was received a few days ago. The central observatory, near Johannesburg, was first occupied in May, 1904, and is situated on an abrupt ridge of hills, nearly 6000 feet above sea-level. The department has been very active in supplying verified instruments, and has already some 250 stations in different parts of the colony, the majority of which record rainfall only; the observers are mostly volunteers, and receive no remuneration. The report, however, contains complete meteorological observations, or monthly results, for a considerable number of places, and very useful maps exhibiting the climatological features of the year in various districts. The diurnal periodicity of rainfall, so far as given, shows that the greater part occurs between noon and midnight. Nearly every fall of rain is said to be accompanied with thunder and lightning; some of the storms are very heavy, and a lightning recorder has been erected at Johannesburg which gives a permanent record of their intensity and duration. On the High Veldt the mean temperature of the twelve months ranged from 57° at Volksrust to 65° in the Waterberg, the extreme maxima from 87° to 104°, and the extreme minima from 14° to 29°. Telegraphic messages are received and exchanged daily, and the Government has sanctioned the appointment of an assistant, to be trained in weather forecasting at the Meteorological Office in London.

THE THEORY OF FREQUENCY-DISTRIBUTIONS.[1]

THREE brief but important notes on the theory of the law of error were communicated to the Royal Academy of Sciences at Stockholm last year by Mr. Charlier, director of the astronomical observatory at Lund. The first of these ("Ueber das Fehlergesetz") is a discussion on the lines, generally, laid down by Laplace. An "error" is supposed to be given by the sum of a large number of elementary errors, each with its own law of frequency; these laws need not be the same, but are subject to the condition that the frequency should not fall off with great rapidity on either side of the mode. On this condition, the law reached is the known expansion in terms of the normal function and its differentials, recently discussed in detail by Prof. Edgeworth (Camb. Phil. Trans., vol. xx.). In his second note ("Die zweite Form des Fehlergesetzes") Mr. Charlier discusses the complementary case, in which the condition stated does not hold, supposing, for instance, that each elementary error can only take the value zero or a, and that the probability of a is very small. The normal function of the former series is now replaced by an auxiliary function of more complex form. These two laws are referred to as Type A and Type B. The third note ("Ueber die Darstellung willkürlicher Funktionen") bears on the general mathematical method employed.

The present memoir, which is written in English, is a sequel to these purely mathematical notes, discussing the practical work of fitting such curves to given statistics and so forth. The method of fitting used throughout is Prof. Pearson's "method of moments," which has proved so widely applicable. The illustrations are numerous; for Type A, frequencies of stigmatic rays in Papaver, Johannsen's distributions of weight in beans, cephalic indices of Swedish recruits, and deaths from typhoid fever in groups of three successive days during an epidemic at Lund; for Type B, De Vries's statistics of numbers of petals in Ranunculus, and Johannsen's figures for sterility in barley. Davenport and Bullard's data for the numbers of glands in the fore-legs of swine are discussed under both heads. These illustrations are followed by a short section on the dissection of a compound curve by Pearson's method (Phil. Trans., 1893). One or two possible cases of approximation are discussed, and an interesting suggestion made as to the employment of a graphic method to lighten the labour of solving the fundamental nonic. The text of the memoir is followed by some tables giving, *inter alia*, the third and fourth differentials of the normal function, and values of the auxiliary function for Type B.

There are several incidental points of interest; a proof of the empirically discovered rule that the difference between mean and median is one-third of the difference between mean and mode for Type A deserves mention, and a suggestion as to an arithmetical check in calculating moments is worth consideration from the practical standpoint. If one may judge from a diagram (Fig. 5), curves of Type A may be bi-modal. Is this so? The point does not appear to receive special attention in the text. The statement on p. 15 that "as a rule it may be advisable to take the class range smaller than the standard deviation" would seem to be rather incautious. Surely, as a rule, it should be not merely smaller, but a good deal smaller—say one-third of the standard deviation or less?

The memoir and its preceding notes must be commended to the attention of all who are interested in the theory of frequency distributions either from the mathematical or the statistical side.

G. U. Y.

[1] "Researches into the Theory of Probability." By C. V. L. Charlier. Pp. 51. (Meddelanden från Lunds Astronomiska Observatorium, Serie ii. Nr. 4. Kongl. Fysiografiska Sällskapets Handlingar. Bd. 16.) (Lund, 1906.)

A PLEA FOR AN EXPEDITION TO MELANESIA.

DR. A. C. HADDON, F.R.S., recently brought before the research department of the Royal Geographical Society a plea for the investigation of biological and anthropological distributions in Melanesia. The Melanesian islands constitute a fairly well-marked biological province. Many of the islands are of large size, and there is reason to believe that some of these are vestiges of an ancient land-mass that probably became submerged in the Mesozoic period. The islands of Melanesia have yet to be studied from a geomorphological point of view, and their geology is extremely little known. Botanists would welcome a more ample knowledge of the flora of the district as a whole and of particular portions of it, and many problems of plant structure, distribution, and œcology require detailed investigation on the spot. The same remarks apply to zoologists. Botanists and zoologists alike would welcome an opportunity for extensive or intensive study of the systematic distributional or biological problems of plants and animals in Melanesia.

There are also many anthropological problems in Melanesia that require investigation in the immediate future, since the dying out or modification of arts, crafts, customs, and beliefs that is now taking place, and the shifting and mixing of populations, will soon render their solution difficult and even impossible. On the other hand, there are many districts never yet visited by a white man, and many islands of which science has no knowledge.

There is a certain amount of variation in the physical character of the people of these archipelagoes that requires local study for its explanation. A good deal is known in a general way about the arts and crafts of the Melanesians, but an investigation of the kind proposed would verify existing data, add an immense number of trustworthy facts, and localities could be ascertained of unlocated specimens in our museums, and the uses of doubtful objects could in many cases be discovered. By a combination of these two lines of inquiry, the physical and the cultural, the nature, origin, and distribution of the races and peoples of the West Pacific could be elucidated. Melanesia is peculiarly suitable for studying the stages of the transition from mother-right to father-right, and it would be important to discover the causes that have led to this transformation, and the steps that mark its progress. With this is associated the evolution of the family and the distribution and inheritance of property. Melanesia is also a favourable area for tracing the emergence of government. What are required at the present day are intensive studies of restricted areas, since it is only by careful regional study that the real meaning of institutions and their metamorphoses can be understood. The same applies equally to all the manifold beliefs and usages that are grouped under the term religion. The psychology of backward peoples has been greatly neglected, and the opportunity of a well-equipped expedition would do much to encourage students to undertake this research.

It is superfluous to extend this plea, as all ethnologists will agree that this work requires to be done, and that without delay. The presence of Government officials, missionaries, traders, and of returned indentured labourers tends rapidly to modify or destroy the old customs. Much has already disappeared in many places; we are yet in time in many others if we do not delay.

Dr. Haddon is convinced that the best means of accomplishing the end in view is to organise a prolonged expedition to the Pacific with the absolute control of a comfortable and steady steamer. The permanent staff on board should consist at least of the director, doctor, photographer, two stenographers, who should also be typists, and, if possible, an artist. Accommodation should be provided for a number of investigators, but these would not necessarily form part of the permanent staff. They would be conveyed to the district which they were to study and be removed therefrom when it was time to leave. The director would arrange with each investigator when the vessel would return, and the investigator would be left with all the apparatus, food, and trade that he required.

The general routine should be as follows:—an anthropological investigator would be expected to work on the general lines laid down by the director. When the vessel returned, all those on board would be required to help the investigator according to their several abilities; the expedition photographer would be placed at his disposal, and dances and ceremonies would also be kinematographed. The investigator would orally amplify his rough notes and dictate them to the stenographers, and, so far as possible, all notes should be typed in duplicate before the departure of the investigator, and a revision made of them before finally leaving the spot.

The foregoing remarks apply to anthropological investigators, but suitable arrangements could be made for geological, geographical, botanical, or zoological investigators; equal facilities should be given to American and foreign students; investigators should be of either sex.

It is only by an expedition of this kind that the anthropology of Melanesia can be studied as a whole and in detail. It would be an expensive undertaking, but the results obtained would amply justify the expenditure of time, labour, and money, and the data so obtained would constitute a mine of information for the present and future generations of students of man.

In the discussion which followed, Sir George Goldie, the president of the society, Dr. Herbertson, Mr. Chisholm, Dr. Seligmann, Mr. J. L. Myres, Mr. S. H. Ray, Mr. N. W. Thomas, Captain Wilson Barker, Major Darwin, Colonel Church, and the chairman, Sir Thomas Holdich, gave their cordial support to the proposed scheme. Several practical difficulties were pointed out, but none of them was insuperable. Some useful suggestions were also made. More than one speaker recognised that an expedition of this kind would serve as a valuable opportunity for increasing geographical, oceanographical, and meteorological knowledge.

DESTRUCTION OF ANIMALS IN AUSTRALIA.

IN the course of his address to the annual meeting of the Linnean Society of New South Wales, held on March 28, Mr. T. Steel, the president, alluded to a proposed method of destroying rabbits by means of an infectious disease, the precise nature of which is not yet disclosed. The idea, it appears, originated in Paris, and since the necessary funds have been subscribed by stock-owners and agriculturists, it is proposed to commence the experiment on a small island selected for the purpose. After discussing the arguments for and against the proposal, the president considered it highly undesirable that any such disease should be wilfully communicated to any species of animal, by means of which it might be disseminated throughout the country. As to the extermination of the rabbit, that is considered an impossible contingency; but means ought, and can, be found to keep the species in check without recourse to infectious diseases, which may be a danger to the community.

In the course of the same address Mr. Steel alluded to the necessity of special efforts if the native Australian fauna and flora are to be saved from destruction. Poison spread for rabbits is responsible for the destruction of a large number of indigenous mammals and birds, while, sad to relate, there are Europeans who will deliberately shoot down such harmless and peaceful creatures as the koala, or native bear, for the sake of so-called sport. Shooting domesticated sheep, it is remarked, would be equally worthy of such sportsmen.

A very similar note of alarm is sounded in the April issue of the *Victorian Naturalist* in the course of an account of a recent excursion by the members of the Field Naturalists' Club to the reserve for wild animals at Wilson's Promontory. Here the chief destruction is caused by half-wild dogs, which are not true dingoes, but the produce of a cross between the latter and dogs escaped from the fishermen of the district. If these pests are not soon exterminated there will be little hope of preserving any indigenous terrestrial animals in the reserve. With regard to the reserve itself, it is mentioned as a subject for regret that the whole area is cut off from the sea by a narrow strip of land which ought certainly to be added to the protected zone. If this were done, and certain neighbouring sawmills abolished, the reserve would probably flourish, provided it were separated from the mainland by a dog-and-rabbit-proof fence, and certain indigenous animals turned in from the adjacent districts. We wish every success to the movement.

ABERDEEN UNIVERSITY QUATERCENTENARY CELEBRATIONS.

ACTIVE preparations are being made in connection with the quatercentenary celebrations of the University of Aberdeen, and the new buildings at Marischal College, which His Majesty the King is to open in the last week of September, are approaching completion. The handsome new block—"a dream in granite"—which completes the quadrangle includes new class-rooms and laboratories for physiology, geology, and agriculture; new rooms for education, medicine, modern languages, &c.; a new library for scientific literature, and new offices.

Among the distinguished guests who have accepted the University's invitation are:—Lord Avebury, Sir Robert Stawell Ball, Prof. A. H. Becquerel, Prof. Behring, Sir William Broadbent, Sir Jas. Crichton Browne, Mr. Thomas Bryant, Lord Balfour of Burleigh, Mr. W. S. Bruce, of the *Scotia*, Mr. James Bryce, M.P., Sir William Crookes, Dr. Casimir De Candolle, Prof. Watson Cheyne, Prof. Yves Delage, Dr. Anton Dohrn, Sir Michael Foster, Sir Joseph Fayrer, the Duke of Fife, Sir Edward Fry, Dr. R. T. Glazebrook, Prof. A. Giard, Mr. Jonathan Hutchinson, Prof. Stanley Hall, Prof. Harald Höffding, Mr. R. B. Haldane, M.P., Prof. F. Hueppe, Prof. Jensen, Prof. Joseph Larmor, Sir Norman Lockyer, Prof. Lombroso, Sir Alfred Lyall, Dr. Donald Macalister, Major P. A. MacMahon, Signor Marconi, Prof. Mendeléeff, Prof. Menschutkin, Prof. Alexander Macalister, Prof. A. B. Macallum, Sir Alexander C. Mackenzie, Prof. Hugo Münsterberg, Sir John MacFadyean, Prof. Middleton, Prof. Mahaffy, Sir John Murray, Prof. Wilhelm Ostwald, Sir William Ramsay, Sir Henry Roscoe, Major Ronald Ross, Field-Marshal Earl Roberts, Sir James A. Russell, Dr. D. H. Scott, Dr. J. Hutchison Stirling, Dr. William Somerville, Prof. W. R. Sorley, Prof. Stirling, Mr. Thomas Shaw, M.P., Lord Mount-Stephen, Prof. J. J. Thomson, Dr. Thomas E. Thorpe, Prof. W. A. Tilden, Prof. G. D. Thane, Prof. Henry Turner, Prof. Giuseppe Veronese, Dr. J. A. Voelcker, Prof. Paul Vinogradoff, Prof. J. W. Wijhe, Prof. Weichselbaum, and Sir John Williams.

The following among other universities, colleges, and learned societies are to be represented by delegates:—University College, Bristol, Principal C. Lloyd Morgan; University of Cambridge, Dr. Henry Jackson, Dr. James Adam, and Mr. W. L. Mollison; University College, Cardiff, Dr. E. H. Griffiths; Trinity College, Dublin, Dr. Anthony Traill; Royal Society of Edinburgh, Lord MacLaren; Universities of Edinburgh, Glasgow, and St. Andrews; University of Leeds, Dr. Bodington; Royal Society of London, Sir Archibald Geikie; British Academy, Dr. J. A. H. Murray; Royal College of Physicians, Sir R. D. Powell; Royal College of Surgeons, Mr. Edmund Owen; University of Manchester, Dr. A. Hopkinson; University of Oxford, Dr. W. M. Merry, Prof. Henry Goudy, and Prof. Arthur Thomson; University of Wales, Principal H. R. Reichel; R. Accademia dei Lincei, Rome, Prof. Lanciani.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The Harkness scholarship in geology has been gained by B. Smith, of Sidney, and the Wiltshire prize in palæontology by W. A. R. Wilks, of Gonville and Caius.

The Cavendish professor announces a course of demonstrations in physics at the laboratory during the long vacation, beginning on July 4.

The Victoria medal of honour has been awarded by the Royal Horticultural Society to Mr. R. I. Lynch, curator of the Botanic Garden.

A thousand willow-cuttings have been supplied from the garden to the Midlands Re-afforesting Association for the planting of waste-heaps in the "Black Country."

In the Natural Sciences Tripos, part i., thirty-eight men and no women obtain a first class; in part ii., twelve men and three women are in the first class, six being distinguished in physics and four in physiology.

MR. H. O. WILLS, of Kelston Knoll, near Bristol, has promised a contribution of 10,000*l*. towards the foundation of a university at Bristol.

THE annual garden-party will be held at Guy's Hospital on Wednesday, July 4, when Sir W. Cameron Gull, Bart., will distribute the medals and prizes to the successful students.

A GEORGE COMBE lectureship in general and experimental psychology has been established in connection with the philosophical department of the University of Edinburgh. The funds for the lecturer's salary will be provided mainly by the Combe trustees, who have also contributed 300*l*. towards the equipment of a laboratory.

THE Senate of the University of Dublin has decided to confer, at the summer commencements on July 31, the honorary degree of Sc.D. on Colonel David Bruce, C.B.; Prof. J. H. Poincaré, professor of mathematics and astronomy at the Sorbonne; Mr. E. T. Whittaker, F.R.S., Fellow of Trinity College, Cambridge, Astronomer Royal of Ireland; and Dr. A. E. Wright, F.R.S.

THE *Daily Chronicle* (June 20) announces that Sir William Macdonald has presented an agricultural college and an endowment of two million dollars (400,000*l*.) to the McGill University, Montreal. Sir William founded this agricultural college some time ago, in order to provide the youth of Canada with facilities for a thorough scientific education in agriculture.

AT University College (University of London) on July 3 the dean of the faculty of arts will read a report on the work of the session; the result of the University, scholarship and class examinations will be announced, and prizes and medals will be distributed by Dr. G. Carey Foster, F.R.S. (emeritus professor of physics, and formerly principal of the college). Lord Reay, president of the college, who will preside, will receive for the college from Prof. F. T. Trouton, acting on behalf of the subscribers, the portrait of Dr. G. Carey Foster, painted by Mr. Augustus John, and will present a replica thereof to Mrs. Carey Foster.

A COURSE of demonstrations and practical work in field and laboratory, on the applications of science to rural life and outdoor industries, will be held at the South-Eastern Agricultural College, Wye, about the last week in July or the first week in August. The course will be designed to meet the needs of science masters in rural secondary schools who have to teach various branches of science to country children. The work will be mainly practical investigation into the bearing of science on outdoor life, and lectures will be given to indicate the lines on which science teaching in rural secondary schools could be developed usefully. The cost of the fortnight's course will be 5*l*., including board and residence in the college. Full particulars may be obtained from the principal, Mr. M. J. R. Dunstan, at the college.

FURTHER generous gifts to education by American men of wealth are announced by *Science*. Mr. David Rankin, of St. Louis, has decided to give 400,000*l*. to found an industrial and manual training school in St. Louis. Mr. Clarence H. Mackay and his mother have together given 10,000*l*. for the immediate erection of a building for the College of Mines in connection with the University of Nevada. This building is to house the department of mining and metallurgy and that of geology and mineralogy. A recent State appropriation for the metallurgical laboratory has provided the University with a new ore-treating equipment which will be suitable for installing in the new quarters. The building will also contain a geological museum. Furthermore, Mr. F. M. Smith has arranged to provide an income of 200*l*. a year to be used for the support and encouragement of students in the mining school. This will in general be divided into five annual scholarships of 40*l*. each to be known as the F. M. Smith scholarships open to deserving students irrespective of citizenship or residence.

IT is satisfactory to know that the attempt made at the meeting of the Liverpool City Council to reduce the grant of 10,000*l*. to the University of Liverpool met with scant support. The grant was renewed by an overwhelming majority. We should like to agree with Sir Charles Petrie, who said at the meeting he could not think the mover and seconder of the amendment were serious, but there is still in this country a widespread want of appreciation of the national value of university teaching and research, and no effort must be spared to bring home to local authorities the duty devolving upon them to assist every grade of education to the fullest extent possible. As Chancellor of the University of Liverpool, Lord Derby has formally accepted from Miss Isabella Gregson, formerly of Liverpool, the gift of the Gregson Memorial Institute and Museum. The gift is to be utilised for university extension purposes, and represents in money value, with an endowment of 5000*l*. added by the founder, about 300,000*l*. It was erected some years ago by Miss Gregson at her mother's request for purposes of scientific recreation in memory of her father, mother, brother, and sister.

IN the foundation oration in connection with the Union Society, delivered at University College, London, on June 13, Sir Arthur Rücker, F.R.S., took for his subject the forthcoming incorporation of the college in the University of London. He emphasised the fact that University College is undenominational, and is to be united to an undenominational university. University College was the first great step towards bringing university teaching into the centre of the great masses of population. It may be said that the University of Cambridge owes indirectly its great physiological school to the college, for it was one of its students who developed there the idea. The college with its large resources has offered itself to the new university, and has made possible an absolute fusion. A sum of about a quarter of a million has been raised with this object in view. It is an open secret, Sir Arthur Rücker continued, that the University is in full negotiation with King's College with the view of that also becoming a college of the University. The University does not intend to injure or destroy University College in any way whatever; the college has a name and a reputation with which none but a madman would attempt to interfere. If the principal educational institutions in London are drawn together, it is hoped that the University will obtain the recognition, appreciation, and loyalty which are required for success. In conclusion, the principal of London University expressed the hope that the members of University College will support all movements for drawing the students of the University more closely together. All wanted to create a great university, and this would be of the very greatest importance to the whole of London.

THE Duke of Devonshire, as president of the National Association for the Promotion of Technical and Secondary Education, took the chair at the annual meeting held on June 15. During his opening speech the president said, in consequence of the exertions of the association in past years the position of technical and secondary education has been completely changed, the Government and the local authorities having taken up the question. The work for which the association was established to carry on has been to a great extent accomplished. The association is now no longer necessary for stimulating interest in the question of technical education or for promoting legislation. But, in the course of its existence, the association has done more than this; it has become the centre to which local authorities engaged in the work have been accustomed to look for advice, for information, and, to a certain extent, for guidance. Much of the work of the association is capable of being performed by the Government department. But from some communications which he had with the Board of Education a year or two ago, the Duke of Devonshire found that the department did not consider itself then in a position to undertake the whole of what is done by the association. It is, perhaps, possible that the present Treasury may take a different view, and that the Board of Education may be permitted by the Treasury to undertake a part of the work which has hitherto been exclusively carried on by the association. He therefore suggested that during the next year, in which provision is made for the continuance of the efficient work of the association, the executive committee should ascertain, by communication with the Government, how far the Board of Education is in a position to take up any part of the functions which the association has hitherto assumed; and if it should be found that those functions can be more usefully discharged in the future by a private association than by a department of the Government, practical consideration must be given to the manner in which it may be possible to secure a larger amount of assistance from the public. Lord Avebury and Sir Henry Roscoe also addressed the meeting.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 3.—"The Action of Pituitary Extracts upon the Kidney." By Prof. E. A. **Schäfer**, F.R.S., and P. T. **Herring**.

Intravenous injections of saline extract of the infundibular part of the pituitary body produce dilatation of kidney vessels accompanied by increased flow of urine; *i.e.* the extract has a diuretic action.

With the first injection this result is accompanied by rise of blood-pressure and contraction of systemic arteries. With subsequent injections the diuresis is usually attended, not by a rise of blood-pressure, but by a fall. This furnishes evidence that the diuresis is independent of the effects upon blood-pressure, and leads one to suppose that it is produced by a special constituent of the extract.

This conjecture is confirmed by the result of treating the extract with certain reagents which tend to abolish the rise of blood-pressure which is produced by a first injection, but leave the diuretic effect of the extract unaltered.

The diuretic as well as the pressor and depressor constituents of the extract are not destroyed by boiling. They dialyse through parchment paper. They are insoluble in absolute alcohol and ether.

Intravenous injections of extracts from the anterior or epithelial lobe of the pituitary body do not produce diuresis; these extracts exhibit no physiological activity.

It is concluded that the infundibular part of the gland produces an internal secretion which passes into the blood, and which, both indirectly owing to its general action upon the vascular system and directly by its special action on the renal vessels and renal epithelium, assists in promoting and regulating the secretion of urine; in other words, the internal secretion of the gland is ancillary to the renal functions.

May 10.—"A Variety of Thorianite from Galle, Ceylon." By Wyndham R. **Dunstan**, F.R.S., and B. Mouat **Jones**.

Specimens of thorianite from the Galle district of Ceylon were found to contain from 58·84 per cent. to 63·36 per cent. of thoria associated with from 32·7 per cent. to 27·9 per cent. of oxide of uranium. Ordinary thorianite from the Balangoda district contains 78·98 per cent. of thoria and 13·40 per cent. of oxide of uranium. The authors direct attention to the inter-replacement of thorium and uranium in the mineral, and conclude that the oxides of the two elements are present in isomorphous mixture, and are not chemically combined.

Chemical Society, June 7.—Prof. R. Meldola, F.R.S., president, in the chair.—Ammonium selenate and the question of isodimorphism in the alkali series: A. E. H. **Tutton**. Normal ammonium selenate crystallises differently from the seven rhombic normal sulphates and selenates of the alkalis already investigated, namely, in monoclinic prisms or tables. Rhombic mixed crystals of ammonium selenate and sulphate have been obtained, and it is concluded that ammonium selenate is dimorphous, and that the whole series of sulphates and selenates is probably isodimorphous.—The vapour pressures of binary mixtures, part i., the possible types of vapour-pressure curves: A. **Marshall**. By differentiating the equation of Duhem and Margules, $x d \log p_1 + (1-x) d \log p_2 = 0$, it has been found possible to classify the total pressure curves into twelve types, all of which are known to occur. The vapour pressures of the following pairs of liquids have been investigated experimentally:—nitroglycerol and acetone, diethylamine and acetone, ethyl alcohol and methyl ethyl ketone, water and methyl ethyl ketone, water and methyl acetate, water and ether, water and amyl alcohol.—The behaviour of acetylene with electrical discharges of high frequency: H. **Jackson** and D. N. **Laurie**. A semi-solid brown substance is formed when acetylene is subjected to discharges from an ordinary high-frequency apparatus, which sets to a hard and very insoluble solid on exposure to air. It is apparently a polymeride of acetylene. It absorbs oxygen readily up to about 8 per cent.—The behaviour of the vapours of methyl alcohol and acetaldehyde with electrical discharges of high frequency: H. **Jackson** and D. N. **Laurie**. Working with discharges of very short duration, the first change in the vapour of methyl alcohol is the formation of carbon monoxide and hydrogen; in the case of acetaldehyde the greater part of the vapour breaks up into methane and carbon monoxide, but acetylene and water are also produced in smaller quantities.—Note on 4-bromo-2-nitro-1α-naphthylamine: R. **Meldola** and H. G. **Dale**.—Dinitroanisidines and their products of diazotisation (second communication): R. **Meldola** and F. G. C. **Stephens**.—The action of sulphur dioxide and aluminium chloride on aromatic compounds: S. **Smiles** and R. **Le Rossignol**. The authors have previously shown that thionyl chloride reacts with phenetole in the presence of aluminium chloride, giving rise successively to a sulphoxide and a sulphonium base; it has since been found that this reaction may be brought about by sulphur dioxide with the aid of the same condensing agent.—Action of sodium on αα-dichloropropylene: Miss I. **Smedley**.—Resolution of lactic acid by morphine: J. C. **Irvine**. Fermentation lactic acid may be readily resolved into its active components by the crystallisation of the morphine salts.—Brazilin and hæmatoxylin, part viii.: W. H. **Perkin**, jun., and R. **Robinson**.—A study of the reaction between hydrogen peroxide and potassium persulphate: J. A. N. **Friend**. It is shown that solutions of hydrogen peroxide and potassium persulphate interact according to the equation $H_2O_2 + K_2S_2O_8 = 2KHSO_4 + O_2$. The reaction, however, is monomolecular, due to the formation of an intermediate and highly unstable compound.—The action of magnesium methyl iodide on dextrolimonene nitrosochlorides: W. A. **Tilden** and F. G. **Shepheard**. The same compound is formed from the α- and β-nitrosochlorides. It is insoluble in aqueous alkalis and in acids, though easily soluble in the usual organic solvents, and has the formula $C_{20}H_{32}ON_2Cl_2$.—Electrolysis of potassium ethyl dipropyl malonate: D. C. **Crichton**. A concentrated aqueous solution of potassium ethyldipropylmalonate yields on electrolysis the ethyl esters of α-propyl-β-ethylacrylic acid, dipropylglycollic acid, tetrapropylsuccinic acid, and probably dipropylacetic acid.—A new method for the measurement of hydrolysis in aqueous solution based upon the consideration of the motion of ions: R. B. **Denison** and B. D. **Steele**.—The oxidation of hydrocarbons by ozone at low temperatures: J. **Drugman**. Ozone acts slowly on saturated hydrocarbons, and the process is one of gradual hydroxylation. The reaction with an unsaturated hydrocarbon, such as ethylene, is instantaneous, even at temperatures far below 0°, and a very explosive addition compound is first formed.—Reactions involving the addition of hydrogen cyanide to carbon compounds, part v., cyanodihydrocarvone: A. **Lapworth**.—

Thiocarbamide as a solvent for gold: J. **Moir.** Two new complex gold salts have been obtained by dissolving gold in an acid solution of thiocarbamide. Their formulæ are $C_6H_{20}N_{12}S_6Au_2(SO_4)$ and $C_8H_{26}N_{16}S_8Au_3Cl_3$ respectively.—An improved Beckmann apparatus for molecular weight determinations: J. McConnell **Sanders.**

Linnean Society, June 7.—Prof. W. A. Herdman F.R.S., president, in the chair.—*Exhibit.* Tubes showing stages in the metamorphosis of a young flat-fish (*Pleuronectes platessa*), the plaice, leading from the symmetrical larva to the asymmetrical young flat-fish: the **President.** These fish were hatched and reared in the Port Erin Biological Station. Reference was also made to the operations conducted this year in hatching and liberating some millions of young plaice.—Two new species of Populus from Darjeeling: H. H. **Haines.** *Populus ciliata*, Royle, was re-described, and the two new species characterised, namely, *P. Gamblei*, which may or may not be the species described by Dode from imperfect material, and *P. glauca*, Haines.—Two reports dealing with Biscayan plankton collected during a cruise of H.M.S. *Research* in 1900: Dr. G. H. **Fowler.** (1) The Cephalopoda: W. E. **Hoyle.** Among seventeen specimens, five genera and two species were recognised; all but one (750 fathoms to 500 fathoms) apparently belonged to the epiplankton; not a single specimen was captured at the actual surface. (2) The Medusæ: E. T. **Browne.** As the area investigated was oceanic, the neritic Anthomedusæ were represented by only three species; while the Trachomedusæ and Narcomedusæ, which are essentially oceanic, were represented by seven and three species respectively, three species of Trachomedusæ furnishing 85 per cent. of the total specimens captured. Four rarities were recorded; one Narcomedusan was apparently new to science, and of interest as showing medusa-buds (which were not parasitic) developing as outgrowths of the stomach pouches.—The Conifers of China: Dr. M. T. **Masters.** The paper described the whole coniferous flora now known, including the discoveries of Messrs. E. H. Wilson and B. Hayata; eight new species are fully set out, five of these being of the genus Picea.

Royal Astronomical Society, June 8.—Mr. W. H. Maw, president, in the chair.—The ancient eclipses of the sun: E. **Nevill.**—Mr. Cowell's discussion of ancient eclipses of the sun: S. **Newcomb.** The above papers were discussed by Mr. Cowell in reference to his corrections to the secular acceleration. He concluded that, with the exception of the eclipse of Archilochus, which Mr. Nevill had shown to be entirely uncertain, they agreed with the theory, which was also supported by the Chinese eclipses now brought forward by Mr. Nevill.—Errors in the tabular places of Jupiter from photographs taken with the astrographic refractor at the Royal Observatory: **Astronomer Royal.**—Notes on polarisation phenomena in the solar corona, 1905 August 30: H. F. **Newall.**—Photographs of the corona of 1905 August 30, taken at Sfax, Tunis: **Astronomer Royal.**—In an oral communication Prof. H. H. **Turner** brought forward some results of his polarisation observations during recent solar eclipses, considered in reference to the constitution of the corona. Father Cortie said that we should consider the effect of explosive outbursts on the solar surface, and not regard the coronal phenomena as due only to the pressure of light.—A spherical slide-rule, consisting of two superposed stereographic projections of the sphere, arranged for solving various problems in spherical trigonometry: W. B. **Blaikie.**

CAMBRIDGE.

Philosophical Society, May 14.—Dr. Fenton, vice-president, in the chair.—The influence of a very strong magnetic field on the spark spectra of palladium, rhodium, and ruthenium: J. E. **Purvis.** The strength of the field was 39·980 units, and the general results are:—(1) Most of the lines divide into triplets, and several become quadruplets. (2) The value of $d\lambda/\lambda^2$ was calculated from the measurements of the distances of the constituents, and in several quadruplets the value is the same; the general appearance in intensities and polarisation of the separate constituents is also very similar. This is well seen in the quadruplets from palladium 3400·4 and 3258·7 when compared with the quadruplets from rhodium 3502·7 and 3474·7. In the triplets there are also lines which may be classified in the same way. (3) The displacements of the constituents of some of the divided lines are simple multiples of one another.—Experiments on the band spectrum of nitrogen in a magnetic field of 41·000 units: J. E. **Purvis.** The bands in the red, orange, and yellow become very weak, whilst those in the green, blue, and violet are brighter and stronger. But there was no shift of the bands, nor did there appear to be any widening or division of the lines forming the bands.—The ionisation of gases exposed simultaneously to Röntgen rays and the radiation from radioactive substances: T. **Noda.**

EDINBURGH.

Royal Society, May 28.—Sir John Murray, K.C.B., vice-president, in the chair.—Life in reservoirs in relation to water supply in towns: James **Murray.** The paper was a detailed discussion of the types of life met with in reservoirs, the time needed for new reservoirs to become stocked with animal life, and the conditions under which such life might do harm to the water. Rise of temperature was always followed by a great increase in the number of animals in the water, but so long as the loch or reservoir was large there was little chance of any serious results. The conditions under which animal life might possibly get into the mains were also discussed, and it was pointed out that Nature herself supplied a preventive in the tendency of free-swimming animals to swim against the current.—The Rotifera of the Scottish lochs: James **Murray.** Of the 177 species which had been discriminated, five were new. Many new observations on the structure and habits of the various species were recorded.—The Tardigrada of the South Orkneys: James **Murray.** Fourteen forms, obtained from a single tuft of moss, were more or less fragmentary. Two had been known before, but only three could be described as new.—The temperature of fresh-water lochs of Scotland, with special reference to Loch Ness: E. M. **Wedderburn.** The paper discussed the temperature distribution in the loch at different times and in different months. In addition to the usual type of sounding thermometer, a platinum thermometer was used in conjunction with Callendar's self-recording apparatus. The record showed on certain occasions the very rapid change of temperature which may take place at depths of 150 feet or 200 feet. This was traced to the slight rise or fall of the layer of water in which the temperature is changing most rapidly with depth, the so-called "Sprungschicht." Clear evidence was also obtained of the temperature seiche, first noticed by Mr. Watson. The observed period was in fair agreement with that calculated from the theoretical formula. At a depth of 5 feet very rapid changes of temperature were sometimes observed during night time, due clearly to convection currents. A sunshine recorder could, when required, be connected with the self-recording apparatus instead of the thermometer. At a few feet depth the effect of the direct action of the sun was very small. At a depth of only 2 feet it was impossible to detect the passage of a cloud in front of the sun. An estimation of the amount of heat which entered the water of the loch during the day was made, and came out at about a sixth or seventh part of the whole amount of solar heat available, according to Knott's calculation.

PARIS.

Academy of Sciences, June 5.—M. A. Chauveau in the chair.—The utilisation of turf for the intensive production of nitrates: A. **Müntz** and E. **Lainé.** The authors, continuing their researches on the artificial production of nitrates, find that if the animal charcoal used in their former work is replaced by turf as the medium for the growth of the nitrifying bacteria the yield is multiplied eight times. Fresh salts of ammonia can be added to the weak nitrate solution resulting from the first nitrification, and this again passed through the turf bed, and this process can be repeated until the percentage of nitrate present in the liquor is sufficient for its economical extraction commercially. The possibility of the turf itself furnishing the necessary ammonia compounds is discussed, and a method of distillation of the turf in superheated steam has been worked out, by means of which the yield of ammonia is greatly increased.—The dry avalanches and mud torrents in the recent eruption of Vesuvius: A. **Lacroix.**—The occurrence of crystals of sylvite in blocks thrown out by the recent eruption of Vesuvius: A. **Lacroix.** The crystals of sylvite (potassium chloride) were remarkable for their size, forming cubical crystals of more than 2 cm. in the side. In several specimens the sylvite crystals were covered with large cubical crystals of halite (sodium chloride). A description is also given of a rare mineral consisting of a chloride of sodium, potassium, and manganese.—Researches of the hydroxides of rubidium, cæsium, and lithium; M. **de Forcrand.** The hydroxides of rubidium and cæsium obtainable commercially both contain one molecule of water of crystallisation; the anhydrous hydroxides can be prepared from the commercial products by heating in a silver crucible, an atmosphere of hydrogen being necessary in the case of the cæsium compound to prevent the formation of higher oxides of cæsium. Anhydrous lithium hydroxide is readily prepared from the hydrate. The heats of dissolution of the three hydroxides were measured.—A theorem on plane algebraic curves of order n: G. B. **Guccia.**—An azimuth circle with reading microscopes for technical survey work: Ch. **Lallemand.** The circles are divided into tenths of degrees, and are read by estimation by bent microscopes carrying a cross-wire. The arrangement has the advantage of rapidity and simplicity, and a comparison with the various types of instrument in common use showed that it is only surpassed in accuracy by instruments furnished with reading microscopes carrying a micrometer screw.—The electrical control of synchronised clocks: Jean **Mascart.** A discussion of the possible accidents to a synchronised clock system, and the various means that have been adopted to inform the public that the electrical control of one of the clocks on the system has failed.—An experiment due to Hittorf and the generality of Paschen's law: E. **Bouty.**—The properties of surfaces for which the apparent angle of contact of water is zero: H. **Ollivier.**—The action of silicon chloride on nickel: Em. **Vigouroux.** By the action of silicon tetrachloride upon heated nickel two substances have been isolated, $SiNi_4$ and $SiNi_2$. That the former silicide is homogeneous and free from metallic nickel is rendered probable by the fact that it is not magnetic.—The decomposition of copper sulphate by methyl alcohol: V. **Auger.** A basic copper sulphate is formed, the sulphuric acid removed probably forming methyl-sulphuric acid.—Dibromodimethyl- and dibromodiethyl-amidobenzoylbenzoic acids and their derivatives: E. **Séverin.**—The variations in the size of the particles in colloidal hydrochloric-ferric chloride solutions: G. **Malfitano.**—A new micro-organism producing acetone: L. **Bréaudat.** The chromogenic organism described was found in the drinking water of Saigon, Cochin-China, and is capable of producing acetone from proteid material. The name proposed for the new species is *Bacillus violarius acetonicus*.—Contribution to the study of the soluble albuminoid materials of milk: M. **Lindet** and L. **Ammann.** It is shown that the casein of milk is, in part, dissolved by the calcium phosphate present. Experiments are described throwing light upon the causes of clotting of milk.—Contribution to the cytological study of bacteria: S. **Guilliermond.** The author concludes from his observations that a true nucleus does not exist in bacteria, and considers that the nuclei described by various authors are due to misinterpretation of the facts observed.—A new parasitic copepod of *Amphiura squammata*: E. **Hérouard.**—A new type in the family of the Virgularidæ: Ch. **Gravier.**—The excretion of the endogenous purins and uric acid: Pierre **Fauvel.** The quantity of endogenous purins and uric acid is constant even for a subject whose diet is free from purins, and this is still the case whether a milk diet, strictly vegetarian diet, or mixed milk-vegetarian diet be followed. This quantity varies little with the individual, and averages 0·4 to 0·5 gram of purins and 0·28 to 0·35 uric acid in twenty-four hours.—The state of the adductor muscles during life in the acephalous molluscs: F. **Marceau.**—Pulmonary tuberculosis in the tiger: P. **Achalme.**—A new explanation of glacial erosion: Jean **Brunhes.**

DIARY OF SOCIETIES.

THURSDAY, JUNE 21.

ROYAL SOCIETY, at 4.30.—The Transition from the Liquid to the Solid State and the Foam-structure of Matter: Prof. G. Quincke, For. Mem. R.S.—Experimental Evidence of Ionic Migration in the Natural Diffusion of Acids and Salts: R. G. Durrant.—On the Behaviour of Certain Substances at their Critical Temperatures: Prof. M. W. Travers, F.R.S., and F. L. Usher.—Note on the Phenomenon of Opalescence at the Critical Temperature: Prof. S. Young, F.R.S.—Ionic Velocities in Gases at Different Temperatures: P. Phillips.—The Action of Radium and Certain Other Salts on Gelatin: W. A. Douglas Rudge.—Barometric Variations of Long Duration over Large Areas: Dr. W. J. S. Lockyer.—On the Electric Inductive Capacities of Dry Paper and of Solid Cellulose: A. Campbell.

CHEMICAL SOCIETY, at 8.30.—The Cleve Memorial Lecture: Prof. T. E. Thorpe.—The Constituents of the Essential Oil from the Fruit of *Pittosporum undulatum*: F. B. Power and F. Tutin.—Mobility of Substituents in Derivatives of β-Naphthol: J. T. Hewitt and H. V. Mitchell.

LINNEAN SOCIETY, at 8.—On the Botany of Southern Rhodesia: Miss L. S. Gibbs.—On the Authentic Portraits of Linnæus (lantern slides): W. Carruthers, F.R.S.—Plantæ novæ Daweanæ in Uganda lectæ: Dr. Otto Stapf.—On the Genitalia of Diptera: W. Wesché.

FRIDAY, JUNE 22.

PHYSICAL SOCIETY, at 5.—The Effect of Radium in Facilitating the Visible Electric Discharge *in vacuo*: A. A. Campbell Swinton.—A Comparison between the Peltier Effect and other Reversible Heat Effects: A. O. Allen.—The Effect of the Electric Spark on the Actinity of Metals: T. A. Vaughton.—Dielectric Strength of Thin Liquid Films: Dr. P. E. Shaw.—The Effect of Electrical Oscillations on Iron in a Magnetic Field: Dr. W. H. Eccles.

WEDNESDAY, JUNE 27.

GEOLOGICAL SOCIETY, at 8.—Interference-Phenomena in the Alps: Dr. Maria M. Ogilvie Gordon.—The Influence of Pressure and Porosity on the Motion of Sub-surface Water: W. R. Baldwin-Wiseman.

THURSDAY, JUNE 28.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: Sex-determination in Hydatina, with some Remarks on Parthenogenesis: R. C. Punnett.—On the Julianiaceæ, a New Natural Order of Plants: W. THURSDAY, JUNE 28, 1906.

THE ORGANISATION OF AGRICULTURE.

(1) *The Transition in Agriculture.* By Edwin A. Pratt. Pp. x+354. (London: John Murray, 1906.) Price 5s.

(2) *An Introduction to the Study of Agricultural Economics.* By Henry C. Taylor. Pp. viii+327. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1905.) Price 5s.

(3) *The Development of Agriculture in Denmark.* By R. J. Thompson. A paper read before the Royal Statistical Society, May 15, 1906.

(1) THIS is the work of an author whose previous writings on subjects of agricultural economy have attracted considerable attention. The present volume has a three-fold purpose—to describe recent developments of subsidiary branches of agriculture, the progress of agricultural cooperation, and the principles on which small holdings may have the best chance of success.

Mr. Pratt states that "it is open to consideration whether the bitter cry of the distressed British agriculturist has not been persisted in with undue energy of late years." It is certain, however, that the last period of agricultural depression, which reached its culminating point about 1892, was terribly acute, and the subsequent recovery has been correspondingly slow. That there has been recovery few authorities will deny, and we believe that the general agricultural outlook is more hopeful than it has been for some time. This is certainly the impression we gain from a careful perusal of Mr. Pratt's book; yet at the same time the author scarcely touches upon the main features of British agriculture, and in this respect the title of the work is not altogether justified. Wheat-growing has declined, it is true, to a very marked extent, and a great deal of arable land has been converted into pasture during the last quarter of a century. On the other hand, the decline in the wheat acreage has been somewhat balanced by an increase in the acreage under oats. The increases in the areas of those subsidiary branches of agriculture, as Mr. Pratt calls them, with which his book mainly deals, are relatively unimportant.

The breeding of live-stock, and especially the home and export trade in pure-bred pedigree animals, the fattening of cattle, sheep and pigs, grazing and dairying, all involve operations upon such a large scale, and require individual skill of such a high order, that we cannot conceive of any "transition in agriculture" which would seriously interfere with the size of the holdings, the acreage of the crops, or the capital necessary to maintain them. But if we except agriculture on the large scale as it has been and in all probability will continue to be carried on, we admit that Mr. Pratt has done useful service in bringing under review those important developments of comparatively minor industries which are not only of benefit to agriculture, but are nationally advantageous by helping to create and maintain a sturdy, independent race of Englishmen.

An interesting account is given of the commercial aspects of milk selling. The facts related are not new, though it may well be that they have not attracted much attention outside the districts affected or on the part of persons not immediately concerned. Farmers in the dairying districts have found it pay much better to sell fresh milk than to turn it into butter and cheese. The sale of fresh milk and cream is, in fact, practically our only agricultural monopoly, and it is not likely that foreign competition will seriously threaten it. But whereas formerly the milk producer was an individual unit at the mercy of the urban wholesale dealer or middleman, judicious combination amongst dairy-farmers has enabled them to protect their interests, and especially to secure a uniform and equitable price for the milk produced. In Staffordshire, Derbyshire, Cheshire, Essex, and Somerset, associations have been formed with this object in view, and their success has been remarkable. In one case, Mr. Pratt states, the financial gain thus secured through combination amounts to from 30,000*l.* to 40,000*l.* annually, or an average annual gain per member of from 30*l.* to 40*l.*

The descriptions of fruit-farming and the production of flowers, bulbs, vegetables, poultry, and eggs will repay careful study, and they may well encourage the further extension of similar crops in districts suited to them upon the cooperative principles that have proved successful.

We come finally to the author's views on small holdings. This question is now under consideration by a Departmental Committee of the Board of Agriculture, and it is well known that the new President of the Board, Lord Carrington, is deeply interested in the subject, his own experiments in that direction in Lincolnshire and elsewhere having met with striking success. Mr. Pratt discusses the question as to whether ownership or tenancy is the more expedient form of tenure, and he pronounces unhesitatingly in favour of tenancy. We believe that his conclusions on this subject are sound, and that the example of countries where freehold occupancy has resulted in heavy mortgages with the payment of "rent" in its most odious form should be avoided.

(2) Dr. Henry C. Taylor, the author of the book on "Agricultural Economics," is assistant professor of political economy in the Wisconsin University, and an expert in the Office of Experiment Stations of the United States Department of Agriculture. His work forms part of the "Citizen's Library of Economics, Politics, and Sociology," and is in effect a studious effort to apply to practical agriculture the principles of political economy. As such it should prove useful to young agricultural students in connection with their ordinary course of "political arithmetic." Dr. Taylor himself states that one of the aims of his book is the setting forth of "fundamental economic principles, which, when carefully followed, lead the way to success in agricultural production."

In thirteen chapters the author deals with the factors of production, the organisation of the farm, the size of farms, the prices of agricultural products, the distribution of wealth, the value of land, the methods of its acquisition, and the relations between landlord and tenant. He uses the term "capital-goods" to represent the live-stock and implements essential to agricultural production, and the word "capital" to represent the money-value of capital-goods. Land, capital-goods, and labour being the three factors of agricultural production, he discusses the economic properties of each. In regard to labour, which includes the work of the farmer himself, he advances some interesting economic propositions, especially as to the "qualitative and quantitative efficiency of farmers"—qualitative efficiency relating to the return a man can obtain from a given piece of land with a given supply of capital-goods, and quantitative efficiency to the quantity of land and capital-goods which a man can operate. He shows that the farmer with the highest degree of qualitative efficiency can make not only more than a living upon land of any grade, but that he can make the largest net profit on the most productive land after outbidding all competitors for its use. Thus, "owing to the higher rents which the more efficient are willing to pay for the better grades of land, the farmer can secure the largest net profit by employing that grade of land which corresponds to his degree of qualitative efficiency."

In discussing the principles which determine different methods of farming, the author points out that whereas formerly agricultural conditions demanded that farms should produce all that was required by the cultivators, modern conditions of increased population and improved facilities of transport have given rise to what is described as commercial agriculture, the system under which agricultural produce is grown in bulk, and marketed in return for other commodities required but no longer produced by the seller.

In this country we pride ourselves upon the superior yield of our agricultural crops. This is, however, due to a system of intensive cultivation, and Dr. Taylor shows that the extensive system of cultivation as pursued in the United States is that which is at present best suited to the economic conditions of the country. Pressure of population in the older States of the American Union is already causing a more intensive cultivation than that previously followed. "In new countries," Dr. Taylor writes, "where land is relatively abundant, extensive culture is generally most profitable, and the average size of farms is usually greater than in older countries where land is scarce, land values very high, and intensive culture most profitable."

Incidentally, the book contains many statistical details relating to the United States that are not readily accessible to the general reader. For instance, the land area of the United States is given as 1,900,947,200 acres. The area of the United Kingdom is 77,671,319 acres. The percentage of improved land, or, as we describe it, "land under crops and grass," is in the United States about 22, in England about 76, and in Germany about 60. Again, with regard to the size of farms, in the United States the average is given as 146.6 acres. In England it is about 65 acres (or 85 acres if holdings above one acre and not above five acres be not included); in Germany it is 19.2 acres, and in France 21.4 acres. This variation in the average size of holdings is, of course, significant of the different systems of land tenure, tenant-farming prevailing in England and peasant-proprietorship in France and Germany. In the United States most of the land is either cultivated by its owners or on the sharing principle. According to the census of 1900, the different classes of farmers in the United States are represented in the following proportions:—

Owners	54·9	per cent.
Part Owners	7·9	,,
Owners and Tenants	0·9	,,
Managers	1·0	,,
Cash Tenants	13·1	,,
Share Tenants	22·2	,,
	100·0	

An interesting description is given of the American system of "share-tenancy," which is scarcely, if at all, practised in this country. The principle of it is something akin to *métayage*, as adopted in France, Italy, and Spain. A share-tenant in America pays for the use of the farm a proportion (such as one-third or one-half) of the crops cultivated. The share is delivered to the owner in kind. The owner participates in the management of the farm, and, in fact, directs all the more important operations. Under this system the landlords are usually the older and more experienced men, who own more land than they can well cultivate, whilst the tenants are younger men who prefer share tenancy to fixed rent, because their risk of loss is less.

(3) Denmark is a concrete example of the successful development of "commercial agriculture." Mr. Thompson has made an elaborate statistical study of the agricultural conditions prevailing in Denmark, and his facts and figures are well worthy of careful study on the part of economists. Most authorities agree that the prosperity of Denmark is attributable to three causes—the system of land tenure, education, and cooperation. Thrift, the art of wisely saving and wisely spending, is a national characteristic of the Danes, and this, combined with the admirable organisation of their export trade in dairy produce, has enabled them to attain to a greater relative degree of agricultural prosperity than perhaps any other country. Whilst there may be much to admire and copy in the methods of agricultural organisation pursued in Denmark, it should be remembered that this little country is almost entirely dependent upon its exports to the free and immense markets of Great Britain, and that its system of wholesale grading for despatch to one country could not be applied, without modifications, to Great Britain, which has little or no export trade in dairy produce, and whose local home markets are scattered and unlinked with any central administration.

E. H. G.

THE MANUFACTURE OF CYANIDES.

The Cyanide Industry Theoretically and Practically Considered. By R. Robine and M. Lenglen. Translated by J. Arthur Leclerc, Ph.D., with an appendix by C. E. Munroe, Ph.D. Pp. xi×408; illustrated. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1906.) Price 17s. net.

THE stimulating effect on industrial research caused by the prospect of immediate material gain is strikingly illustrated by the progress of the cyanide industry. Until cyanide of potassium was applied to the treatment of gold ores, comparatively little interest was taken in its manufacture. The consumption amounted to about fifty tons a year only, and the old expensive and wasteful methods of obtaining it from ferrocyanide which had been made by the use of nitrogenous organic substances were deemed sufficient for the purpose. When the demand was rapidly growing in the 'nineties there was a rush of investigators to discover new and cheaper methods of manufacture. A fair amount of success was attained, and some thousands of tons of cyanide are now produced annually in Great Britain and Germany and sold at one-third the former price. The older processes have been abandoned and new ones introduced, and, although some doubt still remains as to the future of the industry, the field for useful research has been narrowed, and once again offers little attraction to the chemical "pot-hunter." Comparatively little cyanide is produced in France, however, and apparently it was the apathy of their fellow-countrymen on the subject which induced MM. Robine and Lenglen to write the book which has just been translated.

The authors divide their book into four parts, of which part iii., on the methods of manufacturing cyanide compounds, is alone of any real importance.

Part i., occupying sixty-five pages, deals with the chemistry of cyanogen and its derivatives. It contains no correct statement that does not appear in ordinary text-books of chemistry, and is distinguished by an extraordinary number of misprints or misstatements, such as "cyanogen does not unite directly with hydrogen," "it [cyanogen] becomes a liquid at 20°.7 under ordinary pressure," and "If the cyanide contains chlorides, the method [of estimation of cyanide by means of silver nitrate] is not accurate." There are no references to the sources of information, and the whole section seems to have been drawn up in a perfunctory way.

Of even less value is part ii., which occupies twelve pages, and is on "The Present Condition of the Cyanide Industry." None of the information given in this part appears to be of later date than 1901, and some of the tables of figures end in 1896. The tables refer mainly to France, but there is a list of works producing cyanide compounds which applies to the whole world.

Part iii. occupies 213 pages, and gives a clear account of a very large number of methods of manufacture, most of which, as the authors are careful to point out, have never been successful on an industrial scale. All the chief cyanide compounds are dealt with, and separate chapters are devoted to the manufacture of cyanides, ferrocyanides, ferricyanides, and sulphocyanides. Sulphocyanides and, to a less extent, ferrocyanides owe their importance to their use in the preparation of cyanides, but the authors devote most attention to the interesting direct synthetic processes of making cyanides from carbon and nitrogen or ammonia.

The fixation of atmospheric nitrogen is a fascinating problem which is likely to continue to exercise the minds of chemists, and the translator, as an agricultural chemist, expresses the daring hope that the publication of this volume will result in the solution of the problem on an industrial scale. It is, of course, well known that cyanides are formed in blast furnaces, and many attempts have been made to apply this knowledge, beginning with Bunsen's special furnace, which was built in 1845. In most of the later processes, atmospheric nitrogen, freed from oxygen by passing it over heated metals or by distilling liquid air, has been passed over carbides of metals heated in electric or other furnaces, but although some progress has been made, the cyanide industry still continues to depend on more roundabout chemical actions. One of these is the synthesis of sulphocyanide by the action of ammonia on carbon bisulphide in the presence of a base such as lime, followed by the reduction of the sulphocyanide by means of carbon, metals, or hydrocarbons.

Illuminating gas and its residues constitute a source of cyanide which has not been fully exploited. The authors anticipate that in the future a large proportion of the required cyanides will be obtained from gas works, and estimate that in France alone 4,000,000 tons of coal used annually in the manufacture of illuminating gas could be made to yield cyanide compounds worth from eight to twelve million francs, all of which is now lost. In other countries, however, the matter has not been overlooked, and it is certain that the illuminating gas used in the world could be made to yield far more cyanide than could possibly be disposed of, unless new uses for cyanide should be discovered. The progress of the cyanide industry is checked rather by well-founded fears of overstocking the market than by the neglect by manufacturers of their opportunities or by the need of fresh sources of supply.

In part iv., which occupies twenty-seven pages, there is an adequate account of the use of cyanogen compounds, and this is followed by an appendix of seventy-one pages. Here a digest is given of the United States patents relating to cyanide processes for the recovery of the precious metals. No doubt the list is fairly complete, but it has nothing to do with the main subject of the book, and does not contain any reference to patents relating to the manufacture of cyanides. However, as it shows the activity of the consumers of cyanide, it may be taken as a tonic by disheartened manufacturers, who, after all, are probably more interested in markets than in chemical formulas.

T. K. Rose.

A YEAR ON THE "SIBOGA."

Ein Jahr an Bord I.M.S. Siboga. Von Frau A. Weber van Bosse. Beschriebung der Holländischen Tiefsee-Expedition im Niederländisch-Indischen Archipel 1899–1900. Nach der II Auflage aus dem Holländischen übertragen von Frau E. Ruge-Baenziger. Pp. xiii+370. (Leipzig: W. Engelmann, 1905.) Price 6s. net.

IN this book Mrs. Weber gives a popular account of the expedition the scientific results of which have been described in the "Siboga-Expeditie" edited by Dr. Max Weber.

The *Siboga*, a twin-screw vessel of the Royal Dutch Navy, built for the East Indian service, deprived of her armament, and specially fitted for her scientific voyage, left Surabaya, on the north coast of Java, on March 7, 1899, and returned thither on February 26, 1900, having spent the interval—practically a year—in exploring the marine, and especially the deep-water, fauna of the East Indies. The expedition consisted of Prof. Max Weber and Mrs. Weber, two scientific assistants, a doctor, and a draughtsman, and received from the naval staff of the vessel those ungrudging and invaluable services which the officers of our own Navy so invariably put at the disposal of the scientific members of an expedition. The investigation of the marine flora was in the hands of Mrs. Weber.

The course of the *Siboga* lay at first along the coasts of the Lesser Sunda group from Java to Timor, then across the Flores Sea to Saleyer Island, and to Macassar, in Celebes, where the expedition was landed for a time while the ship made a trip to Surabaya. On her return the voyage was continued through the Macassar Straits to the Sulu Islands, then southwards across the Celebes Sea to Kwandang, in Celebes, northwards again to the Sangir and Talaur groups, southwards through the Molucca Straits to Obi, and eastwards across the Halmahera Sea to the coast of New Guinea. From Atjatuning, in New Guinea, the ship sailed by Ceram, Amboyna, Buru, and Buton to Saleyer again. Here the expedition was left during a second trip of the *Siboga* to Surabaya. When a fresh start was made the course lay eastward across the Banda Sea by Amboyna to Aru and back to Amboyna. From this place the *Siboga* returned to Surabaya along the Sunda Islands by a different route from that which she had taken at starting.

The story of this voyage is pleasantly told by Mrs. Weber. Scattered through her account of the everyday life of the ship and the happenings at various stopping-places and dredging-grounds are allusions to the scientific discoveries of the expedition. Some of the soundings are particularly interesting. It appears that the Lombok Straits, instead of being a deep cleft between Bali and Lombok, are in reality quite shallow (170 fathoms). Since Weber has already shown that the fauna of the East Indies changes only gradually from an Asiatic to an Australian character in an easterly direction, we have now probably heard the last of that old friend of our student days, "Wallace's Line"—a picturesque and fruitful hypothesis, for all the contempt with which it is apt to be treated nowadays. On the other hand, interesting soundings of considerable depth were obtained among the islands—some 2700 fathoms in the Banda Sea and in the Celebes Sea, 2200 fathoms in the Ceram Sea, 1500 fathoms between the Banda Sea and the Flores Sea, and 2000 fathoms close to land off Saleyer. Near the latter island great banks of calcareous algæ were found, which recalls Stanley Gardiner's observations on the importance of these organisms in Funafuti and elsewhere. The plankton also seems to have been unusually rich and plentiful. The sea bottom is in many places rough, entirely unlike the oozy bed of the great oceans, and was the cause of much loss and damage to gear.

The book is well got up and illustrated by some good photographs, and should prove interesting to the large class of readers who are attracted by books of travel.

YORKSHIRE FUNGI.

The Fungus Flora of Yorkshire. By G. Massee and C. Crossland. Yorkshire Naturalists' Union Botanical Transactions, vol. iv. Pp. 396. (London: A. Brown and Sons, Ltd., 1905.)

THE Yorkshire Naturalists' Union has held and maintained a high place in the history of British cryptogams, and its published Transactions abound in records of fungi in which the county seems to be peculiarly rich. It is hardly surprising, therefore, that a scientific society of such well-proved eminence should every now and then issue the results of its labours, originally published in its serial journal, in the form of a separate book.

To do this in the case of the fungi required more initiative and enterprise than with most other cryptogams, and the committee is to be congratulated, not only on having carried the work through, since 1902, but on having done it so thoroughly and efficiently.

When we extend our congratulations also to the two authors responsible for the work, we may take the opportunity of pointing out that while one is an amateur field naturalist of that peculiarly enthusiastic and accurate type for which Yorkshire has long been famous, the other is a professional mycologist of high reputation; and the combined labours of the two give us all the advantages of the accurate and industrious notes of a collector who knows his county thoroughly, together with the critical supervision of one who knows his herbarium equally well, and who has had shed on to his shoulders the cloak of Berkeley, and has been a fellow-worker with Cooke.

The book consists of 365 pages with appendices and an index, a too meagre bibliography, and more than 2600 entries. There is a short introduction and classification, with notes on the distribution within the county. The work is by no means a mere catalogue, though in many cases little more than the record of the name is given, together with the localities in which the fungus has been found growing. Interesting notes as to the habit of the fungus abound, and while it is, of course, impossible in such a work to define species or even genera, there are excellent explanatory notes here and there for the use of the critical systematist.

The volume, which is neatly printed, is, in spite of rather too many misprints, indispensable to every professional mycologist, and will, of course, be the basis for all other fungus floras of Yorkshire and other counties.

The work affords a very good example of the excellent services to science which may be contributed by the collaboration of individual workers who are experts in different departments and will join their forces loyally for the benefit of the rest.

Of course, it is not claimed that all the fungi of the large area covered are recorded, and much remains for other workers, especially in the domain of the smaller and lower fungi; but, as has already been pointed out, we have a firm basis for the benefit of further workers, and shall hope to see the records gradually rendered more and more complete.

OUR BOOK SHELF.

The Principles and Practice of Iron and Steel Manufacture. By Walter Macfarlane. Pp. xi+266; 96 figures. (London: Longmans, Green and Co.) Price 3s. 6d. net.

THIS is a difficult book to review so as adequately to represent the nature of its contents to the "technical students, metallurgists, engineers," and others for whom it is intended. The somewhat florid style of the introduction, "Machinery ponderous and powerful or nimbly delicate and deft . . ." would lead one to expect a kind of poetic phantasy woven to give joy to the general reader, and the expectation is supported by the last sentence, about iron being the Master Metal because it has so many good qualities in well-balanced proportion. Really it is quite human, however, in that it has many wicked ways also, well known to the aforesaid engineers.

Later in the work there is a compound of the general and the technical, as is evidenced by the type of illustrations, numbering about a hundred, of which a considerable proportion are reproductions from photographs; thus, "Fig. 6, Charging a puddling furnace"; "Fig. 44, Siemens casting pit with ladle in the distance," evidently taken with a short-focus lens, for the ladle seems about half a mile away; "Fig. 54, Shovelling lime into a steel melting furnace"; while "Fig. 52, Empty steel ladle," may be introduced to finish with a little humorous touch. Taking at random the working of an acid open-hearth charge, the author says that after melting (p. 117) "Oxidation steadily proceeds. In the first two stages the oxidation is effected by the excess air which enters the furnace along with the producer gas. The oxidised products SiO_2, MnO, and some FeO and Fe_2O_3 go into the slag. In the third stage oxidation is largely due to the oxygen in the ore which is fed in." On p. 122 the author distinctly says, "During the third or boiling stage . . . when this stage is reached ore is cautiously fed into the furnace. . . ." How long it would take an ordinary charge to come on the boil without ore one could hardly guess, but to bring it on in a reasonable time requires very considerable additions of ore to get the slag into proper condition. This is a grave error for an author who has been fourteen years in iron and steel works, and is also very misleading to a student of the subject. The matter has been dealt with in recent and ancient literature.

To sum up, the work may be of considerable interest to the general reader, but can hardly be recommended as a guide to the technical man engaged in such work as the manufacture of steel.

On Models of Cubic Surfaces. By W. H. Blythe. Pp. xii+106. (Cambridge: University Press, 1905.) Price 4s. net.

MR. BLYTHE has attempted a difficult task, to give an account of methods of constructing models of a cubic surface without either assuming all the theory of the surface as known or recapitulating it; the result, so far as the introductory portions of the book are concerned, is an unsatisfying mixture of rudiments and quotations and references to difficult theorems. As regards the latter portion Mr. Blythe may best speak for himself. "About ten years ago my attention was drawn to arranging the twenty-seven straight lines. . . . After constructing several models, I did not continue the series, for I subsequently found that a complete set had been made in Germany. . . . Copies of these models can be purchased. Still the models described in this book are sufficient to give an idea of the shape of a cubic surface."

We think Mr. Blythe is too modest, and that this little book of a hundred pages will be of interest to those who are studying the surface and desire actually to make models; but it must be confessed that in our opinion the writer would have been better advised either to make the theoretical portions more systematic or to have omitted them, and given a fuller account of the models with many more figures. Perhaps it is fair to say that Mr. Blythe's book is a good example of what may in cases be the bad effects of a too rigid and uniform examination system; it happens that cubic surfaces are outside what is regarded as the normal course of geometry for a student for the mathematical tripos; under a free and stimulating system, when Mr. Blythe first began to take an interest in models of cubic surfaces he would have been encouraged by his environment to go on and make a complete set, and other students would have helped him, and there would have been formed a fresh rootlet for the mathematical school to grow from; as it is, the environment requires either that he should invent a completely novel theory of the surfaces or models, or pay the penalty of being regarded as off the track, except by those few who value mathematics as they find it interests them.

A Synonymic Catalogue of Homoptera. Part i. Cicadidæ. By W. L. Distant. Pp. 207. (London: Printed by Order of the Trustees of the British Museum, 1906.)

MR. W. L. DISTANT has for many years made a study of the Rhynchota, and has paid particular attention to the Cicadidæ. The catalogue of this family, together with a synopsis of the subfamilies and genera now published, was, we learn from Prof. E. Ray Lankester's preface, generously placed at the disposal of the Trustees of the British Museum by Mr. Distant. This work should be of great assistance to students of this group of insects.

Iona. By Elizabeth A. McHardy (Mrs. Raymond Smith). Pp. 48. (Glasgow: R. Gibson and Sons, Ltd., n.d.) Price 1s. net.

THIS attractive booklet provides brightly written and well illustrated accounts of Iona—"the Blessed Isle"—and of Staffa with its wonderful Fingal's Cave, together with an appreciation of St. Columba. It should not be long before the little publication secures a wide popularity among visitors to the west of Scotland.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Kew Publications.

As I was responsible before I left Kew for the publications noticed in NATURE of June 21 (p. 180), perhaps I may be permitted a few words of explanation.

The Kew Bulletin was not intended at the outset to rank with scientific journals. It was started at the desire of Parliament for the purpose of issuing, for public use, information for which there happened to be a demand, and of a commercial, or at any rate economic, kind. It was subsequently decided by the Government that it should be the vehicle for other matter, scientific or otherwise, for which prompt publication seemed desirable.

It is sent out to all the botanic and agricultural departments in correspondence with Kew in India and the colonies, and much of its contents is usually reprinted in the local journals.

It also serves the purpose of expeditiously answering inquiries at home. A stock of the numbers is kept at Kew for communication to correspondents. So useful has it proved in this way that it has been necessary to reprint more than once a large number of the articles. The output in any one year may have been exiguous; but if there was no urgent demand for information on some new subjects, there was usually more pressing work on hand than the mere manufacture of padding. As, however, the Bulletin is filed in many libraries, I was glad to have the leisure to put the successive annual volumes into a shipshape form. When the next general index is issued the whole series of volumes will form a sort of rough, though necessarily incomplete, encyclopædia of practical information on Indian and colonial agriculture and products.

The announcement of appointments may have been belated, but that again is of little consequence, as they are only intended to be items in a continuous record.

The catalogue of portraits was not supposed to be exhaustive, and does not compare, therefore, with the "Catalogus Stockholmiensis." It is simply a hand-list for the use of visitors of the portraits exhibited in Museum No. 1. The Kew collection has always been popular, and, as I know of no other, *is* "probably unique," but it has latterly grown out of all bounds. As the available space was restricted, I made a selection, and, so far as prints were concerned, had them uniformly framed. I was guided by considerations which I have stated in the preface, and I confess I was largely influenced for the purpose of public exhibition by artistic merit. Mere trivial photographs and cuttings from illustrated papers, though valuable so far as they go, seem to me most conveniently preserved in portfolios.

The personality of those who have made a mark in scientific history has, I think, a peculiar, because intimate, interest. The world is certainly the poorer for having no portrait of Gilbert White. Only recently I have seen the posthumous portraits of two distinguished men of whom no memorial now remains which bears the impress of vitality.

In the seventeenth and eighteenth centuries few men of any note disdained to transmit their portraiture to posterity by the aid of the engraver. It was not, indeed, until the middle of the last century that the practice expired in the more feeble art of the lithographer. Some examples of its decadence I felt obliged to withdraw as painful caricatures. Nowadays, modesty or indifference seems to leave neglected all but the most eminent. I am not without hopes that more space may be found at Kew for portraits. I hope the collection may continue, as in the past, to be the recipient of gifts from private liberality, and that in this way many obvious gaps may be filled up.

W. T. THISELTON-DYER.

Witcombe, Gloucester, June 25.

A Remarkable Lightning Discharge.

THE afternoon of Saturday last, June 23, was sultry, and it was therefore without surprise that about 8.30 p.m. we observed the reflection in the clouds of lightning to the west and south-west, and heard from time to time the low sounds of distant thunder; there was no indication of the storm coming near to us until 9.30 p.m., when we were startled by a tremendous explosion and a brilliant flash of light, which, according to some observers, was continued after the explosion took place. This explosion was, I think, the loudest that I ever heard, and the impression on all of us was that it was quite close, and I am told that it was heard nearly two miles off as if it was close at hand. The thunderstorm continued for some hours after this explosion, but never came near to us.

It was not until the next morning that we discovered the scene of the explosion of the fire-ball, if such was the nature of the agent.

In one part of the garden here there is a mound—the remains of an old greenhouse—of irregular form and height—on the northern side grown over with ferns, ivy, and weeds, from which, towards its western end, grows an ash tree of moderate size, which gives out its first branches between 16 feet and 17 feet from the ground. The leaves of the tree seem intact, but the ivy of the trunk, from immediately below the branches down to the mound, has been more or less stripped of its leaves; a space half round the tree has been disturbed, and the weeds and plants thrown down, very much as if they had been trampled down by human feet; and this disturbance is continued in a line down the mound on the northern side, the plants being depressed from above downwards, and the gravel path at the foot of the mound broken up more than halfway across. Many of the leaves of the ivy have been scattered about, and many of the leaves lying on the mound have been torn to pieces. Several pieces of dead wood on the mound have been broken asunder. A branch of ivy close to the root of the ash tree has been stripped of its bark; an old brick lying on the mound under the vegetation was broken into four pieces, two small pieces and two large of nearly equal size; one of these larger pieces was found on the mound, one was found about 7 feet 6 inches from the point at the foot of the mound where the disturbance was seen, one smaller piece was about 7 feet beyond this, and another yet 2 feet further beyond the last. A piece of highly-crystallised Old Red Sandstone lying on the mound was found with a new and unweathered exposure several inches in length, and fragments of the same stone with new faces were lying near.

The conclusion from these facts seems to me to be that the electric agent, whether a fire-ball or not, must have approached the ash tree in a nearly horizontal line and struck it just below the lowest branches, have passed down the tree to the mound, have disturbed the vegetation to the south of the trunk of the tree, have passed then towards the north down the mound, and then to have nearly crossed the garden path, when it disappeared. When exactly the explosion took place I feel at a loss to ascertain, but perhaps some of your readers may be able to assist in determining this point.

Failand, near Bristol, June 25.

The Magnetic Inertia of a Charged Sphere in a Field of Electric Force.

DR. O. HEAVISIDE has investigated (NATURE, April 19) the slow motion of a charged conducting sphere through a uniform electric field, in a direction *parallel* to the electric force of the field, and has calculated the increase in the magnetic energy and inertia of the sphere resulting from the re-distribution of the charge under the influence of the field. His paper has suggested the following investigation, in which the slow motion of the sphere is *at right angles to* the direction of the electric field. But, as Dr. Heaviside has pointed out to me, this problem has no single definite solution. For, if the sphere, initially at rest in the field, be set in motion, the motion of the unequally distributed charges on the surface of the sphere will tend to give rise to magnetic force in the interior; but the magnetic force will only gradually penetrate into the interior, and electric curents circulating in the sphere in parallel planes will cause a magnetic force opposed to that due to the moving charges. If the conductivity be perfect, these currents will persist, and the interior of the sphere will be permanently free from either electric or magnetic force; but, with finite conductivity, the currents will die away, and the magnetic force will finally attain a definite value inside the sphere, although the electric force vanishes. In each of these cases a solution is easily found; but while the currents are dying away the magnetic energy gradually changes, and the calculation of the energy at any given time might be difficult. I therefore confine myself to the two limiting cases. The case of the final stage when there is finite cunductivity I had solved when Dr. Heaviside suggested to me that I should include the case of infinite conductivity in my investigation. The present communication is the outcome of that suggestion.

The sphere is of radius a, and carries a charge Q at a speed u, which is very small compared with v, the velocity of light; the strength of the field is F, and the specific inductive capacity is c. I employ Dr. Heaviside's units in order that my results may be comparable with his. The origin is at the centre of the sphere, and the axes of x and y are respectively parallel to the direction of motion and to the direction of the uniform electric field.

When u/v is very small, the electric force E, *due to the moving sphere*, is the same as if the sphere were at rest, and is therefore derivable from a potential function. Since there is no electric force inside the sphere, the induced distribution on the sphere produces the potential Fy at internal points, and hence produces the potential Fa^3y/r^3 at external points. Thus at internal points the components of E are

$$E_1=0, \quad E_2=-F, \quad E_3=0,$$

while at external points they are

$$E_1=\frac{Qx}{4\pi cr^3},$$

$$E_2=\frac{Qy}{4\pi cr^3}+Fa^3\left(\frac{3y^2}{r^5}-\frac{1}{r^3}\right),$$

$$E_3=\frac{Qz}{4\pi cr^3}+Fa^3.\frac{3yz}{r^5}.$$

Finite Conductivity, Final Stage.—In this case the magnetic force is entirely due to the motion of the charge on the sphere, and we have

$$H_1=0, \quad H_2=-ucE_3, \quad H_3=ucE_2,$$

and thus $H^2=u^2c^2(E_2^2+E_3^2)$.

If, now, we write

$$x=r\cos\theta, \quad y=r\cos\phi\sin\theta, \quad z=r\sin\phi\sin\theta,$$

we find that for internal points $H^2=u^2c^2F^2$, and that for external points

$$H^2=u^2c^2\left[\frac{Q^2\sin^2\theta}{16\pi^2c^2r^4}+\frac{QFa^3}{2\pi cr^5}\cos\phi\sin\theta(3\sin^2\theta-1)\right.$$
$$\left.+\frac{F^2a^6}{r^6}\left(1-6\cos^2\phi\sin^2\theta+9\cos^2\phi\sin^4\theta\right)\right]$$

The magnetic energy is $\frac{1}{2}\mu H^2$ per unit volume, and thus the total magnetic energy is

$$T=\tfrac{1}{2}\mu u^2c^2F^2.\tfrac{4}{3}\pi a^3+\tfrac{1}{2}\mu\int\int\int H^2r^2\sin\theta\,dr\,d\theta\,d\phi,$$

where r ranges from a to infinity, ϕ from 0 to 2π, and θ from 0 to π. On effecting the integration, we find

$$T=\tfrac{1}{2}u^2[\mu Q^2/6\pi a+16\pi\mu c^2F^2a^3/5]=\tfrac{1}{2}mu^2,$$

where m is the magnetic inertia.

For motion parallel to F instead of right angles to it, Dr. Heaviside finds (Nature, April 19)

$$T=\tfrac{1}{2}u^2[\mu Q^2/6\pi a+8\pi\mu c^2F^2a^3/5].$$

When the quantities are measured in ordinary units the results become

$$T=\tfrac{1}{2}u^2[2\mu Q^2/3a+4\mu c^2F^2a^3/5] \qquad \text{(Searle)}$$

and

$$T=\tfrac{1}{2}u^2[2\mu Q^2/3a+2\mu c^2F^2a^3/5], \qquad \text{(Heaviside)}$$

where, if we use C.G.S. electromagnetic units, we have $\mu=1$ and $c=(3\times10^{10})^{-2}$.

Infinite Conductivity.—In this case a system of currents flows round the sphere, on its surface, in planes normal to the axis of z, the distribution being such as to give rise to a magnetic potential $-ucFz$ at internal points. The magnetic force due to these conduction currents then neutralises, at internal points, the magnetic force ucF due to the moving charges. The external magnetic force *due to the conduction currents* will satisfy Laplace's equation for very slow speeds, and must, therefore, be expressible in zonal harmonics, while, for all speeds, the magnetic force normal to the sphere must be continuous. If $z/r=\cos\psi$, the normal force at points just inside the sphere is $ucF\cos\psi$. The conditions are satisfied by the external potential

$$\Omega=ucFa^3\cos\psi/2r^2=ucFa^3z/2r^3,$$

for this is a zonal harmonic, and gives rise to the normal force $ucF\cos\psi$ at the surface.

Thus, at external points,

$$H_1=-d\Omega/dx, \quad H_2=-d\Omega/dy-ucE_3, \quad H_3=-d\Omega/dz+ucE_2,$$

where E_1, E_2, E_3 have the values already given. We thus find

$$H_1=\frac{3ucFa^3xz}{2r^5},$$

$$H_2=-\frac{ucQz}{4\pi cr^3}-\frac{3ucFa^3yz}{2r^5},$$

$$H_3=\frac{ucQy}{4\pi cr^3}+ucFa^3\left[\frac{6y^2+3z^2}{2r^5}-\frac{3}{2r^3}\right].$$

It will be found that $xH_1+yH_2+zH_3=0$ for all values of r, and thus the magnetic force is tangential to the sphere, a condition pointed out to me by Dr. Heaviside.

Hence we find

$$H^2=u^2c^2\left[\frac{Q^2\sin^2\theta}{16\pi^2c^2r^4}+\frac{3QFa^3}{4\pi cr^5}\cos\phi\sin\theta(2\sin^2\theta-1)\right.$$
$$\left.+\frac{F^2a^6}{4r^6}\left\{36\sin^4\theta\cos^2\phi-9\sin^2\theta(4\cos^2\phi+\sin^2\phi)+9\right\}\right].$$

Remembering that $H=0$ at points inside the sphere, we find, on integration through the external space, that the magnetic energy is

$$T=\tfrac{1}{2}u^2[\mu Q^2/6\pi a+6\pi\mu c^2F^2a^3/5].$$

When the quantities are expressed in ordinary units the result becomes

$$T=\tfrac{1}{2}u^2[2\mu Q^2/3a+3\mu c^2F^2a^3/10].$$

If an electron be a conducting sphere of radius 10^{-13} cm. with a charge of 10^{-20} electromagnetic units, an electric force of a billion volts, or 10^{20} C.G.S. units, per centimetre, would not change its magnetic inertia by so much as one part in ten billions, and the results are of no consequence in experiments on the electrostatic deflection of kathode rays; but it is possible that there are other cases where it would be necessary to take the change of magnetic inertia into account.

When u becomes comparable with v, the analysis becomes more complicated, but does not present any difficulty, at least in the final stage, with finite conductivity, provided a Heaviside ellipsoid be substituted for a sphere.

In conclusion, I desire to acknowledge the help I have received from Dr. Heaviside's suggestions, and to thank Mr. Norman R. Campbell for verifying the formulæ.

G. F. C. Searle.

The Date of Easter.

That the formula of Gauss for finding the date of Easter fails in certain cases, of which the year 1954 is one, was pointed out by Gauss in his original paper in the *Monatliche Correspondenz* (vol. ii., p. 129), where he shows that there are the following two exceptions to the formula in the Gregorian calendar:—

(1) When the formula gives April 26, Easter falls on April 19.

(2) When the formula gives $d=28$, $e=6$, while $11M+11$ divided by 30 gives a remainder smaller than 19, then

Easter does not fall on April 25, as given by the formula, but on April 18.

These exceptions are caused by an inconsistency in the Gregorian rule, caused by the adherence to the old custom, that Easter should never fall later than April 25.

Armagh Observatory, June 22. J. L. E. DREYER.

THE discrepancy between the date of Easter, 1954, April 18 as given by the tables in the Book of Common Prayer, and April 25 as given by the formula of Gauss, arises from a purely artificial contrivance of Clavius, who arranged the reformed calendar, which is thus described on p. 55 of "The Prayer Book Interleaved," 1873, in an account of the calendar founded on a paper by Prof. De Morgan:—"It will never happen as to mean lunations, and rarely as to real ones, that in the same cycle there should be the lunation of a given month beginning on the same day in two different years of the cycle; and such a thing never happened in the unreformed Calendar. Clavius thought it desirable to imitate this in the new Calendar; and he observed that by taking the preceding day whenever the Epact was xxv., and the year of the cycle after the 11th, he could avoid the reiteration, and thus make the desired resemblance." "Whenever the Epact should be xxv., the year of the cycle being upwards of 11, say that the Epact is 26. This is not an astronomical correction, but a mere conventional mode of reconciling the choice which Clavius made of the mode of writing the Epacts with an essential peculiarity of the old cycle of 19 years which that mode of writing would have otherwise destroyed." "In 1954 the Golden Number is 17, the Sunday letter C, and the Epact according to the ordinary rule, xxv. *Call it therefore* xxvi. Thence April 17 will be the 14th day of the Paschal Moon, April 18, Easter Day. If the Epact xxv. were used April 25 would be Easter Day." The paper by Prof. De Morgan will be found in the "Companion to the British Almanac" for 1845.

My copy of NATURE for April 5 has long since gone to Bolivia, but probably your correspondents will find that Gauss did not take into account this artifice of Clavius. If in this century golden number 6 and Sunday letter C had coincided, Easter would have been set on April 25, because 6 comes in the cycle before 11 instead of after it as 17 does. An inspection of Table III. for finding Easter will show in the two half-lines for April 17 and 18 the arrangement made by Clavius. C. S. TAYLOR.

Banwell Vicarage, June 22.

Musical Thunder.

EARLY this morning a storm broke in this neighbourhood accompanied by heavy thunder. During the storm I noticed that two of the peals began with a musical note of distinct and definite pitch. The "musical" portion of the peal lasted for about two seconds in each case, and the frequency of the note was both times about 400 per second.

This sound closely resembled a foot-fall in a narrow alley between high walls, and was only heard in two consecutive peals, separated by an interval of about a minute, the first being much more definitely musical than the second. In each case the interval between the flash and the first sound of thunder was about five seconds.

As is well known, a peal of thunder from lightning near at hand frequently sounds like a quick succession of raps or a volley of guns. Can the successive raps have followed one another so rapidly in this case that they combined to form a note?

If so, and if this note was due to a special configuration of reflecting surfaces in the clouds, possibly to others in slightly different positions, considerably different frequencies may have been observed.

The fact that two peals only sounded in this manner separated by the short interval of about one minute, and that the second was not so decidedly musical as the first, seems to indicate that they were due to some rapidly changing source such as one might expect the reflecting surfaces of a cloud to be. I listened carefully to determine that the note had its origin outside and was not due to resonance within the room, and in the second peal it was certainly outside, and probably had the first had its origin within the room I should have observed it.

I should be very glad to hear if anyone has observed a similar phenomenon. G. H. MARTYN.

1 Marden Road, S. Tottenham, N., June 24.

How do Inquiline Bees find the Nest of their Host?

THE following observation may serve to throw light on the above question, which has doubtless occurred to many entomologists. Yesterday I saw a specimen of the inquiline *Coelioxys quadridentata* enter the burrow of a leaf-cutter bee, *Megachile circumcincta.* I dug the nest out of the burrow, and in so doing scattered the sand over an area of several square inches, completely destroying all appearance of a burrow. I sat down to await the return of the Megachile, in order to identify the species, and was much astonished to see (and capture) in the course of the next ten minutes two more specimens of Cœlioxys, which came hovering over the spot and alighted on the disturbed soil. I can think of no other explanation than that these "cuckoos" were attracted to the spot by the scent of the excavated nest. I may add that during several hours spent on the heath where this occurred I saw no other specimens of Cœlioxys, and, further, that there was a fresh south-east breeze blowing at the time, and that the bees came up against the wind.

OSWALD H. LATTER.

Charterhouse, Godalming, June 24.

THE DISTURBANCE OF GREENWICH OBSERVATIONS.

IN the House of Lords on Thursday last, June 21, attention was directed to the threatened danger to the continued efficiency of the Royal Observatory, Greenwich, caused by the great electrical generating station erected by the London County Council about half a mile due north of the observatory. The danger was referred to by the Astronomer Royal in his report to the Board of Visitors on May 30, a summary of which appeared in NATURE of June 7 (p. 135). The generating station is situated exactly in the Greenwich meridian, as will be seen from the accompanying photograph of a view looking north over the top of the transit room; and the tall chimneys shown in the picture, as well as the heated air from them, will obviously interfere with some observations of northern stars, which are essential for latitude and refraction. Moreover, from tests already made it appears that the powerful engines which are being installed at the generating station will cause vibrations that will seriously affect the value of observations by reflection from a mercury horizon, required for the fundamental work of the observatory.

This is not the first time that the effects of generating stations and electric tramway systems in the neighbourhood of the observatory have been pointed out. About six years ago the question of the possible effect of disturbances from electric railways on the magnetic work carried on at the observatory was given careful consideration; and the hope was then expressed that in the event of future electric tramways regulations would be laid down by the Board of Trade to secure adequate protection for the magnetic work. The records in this department of the observatory have been obtained continuously on a general system for sixty-five years, but the astronomical work extends over more than two centuries and a quarter, and it would be unfortunate if circumstances should arise to break this chain of continuity.

The generating station established at Deptford—nearly a mile from the observatory—to supply the London County Council Tramways with electric power, has not caused such serious tremors as are produced by the small portion of the engineering plant now available for work at the new station, which is much nearer and larger. It appears, therefore, that if the new station is completed and equipped to supply electric power over London, though it was authorised only for the requirements of tramways, the work of the observatory will be impaired to no slight extent. When the scheme was first put forward, it was not supposed that the works or the engines would assume the gigantic and overpowering proportions now contemplated, and the Astronomer Royal, in referring to this point in his report, remarks :—

The question arises why the immediate neighbourhood of the observatory should be selected for the planting of generating stations on an unprecedented scale to supply electric power to distant districts. The very powerful engines required for such a large output are liable to cause

FIG. 1.—View of chimneys of the electrical works of the London County Council, looking north over the transit room of the Royal Observatory, Greenwich. The roof of the transit room is shown at the bottom of the picture.

vibrations the extent of which could hardly be anticipated from previous experience of ordinary engineering plant or of railway trains, which have hitherto not affected the work of the observatory.

The question as to the action the Government proposes to take to prevent the Royal Observatory from being injuriously affected by electric stations or other works, either at present or in the future, was asked in the House of Lords by Lord Ellenborough, who remarked that the difficulty which has arisen might have been obviated to some extent by the installation of turbines or triple-expansion horizontal engines instead of vertical engines. The Earl of Crawford pointed out that the interference with observations would arise from the heated air of the chimneys and the tremors due to machinery in motion. He said in the course of his remarks :—

The essentials for observation of an astronomical kind are stability and quietude. Nothing is so dangerous in astronomical observation as the unknown errors which have to be guarded against at the present time. If an error is known no great harm is done. In connection with the meridian, careful observations of the moon require to be made. For very many years the moon has been given over by the scientific world to Greenwich Observatory. The Royal Observatory has specialised on the moon mainly owing to the grand labours of Sir George Airy, the late Astronomer Royal, so that the position of the moon at a given time hence may be fairly accurately predicted. The observations at Greenwich, and the manner in which they have been carried out by the late Astronomer Royal, have led the whole scientific world to say, "Gentlemen, you know your moon so well, pray continue to be responsible for her." If now Greenwich is reduced to the position of saying that its lunar observations have not the weight and value which so far have attached to them, it will be a terrible blow to the reputation of the Royal Observatory and also to our existence as a scientific country. Another difficulty is that disputes as to boundaries between countries are mainly settled by astronomical observation as to the position of the moon, and as the moon is being constantly watched at Greenwich Observatory, applications are frequently received from foreign countries as to the error of the moon at such an hour on such a day. This also shows how extremely importanr it is that the observations at Greenwich should be trustworthy.

The suggestion that the observatory should be moved from Greenwich was considered by Lord Kelvin to be a most undesirable solution of the difficulty. He added :—

Even at present we may look forward to possible changes in the arrangement of the works by which the electricity will not seriously disturb or practically cripple the astronomical observations at Greenwich. The disturbance caused at the observatory by the vibration from the electric works may be to some extent avoided by the substitution of steam turbines for reciprocating engines and the use of different electric dynamos. It is no exaggeration to say that the whole world outside, as well as the British Empire, would deplore anything that would injure the great and good work done in the Royal Observatory at Greenwich, and both Houses of Parliament should unite in preserving it.

As further development of the machinery equipment must increase the effects shown by the tests already made, Earl Cawdor considered that powers should be obtained, or set in action, to prevent the County Council from carrying out works that injure the observatory, and that the half a million pounds expended by the Council is a small sum compared with the matter at stake.

Replying on behalf of the Government, Lord Tweedmouth, First Lord of the Admiralty, made the following statement of the case; and his remarks, with those contained in the recent report of the Astronomer Royal to the Board of Visitors, are the only official comments available upon the subject :—

Since the subject was raised it has been closely considered at the Admiralty. As to the origin of this generating station, in 1901 the London County Council resolved on it, and in 1902 a Bill was passed through Parliament. In this Bill was inserted a clause, known as the Observatory clause, which gave to the Board of Trade the power, if any use of electrical power was likely to affect injuriously the instruments used in the observatory, to require reasonable and proper precautions to be taken. This proposal was made public and approved by Parliament. It is a pity that the County Council did not more closely apprehend the possibility of danger in choosing this particular site, but some responsibility must also be attached to the various departments and to Parliament. At present, at any rate, no absolute damage has been done, but there is an apprehension of it when the station is developed to its fullest power. It will be almost the biggest generating station in the world when completed. Eight engines will work up to 52,000 horse-power, and the electricity generated will be sufficient to work the whole of the London tramway system. At the present time the Astronomer Royal said that no serious effect has as yet arisen in the working of the principal meridian instrument. The Astronomer Royal, however, says that the instrument which has been affected is the portable transit instrument used for determining longitude. From the large generating station at Deptford no damage has resulted, and there is no indication of any disturbance. What the authorities have to do is to take very careful observation as to what is exactly going on at Greenwich. At present the station is never worked up to more than 3000 horse-power. A trial has been made of two engines, but the experiments are neither complete nor satisfactory. It is proposed to ask Prof. Ewing to represent the Admiralty in the observations to be taken, which must extend over a considerable time. The disturbances vary very much, and there is a great deal to be said as to the possibility of meeting the difficulties by reducing the high chimneys, though the Astronomer Royal does not think that the vapour of the chimneys seriously interferes with the observations. It is proposed also to ask the County Council to appoint a representative of its own for observation in order to have an independent report as to the exact amount of disturbance that might arise. The London County Council will not go on with the two chimneys, which are now only partly erected. Before doing anything it is necessary to discover whether by any re-arrangement of the machinery the threatened damage can be averted. Every effort will be made to make the inquiry a thorough one, and one which should command everyone's respect.

The position then, as stated by Viscount Goschen, is that a mistake has been made—a mistake by the Admiralty, by the Astronomer Royal, by the County Council, and by Parliament. The matter affects, not only the Royal Observatory, but the whole world; and the best scientific knowledge available should be utilised to avert any danger which imperils the useful existence of the observatory or interferes with its work.

THE SEA-SERPENT.

THE narrative of an encounter with the "sea-serpent" on December last off the coast of Para, given by Messrs. Nicoll and Meade-Waldo at the meeting of the Zoological Society held on June 19, has once more awakened interest in the question as to the possibility of the existence of a large unknown marine vertebrate animal. The appearance of the so-called "sea-serpent" has been recorded from time to time by quite a number of witnesses. Many of these alleged appearances were evidently based on objects other than vertebrate animals unknown to science, but others, as being witnessed by trustworthy and educated observers, are evidently worthy of more serious consideration. The importance of the recent case—of which more anon—is that it was witnessed by two gentlemen who have undergone a long training in the observation of animals, and are therefore far less likely to be mistaken than persons who have not specially devoted themselves to the study of natural history.

To attempt to record on the present occasion all the trustworthy cases of the alleged appearance of the sea-serpent (for the sake of convenience we may discard the inverted commas) would much exceed our limits of space, and we may therefore refer our readers to the volume by Mr. A. C. Oudemans entitled the "Great Sea Serpent," published in 1892, where all the more important ones up to that date will be found mentioned. It may be profitable to refer, however, to a few of the published opinions of naturalists on the sea-serpent question. In his *Challenger* book, the late Prof. H. N. Moseley wrote as follows:—

"The sea-serpent, however, is always open to criticism. This wonderful animal has hardly ever been seen alike by any two observers. It is nearly always easy to a naturalist to understand the stories told. Sometimes it is a pair of whales that is seen; sometimes a long mass of floating seaweed deceives the distant observer; sometimes the serpent has large eyes and a crest behind the head; then it is a ribbon-fish. I myself am one of the few professed naturalists who have seen the serpent. It was on a voyage to Rotterdam from the Thames. . . . It was a flock of cormorants, which were flying in line behind the waves, and which were viewed in the intervals between them with a sort of thaumoscopic effect."

Clearly Mr. Moseley was not "on the side of the angels"; neither was Sir Richard Owen, who attempted to explain the undermentioned appearance seen by the officers of the *Daedalus* by the seaweed theory; and that some of the appearances can be explained by Moseley's suggestions, or by a school of porpoises, may be candidly admitted.

Mr. F. A. Lucas, on the other hand, in his "Animals of the Past," although confessing himself an "agnostic" in regard to this subject, takes up a somewhat less uncompromisingly hostile attitude.

"Like the 'fossil man,'" he writes, "the sea-serpent flourishes perennially in the newspapers, and despite the fact that he is now mainly regarded as a joke, there have been many attempts to rehabilitate this mythical monster and place him on a foundation of firm fact. The most earnest of these was that of M. Oudemans, who expressed his belief in the existence of some rare and huge seal-like creature whose occasional appearance gave rise to the reports of the sea-serpent. Among other possibilities it has been suggested that some animal believed to be extinct had really lived to the present day. Now there are a few waifs, spared from the wrecks of ancient faunas, stranded on the shores of the present, such as the Australian ceratodus and the gar-pikes of North America. . . . If a fish of such ancient lineage as the gar-pike is so common, why may there not be a few plesiosaurs or a mosasaur in the depths of the ocean? The argument was a good one, the more that we may 'suppose' almost anything; but it must be said that no trace of any of these creatures has so far been found outside of the strata in which they have long been known to occur, and all the probabilities are opposed to this theory."

The event recorded by Messrs. Nicoll and Meade-Waldo took place in the forenoon of December 7, 1905, when they were on board the yacht *Valhalla* off the coast of Para. At a distance of about 100 yards from the vessel the two observers saw what appeared to be the vertical dorsal fin of some large animal, and a short time afterwards the head and neck of an animal was raised above the water some distance in advance of the fin. The head was compared to that of a turtle, while the neck appeared to be about 6 feet in length. The description, so far as we can judge, suggests a creature of not more than about 20 feet or 25 feet in length. Although the vessel was subsequently put about, no further signs of the sea-serpent were seen during daylight. It is, however, noteworthy that during the night two of the ship's officers became aware of the presence of some large animal swimming alongside the yacht at a rapid pace; the two officers, it is stated, had no cognisance of the events of the morning.

A most significant feature in this circumstantial account is that it tallies to some extent with the narrative given by the officers of H.M.S. *Daedalus* of the appearance of the sea-serpent seen by them in the year 1848 in the Atlantic.

In the figures given by Oudemans the (double) back-fin is very low, and the neck seems relatively short and ill-defined. Revised restorations, however, give a longer neck and no back-fin. It is possible, if a fin was present, that its apparent difference in height in the two instances was due to the animal swimming faster in one case than the other. *Megophias megophias*, it appears, is a name which has been suggested for the creature. In 1903 Prof. Racovitza (Bull. Soc. Zool. Paris, xxviii., p. 11) gave an account of a sea-serpent seen by Lieut. Lagresille in 1898 in Along Bay, Tonkin, and in 1904 M. Vaillant (Bull. Mus. Paris, x., p. 217) mentioned another apparition of an apparently similar creature in the same locality. In this second account the animal is described as being probably scaled, with a head like that of a turtle or a seal, and as "spouting" from terminally placed nostrils. It was also stated to move in undulations—at one time vertical, at another horizontal. Two occurrences in the same locality are very noteworthy.

In each of these four instances it can scarcely be doubted that the object seen was a living creature (or creatures) of some kind, and that it (or they) was of the same general type. If the object were formed by more than one animal, *cadit quaestio*. If, on the other hand, it consisted of a single individual, furnished with a dorsal fin, a long, snake-like neck, and a head like a turtle, it could scarcely be any known living animal. Neither, it may be suggested, could it be even an unknown type of seal, especially since all the known members of that group come ashore to breed. The next question is, Could it have been a survivor of some Mesozoic reptilian? Two arguments, so far as they go, are against this. Firstly, the one referred to by Mr. True as to the absence of the remains of any such creature in Tertiary deposits, and secondly (on the hypothesis that it is an air-breathing vertebrate, and if not, why should it come to the surface at all?), the rarity of the sea-serpent's appearance, the latter argument being applicable whether the creature is considered to belong to a supposed extinct group or not.

With regard to the fossil theory, it might be urged that the creature is an inhabitant of the deep sea, and consequently that its remains should not be expected to occur in Tertiary deposits, which belong for the most part, at any rate, to more or less shallow water. For what it is worth, it may be mentioned in reply that no traces of the creature have been found on the ocean bottom, where sharks' teeth and cetacean ear-bones are common. A more forcible objection is that, if the creature is in the habit of coming to the surface (as on the hypothesis of its existence it must), it cannot be a denizen of the abysses, no animal (despite the old belief in regard to whales) being able to live under such diversities of pressure. *Ergo*, its remains ought to occur in Tertiary deposits. Its stranded carcase ought also to have been found. If the creature be a "living fossil," the plesiosaurian group has the strongest claim to its ownership, as, although the zeuglodont cetaceans are the latest in time of possible extinct representatives, the smallness of its head prevents the reference of the sea-serpent (as described) to that group. As to the rarity of its appearance, it can scarcely be urged that only two or three (or even half a dozen) examples of the creature are in existence.

Without offering any suggestion as to what the nature of the object seen by Messrs. Nicoll and Meade-Waldo really was, it may be pointed out that the testimony of two such trained observers (supplemented by that of the officers of the *Daedalus* and by the two "apparitions" off Tonkin) cannot possibly be brushed aside in the light-hearted manner with which Prof. Moseley treated the evidence available in his time.

R. L.

THE ROYAL SOCIETY CONVERSAZIONE.

MANY of the exhibits of scientific apparatus and objects at the second, or ladies', conversazione held at the Royal Society on June 20 were the same as those shown at the gentlemen's conversazione on May 9. As these have already been described (May 17, p. 59), it is only necessary to refer now to the new exhibits. During the evening demonstrations, with lantern illustrations, were given by Dr. Tempest Anderson, Sir William Crookes, and Mr. Fred. Enock. Dr. Tempest Anderson described the recent eruption of Vesuvius, his photographs showing the phenomena during the later stages of the eruption, as well as some of the results. In several cases the views afforded a comparison with the conditions of the same places as previously observed. Sir William Crookes gave a short address with experiments in illustration of some properties of the diamond; and Mr. Fred. Enock described slides showing by means of colour photography (Sanger Shepherd process) the adaptability of lepidopterous insects to their environment.

In the subjoined summary of the official catalogue, the exhibits are arranged roughly in groups of related subjects.

Dr. H. Forster Morley on behalf of the International Catalogue Committee: A map of the world was shown upon which thirty-one countries or regions were coloured. Each of these has established a Regional Bureau for indexing its scientific literature. The literature indexed is that published since January 1, 1901. Each annual issue of the catalogue contains seventeen volumes, dealing with seventeen sciences. A copy of the second annual issue was shown. The Regional Bureaus for France, Germany, and that for Polish literature employ the material prepared for the International Catalogue for the compilation of bibliographies of their own scientific literature. Specimens of these bibliographies were shown.—*Prof. H. McLeod on behalf of the Committee of the Royal Society's Catalogue of Scientific Papers:* An exhibit illustrating the course of operations in the preparation of the catalogue, which was fully described in an appendix to the descriptive programme of the conversazione.

Sir James Dewar, F.R.S.: (1) New charcoal calorimeter and thermoscope. Charcoal at the temperature of liquid hydrogen that has absorbed at atmospheric pressure considerable quantities of helium or hydrogen—or alternatively of nitrogen, oxygen, or air at their respective boiling points—is utilised in this instrument as a material that, by reason of changes in the volume of the occluded gas, exhibits great sensibility to heat and light radiation, and can be used in calorimetry at the temperature of solid hydrogen. (2) Charcoal vacua. Electric discharge tubes showing gradual gas absorption by charcoal cooled in liquid air until, after the Röntgen radiation stage, the electric resistance becomes so great that a discharge will not pass. (3) Spectrum tubes. (*a*) The less condensable gases of the atmosphere—helium and neon. (*b*) The more condensable gases of the atmosphere—krypton and xenon, each set of gases being separated by the charcoal method. (4) Some scientific uses of liquid air. (*a*) Electric ice crystals. (*b*) Rough measures of relative thermal conductivities in metals and alloys, by observing the height of the deposited ice cap when similar wires are placed alongside each other and the ends immersed in liquid air. The relative conductivities are as the squares of the height of the ice columns. (*c*) Spheroidal state of liquid air on the surface of different fluids and solutions, showing changes of volatility from the varying amount of vapour condensation; at the same time exhibiting interesting rotatory and translatory movements.—*Department of Applied Mathematics, University College, London:* (1) Investigation into the stresses in masonry dams, Prof. Karl Pearson, F.R.S., and Mr. A. F. C. Pollard. The investigation suggested that the shear distribution should in each case be found from a model dam, before the stresses are determined by graphical methods. The existence of stretch in the tail of dams of ordinary type is confirmed by the experiments illustrated. (2) Solution of the problem of the random walk, Prof. Karl Pearson, F.R.S., and Mr. J. Blakeman. The diagrams shown give the sections of the frequency surface for two, three, four, five, six, and seven stretches or flights, and show the passage of the discontinuous function into Lord Rayleigh's continuous surface. The problem is of considerable importance from the standpoint of the migration of species, and was suggested by Major Ross's investigations into the infiltration of mosquitoes into a cleared district. The solution has been obtained by successive mechanical integration from the first case by using the functional relation between successive flights.—*Mr. A. A. C. Swinton:* Visibly luminous electrical discharges *in vacuo* obtained with comparatively low electrical pressures. Edison, Fleming, and others have shown that the passage of the electric discharge *in vacuo* is much facilitated by heating the kathode. Owen and Wehnelt have proved that this effect is enormously increased if the heated kathode be coated with oxides of the alkaline metals. The present experiments show that similar results can be obtained by coating the kathode with radium, and that the effect will be greater when the kathode is heated than obtains without heating.—*Mrs. Watts-Hughes and Mr. Richard Kerr:* Floral, geometric, and other forms produced by the human voice in singing. Moistened water-colour is spread on paper attached to an india-rubber disc stretched over a cup-shaped vessel. The sound vibrations are communicated to the under side of the india-rubber through a tube in the side of the cup.—*Mr. Oliver S. Dawson:* Photographic prints in natural colours (Smith-Merckens process).—*Messrs. Carl Zeiss, Jena:* Photomicrographic apparatus for ultra-violet light (designed by Dr. A. Köhler).

Mr. R. G. Durrant: Evidence to show that ionic separation occurs when solutions of acids or of salts are allowed to diffuse into sensitised jellies or solutions.—*Dr. O. Silberrad and Dr. R. C. Farmer:* Stability test for cordite. This exhibit illustrated a method recently devised at the Chemical Research Department, Royal Arsenal, Woolwich, for the determination of the stability of cordite and other propellant explosives. It is well known that these explosives decompose gradually on storage, and may eventually ignite spontaneously, if their stability be not tested from time to time. The principle of the new test is based upon the results of several thousand experiments, and is the only method known which gives trustworthy results with cordites. The test has been adopted by the Service, and will shortly be made use of as a safeguard against spontaneous explosions in powder magazines, particularly in the tropics, where the deterioration takes place most rapidly. In examining cordites the procedure is briefly as follows:—50 grams of the explosive are maintained at 70° C. in a glass vessel fitted with a mercury manometer; the alteration in pressure is measured at intervals. A contraction takes place at first owing to the absorption of oxygen from the air; subsequently a gradual expansion occurs; the former of these phenomena has never previously been observed.—*Dr. F. D. Chattaway:* Copper mirrors obtained by the deposition of metallic copper upon glass. The method of silvering glass by depositing the metal in a thin film by reduction of some soluble silver compound has long been employed in the production of mirrors, but hitherto no method of similarly depositing copper in a brilliant film has been discovered. The exhibit showed a number of glass vessels on which copper had been thus deposited by a slow reduction of the black oxide. The metal being protected from the air, such mirrors retain their lustre permanently.

Mr. G. F. Herbert Smith: Precious stones and simple methods for their identification. This exhibit illustrated the variety of precious stones which are available for ornamental purposes. A gem stone must be hard enough to resist the abrasive action of ordinary dust, and at the same time be either transparent or; if opaque, of pleasing colour. The number of mineral species suitable for the purpose is not so restricted as popularly supposed. The names employed by jewellers frequently differ considerably from the scientific nomenclature, being often associated with certain colours rather than particular species, *e.g.* topaz (yellow), sapphire (blue), ruby (red), emerald (green), and amethyst (violet). The colour, though the most obvious character of a stone, is the least trustworthy; and the hardness, while of immense importance as regards its durability, is of little discriminative value. On the other hand, the optical characters (refractivity, double refraction, and dichroism) and the specific gravity may be easily and accurately determined, and lead to the precise identification of the stone. In the case of practically all faceted transparent stones the refractivity and double refraction are sufficient for the purpose, and the stone need not be removed from its setting.—*Sir William Crookes, F.R.S.:* (1) Occurrence of the diamond. (*a*) Example of "blue ground" in which diamonds are found, from the 1320-feet level, De Beers Mine; (*b*) diamantiferous gravel from the Pulsator, De Beers Mine; (*c*) selected stones from the Pulsator, De Beers Mine. (2) Models of crystals of diamond. (3) Cut and polished section of a piece of silicified wood found about twelve years ago in the untouched "blue ground" of the Du Toits Pan Diamond Mine, Kimberley. (4) Polished section of the Cañon Diablo meteorite in which diamonds have been found.—*Prof. W. Gowland:* (1) Portion of a meteorite containing diamonds found near Cañon Diablo, Arizona, and specimens of diamonds extracted from it. (2) Alloys of copper and calcium. A series of alloys ranging from 0·8 per cent. to 61·5 per cent. of calcium. All are brittle, and those containing 6 per cent. to 7 per cent. calcium extremely hard. The higher alloys decompose water, and are readily oxidised in the air. Specimens were also exhibited showing the effects of calcium on lead, tin, bismuth, aluminium, and coinage bronze.—*Miss Rhodes:* Stereoscopic views of the Victoria Falls and the Batoka Gorge of the Zambezi, and of the Batoka country east of the Falls. Photographed by the late Colonel F. W. Rhodes.

The Director, Royal Gardens, Kew: Sturt's desert pea (*Clianthus Dampieri*). A prostrate herbaceous plant, native of West Australia, first collected by Captain William Dampier. Under cultivation it is very delicate, but when grafted on the bladder senna (*Colutea arborescens*) it grows with vigour and flowers freely.—*Dr. F. E. Fritsch:* Method of colonisation of free surfaces by subaërial Algæ (Cyanophyceæ) in the tropics.—*Mr. E. A. Newell Arber, Miss M. Benson, Miss W. Brenchley, Prof. F. W. Oliver, F.R.S., Dr. D. H. Scott, F.R.S., and Prof. F. E. Weiss:* Fossil plants from the English Coal-measures.—*Mr. W. Saville-Kent:* Stereoscopic and other natural-colour photographic transparencies illustrating the fauna of the Polynesian coral reefs. This series of natural-colour photographs was more particularly illustrative of the coral-frequenting fishes of Polynesia. A notable genus of mostly minute percoid fishes, Tetradachnum, represented in the series, habitually make isolated bushy coral stocks their headquarters. They cruise around these coral growths in sport and in search of food, retreating within the coral's ramifications to rest or to escape from any enemy.

The Solar Physics Observatory, South Kensington: Recent photographs of some British stone circles.—Dr. *W. M. Flinders Petrie, F.R.S.:* (1) Hyksos fortress model, and pottery, 2000 B.C., Egypt. (2) Model of the temple and city of Onias, Egypt. (3) Photographs, enlarged, from Sinai. The Egyptian turquoise mines were worked from 5000 B.C. The oldest rock sculptures are those of the middle of the first dynasty of kings. Both centres of mining, Wady Maghara and Serabit el Khadem, were shown.

NATIONAL PHYSICAL LABORATORY.

OPENING OF NEW BUILDINGS FOR ELECTROTECHNICS AND PHOTOMETRY.

THE new buildings of the National Physical Laboratory for electrotechnics and photometry were opened on Monday, June 25, by Mr. Haldane, Secretary of State for War. A large company assembled at the invitation of Lord Rayleigh and the general board, and among those on the platform were Lord Rosse, Lord Kelvin, Sir John Wolfe Barry, Sir J. Lawrence, M.P., Sir John Brunner, M.P., Sir William White, Mr. Gavey, M. Hospitalier, Herr W. von Siemens, Prof. Semenza, M. Gerard, Sir Thos. Wrightson, and Sir Chas. Tupper.

Among the audience, numbering nearly six hundred, were representatives to the International Electrical Congress, now being held in London, from the American, German, French, Swiss, Italian, and other electrotechnical societies.

Lord Rayleigh presided, and in opening the proceedings said that the gathering marked another stage in the evolution of the institution, and they all hoped the new buildings would play a considerable part in the science of electrotechnics in this country.

The director, Dr. Glazebrook, then made a statement concerning the new extensions, and detailed the gifts which had been made towards equipment by numerous firms and individuals. The Chancellor of the Exchequer had asked Parliament for a grant of 5000*l*. last session for new buildings, and this year's grant towards the cost of the further extensions in the engineering, chemical, and metrological departments was 10,000*l*. The building in which they were assembled had cost only about 7000*l*., largely owing to the liberal treatment accorded to the laboratory by the contractors, Messrs. Mowlem, and by Messrs. Mott and Hay, who gave their services as architects. The director expressed his indebtedness to the members of the staff, who had helped in designing and fitting up the building, especially to Mr. Paterson, Mr. Rayner, and Mr. Melsom, who had all given much time and careful thought to the plans.

Mr. Haldane then addressed the meeting and declared the laboratory open. The meeting terminated with votes of thanks to Mr. Haldane, proposed by Sir John Wolfe Barry and seconded by Sir John Brunner, M.P., and to the chairman, proposed by Mr. Gavey.

The objects of the new building are the provision of suitable accommodation for the rapidly extending work of the laboratory in electrotechnics and photometry. In the old building will remain all the fundamental-standard work relating to measurements of current, electromotive force, resistance, capacity, and inductance. The main portion of the new extension consists of a top-lighted shed, 120 feet by 50 feet, divided into two bays, each 25 feet wide. The southern bay is divided transversely, forming two rooms, each 60 feet by 25 feet. The inner of these has a glass ceiling, and the lights above are glazed with double glass, and face north. The space between the ceiling and the roof can be heated, and by means of a large fan artificial ventilation is provided. It is hoped by this means to maintain the temperature fairly uniform. This internal room is intended for resistance measurements. The other half of the same bay is designed for heavy-test work. Two bed-plates are provided for machine testing, and arrangements have also been made for addition of a travelling crane.

The large bay to the north side, in which the ceremony was held, is for general electrotechnical testing. At the west end of this is the main switchboard, receiving power from the dynamo room, and also from the mains of the supply company, and distributing it to the machines in the building and to the batteries.

Near by is provided space for the special electrotechnical machine equipment. This includes a 5 kilo-watt motor-generator set for single or three-phase current, the frequency of which can be widely varied, another motor-generator of specially high efficiency for life-tests on lamps, and a third for transformer and high-tension experiments. The rest of the bay is assigned to experimental work, the western portion being reserved for alternating-current experiments, and the eastern portion for direct-current. The batteries are on the top floor of an annexe to the east of the main block, above the rooms reserved for photometry; thus the direct-current work requiring heavy currents will go on in the extreme eastern portion of the main bay.

Four new accumulator batteries are provided, and to charge these and furnish the additional power necessary for general work a 50 kilo-watt motor-generator has been provided in the power-house, driven from the supply mains of the local company. For ammeter-testing, currents up to 6000 amperes for an hour can be obtained by paralleling of one of these batteries, and 10,000 amperes for short periods. A special 300-volt battery is reserved for photometric experiments.

The remainder of the new building is intended for photometry. On the ground floor is a large room for life-tests of electric and gas lamps, and, above, a room for standard photometry and a specially arranged gallery for arc-lamp testing. A length of 90 feet is available for photometry of specially high candle-powers, and in the arc-lamp room a height of nearly 35 feet.

FIG. 1.—New Buildings of the National Physical Laboratory.

No money has been spent on unnecessary adornment of the buildings, marble and granite being conspicuous by their absence, but already the grounds have been planted with flowers and creepers, and the exterior, though plain, is by no means an eyesore.

After the opening ceremony the visitors proceeded to the old buildings and the garden, and inspected the various laboratories, where the assistants in charge explained the work of their own departments. The objects which appeared to attract most attention were the new ampere balance in the main electrical room, the various electric furnaces, the radiation pyrometers in the thermometric department, and the new measuring machines in the department of weights and measures.

A summary of the *Times* report of Mr. Haldane's address is subjoined.

The Government is keenly interested in the development of science, and a donation by the Chancellor of the Exchequer on a scale of double what was anticipated last year is an earnest of what it means. A contrast may be made between the German and the British attitude towards science. Prussia began her emancipation by founding a university as an answer to the conqueror. Germany became the victor by the sheer might of thought and by the wonderful organisation which that might of thought enabled her to make the foundation of her future power. We, on the contrary, have always made the effort after material prosperity first, and when prosperity has been attained have strained after science. This is rather an outcome of the Anglo-Saxon temperament. There is an aversion in this land from anything that is abstract, a desire to do as much as possible by individual effort, and finally to turn to science and to the aid of thought and organisation for the completion rather than the foundation of the edifice. It is a good sign that brotherhood of science brings men of different races and different temperaments together. The possession of common conceptions and intellectual instruments, the passion for, and fascination of, common problems, the fact that the minds of men of the most varying temperaments and the most differing races are making toward a common point, has brought about a great intellectual common ground, and united men for the effort to accomplish a common task. The functions of the State are becoming more and more recognised, and more and more people in different parts of the world are beginning to feel that it is not merely the State, but the great individualities of which we are proud—individualities which form a common heritage. It is not merely Frenchmen who are proud of Laplace and Lavoisier, nor merely Germans who rejoice in the names of Weber, Helmholtz, Gauss, and Riemann, nor merely Englishmen who speak with pride of Newton and of Darwin. These and many other names belong to the world at large, are the inheritance of those who have drawn in the breath of the Time-Spirit to see it come forth again in the concentrated form of genius in conspicuous individuals too great to be the representatives of any one race, satisfied with being nothing less than the embodiment of the finest genius of humanity. In an ideal State, the ruler would take thought, not merely for the day, but for the morrow; but there is very little thought taken for the morrow in the government of almost any nation. What an infinite amount of friction would have been avoided, what an enormous quantity of waste would have been obviated, had there been only thinking organisation, plain principles not hurriedly to be departed from, at the root of policy! In the National Physical Laboratory we have a sign, a portent of the times, the evidence that we are advancing. But a few years ago and such an institution would have been impossible. We may look at it as a sign that we are coming into line with the rest of the world, and recognising that it is to science, and science in the main, that we must look for the means of maintaining ourselves in the vast competition of the world.

NOTES.

THE programme of events in connection with the international celebration of the coal-tar colour jubilee has now been definitely arranged. The steps leading up to the celebration have been described in these columns already (vol. lxxiii., p. 419). The celebration will be held on July 26 and 27. On the first day a meeting will take place at 11 a.m. at the Royal Institution for the presentation to Dr. W. H. Perkin of his portrait and bust, and in the evening a banquet has been arranged at the Whitehall Rooms, Hotel Metropole, when many distinguished guests are expected to be present. On July 27 a visit will be paid to the original works at Greenford Green, where mauve was first manufactured, and a garden-party will be held at Dr. Perkin's house. In the evening a soirée will take place at the Leathersellers' Hall, at the invitation of Dr. and Mrs. Perkin. The international committee arranging the ceremony includes distinguished representatives of science, especially chemical science, in France, Germany, and Switzerland, as well as in this country. Applications for tickets and invitations should be made to Dr. J. C. Cain, 28 Pembury Road, Clapton, N.E., who is acting as assistant honorary secretary to the executive committee.

WE learn from the *Chemist and Druggist* that the Chemists' Club of New York has also decided to honour Dr. Perkin. At a meeting held on May 28 the committee (of which Prof. Chandler is chairman) reported in favour of the establishment of a library, probably to be known as the Perkin Library, and to cost 10,000*l.*; the appropriation of 1000*l.* for a Perkin medal and a token to Dr. Perkin; and a dinner on October 6, at which Dr. Perkin is expected to be present. The proposals were adopted. The Perkin medal is to be awarded annually to an American chemist for distinguished work in technical chemistry.

MUCH correspondence has appeared in the *Times* and other journals during the past week with reference to the Wireless Telegraphy Bill which has just passed its third reading in the House of Lords. The Bill is merely to extend the Act of 1904, a summary of which appeared in our columns at the time (vol. lxx., p. 349). The original Act expires in July of this year, but will now be extended to 1909. The extreme importance of wireless telegraphy for the purpose of national defence has been recognised from the very first, and in consequence exercise of control had to be placed in the hands of the Government, especially in view of the fact that—all claims to the contrary notwithstanding—it cannot be said that any system has yet been perfected which is completely immune from interference or cannot interfere with other systems. It is outside our province to enter into the legal dispute between the Marconi Company and Lloyd's, but it is to be hoped that a settlement will be arrived at which will give the public the full advantages in connection with shipping that wireless telegraphy affords.

PARAGRAPHS have appeared in the daily papers alluding to a "new disease" which was said to have appeared in Essex about ten days ago. Some children at Highwood, near Chelmsford, were found to be suffering from a rash on the hands, face, and neck, accompanied with great irritation of the eyes and skin. On inquiry it was found that the children had been playing with some caterpillars taken from the hawthorn hedges. Much amusing "newspaper science" has appeared, and the name *Plusia gama* (sic) has been applied to the insect. The caterpillars were undoubtedly those of the Gold-tail Moth (*Liparis auriflua*), which is now common on the hedges. It is a pretty creature, but the hairs which cover its body are very easily detached, and, being exceedingly fine, readily enter the soft skin of children, and thus set up inflammation. It is doubtful whether any poisonous secretion accompanies the hairs, or whether the painful injury is purely mechanical. The malady is well known to practical entomologists, most of whom have learnt by experience to banish Liparis from their breeding-cages. An allied species, *Liparis chrysorrhoea* (the Brown-tail Moth) is in some seasons abundant on bushes on the Essex coast, and is even a greater irritant than its congener, but it is one of our immigrant moths, and is not seen every year.

A VIOLENT shock of earthquake was felt yesterday, June 27, at 9.45 a.m. over the whole of South Wales. At Swansea a chimney was thrown down, while at Cardiff the Exchange and other big buildings were shaken. The shock lasted about three seconds. The earthquake was felt at Knighton at 9.46 a.m., and tremors were also experienced at Llandrindod Wells and in South Shropshire. A slight shock was felt at Abergavenny and Carmarthen, and at Bridgend people walking in the street were nearly thrown down. At Newport (Mon.) also the disturbance was felt distinctly.

A BANQUET was given by the Institution of Electrical Engineers on Monday night in honour of the delegates from kindred institutions in Canada, France, Germany, Italy, Switzerland, and the United States who are visiting this country. Mr. John Gavey, C.B., president of the institution, presided, and there were about 450 guests and delegates present. The toast of the visiting delegates, proposed by the president, was responded to by Prof. J. L. Farny, representing the Association Suisse des Électriciens; Mr. P. J. B. E. Auzépy, Consul-General of France; Prof. E. Budde, president, Verband Deutscher Elektrotechniker; Dr. Emil Naglo, representing the president of the Elektrotechnischer Verein; Mr. S. S. Wheeler, president of the American Institute of Electrical Engineers; and Mr. Guido Semenza, hon. general secretary of the Associazione Elettrotecnica Italiana, who during his response presented to the institution, in the name of the Associazione Elettrotecnica, a bust of Alessandro Volta. A conversazione in honour of the visitors was held at the Natural History Museum on Tuesday evening.

DR. T. P. ANDERSON STUART has been elected president of the Royal Society of New South Wales for the current year.

THE Guy medal in silver of the Royal Statistical Society has been awarded to Dr. W. N. Shaw, F.R.S., for his paper entitled "The Seasons in the British Isles since 1878," read before the society in March, 1905.

THE presidency of the Yorkshire Naturalists' Union for 1907 has been offered to, and accepted by, Mr. C. Crossland, of Halifax, joint author of the recently-published "Fungus Flora of East Yorkshire."

A SPECIAL meeting of the Faraday Society, to which the public is invited, will be held at the Society of Arts on Monday, July 2, when Prof. Kr. Birkeland, of Christiania, who is at present on a visit to England, will read a paper on the oxidation of atmospheric nitrogen in electric arcs. At the same meeting Mr. F. W. Harbord will communicate a paper, by Dr. Eugen Haanel, of Ottawa, describing the recent experiments on electric iron and steel smelting that were made at Sault Ste. Marie on behalf of the Canadian Government.

SIR DANIEL MORRIS, K.C.M.G., the Imperial Commissioner of Agriculture for the West Indies, has arrived in this country on a short visit, and will attend the forthcoming International Conference on Hybridisation and Plant Breeding to be held in London under the auspices of the Royal Horticultural Society at the end of July. Sir Daniel will read a paper on the hybridisation of the sugar cane, a subject with which he has been actively associated for many years.

BY the regretted death of Lieut. Forbes Tulloch, R.A.M.C., last week, another name is added to the honoured roll of the martyrs of science. Lieut. Tulloch, in association with Lieut. Grey, had been for the past year investigating sleeping sickness at Entebbe, Uganda. In March, while making a *post-mortem* on an inoculated rat, he accidentally scratched his finger. In a short time fever developed, and an examination of his blood showed the presence of the dreaded trypanosome. Although at once invalided home, the disease ran a very acute course and ended fatally as stated. Lieut. Tulloch had, in cooperation with Lieut. Grey, made the important observation that trypanosomes multiply in the tsetse fly, and was regarded as a worker of great promise. His untimely death is much to be deplored.

ON Thursday last, June 21, a paper was read before the Royal Society of Antiquaries by Dr. Jonathan Hutchinson, F.R.S., and Mr. E. W. Swanton, on prehistoric remains found during recent years in the neighbourhood of Haslemere. The authors commented on the large number of Neolithic implements which had been found, chiefly by Mr. Allen Chandler. Many were obtained from the site of a Neolithic flint factory on Blackdown, 912 feet above sea-level, and ten miles away from the nearest chalk-with-flints bed. Among the objects from this spot were rubbing stones and perforated circular hammer stones of quartzite, also a very fine series of the so-called "pigmy flints." The second part of the paper detailed the discovery of a Celtic urn-field adjacent to Haslemere town. Crude flint chips, and in one case a fragment of a bronze fibula, occurred among the fragments of calcined bone in the cineraries. No iron was found, and but one piece of bronze. A hole in the base of one of the cineraries had been repaired by inserting a plug of lead. Many accessory vessels had been placed around some of the urns; several in almost perfect condition were exhibited, they were of various shapes and sizes, and the paste was of several qualities. In the discussion which followed it was agreed that the pottery belonged to the later Celtic period or early Iron age, B.C. 50 approximately. The vessels and flints from this urn-field have been presented to the Haslemere Museum.

MR. GEORGE JAMES SNELUS, F.R.S., who died on June 18, was the first to eliminate phosphorus during the Bessemer process by the use of a basic lining to the converter. He took out a patent for the idea in 1872, and subsequently made five tons of steel by this method. The process was, however, not brought into commercial operation until after the work of Thomas and Gilchrist. Mr. Snelus's share in the invention was recognised by the Iron and Steel Institute, which in 1883 awarded him, jointly with Sidney Thomas, the Bessemer gold medal. Mr. Snelus, who was born on June 25, 1837, in London, was educated at St. John's College, Battersea, and at Owens College, and subsequently obtained a scholarship at the Royal School of Mines, where he took the associateship in metallurgy and in mining, and received the De la Beche medal for mining. His first appointment was as chemist to the Dowlais Ironworks. In 1871 he went as expert for the Iron and Steel Institute to the United States to report on the Danks rotatory puddling furnace. He was elected a Fellow of the Royal Society in 1887. He wrote a large number of papers on the metallurgy of iron, which were contributed to the Proceedings of the Iron and Steel Institute, of which society he was an original member, and at the time of his death occupied the position of vice-president. He possessed unusual talents for experimental research.

IN place of the usual autumn meeting, the Iron and Steel Institute will this year hold a joint meeting with the American Institute of Mining Engineers in London on July 23–26. Under the chairmanship of the Lord Mayor, an influential reception committee has arranged an attractive programme of entertainments, visits, and excursions. The King will receive a deputation of the institute's American guests. There will be a banquet in the Guildhall of the City of London, evening receptions by the president and by the Lord Mayor, and entertainments at the Earl's Court Exhibition and at the Crystal Palace. Technical interests have not been neglected, the programme including visits to the National Physical Laboratory, to the power stations at Greenwich and Chelsea, to the Wellingborough blast-furnaces, to the Dover Harbour works, and to various engineering, shipbuilding, and cement-manufacturing works. The Iron and Steel Institute has down on the programme for reading a list of twelve papers, and the American society eleven more. These have all to be dealt with in three morning sessions. The papers likely to prove of chief interest are communications on blast-furnace gas engines, by Prof. H. Hubert (Liége), Mr. K. Reinhardt (Dortmund), and Mr. T. Westgarth (Middlesbrough); on the crystallography of iron, by Mr. F. Osmond (Paris); on high-speed tool steels, by Dr. H. C. H. Carpenter (National Physical Laboratory); and on segregation in steel ingots, by Mr. H. M. Howe (New York). For the week following the London meeting a tour to York, Middlesbrough, Durham, Newcastle-upon-Tyne, Glasgow, and Edinburgh has been arranged for the institute's American guests by a committee of which Mr. R. A. Hadfield, president of the institute, is chairman, and Mr. Bennett H. Brough secretary.

The latest issue to hand (March) of the Proceedings of the Philadelphia Academy contains the completion of Dr. B. Smith's communication on the phylogeny of *Volutilithes petrosus* (already noticed in our columns), and an article by Mr. H. W. Fowler on the fishes and reptiles of the Florida keys.

Two papers bearing on the Mendelian doctrine, more especially as regards the theory of pure gametes, have been recently published by the Carnegie Institution, one, by Messrs. Castle and Forbes, on the heredity of hair-length in guinea-pigs, and the other, by Mr. W. E. Castle, on the origin of a polydactylous race of these rodents. Considerations of space alone prevent fuller notice.

Limitations of space must likewise be our excuse for not noticing in detail an important paper on the germ-cells of Aphides, by Mr. N. M. Stevens, also published by the Carnegie Institution. The present classification of aphides is considered imperfect, and reference to the cytology of the germ-cells will probably be necessary before an improvement can be made. Special attention is directed to the fact that while in some species parthenogenetic and sexual modes of reproduction alternate irregularly, in others parthenogenesis continues throughout the summer.

The contents of the fourth part of vol. lxxxi. of the *Zeitschrift für wissenschaftliche Zoologie* are entirely devoted to invertebrates. In the first article Mr. W. Mayer discusses the dermal sense-organs of leeches; spermatogenesis in earthworms forms the subject of the second article, by Mr. Depdolla; in the third Dr. M. Nowikoff has remarks on the median eye and frontal organ of the crustacean Artemia; while in the fourth Mr. E. Martini describes certain superficial structures in nematode worms.

The report for 1905 of the Marine Biological Association of the West of Scotland has just been received. "At no time has the station been so efficient as an instrument of research, of organised education, or of general instruction as it now is. At no time, either, have its prospects of growth in usefulness and efficiency on all these lines been so promising." At the same time, if the work is to be properly carried on, a large increase in the endowment fund is essential, and for this a special appeal is made in the report. Provision must likewise be made for the upkeep and working of the *Mermaid*, the five years' fund generously provided by Mr. J. Coates having now come to an end. An increase of the staff by the addition of a trained assistant is also a matter of urgency, but for this no funds are at present available.

In the Oregon University Bulletin (vol. iii., Supp., No. 3, May) Mr. T. Condon describes, under the new generic and specific title of *Desmatophoca oregonensis*, the skull of a seal, referable to the family Otariidæ, from the Miocene of the Oregon coast. The author claims this as the first Miocene seal yet described. Evidently he is unacquainted with the seal-skull, referable to the same family and from the same formation (at Empire City), described by Mr. True in the quarterly issue of the Smithsonian Miscellaneous Collections for May, 1905, under the name of *Pantoleon magnus*. Although Mr. True's specimen is considerably the larger of the two, there is no apparent reason why it should not be the male of the skull described by Mr. Condon. The latter author urges that the Miocene age of the Oregon seal is a bar to the view that the Pinnipedia are descended from the bears.

Vertebrate osteology constitutes the main item in the contents of the first three parts (issued in one fasciculus) of vol. xix. of the Bulletin of the Imperial Society of Naturalists of Moscow. In the first article, for instance, Mr. L. P. Kravetz discusses the development of the mammalian sternum and presternum, more especially in relation to the conflicting views which have been expressed in regard to the origin of these structures. The skeleton of the cat-fishes (Siluridæ), as exemplified by the skull of the Old-World genus Clarias, forms the subject of a long communication by Mr. G. Schelaputin, in which the author revives the view that the fully ossified and sculptured cranial roof indicates some kind of affinity with the Palæozoic Coccosteus. The skeleton of the cat-fishes (inclusive of the American Loricariidæ) forms the subject of another article, by Mr. D. N. Koschkaroff, constituting a portion of a dissertation on teleostean osteology in general. A phylogenetic tree of the silurids and loricarids is included in this paper.

The results of experiments in Barbados for the seasons 1903–5 with new seedling canes and manurial experiments on sugar-cane plots have been published in the pamphlet series, No. 40, issued by the Imperial Department of Agriculture for the West Indies. One or two of the varieties have now been under trial for six years, while others are newer and have only been tried for two or three seasons; one of the latter is B 1529, that with the highest quotient of purity takes the first place among plant canes. The manurial experiments confirm the results obtained in previous years, pointing to the value of nitrogen and potash and to the detrimental effects of phosphatic fertilisers.

Mr. H. H. Cousins contributes a third article on cassava trials at the Hope Experiment Station to the Bulletin (April) of the Department of Agriculture, Jamaica. The object has been to compare the yields of different varieties when grown for different periods. It was found in one instance that the yield of starch per acre was increased from $3\frac{1}{2}$ tons at the end of a year to $7\frac{1}{4}$ tons after cultivation for twenty-one months, so that as far as cultivation alone is concerned a biennial crop would be the most profitable. On the subject of oranges, Mr. Fawcett offers some practical advice on the treatment of trees to produce early ripening of the fruit, recommending root pruning and timely clearance of all fruit at the end of the season.

The regulations governing the training of probationers at Oxford for the Imperial staff of the Indian Forest Service naturally arouse keen interest in India, and an editorial article in the *Indian Forester* (April) compares the course of studies prescribed at Oxford with the course given to recruits for the subordinate executive service at the Imperial Forest School, Dehra Dun. The opinion is expressed that the course at Oxford requires stiffening, and the immense advantage of obtaining practical experience at Dehra Dun under Indian forestry conditions as contrasted with those in European forests is emphasised. An article on felling timber in Bashahr, contributed by Mr. G. S. Hart, in which the felling of trees uphill is advocated, is accompanied by some interesting photographs.

In the *Naturwissenschaftliche Wochenschrift* (June 17) there is an excellent summary of what is known respecting the structure of the reproductive cells, illustrated with a number of particularly good figures. The author is Dr. C. Thesing.

The Bulletin of the Johns Hopkins Hospital for June (xvii., No. 183) contains articles on the use of quinine during the Civil War, by Dr. J. W. Churchman; on an experimental study on the regeneration of lymphatic vessels, by Dr. A. W. Meyer; and various medical papers.

The Livingstone College "Year-book" for the current year contains the annual report, extracts from letters of former students, &c. The college is doing a useful work in giving to those about to become missionaries elementary training in medicine, surgery, and hygiene.

The New Jersey State Legislature has recently passed an Act for the extermination of mosquitoes. The title of the Act is as follows:—"An Act to provide for locating and abolishing mosquito-breeding salt-marsh areas within the State, for assistance in dealing with certain inland breeding places, and appropriating money to carry its provisions into effect." The full text is given in *Science* (June 1).

The preservation of brains for anatomical and anthropological investigations is the subject of an elaborate paper by Mr. Ales Hrdlicka (Proc. U.S. National Museum, xxx., p. 245). It is found that the best preservative is a mixture of formalin, water, and 95 per cent. alcohol in varying proportions according to size: formalin 3 parts, distilled water 45–25 parts, alcohol 52–75 parts; less water and more alcohol being used for the larger sized brains.

The Local Government Board has published a further report on the destruction of rats and disinfection on shipboard with sulphur dioxide, by Dr. John Wade (No. 232). It is found that rats and insects are destroyed in less than two hours by air containing 0·5 per cent. of sulphur dioxide, a condition easily realised in cabins, empty holds, spaces round cargo, &c., but for adequate penetration of closely packed cargo, air containing 3 per cent. of the gas must be circulated around the cargo for eight to twelve hours. Non-sporing pathogenic bacteria are also killed by this treatment. Textile fibres and fabrics, metal and furniture, are not affected by sulphur dioxide, but are liable to injury by the accompanying sulphuric acid when the gas is generated by burning sulphur, unless they are protected. Meat, fruit, vegetables, and wheat in bags are deleteriously affected. Liquid sulphur dioxide may be employed as a source of the gas, but burning sulphur, as in the Clayton process, is on the whole preferable on the ground both of convenience and of economy.

In the *Engineering Magazine* (vol. xxxi., No. 3) Mr. J. A. Macdonald gives an interesting account of twelve months' prospecting and surveying in northern Ontario, and also a detailed account of the occurrence of cobalt ore and of the development of the deposits. These deposits, which contain silver, cobalt, nickel, and arsenic, are among the most remarkable now engaging the attention of the mining world.

We have received from the director, Prof. G. Gerland, a circular summarising the work of the Central Bureau at Strassburg of the International Seismological Association. The bureau was founded in 1903 by the second International Conference of Seismology. The observatory or central station in connection with the bureau is furnished with a triple horizontal pendulum with photographic registration, a Rebeur pendulum for recording photographically two components, a Milne pendulum, a Wiechert pendulum, a Vicentini microseismograph, Omori and Bosch horizontal pendulums, and a trifilar gravimeter. The apparatus and records are always at the service of foreign observers. The bureau and the station have distinct organisations, but work together. The director hopes that seismologists in other countries will transmit regularly to the central bureau accurate observations of any seismological disturbances in their respective districts. The most practical way, Prof. Gerland suggests, would be for observers at the various stations to send copies of important earthquake records to the bureau at Strassburg, where they would be available for inspection by students of seismology.

With the advance of refractometry in chemistry, Messrs. Carl Zeiss, of Jena, have introduced several forms of refractometers suitable for special purposes, and have issued pamphlets descriptive of these. Their "dipping refractometer" is specially applicable in analysis, particularly in ascertaining the proportion of alcohol and extract in beer. For scientific purposes it gives very accurate values between the ranges of $\mu_D = 1·325$ and 1·366, and is especially adapted for the examination of aqueous solutions. The firm has issued in pamphlet form a bibliography of papers dealing with their well-known Abbe refractometer, and the refractometers used in examining milk and butter respectively.

In continuing their studies in luminescence, Messrs. E. L. Nichols and Ernest Merritt in No. 5 of the *Physical Review* investigate the law of decay of the phosphorescence of Sidot blende. In previous experiments in this connection the decay of the total light has been measured, the assumption being made that all portions of the light decay at the same rate. In the present investigation the decay of light of a definite wave-length in the phosphorescence spectrum has been observed, and it is shown that in such a case the intensity of the light diminishes according to the law originally proposed by H. Becquerel, $I^{-\frac{1}{2}} = a + bt$, where a and b are constants. This law can be deduced from different theoretical conceptions from those originally suggested by Becquerel. It is only necessary to apply Wiedemann's hypothesis of the cause of photoluminescence and to assume a law of recombination of the dissociated parts of the substance similar to that which has been applied to the case of ionisation of gases. With such an assumption it is deduced that the quotient a/b should be the same for different wave-lengths when the excitation and other physical conditions are the same. The measurements given in the paper show that between the limits $\lambda = 483\ \mu$ and $\lambda = 547\ \mu$ this is very approximately true.

We have received from Messrs. W. and A. K. Johnston, Ltd., a convenient pad of sectional paper ruled in inches and tenths. The size of the sheets is 8 inches by 10 inches, and the price of the pad 1s. 6d. net.

Mr. John Murray has published a fourth edition of Mr. W. C. Clinton's "Electric Wiring." The first issue of the primer was reviewed in Nature for October 23, 1902 (vol. lxvi., p. 629). Of the present edition it will suffice to say that in its revision an effort has been made to bring it up to date without increasing its size unduly.

The current issue of *The Central*—the magazine of the Old Students' Association of the Central Technical College —commences the third year of publication of what has become an enterprising periodical. Some impressions of South Africa, by Prof. O. Henrici, F.R.S.; with the British Association in South Africa, by Dr. E. F. Armstrong; Mr. Freeman's account of the Witwatersrand, and Mr. Ashcroft's description of a lecture-table testing machine are all interesting contributions; and there are numerous first-rate illustrations.

A second edition of Dr. W. D'Este Emery's "Handbook of Bacteriological Diagnosis for Practitioners" has been published by Mr. H. K. Lewis under the new title "Clinical Bacteriology and Hæmatology for Practitioners." Though the general scope of the book remains unaltered, several additions have been made. The additions to the bacteriological portion are mostly concerned with the examination of materials from special parts of the body. The hæmatological portion is almost all new, and provides a practical guide to blood examinations, especially their application to the diagnosis of disease. The price of the new edition is 7s. 6d. net.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences in July:—

July 2. 7h. 55m. to 8h. 52m. Moon occults γ Libræ (mag. 4·1).
,, 12h. Neptune in conjunction with the Sun.
5. 15h. 15m. to 16h. 15m. Moon occults ξ^2 Sagittarii (mag. 3·5).
6. 12h. 2m. Minimum of Algol (β Persei).
15. 3h. Mercury at greatest elongation (26° 39′ E.).
,, 8h. Mars in conjunction with the Sun.
,, 13h. 34m. to 14h. 31m. Moon occults Tauri (mag. 4·3).
,, Venus. Illuminated portion of disc = 0·760; of Mars = 1·000.
16. 7h. Ceres in conjunction with Moon. Ceres 0° 38′ S.
,, 14h. 10m. to 15h. 2m. Moon occults γ Tauri (mag. 3·9).
17. 0h. 40m. Moon approaches near to α Tauri (mag. 1·1).
18. 14h. 0m. Jupiter in conjunction with Moon. Jupiter 3° 21′ N.
19. 14h. 0m. to 16h. 40m. Transit of Jupiter's Satellite III. (Ganymede).
21. 1h. 14m. Partial eclipse of the Sun invisible at Greenwich.
24. 7h. Venus in conjunction with Moon. Venus 1° 23′ S.
29. 10h. 33m. Minimum of Algol (β Persei).

The Figure of the Sun.—In his discussion concerning the variable figure of the sun, which was referred to in these columns on January 18, Dr. Poor included the heliometer measures of the polar and equatorial diameters made by Messrs. Ambronn and Schur at Göttingen during the period 1890 to 1902, and found from them a confirmation of his previous conclusions.

The validity of the conclusions thus obtained is now questioned by Dr. Ambronn in No. 4, vol. xxiii., of the *Astrophysical Journal*. He points out that the variation, if it exists, cannot, according to the heliometer measures, exceed 0″·1 by any appreciable amount, and suggests that the measurement of the earlier photographic plates could not produce results accurate to this figure. Further, the measurements for 1894 furnish, for the more recent photographs, a proof that the oscillations adduced by Dr. Poor are not present.

After several other explanations Dr. Ambronn states that the most thorough investigation of the large amount of data collected at Göttingen has convinced him that this furnishes no justification for the suggested periodicity.

Discovery of Algol Variables.—Circular No. 117 from the Harvard College Observatory announces the discovery that the star H1236 (−30°.16169 C.DM.) is an Algol variable having a range of about one magnitude and a period slightly exceeding two days.

This variable was discovered by Mrs. Fleming on a plate taken in accordance with the multiple-image method described in a previous Circular, and by which it is hoped to discover all the short-period variables of magnitude 10·0 and brighter. In this method a dozen or more exposures, each of thirty minutes' duration, are made on the same plate moved by a small amount between each exposure.

Plates covering nearly the whole of the sky have now been obtained under these conditions, but only a few have so far been examined; nevertheless, this is the second Algol variable thus discovered by Mrs. Fleming.

An Interesting Minor Planet.—A recently-discovered minor planet (T.G.) proves to be of exceptional interest owing to its great mean distance.

Elliptical elements recently deduced by Dr. Berberich indicate that the mean distance of this asteroid is slightly greater than that of Jupiter, whilst its aphelion distance is nearly one unit beyond Jupiter's orbit. This discovery extends the limits of the asteroids so that they now include a distance of 1·1, the perihelion distance of Eros, and one of 6·0 units, the aphelion distance of the newly-discovered T.G. (the *Observatory*, No. 371).

Observations of Jupiter in 1903 and 1905–6.—In continuation of his record of the observations of Jupiter made during the years 1898–1902 inclusive, which was published in vol. lxiii. of the Monthly Notices, Mr. Denning now publishes (in vol. lxvi., No. 7) his results for the oppositions of 1903 and 1905–6.

During 1903, 1388 transits were observed, and of these 1188 were utilised in determining the rotation periods of the different zones as given in the present paper. The periods determined vary from 9h. 55m. 54·3s. for the N. temperate markings to 9h. 50m. 27·9s. for the equatorial; only the latter, however, gives a value less than 9h. 55m. 6·0s. In the 1905–6 apparition the mean period of rotation of the equatorial spots had increased to 9h. 50m. 32·7s., a value which is a few seconds in excess of that exhibited during the previous eight years. Mr. Denning also gives a number of notes on the apparition of 1905–6, dealing with the appearance and the variations of the different markings in detail. He also states that the best time for examining details on Jupiter is near the time of sunset.

The results of a number of micrometer measures of Jupiter's diameter and of the various belts, made at the Copenhagen Observatory during the recent opposition, are published in No. 4098 of the *Astronomische Nachrichten* by Dr. H. E. Lau.

Photometric Observations of Saturn's Satellites.—In No. 4098 of the *Astronomische Nachrichten* Dr. P. Guthnick publishes the results of a series of photometric observations of Saturn's six brightest satellites. The observations were made during the summer and autumn of 1905 at the Bothkamp Observatory, and the results for Tethys, Dione, Rhea, Titan, and Japetus are set out in tabular form so as to show the anomaly of the satellite and the corresponding apparent magnitude at the time of observation.

New Double Stars.—Forty-two newly-discovered double stars are described by the Rev. T. E. Espin in a catalogue which appears in No. 7, vol. lxvi., of the Monthly Notices (R.A.S.).

The stars are all situated between 30° and 40° N. declination, and the author gives in the catalogue the position (for 1900), the separation, the position-angle, and the magnitudes for each pair.

THE INTERNATIONAL CONGRESS OF ANTHROPOLOGY AND PREHISTORIC ARCHÆOLOGY.

THE International Congress of Anthropology and Prehistoric Archæology held its thirteenth session at Monaco, on the generous invitation of H.S.H. Prince Albert, "Protecteur" of the congress, on April 16–21. The place of meeting was the Grande Salle of the beautiful and now nearly completed Museum of Oceanography in course of erection by this Royal savant. More than 400 members, of whom upwards of thirty were British, assembled under the distinguished presidency of Prof. Hamy, of the Institute of France. To the sincere regret of all the members, the Prince was prevented by illness from opening the proceedings as he had intended, and, indeed, from being present at any of its meetings. He was, however, represented by his son, the Crown Prince, who, accompanied by the high officers of the Principality, attended at the opening seance and read the address which his father was unable to deliver, and from which we quote the following sentences:—"Je me félicite de ce que mes efforts pour le développement de l'anthropologie m'aient permis de réunir, sur ce point de l'Europe où les vestiges de l'Humanité remplissent la terre, une assemblée comme la votre choisie entre les savants de plusieurs pays avancés. Je suis certain, d'ailleurs, que votre Congrès laissera au domaine scientifique, des notions importantes sur l'histoire de notre espèce, car les travaux tout récents de MM. Boule, Verneau, de Cartailhac, de Villeneuve suffisent à lui constituer un monument. . . . C'est dans le Palais de la mer que l'Anthropologie trouve accueil aujourd'hui; et l'union de toutes les sciences alliées contre l'ignorance . . . que l'Océanographie peut déjà relier certaines conquêtes de la Science. Car l'étude des lois physiques et chimiques de la mer conduit a l'explication des remaniements géologiques de notre planète et des luttes successives entre les continents et les mers. Les progrès de la Biologie et de la Zoologie marines permettent d'utiliser les révélations de la Paléontologie pour constituer l'échelle des transformations infiniment nombreuses par lesquelles une force que nous appellons la vie a fait passer la matière organique. Et la Météorologie, si intimement liée avec l'Océanographie par des rapports incessants, nous aide à comprendre les fluctuations, les migrations, et la distribution géographique des êtres, y compris celle de l'homme. Parmi les Congrès précédemment réunis ici même, il en est un, celui de la Paix, dont j'évoquerai le souvenir aujourd'hui, parce que la Science et la Paix sont inséparables et que l'Anthropologie, comme tous les Sciences, doit contribuer au bien-être des hommes. . . ." The congress was formally welcomed also by H.E. M. Ritt, the Governor-General of the Principality, in a most courteous speech, which was acknowledged by representatives of the foreign delegates, Sir John Evans replying on behalf of Great Britain. The inaugural address of the president on the objects of the congress, the importance of its work, and the present position of prehistoric archæology concluded the first day's proceedings.

By an ordinance of the congress, French is the only language permitted in verbal or written communications, a restrictive regulation, we believe, enforced at no other international convention. A proposition was, however, early submitted to the council at Monaco that other languages should be admissible, but it met with favour only so far as regards written communications, which, it was resolved, may now be presented also in English, Italian, or German. All verbal communications, however, must still be in French. This change concedes practically little; for while it may be easy to prepare and read a paper in a foreign language, it is extremely difficult to express on the spur of the moment, in a language with which one is not very familiar, exactly what one wishes to convey. The chief privilege of members is the right to express their views on questions before the congress, but this rule practically disfranchises all those unable to speak French. Considerable dissatisfaction was felt at the severity with which the regulation was enforced. Indeed, many foreigners thus compelled to speak in French were less intelligible even to those acquainted with that language than if they had been permitted to use their own tongue! It is sincerely to be hoped that at the next session, which has been fixed to meet in Dublin in 1909, this harsh bye-law will be entirely abrogated, and that members of all countries may be allowed, equally with their French colleagues, to address the congress in their own language.

The dominant subject of the second seance was the genuineness of the implements known as "eoliths." A series of mill-modelled flint nodules was exhibited, among which there was certainly a number closely resembling many Prestwichian types, but conspicuous by their absence were the decidedly purposeful and rationally usable Kentian forms. A small collection exhibited by Prof. Girod, obtained near Aurilliac, affirmed to be out of a bed of Tortonian (Miocene) gravels containing Hipparion, underlying a massive stratum of basalt, contained at least one "eolith" unquestionably of human manufacture. The occurrence was vouched for, by M. Rutot, of implements of a particular silex identical in form with those from Kent in pre-Glacial beds in Belgium in which no other silex pebbles of the same character and composition were present, and the manufacture and introduction of which could be due only to man. Prof. Ray Lankester submitted that he had recently placed on exhibition in the British Museum a considerable series of specimens selected from Prestwich's collection, all borer-like in form, too identical in shape and so obviously of rational utility for any possibility of their being the result of fortuitous natural collisions. The congress was, however, divided in opinion on the subject. At a later meeting a telegram from Prof. Schweinfurth, in Egypt, was read announcing full confirmatory evidence of the occurrence of eoliths in the Nile Valley. The most important part of the day's programme was the visit paid to the Grimaldi caves at the Red Rocks, between Mentone and Ventimiglia, the inspection commencing with the most easterly—the Grotte du Prince. This cave has been most systematically and scientifically explored by a trio of distinguished archæologists, Prof. Marcellin Boule, the Abbé de Villeneuve (director of the Archæological Museum of Monaco), and Prof. Verneau. With much trouble and no little risk to limb, the grotto-walls had been marked by labels and lines of paint to indicate the limits of the various horizons in correspondence with those on a diagram of a longitudinal section of the cave distributed to members. From an elevated crag the Abbé de Villeneuve gave an account of the method of excavation and of the discoveries made at the various levels, while Prof. Boule detailed the sequence of events from the geological and palæontological point of view. So lucid were both these demonstrations that no one could fail to carry away a perfectly clear comprehension of the original contents of the cave, and form their own opinion on the evidence for man's antiquity in this region afforded by its exploration. No human osseous remains were met with in this grotto, but worked implements occurred in abundance from the lowest to the highest layers. Those from the lowest beds, which were roughly worked and chiefly Mousterian in type, occurred in association with bones of *Rhinoceros merckii*, *Elephas antiquus* and hippopotamus, and with specimens of *Cassis rufa*, an Indian Ocean mollusc which may perhaps have been acquired by barter. The contents of this cave have been transported to the Archæological Museum in Monaco, and arranged with such care by the Abbé de Villeneuve in the order of succession of the various strata, and so accurately labelled, that it is impossible to overestimate the importance to anthropological science of this comparatively small collection.

The Barma (=Grotte) Grande next claimed attention under the special guidance of Prof. Verneau, by whom the greater part of its exploration had been carried out. As is well known, this cave yielded several human skeletons, all of the Cro-Magnon type, the most deeply interred lying in association with bones of the reindeer. Several of these have been left *in situ* preserved under glass; while in a small museum erected, close by the mouth of the grotto, at the expense of Sir Thomas Hanbury, are arranged the bones and other objects discovered in it. After a hasty visit to the Grotte du Cavillon the congressionists proceeded to inspect the famous Grotte des Enfants under the same excellent guidance. The two celebrated skeletons from the lowest *foyer* of this cave, the types of Verneau's negroid *Race Grimaldi*, are safely preserved in the Monaco Museum. These discourses *sub divo* were necessarily succinct, but they were supplemented by fuller addresses of extreme interest during the following forenoon by the Abbé de Villeneuve, Profs. Boule and Verneau, and M. Cartailhac, under whose joint authorship a beautifully illustrated volume on the results of their exploration of these caves will shortly be published by the generous provision of the Prince of Monaco.

The next day's programme was reserved specially for papers on the engravings and frescoes on the walls of prehistoric caverns. The Abbé Breuil presented a communication on the process of the evolution of art during the Reindeer age, a *résumé* of a large work on which he is engaged, resulting from his laborious copying of the wall pictures of many caverns in collaboration with his colleagues Cartailhac, Capitan, Peyrony, and Bourrinet. The most important as well as most attractive item, however, was the exhibition by Dr. Capitan of a long series of lantern-slides of mural, engraved, and polychrome pictures—the latter in colour—most carefully copied by himself, the Abbé Breuil, and their associates named above, under the most trying and difficult conditions in the grottoes—more frequently than not far in their dark, damp, and cramped recesses—of Mas-d'Azil, Combarelles, Marsoulas, Bernifal, Les Eyzes, de Freye (Dordogne), la Mouthe, Altamira, Font de Gaume, de Teyjat, La Greze, and others. The number and variety of subjects depicted indicates powers of accurate observation and a mastery of hand in the arts of sculpture and drawing at that early age which are really astonishing, and it is evident that this wonderful capacity for art was the common heritage of Palæolithic man in all parts of Europe. *Rhinoceros merckii* and some dozen other extinct quadrupeds appear to have been his favourite studies. *Bison priscus*, however, was the species most frequently and most characteristically represented, being perhaps the commonest or the most dreaded member of his fauna. The human figure was less frequently, and always rudely, portrayed, and usually with monstrous or grotesque faces, suggesting that actors in some ceremonial were intended to be depicted in masks, recalling the dance-masks of the Chiriqui and Arizona Indians. Further papers on the same theme occupied also a great part of the following morning's sitting, at which the most interesting exhibition was a series of burins and scrapers of flint from the Grotto of Eyzes, exquisitely manufactured of every degree of fineness—some of them worked at both ends—to serve the manifold purposes of the artist. They were unquestionably the very tools by which the wall pictures beside them had been executed. With the exception of a short note by Dr. Arthur Evans (who on rising was very warmly greeted by the congress), on the Ægean, Minoan, and Mycenæan epochs, the remainder of the communications on the day's programme dealt with the Bronze and Iron age in Europe.

The sitting of the forenoon of Saturday, April 21, was given up chiefly to the archæology of northern Africa. The most important communication was M. Flammaud's, on his discovery in the Sahara of megalithic monuments of new shapes and of peculiar sculpture, and on the numerous evidences he had obtained of contact between the interior of Lybia and Egypt in the Neolithic age. The afternoon was spent on an excursion through beautiful scenery *viâ* the well-known *Tropaea Augusti* at La Turbie to the mysterious prehistoric entrenchments occupying the summit of Mont Bastide, as that of many of the other foot-hills of the Maritime Alps. The congress assembled on Sunday afternoon for the formal closing ceremonies usual on such occasions, the Prince of Monaco being again represented by his son, who, at the palace previous to the meeting, had, on his father's behalf, conferred the decoration of St. Charles on the presidents, the secretaries, and several of its more distinguished members, of whom Sir John Evans received the cross and ribbon of the Order.

Several social entertainments were given during the week "en l'honneur des congressistes," including, besides a reception at the palace, an evening performance of *Méphistofèles* and a *matinée* concert, both in the beautiful Casino Theatre.

For those—and they proved a goodly company—who could spare the time, a whole-day excursion, under the able leadership of M. Paul Goby, to the prehistoric monuments—dolmens, tumuli, and entrenchments—in the neighbourhood of Grasse was arranged by the excellent committee of organisation as a pleasant termination to a very successful and profitable session of the congress.

SUMMER TEMPERATURES OF THE NORTH SEA.

THE "Bulletin Trimestriel" of the International Council for the Exploration of the Sea, for the period July to September, 1905, has just been issued. As the observations are for the summer months, they are naturally more numerous than in other seasons of the year, and an immense amount of material is dealt with. The increase in the number of surface observations, and the extension of the area from which they have been obtained, are specially noteworthy; a plate of nine charts showing the variations of mean temperature in the North Sea for ten-day periods, from July 1 to September 30, 1905, is added to the usual quarterly maps. These charts have been prepared by dividing the area into squares of 1°, and ½° close to the coast, and the results checked by mean values from Dutch observations, worked up by a different method.

The sections drawn from the observations of the special steamers sent out by the different countries are very numerous in the narrower seas, forming a close network in the Baltic and the North Sea. A line north-eastward from Scotland defines the conditions across the northern entrance to the North Sea, but it is unfortunate that, except for some very useful lines running seaward from the coast of Ireland, and one section from Iceland to Færöe, information from the western section of the area is somewhat deficient, notably in the Færöe-Shetland Channel. It would be a great matter if observations in the depth could be carried further seaward to the southwest of the British Isles with the view of ascertaining the precise limit to which waters of Mediterranean origin penetrate northward, and in this connection an increase in the number of gas samples analysed would be of value.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting Prof. J. Milne for the degree of D.Sc. *honoris causa* at the Encaenia on June 20:—

In terrae motibus cognoscendis nemini profecto cedit Ioannes Milne. Hic ille est qui nova eademque plurima quaerendi instrumenta commentatus, quibus vim terrae motuum longinquis in locis redundantem emetiretur, ostendit tribus quibusdam momentis rem agi: duobus enim tremoribus medium terrae globum concutientibus succedere tertium latius patentem et in summo volitantem, sicut undam mare supereminentem. His repertis illud etiam consecutus est ut interioris terrae naturam et compagem certius cognosceret. Nullas profecto regiones non peragravit vir acerrimus, dum telluris superficiei studet, praecipuam vero laudem adeptus est quod rei publicae Iaponicae viginti annos inservit, Geologiae doctor insignis, fodinarum publicarum curator peritissimus. Ibi etiam sexcentas stationes disposuit omnia quae ad terrae motus pertinent et observantium et litteris mandantium. His etiam diebus patriae redditus in insula Vecti tale laboratorium constituit vir strenuus, eorum antesignanus qui hanc sectam secuti id agunt ut omnibus in terris eandem ipsi diligentiam praestent. Tantis tot strenuorum virorum laboribus nonne id aliquando fieri potest ut de caecis horum motuum causis paullo certiores fiamus?

CAMBRIDGE.—The Quick professorship of biology is vacant. The professor is to devote himself to the study of the Protozoa, especially such as cause disease. The stipend is 1000*l.* a year. The election will take place on July 26. Candidates are to send their names and references to the Vice-Chancellor by July 19.

Mr. R. A. Herman and Mr. H. W. Richmond have been appointed university lecturers in mathematics.

The Raymond Horton-Smith prize, for an M.D. thesis "On Changes in Sensation Associated with Gross Lesions of the Spinal Cord," has been awarded to Mr. H. Theodore Thompson, of Christ's.

The Gordon-Wigan prize of 50*l.* for a research in chemistry has been awarded to F. E. E. Lamplough, Trinity.

EARL CARRINGTON, President of the Board of Agriculture, will open the new buildings at the South-Eastern Agricultural College, Wye, and distribute the diplomas and prizes, on Wednesday, July 18, at 3.15.

THE Court of the University of Manchester has decided to confer the following honorary degrees:—D.Sc. on Prof. Emil Fischer, professor of organic chemistry in the University of Berlin, and on Prof. Adolf von Baeyer, professor of organic chemistry in the University of Munich; M.Sc.Tech. on Mr. Ivan Levinstein, and M.Sc. on Mr. James Grier, lecturer in pharmacognosis.

PROF. A. MELVILLE SCOTT, late 1851 Exhibition scholar from the University of Toronto, has resigned his position as professor of physics and electrical engineering at the University of New Brunswick to accept the office of superintendent of schools for the city of Calgary, Alberta. His successor will be Prof. W. H. Salmon, a graduate of Cambridge, now of King's College, Windsor, N.S.

NEW science buildings, built and equipped at a cost of 7000*l.*, were opened at Repton School on the occasion of the speech day, June 21, by Sir Oliver Lodge, F.R.S. The buildings are largely the result of the munificence of Lord Burton, until recently the chairman of the governing body. In the course of his address, Sir Oliver Lodge spoke of the importance of the study of science, and particularly of astronomy, in order that a better conception of the universe, of its magnitude, and man's place in it might be obtained.

IT is announced in *Science* that the Woman's College of Baltimore has now received gifts amounting to 116,000*l.* Of this amount 100,000*l.* was needed to clear the college of debt, and 16,000*l.* will be added to the endowment fund. Mr. Andrew Carnegie gave 10,000*l.*, the Massey estate 10,000*l.*; other gifts range from small amounts to 6000*l.* We learn from the same source that Governor Higgins has approved a Bill appropriating 16,000*l.* for a school of agriculture at St. Lawrence University, with an additional 2400*l.* for maintenance. This school, it is understood, will be managed in cooperation with the authorities of the State College of Agriculture at Cornell University. By the will of Catherine L. R. Catlin, of New York, 2000*l.* is left to New York University.

IN the House of Lords on Monday Lord Barnard asked the President of the Board of Agriculture whether he has been able to consider the representations made to the secretary of the Board, on December 5, 1905, by a deputation from universities, colleges, and agricultural institutions, and whether there is any prospect of an increased grant to such institutions. In the course of his reply, Earl Carrington said no money could be better spent than that which is applied to helping farmers to meet the fierce and growing competition which they have to encounter from all sides. Some time ago 4500*l.* was voted towards this object, and in 1906 the vote has risen to 11,500*l.* The sum is small, it is true, when compared with the amounts voted in other countries, but the country has received the full value of the grant owing to the cordial cooperation and good work of the different county councils. He suggested that some inquiry should be held into the system of agricultural education. There has been no inquiry since 1888—nearly twenty years ago. If it should appear that there is good ground for an increase of grant, those who advocated such an increase would find their hands strengthened very considerably.

A MEETING of university extension students and others is to be held at Cambridge on August 2–28. The principal subject of study will be the eighteenth century, especially the period 1714–1789. Among the lectures arranged, the following, dealing with subjects of science, may be mentioned:—Cloud problems in astronomy, by Mr. A. W. Clayden; a total eclipse of the sun, by the Rev. T. E. R. Phillips; great astronomers of the eighteenth century, by Mr. Arthur Berry; the Milky Way and the clouds of Magellan, by Mr. A. R. Hinks; the dawn and progress of modern geology, by Dr. R. D. Roberts; great botanists of the eighteenth century, by Prof. W. B. Bottomley; great zoologists of the eighteenth century, by Mr. L. A. Borradaile; and the beginnings of the steam engine, by Mr. E. K. Hanson. Besides these purely scientific lectures, others of interest to students of the methods of science occur in the programme, such as those by Mr. H. Yule Oldham on the teaching of geography, and by Mr. E. A. Parkin on hygiene in schools. Practical courses in chemistry and botany, primarily for teachers, will also be held. Forms of entry and further information will be supplied by the Rev. D. H. S. Cranage, Syndicate Buildings, Cambridge.

IN the May issue of the Transactions of the Oxford University Junior Scientific Club is a thoughtful paper by Mr. M. H. Godby on the place of natural science in education. The spirit of the paper provides an encouraging sign of appreciation of the value of scientific studies, and serves to show that a generous recognition of the importance of a training in the methods of science is producing a beneficial effect upon the present generation of Oxford students. Mr. Godby first indicates the influence on British education exerted by Bacon in directing the attention of speculative thinkers to the importance of founding theories on knowledge gained from the senses, and subsequently refers approvingly to Herbert Spencer's insistence upon the necessity of training the body and the value of a scientific education. As indicative of modern tendencies at Oxford one or two of the writer's remarks may be cited:—"The man of science perhaps alone of all men understands and appreciates the value of working hypotheses, even when they are wrong." "A great charm, too, of science is that one can always appeal against the decisions of tutors and authorities to Nature herself, and so there is produced a freedom from the awe of authority which must tend to develop self-respect and to encourage independence and originality." "Science is more capable of arousing the interest of its students than other subjects. There is a sort of spirit of antagonism, a feeling that you are pitting yourself against Nature and trying to unravel her secrets, and this feeling is just what will always appeal to the sporting instincts of English boys." It is satisfactory to find that young Oxford is alive to the responsibility of the University for the growth of scientific knowledge.

REPLYING to a question in the House of Commons on Tuesday as to the action which the President of the Board of Education proposes to take on the report of the Departmental Committee on the Royal College of Science, &c.; and as to whether any reorganisation of the University of London is contemplated, with a view to the association with it of the proposed Technological College, Mr. Lough said:—The Board is at present engaged in the preparation of a scheme for the establishment of a new institution on lines corresponding as closely as possible to those recommended by the departmental committee. The Board agrees with that committee in regarding it as of first importance that there should be no delay in the organisation of the institution, and with the recommendation of the committee that its relation to the University of London should, in the first instance, be that of a "school of the University"—a recommendation in which the senate of the University has informed the Board that it concurs. In considering the constitution of the new institution the Board has had under consideration the suggestion of the departmental committee (No. 94, p. 27) that, without delaying the commencement of the new institution's work, a Royal Commission should be appointed to consider whether changes could advisedly be made in the character and constitution of the University which may make it desirable and possible to amalgamate the two institutions. It has also had before it the resolution of the senate of the University deprecating the appointment of such a Royal Commission within so short a period after the reorganisation of the University, and expressing the desire that opportunity should be afforded for conference between the Board and the Senate as to any changes of the kind suggested. In the course of the conference, which took place on March 9, between the Board of Education and a deputation from the University senate upon these matters, the suggestions thrown out by the University deputation seemed to be contingent, practically, upon the incorporation of the new institution within the University. As this would necessitate a prolonged delay in the starting of the institution, which the committee specially recommended should be avoided, the Board has found it impracticable to proceed on those lines, but is hastening as much as possible the preparation of a draft charter on the lines of the report of the departmental committee.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 5.—"On a Method of Obtaining Continuous Currents from a Magnetic Detector of the Self-restoring Type." By L. H. **Walter.** Communicated by Prof. Ewing, F.R.S.

Magnetic detectors for wireless telegraph purposes have proved satisfactory for telephonic reception, but have not hitherto been capable of furnishing continuous currents suitable for use with recording instruments. The author has devised a new form of magnetic detector which is capable of furnishing both continuous and alternating currents, the former for recording purposes and the latter for telephonic reception. The apparatus consists of a form of differential dynamo, having two similar armatures on the same shaft. The armature cores are of iron or steel wires. The electromotive forces generated by the two armatures are opposed to each other and normally balance, so that no potential difference is detectable at the commutator brushes. Oscillations set up in the receiver aërial as a result of signals are led through the magnetic wire forming one armature core, causing it to take up a higher induction, and thus disturbing the balance, a continuous current being obtainable from the brushes so long as the oscillations persist. This current is utilised for actuating the recording instrument or relay. For simultaneous reception of the signals on the telephone, the alternating current generated as a result of the action of oscillations is taken off, by means of slip-rings and brushes, before it is commuted into unidirectional current.

May 17.—"Some Stars with Peculiar Spectra." By Sir Norman **Lockyer,** K.C.B., F.R.S., and F. E. **Baxandall.**

This paper relates to a few stars the spectra of which show certain peculiarities that make them not altogether conformable to any common type. The most notable of these stars are α Andromedæ, θ Aurigæ, α Canum Venaticorum, and ϵ Ursæ Majoris. They are all on the descending side of the Kensington curve of stellar temperature, the first three being of the Markabian type and the last of the Sirian type. A short account is given of the spectrum of each of these stars.

α Andromedæ has recently been found by Slipher, of the Lowell Observatory, to be a spectroscopic binary with a period of about 100 days. Prior to this, an investigation of the various Kensington spectra of α Andromedæ, taken in the years 1900–4, appeared to indicate slight changes in the relative intensity, position, and definition of some of the lines in the various photographs. There does not, however, seem to be any regularity in these changes, either in the lines themselves or in the manner in which they are affected, so that it has not been possible to come to any conclusion as to their real significance. Additional photographs will be necessary to test whether the changes in the spectrum bear any relation to the period established by Slipher. The spectrum of α Andromedæ also shows a set of well-marked strange lines which do not occur in any other celestial spectrum, and for which records of terrestrial spectra afford no satisfactory clue as to origin.

θ Aurigæ and α Canum Venaticorum show several strange lines nearly identical in the two spectra, but entirely different from the strange lines of α Andromedæ. No terrestrial equivalents have been found for these stellar lines.

In ϵ Ursæ Majoris, the chief deviations from the Sirian type are the weakening of the silicium (group ii.) lines and the strengthening of the enhanced lines of chromium.

Entomological Society, June 6.—Mr. F. Merrifield, president, in the chair.—*Exhibits.*—Specimens of *Lomechusa strumosa*, F., taken with *Formica sanguinea* at Woking on May 26 and 29: H. St. J. **Donisthorpe.** Only two other British examples are known, one taken by Sir Hans Sloane on Hampstead Heath in 1710, the other found by Dr. Leach, in the early part of the last century, while travelling in the mail-coach between Gloucester and Cheltenham.—A case to illustrate a large number of the life-histories of Coleophorids, notes on which have appeared in the society's Proceedings or in the Entomological Record: H. J. **Turner.**—A few butterflies from Majorca, captured between April 8 and April 20: H. **Lupton.**—A specimen of *Crambus ericellus*, Hb., taken at Loughton, Essex, August 8, 1899, not previously recorded from further south than Cumberland; two specimens of *Nola confusalis*, H.S. ab. *columbina*, Image, taken in Epping Forest, May 5: S. **Image.** The first examples of this aberration were taken by the exhibitor at the same locality, May 22, 1905, and a specimen of *Peronea cristana*, F., the ground colour of upper-wings abnormally black, even more intensely black than in the ab. *nigrana*, Clark, also taken in Epping Forest, August 19, 1905.—The type of *Spathorrhamphus corsicus*, Marshall, from Vizzavona, Corsica: J. H. **Keys.** This fine Anthribid was supposed by some coleopterists to have been an accidental importation into the mountainous regions of the island, but was no doubt endemic. Mr. G. C. Champion remarked that he had taken *Platyrrhinus latirostris*, in numbers, at the same locality, in the beech and pine forests (*Pinus laricio*) along the line of railway, above the tunnel.—Specimens of African Pierinæ found by Mr. C. A. Wiggins on February 2 settled on damp soil near the Ripon Falls, Victoria Nyanza, and caught, to the number of 153, at a single sweep of the net: Dr. F. A. **Dixey.** Eight species were represented; the examples were all males, and, with one exception, belonged to the dry-season form of their respective species.—Notes on Natal butterflies, received from Mr. G. H. Burn, of Weenen, and the four individuals of *Euralia wahlberghi*, Wallgr., and *E. mima*, Trim., captured by Mr. G. A. K. Marshall, near Malvern, Natal: Prof. E. B. **Poulton.** Prof. Poulton then exhibited Mr. Marshall's latest demonstration of seasonal phases in South African species of the genus Precis, the proof by actual breeding that *P. tukuoa*, Wallgr., is the dry-season phase of *P. ceryne*, Boisd. Prof. Poulton further showed 325 butterflies captured in one day by Mr. C. B. Roberts, between the eighth and tenth mile from the Potaro River, British Guiana, and directed attention to the preponderance of males.—*Papers.*—Some bionomic notes on butterflies from the Victoria Nyanza region, with exhibits from the Oxford University Museum: S. A. **Neave.**—The habits of a species of Ptyelus in British East Africa: S. L. **Hinde,** illustrated by drawings by Mrs. Hinde.—(1) Mimetic forms of *Papilio dardanus* (*merope*) and *Acraea johnstoni*; (2) Predaceous insects and their prey: Prof. E. B. **Poulton.**—Studies on the Orthoptera in the Hope Department, Oxford University Museum, i., Blattidæ; and a note on a feeding experiment on the spider *Nephila maculata*: R. **Shelford.**

Physical Society, June 8.—Prof. J. Perry, F.R.S., president, in the chair.—The solution of problems in diffraction by the aid of contour integration: H. **Davies.** The method adopted is to obtain a solution for unbounded space as a contour integral. The special boundary conditions are then accounted for by adding terms to the previous expression. When the complete expression has been obtained it is then evaluated in the form of a series by the aid of Cauchy's residue theorem.—J. Goold's experiments with a vibrating steel plate: **Newton** and Co. The phenomena peculiar to this plate may be classified under two heads:—(1) beats, simultaneously audible and visible; (2) dispersion figures. In addition to these, vortex-vibration, resonance-effects, and many other experiments may be exhibited by using suitable clamps, &c. The dispersion figures are due chiefly to the interaction of two systems of vibrations of the same pitch working at right angles to each other.—Fluid resistance: Colonel R. **de Villamil.** Prof. Hele-Shaw, in a paper on the motion of a perfect fluid, remarks that one of the most perplexing things in engineering science is the absence of all apparent connection between the higher treatises on hydrodynamics and the vast array of works on practical hydraulics. The reason for this appears to be the immense difference between the flow of an actual liquid and that of a perfect one, owing to the property of viscosity. According to the author, this is not the only reason. There appear to be two fundamental difficulties to be got rid of before they can be reconciled. Engineers assume that a liquid can be "pushed" in any rectilinear direction. This, though a very popular notion, is not correct. The other difficulty is the assumption that in a perfect fluid there can be no resistance of any kind to any body moving in it at any velocity. It is only in an infinite ocean of perfect fluid that there would be no resistance.

Society of Chemical Industry (London Section), June 11.—Mr. A. G. Salamon in the chair.—Purifying and stabilising guncotton: Dr. R. **Robertson.** This communication—published by permission of the War Office—deals with large-scale experiments having for their object the best means of obtaining a pure and stable guncotton by a boiling process. For the elimination of impurities from the guncotton and the rapid attainment of a stable product, boiling in dilute acid at the beginning of the process is superior to an alkaline treatment, which has the additional disadvantage of tending towards an undue hydrolysis of the ester itself. The acid hydrolysis must not be unduly curtailed, or elimination of the impurities will be rendered difficult.—The determination of indigotin in commercial indigo and in indigo-yielding plants: C. **Bergtheil** and R. V. **Briggs.** The authors have investigated the standard methods of estimating indigotin in commercial [illegible]. It is shown that all the methods dealt with are trustworthy when applied to pure indigotin, but that in application to commercial indigo the impurities present lead to errors; only those methods depending on the oxidation or reduction of solutions of sulphonated indigo are found to be applicable in this case.—Recent progress in the cement industry: B. **Blount.** The author compares the condition of the cement industry in 1886 and at the present time, pointing out that at the former date somewhat crude methods of manufacture were in use, whereas now improved processes are in operation under scientific control. The world's production of Portland cement has increased from 2,500,000 tons to some 11,000,000 tons in the last twenty years, and the centre of the industry has shifted from Europe to the United States. The second part of the paper deals with improvements in controlling the quality of cement in the works and by the user which have been made during the last twenty years.

Royal Meteorological Society, June 20.—Mr. Richard Bentley, president, in the chair.—The mean prevalence of thunderstorms in various parts of the British Islands during the twenty-five years 1881–1905: F. J. **Brodie.** The author gives the mean number of days on which thunderstorms, or thunder only, occurred in each month, each season, and in each year at fifty-three stations situated in various parts of the United Kingdom. July is the month with the largest number of thunderstorms over Great Britain as a whole, and August at some places in the north of Scotland and north-west of England, while June is the stormiest month at nearly all the Irish stations. For the whole year the largest number of thunderstorms is over the northern and eastern parts of England, where more than fifteen occur, while there are less than five in the west and south of Ireland and at most places in the north of Scotland. The summer distribution of thunderstorms is very similar to the annual distribution, while the winter distribution is quite different, when the largest numbers occur along the west coasts of Ireland and Scotland and extreme south-west of England.—Typical squall at Oxshott, May 25, 1906: W. H. **Dines.** During the morning there was a steady wind from the south-west of more than ten miles per hour until 11 a.m., when there was some falling off for fifteen minutes, then a rise to more than twenty miles per hour, accompanied by a sudden increase of barometric pressure and a fall of a few hundredths of an inch of rain. After the squall the wind dropped suddenly, and there was almost a dead calm for about twenty minutes. The author, who was flying a kite at the time, gave some account of the changes in the wind at a considerable altitude above the earth. At 11.26 a.m. the squall struck the kite, which was then at a height of 2400 feet. Two minutes later the velocity at the kite had risen to fifty-eight miles per hour, and the wire broke under a strain of 180 lb. Three minutes later the kite fell at a spot $2\frac{1}{4}$ miles distant from Oxshott.

EDINBURGH.

Royal Society, June 4.—Dr. R. H. Traquair, F.R.S., vice-president, in the chair.—Recherches sur la Glauconie: Drs. Léon W. **Collet** and Gabriel W. **Lee.** The paper contained a careful examination of the chemical composition of the mineral glauconite, which was found in what Sir John Murray called, in the *Challenger* expedition reports, the blue and green muds of the ocean beds. It was shown that glauconite was ferric silicate, and not ferrous silicate, as had been stated by Calderon and Chaves, of Madrid.—A rare dolphin, *Delphinus acutus*, recently stranded on the coast of Sutherland: Sir William **Turner,** K.C.B. There were very few previous records of this species having been found in the vicinity of the Scottish shores.—Contributions to the craniology of the people of the Empire of India, part iii., natives of the Madras Presidency, Thugs, Veddahs, Tibetans, and Seistanis: Sir William **Turner,** K.C.B. Among the skulls exhibited were those of some of the famous Thugs who practised highway murder with such skill and secrecy as to elude for long the authorities in India. Their crimes were regarded by themselves as a religious duty. The skulls were all well formed, with no resemblance to what some have called a criminal type. Of the two Tibetan skulls, one was of Mongolian type, but the other was that of a Kham warrior from eastern Tibet, and its dolichocephalic form supported Grierson's theory of the Tibeto-Burman stock. The three skulls from Seistan, in south-west Afghanistan, belonged to two types, one approximating to the Afghan and the other to the Beluchistan type.—Interpolation for a table of fractions, with a notice of synthetic division and its use: Dr. James **Burgess,** C.I.E. All fractions with denominators under 100 and numerators less than 50 were tabulated in order of magnitude. The formulæ $q=n/d=(n+q)/(d+1)$ suggested a simple and rapid way of dividing by any number differing by unity from a simple multiple of 10, 100, 1000, &c.—The length of the normal chord of a conic: Prof. **Anglin.**—The hydroids of the Scottish National Antarctic Expedition: James **Ritchie.** The collection brought home by the *Scotia* was very large. There were forty-five specimens giving one new genus, nine new species, and several new varieties. The new genus had been named Brucella, in honour of Mr. W. S. Bruce. The *Scotia* collection also extended our knowledge of the geographical range of hydroids, especially towards the Antarctic regions.—Prof. D. J. **Cunningham** exhibited a photograph taken from a bridge of a large number of salmon resting in the Corrib River, Galway.

Paris.

Academy of Sciences, June 11.—M. H. Poincaré in the chair.—Some points relating to the study of the specific heats and the application to these of the law of corresponding states: E. H. **Amagat.** It has been shown in a previous note that the specific heat at constant volume, following an isotherm, undergoes a discontinuity at each intersection of this isotherm with the saturation curve. In the present paper the question is discussed as to whether this discontinuity persists in the neighbourhood of the critical point.—The products of the reaction, at a high temperature, of sodium isobutylate and propylate of camphor: A. **Haller** and J. **Minguin.** Camphor, heated at about 230° C. with sodium isobutylate, gives sodium isobutyrate and isobutylcamphol, various derivatives of which have been prepared. The general action of sodium propylate on camphor at a high temperature is similar to that of sodium isobutylate, but the yields are not so good.—Some attempts made in the German Navy to utilise photography in voyages of exploration: A. **Laussedat.**—The orthography of the word *caesium*: M. **de Forcrand.**—Vaccination against tuberculosis by the digestive tracts: A. **Calmette** and C. **Guérin.** The authors summarise the views put forward by them in previous papers as to the exact mechanism of tuberculous infection, laying stress upon the fact that the tubercle bacilli are probably absorbed by the digestive tube, and find their way to the lungs indirectly, and not directly as usually assumed. It has been found that it is possible to vaccinate young calves by the simple intestinal absorption of tubercle bacilli modified by heat, and that this method of vaccination is quite free from danger.—Remarks by M. Emile **Roux** on the preceding paper. The results of experiments carried on by M. Roux since November, 1905, are in general agreement with those described in the preceding paper; it is possible to give immunity to cattle against tuberculosis by means of the digestive tracts.—The problem of the elliptical cylinder: Mathias **Lerch.**—Specific inductive power and conductivity. Electrical viscosity: André **Broca.**—The aurora borealis: P. **Villard.** A complete theory of the aurora is given, and, using this as a guide, it is shown that the characteristic features of the aurora can be reproduced by means of a large spherical bulb placed between the conical poles of an electromagnet.—The liquefaction of air by expansion with external work: Georges **Claude.** Details are given of the arrangements for "compound" liquefaction, this constituting an advance on the previous results. Whereas spontaneous liquefaction under atmospheric pressure gave the author only 0·2 litre of liquid air per horse-power hour, the second step, liquefaction under pressure, gave 0·66 litre per horse-power hour, whilst the compound liquefaction raises the yield to 0·85 litre per horse-power hour.—The magnetic properties of the compounds of boron and manganese: Binet **du Jassonneix.** Of the two manganese borides MnB and MnB_2, the former alone possesses magnetic properties, and the permeability of ingots of manganese boride obtained from the electric furnace is proportional to the amount of MnB present.—The iodomercurates of magnesium and manganese: A. **Duboin.** These salts give rise to solutions of densities approaching 3·0, and various crystalline double iodides were separated and isolated.—The reduction of antimony selenide: P. **Chrétien.** The determination of the fusing points of mixtures of antimony and selenium in various proportions indicated the existence of three new compounds of selenium and antimony, SbSe, Sb_4Se_5, and Sb_4Se_4.—The attack of platinum by sulphuric acid: L. **Quennessen.** In the case of the sulphuric acid of the usual strength sold, it is the oxygen of the air which intervenes as the oxidising agent. In the absence of free oxygen with acids of high concentration, the necessary oxygen for the solution of the metal is furnished by the sulphur trioxide in solution in the acid.—The chlorination of wool: Leo **Vignon** and J. **Mollard.**—The estimation of albuminoid and gelatin materials by means of acetone: F. **Bordas** and M. **Touplain.** The authors have shown that egg-albumin, casein, and fibrin are completely insoluble in pure acetone. Diastases and peptones are also precipitated by acetone. In all cases the aqueous solutions separated by centrifugal action from the precipitate gave on analysis no trace of nitrogen, showing the separation to be complete. Details are given for the processes recommended for the analysis of butter, cheese, and milk.—Researches on the development of *Botrytis cinerea*, the cause of grey rot in grapes: J. M. **Guillon.**—Note on the bathypelagic Nemerteans collected by the Prince of Monaco: L. **Joubin.**—Impregnation and fertilisation: E. **Bataillon.**—The motility of the echinococcic scolex: J. **Sabrazès**, L. **Muratet**, and P. **Husnot.**—The graphitic schists of Morbihan: M. **Pussenot.**—The local winds in the neighbourhood of the Canaries: H. **Hergesell.**

DIARY OF SOCIETIES.

THURSDAY, June 28.

Royal Society, at 4.30.—Sex-determination in Hydatina, with some Remarks on Parthenogenesis: R. C. Punnett.—On the Julianiaceæ, a New Natural Order of Plants: W. B. Hemsley, F.R.S.—On Regeneration of Nerves: Dr. F. W. Mott, F.R.S., Prof. W. D. Halliburton, F.R.S., and A. Edmunds.—The Pharmacology of Ethyl Chloride: Dr. E. H. Embley.—The Alcoholic Ferment of Yeast Juice, part ii., The Co-ferment of Yeast Juice: Dr. A. Harden and W. J. CONTENTS.

THURSDAY, JULY 5, 1906.

SOME RECENT PHILOSOPHY.

(1) *The World's Desires, or The Results of Monism.* By Edgar A. Ashcroft. Pp. xii + 440. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1905.) Price 10*s.* 6*d.* net.

(2) *The Scientific Temper in Religion, and Other Addresses.* By the Rev. P. N. Waggett. Pp. xii + 286. (London: Longmans, Green and Co., 1905.) Price 4*s.* 6*d.* net.

(3) *The Reconstruction of Belief.* By W. H. Mallock. Pp. xii + 314. (London: Chapman and Hall, Ltd., 1905.) Price 12*s.* net.

(4) *The Unit of Strife.* By E. K. Garrod. Pp. v + 194. (London: Longmans, Green and Co., 1905.) Price 3*s.* 6*d.* net.

(1) THE first of these volumes need not detain us. The work is dedicated, by permission, to Prof. Haeckel, and Mr. Ashcroft emulates his master in the range and discursiveness of his work. One would have thought that the "Riddle of the Universe" had settled, at least for a modern monist or realist, the majority of the topics here discussed unless, indeed, the presence of two books in many ways so similar is a part of the riddle to which it is desirable to direct attention. We note that Mr. Ashcroft is able to tell us that "the system of Plato displays few living qualities."

(2) Mr. Waggett's work is one of the very best of its type, viz. of the books that seek to reconcile religion and science. The author's chief characteristics are his boldness and his anxiety that there should be no nervousness or hysteria among the religious-minded when their faith is confronted by the facts of science. "We ought to be positively alarmed at any appearance of unbroken agreement between religion and science." "There is not in the Bible ever any contrast between reason and faith. . . . In point of fact, faith is a kind of knowledge, and not only so, but it is the model and type of all sure knowledge." There is no theological interest, Mr. Waggett maintains, in weakening any particular theory about the physical world. In regard to the gulf between the organic and the inorganic—the classical treatment of which is a famous chapter in "Natural Law in the Spiritual World"—Mr. Waggett has already made terms even with Mr. Burke's radium experiments on sterilised bouillon, experiments on which, at the same time, he passes some acute criticisms. "Our faith would not be shaken if the gulf which lies for thought between organic and inorganic matter were for thought to be bridged; for it has never rested upon this or any other interval." Mr. Waggett is suggestive, too, in dealing with the problem of freedom, pointing out that without freedom there can be no error and no knowledge.

(3) A small part of Mr. Mallock's work was dealt with in the "Notes" columns of this journal when it appeared in the pages of the *Fortnightly Review*. Both the clerical and the philosophical attack on the negative conclusions of science have failed, Mr. Mallock declares. On the other hand, current science has no influence on practical life, and all that is best in modern civilisation is to be traced to the three beliefs of theism, viz. the belief in human freedom, in God, and in human immortality. But if the principles of science be only carried to their logical conclusion, it is clear that everything that now happens must have been pre-arranged in all previous molecular conditions of things, and that this pre-arrangement is due to mind and purpose. The last part of the work deals not unsuccessfully with the difficulties generally urged against a belief in the goodness of the Deity, and the author concludes his suggestive volume with forecasting the difficulties which Christianity has still to face—most of all, the difficulty of competing with a new religious eclecticism. Mr. Mallock is to be congratulated on a work which will undoubtedly add to his reputation.

(4) The strife of which the title of this work speaks is the struggle for existence. The title is the one ambiguity, perhaps the one defect, of what is, on the whole, a very clear and suggestive book. Its writer is concerned mainly with the problem that in man as compared with the lower creation "the quality of fitness to survive has in some way become modified"; "an agency has come into play which had not asserted itself on the same lines in the struggle for life before the appearance of man." What are the modification and the agency referred to? The answer seems to be that in man most clearly of all living things the unit in the struggle is not the individual, but the community, gradually expanding from the family to the tribe, the nation, the empire, and that in close correspondence with this development and expansion there has gone the increasing recognition of law and of some higher power, which is the kernel of all religion.

But this brief analysis almost does injustice to the closeness of the argument and the excellence of the illustrations by which the argument is enforced. The scientific analogies are not overdrawn—the great defect of some similar works not even in one amusing passage where the author compares the walls of Babylon to the external defences of the crustacean, and points out that at a more advanced stage of development protection is given rather by moving masses acting on the offensive, just as for the most part the vertebrate organisms have abandoned the methods of the crustaceans and of insects protected by a horn-like covering.

One statement on p. 90 appears somewhat inexact. The author, showing how an ideal may lose the power of expansion by being enclosed and case-hardened, writes thus:—"Thus to the Israelite, while they retained their lofty monotheistic conception, Jehovah became the Deity exclusively of their own race. He was the Lord of Hosts who warred always on their side against their enemies." On the whole it seems wise to distinguish some things which are here confused, the *henotheism* (as it is called) of the earlier period of Jewish history which regarded Jehovah only as one among many Gods, the one who fought on the side of the Israelites, and who ought to be worshipped by them; and, contrasted with it, the later and truly monotheistic ideal of the prophets, which emphasised the *solity* of Jehovah. It would, at any rate, be difficult to harmonise our author's account with any of the accepted readings of Jewish history, traditional or critical. Part of the page ought probably to be re-written.

TIDES AND WAVES.

A Practical Manual of Tides and Waves. By W. H. Wheeler. Pp. viii+201. (London: Longmans, Green and Co., 1906.) Price 7s. 6d. net.

THE author of this book is a well-known civil engineer, whose practice has been largely concerned with works on the sea coast and tidal rivers. The practical side of the subject treated has consequently required and received from him long and close study; his intention in this volume has been "to give as practical an account as possible, free from all mathematical demonstration, of the action of the sun and moon in producing the tides: and of the physical causes by which the tides are affected after their generation, and of their propagation throughout the tidal waters of the earth." To these subjects the principal portion of the work is devoted; in a comparatively short section the author deals also with wave phenomena, in a manner likely to be useful to practising engineers, and not lacking in interest to a much wider circle of readers. Mr. Wheeler has given much time and thought to the production of the work, and the bibliography of his subjects (contained in an appendix) indicates a wide range of reading. In the text itself a great mass of useful information and data is summarised; this is supplemented by several valuable appendices giving results of tidal and wave observations as well as formulæ of use in engineering practice. A good index makes reference easy to the principal features of the book, and adds much to its value to readers for whom it has been chiefly designed. In one particular the scheme of the author is open to criticism: he has aimed at making "the subjects dealt with in the separate chapters complete," and this has involved some repetition of statement. Probably the explanation is that in some cases papers prepared for separate publication have been embodied in the book; but although the repetition (as the author says) may have "been avoided as much as possible," his scheme for completeness in individual chapters necessarily involves it, and in a book such as this is the result is not altogether satisfactory. This is a small drawback, however, to a work of considerable merit that will undoubtedly be welcomed by the engineering profession as a book of reference bringing together within small compass a great mass of useful information drawn from widely-scattered sources.

A historical sketch of the development of tidal science is first given ranging from the work of Copernicus to that of Sir George Darwin and Mr. Moxly. Next come descriptions in popular language of "the making of the tides," the "propagation of the tidal wave," and the mean level of the sea and range of the tides. All these subjects are illustrated by facts and figures drawn from actual observations. The effect of wind and atmospheric pressure on the tides is considered at some length, as a matter of considerable importance to engineers. Mr. Wheeler has endeavoured to formulate a rule as to variations to be expected with a given force of wind and height of tide; and considers that roughly "the effect of a moderate gale is to raise or lower the tide according to its direction as many inches as it would rise in feet under normal conditions." He gives some striking instances of abnormal tides due to gales of long continuance, the heights attained in some cases exceeding the tide-table heights by six to eight feet. In December, 1904, for example, at Grimsby, the morning tide was raised nearly seven feet, and at Hull, as well as on the Thames, about five feet above normal level by a heavy gale from the north-west. An investigation is also made of the recorded observations of variations in tides accompanying variations in atmospheric pressure, and the conclusion is reached that "it is not possible to lay down any general law applying to all parts of tidal waters." Mr. Wheeler considers that "although variation in pressure may be a primary cause of the alteration in the height of tides . . . yet the wind is a safer and more ready guide for the immediate purpose of navigation."

The chapter dealing with "River Tides" is one of the most interesting in the book, and from the nature of the case is chiefly based on actual observations. Mr. Wheeler traces the progress of the ocean tidal wave up a river channel, and shows how the distance to which the wave action reaches depends on the condition of the channel and the depth of the low-water stream. He describes the "ponding back" of the current in the river by the advance of the tidal wave, and demonstrates the necessity for the duration of the flood tide in rivers being less than that of the ebb. The phenomena of "double flow" are explained, and a distinction made between the propagation of a tidal wave up a river and the tidal current. These movements of river water are accompanied by transport of material carried in suspension, and from the engineering side this is a question of great importance which Mr. Wheeler discusses fully.

Closely related to tidal currents are tidal "bores," which occur in certain rivers. These are very fully described by the author, who summarises the conditions necessary for the full development of a bore as follows:—A considerable rise of tide, a converging channel with a rising bed, the depth of water decreasing as the channel is approached, or a sand bar over which there is not sufficient depth of water to admit of the passage of the approaching tidal wave. Under these conditions, in place of a gradual rise of the water at the entrance to the river, the arrival of the tide is accompanied by a breaking wave with a crest several feet in height, which when formed advances rapidly up the channel. In the Tsien-Tang-Kiang River, China, the range of spring tides is about twelve feet at the mouth; but the tidal wave becomes compressed in advancing towards the head of the estuary, and reaches twenty-five feet in height at ordinary springs and thirty-four feet when an onshore gale is blowing. The bore is said to enter the river at the rate of 14½ miles an hour, and during the first hour the rise of tide is ten feet. Its approach can be heard for a distance of fourteen or fifteen miles. The Severn bore is too well known to need description. Its height has been estimated at three to four feet, and velocity at seven to eight miles an hour.

In another section the author deals with wave motion: first with wind waves and secondly with seismic and cyclonic storm waves. As a civil engineer, his chief interest is with the effects of wave motion upon harbour works, coast defences, and other constructions; but these chapters also give an excellent summary of the theory of deep-sea waves and the results of observations on their dimensions and speeds. Some of the facts recorded as to damage done by wave action are very striking. During the construction of Plymouth breakwater, blocks of stone weighing from seven to nine tons were carried over the top through a distance of 138 feet and deposited inside the breakwater. At Bilbao a solid block of the breakwater weighing 1700 tons was overturned. The partial destruction of the north pier at Tynemouth furnishes another illustration; in that case there can be no doubt that the depth below still-water level to which wave disturbance was likely to go in that locality had been considerably underestimated. As to earthquake and cyclonic waves, Mr. Wheeler has collected a large amount of information of an interesting character, and he deals at some length with "solitary" ocean waves, which he thinks are chiefly due to submarine disturbances. The great majority of the solitary waves that have been observed in the North Atlantic were in a line between places subject to volcanic activity. One of the latest examples of the destructive effect of a solitary wave occurred in October, 1905, to the Cunard liner *Campania* on her outward voyage to New York. A fresh gale was blowing on the Grand Banks of Newfoundland when the ship was suddenly struck by an enormous wave; she lurched over, the water swept over the deck several feet deep, five passengers were washed overboard and twenty-nine others seriously injured. This wave was said to have reached as high as the funnels, but in the circumstances accurate estimates could hardly have been made.

The final chapter deals with tides as a source of power. The author gives full accounts of applications of the principle that have been made at various times, but his conclusion is that the attempt to utilise tides on a large scale with existing mechanical appliances cannot be considered as coming within the lines of commercial economics. In this conclusion he has the support of general engineering opinion.

On the whole, Mr. Wheeler has succeeded in the object he had in view, and has "produced a handbook that will be of interest and practical service to those who have neither the time nor the opportunity of investigating the subject for themselves." W. H. W.

ELECTRICITY METERS.

Electricity Meters. A Treatise on the General Principles, Construction, and Testing of Continuous Current and Alternating Current Meters for the Use of Electrical Engineers and Students. By Henry G. Solomon. Pp. x+323. (London: Charles Griffin and Co., Ltd., 1906.) Price 16s. net.

UNTIL a few months ago the literature on the subject of electricity meters was entirely confined to articles in text-books on electrical engineering, and the advent of a book dealing exclusively with this subject is therefore a matter of importance to those interested in the distribution of electrical energy. In the book just published by Messrs. Griffin, Mr. H. G. Solomon has written a clear and comprehensive treatise on the principles and construction of this most important piece of electrical apparatus.

The first chapters are introductory, and deal mainly with the theory of action of the more important types. In chapter ii. an important section on the behaviour of three-wire energy meters is deserving of attention. The errors in reading due to want of balance, both as regards pressure and current on a three-wire system, when the shunt coils of a three-wire meter are connected respectively across the outers, and between the middle wire and the outer, have been worked out. In the appendix figures are given which show the percentage error in different cases, and the advantage of connecting the shunt coil directly across the outers is clearly proved. The fact that there is any error at all with this arrangement has hardly been recognised, though for switchboard meters the matter is certainly one of importance. The following chapters contain descriptions of the various types of quantity and energy meters for continuous current circuits, and are largely reminiscent, as writing of this kind must always be, of manufacturers' pamphlets.

Mr. Solomon has very wisely excluded all historical and out-of-date meters from this part of his book, and the section contains a clear description, fully illustrated by many excellent drawings, of the meters which the central station engineer has to use and to test. The author is to be congratulated on having almost entirely eliminated illustrations of the outer cases of the instruments which he describes, a type of illustration, unfortunately, all too common in some other works on kindred subjects. Chapter vi. contains a description of continuous meters for special purposes. The last section deals with tramcar meters. The practical importance of this type of meter is hardly yet well recognised. As Mr. Solomon says:—"The careless manipulation of the controller and brake is a matter of serious importance, resulting in a considerable loss of energy. By properly recording the actual energy taken by the cars, and keeping records of the motor men, a saving amounting to from 10 to 20 per cent. of the total used can be effected." The descriptions of the best known types of meter for this purpose are somewhat disappointing.

The chapters dealing with the theory of single phase and polyphase meters is complete and satisfactory. All the best known methods of measuring alternate current power are described. A matter of some importance is the effect of wave shape on the accuracy of registration; errors due to this cause may amount to 5 per cent. or more with meters of the induction motor type when running on non-inductive load, while the same meters record quite accurately when supplied with a sine wave of potential difference. The chapter dealing with tariff meters is full of useful information for the central station engineer, and the subject is well treated. The Hopkinson doctrine (one might almost call it an axiom) that "the charge for a service rendered should bear some relation to the cost of rendering it" is fundamental, but one of the chief disadvantages in its application in the Wright maximum demand system is, as Mr. Solomon says, that "the average consumer experiences considerable difficulty in understanding it, and the attitude of the consumer cannot be ignored."

Chapter xi. gives a description of a large number of pre-payment meters, and in the next chapter tariff and hour meters are dealt with in the same way. In the penultimate chapter some special mechanical features in meter design are described, for the obvious reason that "the proper working of a meter depends on its mechanical as well as its electrical design." The subject of meter testing is discussed at some length in the last chapter.

The book should be of great value both to students and to central station engineers who wish to know something about the instruments in use on their supply systems.

A NEW VOLUME OF THE "FAUNA OF BRITISH INDIA."

The Fauna of British India, including Ceylon and Burma. Published under the authority of the Secretary of State for India in Council. Edited by Lieut.-Colonel C. T. Bingham. Rhynchota, vol. iii., Heteroptera-Homoptera. By W. L. Distant. Pp. xiv+503; figs. 266. (London: Taylor and Francis, 1906.)

THE present series of works was initiated and carried on for upwards of twenty years under the able editorship of the late Dr. W. T. Blanford, and as this is the first volume issued under the supervision of his successor, Lieut.-Colonel C. T. Bingham, this seems to be a fitting opportunity to summarise the progress that has already been made. In Vertebrates eight volumes have appeared—one on Mammalia, by W. T. Blanford; four on Birds, by Eugene W. Oates and W. T. Blanford; two on Fishes, by Francis Day; and one on Reptilia and Batrachia, by G. A. Boulenger. In Invertebrates ten volumes have appeared—one on Butterflies, by C. T. Bingham; four on Moths, by G. F. Hampson; two on Hymenoptera, by C. T. Bingham; one (half-volume) on Arachnida, by R. I. Pocock; and two on Rhynchota, by W. L. Distant.

Respecting future arrangements, Colonel Bingham announces that four volumes on Beetles (including a volume on Phytophaga, by M. Jacoby), a second volume on Butterflies, by Colonel Bingham, and a volume on Land Shells, by the late Dr. Blanford and Colonel Godwin-Austen, are in preparation, of which it is hoped that the volume on Butterflies and a half-volume on Longicorn Beetles may be issued during the current year.

Turning from this highly satisfactory record of progress to the volume before us, we find that it concludes the suborder Heteroptera (the true Bugs), with families 17 to 24, Anthocoridæ, Polyctenidæ, Pelogonidæ, Nepidæ, Naucoridæ, Belostomatidæ, Notonectidæ, and Corixidæ, including collectively sixty-two species; and commences the suborder Homoptera with the families Cicadidæ and Fulgoridæ, of which collectively 570 species are described. There still remain three families of Trimerous Homoptera—Membracidæ, Cercopidæ, and Jassidæ—to be dealt with in a future volume, as well as the Dimera and Monomera, comprising the families Psyllidæ, Aphididæ, Aleurodidæ and Coccidæ. With the exception of the Anthocoridæ and the curious bat-parasite *Polyctenes lyrae*, Waterh., the Heteroptera described in this volume are all aquatic, including the curious water-scorpions, water-boatmen, and the great *Belostoma indicum*, Lep. and Serv., which attains a length of three and a half inches, and is perhaps the largest heteropterous insect found in India, though some of the allied South American species are larger.

Our British species of the suborder Homoptera, of which the froghoppers may be taken as typical, are all small insects, the largest, our only British representative of the true Cicadidæ (*Cicadetta montana*, Scop.), a scarce and local insect, only measuring an inch and a quarter across the wings. But many of the Indian species of Cicadidæ and Fulgoridæ are much larger, the largest Indian Cicada, *Pomponia intermedia*, Dist., measuring seven inches across the wings.

Although many species of Cicadidæ are more or less spotted, and more or less opaque towards the base, yet the tegmina and wings are, in most instances, almost entirely transparent. In a few species, however, they are opaque, and brightly coloured. But in the Fulgoridæ, or Lantern-flies, many of which are of considerable size, measuring two or three inches in expanse, the wings are often opaque, and varied with such bright colours that they might easily be mistaken for butterflies or moths by persons ignorant of entomology. Indeed, one species, *Aphana caja*, Walk., has received its name from its superficial resemblance to a tiger-moth.

Many Fulgoridæ exude a white waxy substance, which is sometimes very abundant and conspicuous. Others, such as the true Lantern-flies or Candle-flies, are conspicuous both for their bright colours and for the long projection on the head of many of the species. Some have short wings, others very long and narrow ones. Mr. Distant's figures are without colour, but they give a very good idea of the wingvenation and curious forms of a very interesting but still much neglected group of insects. These figures have been drawn by Mr. Horace Knight in his usual admirable style.

We have much pleasure in commending this volume (in which a large number of new genera and species are figured and described) to all entomologists who are interested in exotic insects. W. F. K.

OUR BOOK SHELF.

Plants and their Ways in South Africa. By Bertha Stoneman. Pp. ix+283. (London: Longmans, Green and Co., 1906.) Price 3s. 6d.

THE schools in Cape Colony and in other South African colonies are already indebted to the publishers of this volume for several useful educational books. Although this book, and one on geology, are the only ones issued under the title of the "South African Science Series," Messrs. Longmans have previously published an elementary botany and a book on South African flowering plants. The present volume by Miss Stoneman is written for younger children than the two former. The treatment of the subject on an elementary physiological and ecological basis is quite the most suitable, and the author displays considerable originality, although at times she develops a crudity of expression.

A chapter on seeds forms the introduction to the physiological considerations of growth; leaves and their functions are then discussed, and four ecological chapters precede the morphology of flowers, fruits, and seeds. The latter half of the book is devoted to classification, limited wisely to a description of the principal orders, and the writer has drawn up tables for differentiating all the genera mentioned; these are exceedingly useful, but the key for distinguishing the orders according to Bentham and Hooker's system, and the synopsis based on Engler's arrangement, would be more suitable for advanced students.

One of the chief merits of the book lies in the natural manner in which rather difficult subjects, such as the law of correlation of growth, are introduced; also every opportunity is taken to base instruction on practical experiment. Certain mistakes or mis-statements occur that might have been avoided with a little more circumspection, and the mis-spellings are more numerous than is consistent with careful reading; but these defects are slight, whereas the author has succeeded in giving plenty of character to the book, and has written with the object of stimulating observation and inquiry on the part of the reader. The book is well supplied with illustrations, of which a fair proportion has been specially drawn or prepared.

Lectures on Compass Adjustment. By Captain W. R. Martin. Pp. 98; with three charts. (London: George Philip and Son, Ltd., 1906.) Price 5s. net.

IN this book is reproduced a series of eight lectures on compass adjustment in iron and steel ships, delivered at the Royal Naval College, Greenwich, to the classes of senior officers as well as to navigating officers up to the year 1902. There can be no question that these lectures, profusely illustrated by diagrams and supplemented by practical instruction by means of models, were in many ways of great value to officers whose career was bound up with the navigation of ships, where the compass might be either a treacherous guide or a means of safety when adjusted and cared for as the author describes. No doubt the lecturer was able to answer questions asked by his audience and to enlarge upon difficult points to their mutual advantage, but now, when these aids are absent and the student has to read lectures with modified diagrams, it is incumbent on the author of them to write clearly and with precision.

Turning, however, to the text, it can hardly be said that the author has succeeded in making his meaning sufficiently clear in many places. Among the more important of these the following require mention:—"The magnetic force of the earth is of course everywhere acting in only *one* direction" (the italics are the author's), a very misleading assertion. The expression "the line of dip is horizontal at the magnetic equator" is unsatisfactory. Again, what is the student to understand from the words, "the compass, may be regarded as a north seeking particle"?

In lecture vi., following wrong premises, it is stated that at a steering compass in H.M.S. *Powerful* the coefficient $\lambda=0.790$ would be increased to 0.968 after correction by spheres. To obtain such an increase of directive force has long been eagerly sought after in vain, but, unfortunately, observation in the present case shows that a value of about 0.830 is near the truth after correction. Again, the results of observations made as described on p. 70 could not be used in constructing chart No. 1 with any degree of accuracy. With the large number of observations from observatories and results obtained with absolute instruments in the field, as well as relative observations at sea, there is no need to trust to inferior results.

The last lecture is devoted to the methods of adjusting a compass with large errors, but it must be remarked that the directions given are not generally agreeable with the practice of recent years. For example, for all purposes connected with the heeling error, the dip circle has long been discarded in favour of the heeling-error instrument.

Finally, it will be observed that the equipment of torpedo-boat destroyers and torpedo-boats with the liquid compass is not referred to. This is probably an unintentional omission which may be remedied in future editions of this work. E. W. C.

Lotus Blossoms. A Little Book on Buddhism. By Maung Nee. Pp. vi+103. (Rangoon: Printed Privately, 1906.)

A DAINTY booklet in which a number of passages from various Buddhist writings have been gathered together under different headings. As indicative of the high tone and lofty character of the teaching in the Buddhist writings, the following sentences may be quoted: "Strive with all your strength, and let not sloth find a place in your hearts." "The wise man does not remain standing still where he has made a beginning, but ever reaches forward towards fuller enlightenment." "Idleness is a disgrace." These are classed under the heading "correct aim," but equally sound morality can be read in all the sections.

Hydrographic Surveying. Methods, Tables, and Forms of Notes. By S. H. Lea. Pp. 172. (New York: Engineering News Publishing Company; London: Archibald Constable and Co., Ltd., 1905.) Price 8s. net.

THIS is an excellent volume, and thoroughly describes the more complicated branch of hydrographical work, such as rivers, lakes, &c. The book touches very lightly on ocean surveying, and apparently is not intended as a work on this subject. Several of the terms used are not often met with in English works, being American technical terms; but these soon become familiar, and, as usual, are very descriptive and to the point. H. C. LOCKYER.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Osmotic Pressure.

IN the issue of NATURE for May 17 (p. 54) appears a communication by Mr. Whetham in which he attempts to consign actual experimental work on osmotic pressure to the humble *rôle* of showing how far the assumptions made in so-called thermodynamical proofs can be realised experimentally. Among other things, the attempts to apply thermodynamic reasoning to osmotic processes involve the assumption of a membrane which is semi-permeable and which at the same time is quite passive, that is to say, which shows no selective action. Now in my paper (referred to in NATURE for May 3, p. 19) I have demonstrated conclusively by experiment that in actual osmotic processes the selective influence of the membrane is always present, and is the determining factor as to whether osmosis will take place at all, and, if so, in what direction. In studying that paper, the reader will also see that *the more nearly a membrane is semi-permeable in character in practice, the greater is its selective action. In fact, it is the pronounced selective action of the membrane which makes it approximately semi-permeable.* This being the case, it is evident at once that thermodynamic reasoning cannot be applied to actual osmotic processes, and that the experimental work on osmotic pressure does not play that humble *rôle* to which Mr. Whetham would consign it.

Mr. Whetham sees perfect semi-permeable membranes (1) in the surface of growing crystals of pure solvent which separate from a solution when it freezes, and (2) in the free surface of a solution of a non-volatile solute as it evaporates, and states that "from these two facts follows the validity of the thermodynamic relations between osmotic pressure on the one side and freezing point and vapour pressure on the other." Now I must insist that the formation of crystals from a solution, or the concentration of a solution by evaporation, are not osmotic processes. There are, in fact, no actual membranes or septa involved in these processes, and to regard them as "osmotic" in character only causes much confusion, for they have nothing in common with an actual osmotic process, in which a membrane—an additional phase with specific selective action—is always present as a determining factor.

In how far it is allowable to apply thermodynamic reasoning to the evaporation of a solution or the formation of crystals from a solution I shall not attempt to discuss here, for it is quite outside the main subject with which my paper deals, namely, the nature of osmosis and osmotic pressure. For the same reason I shall not enter upon a discussion of Mr. Whetham's contention that the theory of electrolytic dissociation "rests upon electrical evidence, and by such evidence it must be tried." In this connection it may suffice to refer the reader to the paper which I have prepared at the request of the Faraday Society (see Trans. Faraday Soc., vol. i., also *Phil. Mag.* for February, 1905), in which I have directed attention to the fact that in creating the theory of electrolytic dissociation, the actual phenomena of electrolysis have played a minor part.

Concerning the remarks made in NATURE of May 17 (p. 54) by Lord Berkeley and Mr. Hartley, I should like to state that, so far as I am aware, the only direct measurements of osmotic pressure which they have made are some preliminary results published in vol. lxxiii. Proc. Roy. Soc., pp. 436–443. In their article in vol. lxxvii. Proc. Roy. Soc., p. 156, I find no direct measurements of osmotic pressure, but simply results of vapour-tension measurements from which osmotic pressures have been computed by means of a modification of a formula of Arrhenius. Of the results given in the two papers mentioned, there is but one case that is comparable, namely, that at concentration 420 grams sugar per litre, the other determinations having been made at different concentrations, so that they are not comparable. Furthermore, all their direct osmotic-pressure measurements were made without stirring, and they are consequently not at all final. I have also in my paper directed attention to the fact that copper ferrocyanide membranes imbedded in porous porcelain are particularly unsuitable for making conclusive direct measurements of osmotic pressure. In these circumstances, it appears that their claim that they have shown experimentally that aqueous solutions of cane sugar give the same osmotic pressure, whether observed directly or deduced indirectly from their vapour-pressures, is not well founded.

As to the computation which Lord Berkeley and Mr. Hartley make concerning one of my experiments, I would state that they assume as a basis for their calculation that the slight amount of sugar found in the outer liquid occurs there because the solution, as such, has passed through the septum. Now this assumption is entirely untenable in the light of the numerous experiments given in my paper illustrating the nature of the osmotic process, and their criticism is consequently worthless. LOUIS KAHLENBERG.

The Olfactory Sense in Apteryx.

ABOUT a year ago I stated in your columns (May 18, 1905, p. 64) that I was trying to have experiments carried out with the object of ascertaining whether the olfactory sense of the kiwi is perceptibly developed, as one would suppose it to be from certain structural peculiarities in which the bird is unique, viz. the great relative size of the olfactory lobes of the brain and the great size of the olfactory capsule as seen in the skull.

I wrote to the curators of Little Barrier and Resolution Islands, which are reserved as sanctuaries for birds, asking each of them to try certain experiments for me with the object, first, of finding out whether the kiwi exhibited any preference for particular species of earthworm, and, if so, whether any difference in odour, or noticeable difference in colour, was perceptible to them (the curators). I asked whether it was possible to deceive the kiwi in any way by appealing to its sense of smell, while excluding those of sight, hearing, and touch, and formulated a few simple experiments with this end in view.

I recently received a reply from the curator of Resolution Island, in Dusky Sound, who is a careful observer of the habits of birds. Mr. Richard Henry experimented with the larger South Island bird, *Apteryx australis*, usually termed the roa-roa, in opposition to the other South Island bird, the small grey kiwi, *A. oweni.* The former feeds chiefly on earthworms, the latter on grubs of various kinds. Mr. Henry placed a number of earthworms at the bottom of shallow buckets and covered them with four inches of earth. When such a bucket was placed on the ground the roa got quite excited in its hunt through the earth, probing to the bottom for the worms. It must be borne in mind that, according to several good observers, the roa (and kiwi) is practically blind during the day time, and, moreover, the bunch of hair-like feathers at the base of its snout intervenes between its eyes and the ground in this operation, while Mr. Henry states that it makes such a "sniffling noise" that it would be unable to hear a worm, even if the latter made any disturbance in the soil. There remains, therefore, the possibility that the tip of the beak is highly sensitive, and that it finds the worms by touch.

But Mr. Henry writes that the bird seemed readily to be aware whether worms were below the earth without touching the soil, for "when I put down a bucket of earth without worms in it, the bird would not even try it; but the moment a bucket containing worms (covered with earth) was put down the roa was full of interest in it," and commenced to probe at once with its long beak.

Further, Mr. Henry took several dead worms that had been severely pressed by the spade in digging them up the previous day, and put them at the bottom of a bucket of earth, and at the end of half an hour the roa had not left a scrap of worm behind. He tried the roa with a bucket of earth that had been searched by it on the preceding day, but the bird "would not even look at it." Then he placed a couple of worms under the earth at the bottom of the bucket, and again allowed the roa to have access to it;

this time the bird went to work promptly, "as if he knew the worms were there."

I had suggested, amongst other experiments, that he should rub a living worm over some substance that the kiwi does not usually eat, such as bread, so that it should be flavoured and scented by the earthworm juice, and then conceal it; but he has not yet, apparently, carried out the experiment.

Previously to my request Mr. Henry had experimented with a roa that he had trained to eat meat. He "planted" pieces of meat in drills three or four inches deep, and next day found them gone, "though the ground was not raked over by the bird, but probed where the meat had been hidden. This was in an enclosure whither other creatures had no access. If, when the bird was at rest, though hungry, he threw a piece of meat or an earthworm near it, it seemed at once aware of the presence of food, would wake up and reach in the right direction, touching the ground from time to time with the tip of its beak until it came in contact with the meat.

Although other and more crucial experiments are needed —and these could more readily be made in England (at Tring, for instance) under careful supervision—yet I think the above affords a certain amount of evidence for the existence in Apteryx of a keen sense of smell.

I may add that Resolution Island is quite an un-get-at-able place; it is visited about three or four times a year, twice by the Government steamer on its round-trips to supply lighthouses, &c., and occasionally by other vessels at irregular times, so that four or five months may intervene before a reply is received to a letter. For instance, in reply to my letter dated April 30 I only received an answer in October. I once tried to arraoge to visit the island, but the uncertainty of getting back to the mainland in any reasonable time was so great that I had to give up the idea. I hope someone in England will undertake further experiments in this direction.

Molecular Changes in Nickel Steel

MR. MILNE, chronometer maker in Manchester, has kindly given me permission to send you the following interesting information. About two years ago he made a clock having a rod pendulum of Dr. Guillaume's invar steel (iron nickel alloy). It was carefully adjusted, and was recording time in a most satisfactory manner. Recently the gut of the driving weight tore, and the clock received a shock whereby the rate was altered a few seconds per day. This might be due to some mechanical movement. After re-adjustment had been effected, it was found that the pendulum was undercompensated for changes of temperature, and it appears as if the coefficient of expansion, which was said to be 0.0000008 per 1° C., had increased.

The second case is a watch the balance wheel of which was made of invar steel and brass. In March, 1904, it was rated by the National Physical Laboratory, when it was found that there was no middle temperature error. Now, after two years' working, this error is +1.08 seconds per day, ordinary steel and brass balances having a middle temperature error of about $2\frac{1}{2}$ seconds per day. The details are as follows:—

Temperature	1904 Rate	1906 Rate
40°	+0.6	+1.08
90°	+1.6	+0.36
Mean	+1.1	+0.72
65°	+1.1	+1.80
Middle temp. error . .	0.0	1.08

C. E. STROMEYER.

"Lancefield," West Didsbury, June 28.

MANX ARCHÆOLOGY AND NATURAL HISTORY.

IN the year 1886 the House of Keys passed an Act entitled "The Museum and Ancient Monuments Act." I well remember hearing of it, because in the course of that year I visited the Isle of Man for the first time, in order to see some newly discovered Ogam inscriptions. It proved for me the first of a series of visits to the island with the view chiefly of studying Manx Gaelic and Manx folklore. I got to know the island and its people, and noticed among other things the efforts made by two or three men with taste and zeal for archæology and history to interest the Manx people in the relics of antiquity for which the Isle of Man is famous. On one of my rambles, which led me to a public school, I remember being much struck by finding hung on the walls drawings of hatchets, hammers, and other instruments of the ages of Stone and of Bronze, accompanied with letterpress descriptions of them. They were intended to interest the more intelligent of the children in such objects, and especially to help them to recognise them when accidents exposed such treasures to view. It struck me how desirable it was that the same thing should be done in the public schools of this country, but I am not aware that it has ever been done. This example of the Isle of Man is well worth following, but I fear that the present is not a favourable moment for recommending anything so far removed from the burning question of the day. But the present war of creeds and dogmas will, it is to be hoped, be followed by a period of peace when the promoters of education may be allowed to devote more attention to some of the historical aspects of its more secular side.

The first Manx archæologists I came in contact with were Canon Savage and Mr. A. W. Moore, who has since not only become Speaker of the House of Keys, but established the right to be considered the historian of the island. I found them inspired and led by the experienced hand of Prof. Boyd Dawkins. They have been since joined by other and younger men, such as Mr. Kermode, who has made the study of the runic crosses of the island his own. He published a valuable book on them in 1892, but he chose to call it a catalogue of them and of the inscriptions, and now a larger work of his on the same subject is passing through the press, and will contain as illustrations numerous plates and a great number of outline figures. The list of the trustees of the Manx Museum and ancient monuments includes other men of light and leading in the island, such as Mr. Ring, the Attorney-General, not to mention that they have always had the Bishop on that body, and enjoyed the support of successive Governors of the island, including among them the well-known historian, Sir Spencer Walpole. These men have always endeavoured to interest the Manx people in their ancient monuments, and they have succeeded to a great extent, but a great deal still remains to be done in the same direction. The pride of ownership is very strong in a Manxman: perhaps it is in all small nationalities—at any rate, I have noticed it not only in Man, but also in my own country, the Principality of Wales. What may be the explanation I do not know, but a member of a small nationality is a more considerable portion of that nationality than if he belonged to a larger nationality, and perhaps that has something to do with the greater difficulty which he finds in rising to the idea of giving up to the nation anything of which he is the exclusive owner. That is, however, not what I was coming to, but to the fact that, in spite of the pride of ownership, the safe keeping of the object owned is by no means guaranteed either in Man or Wales. But to confine my remarks for the present to Man, I may say that I have known a sad case of perversity of this kind in the matter of a piece of most valuable antiquity, which I abstain from describing more minutely. This is within my own knowledge, and I think no superstitious feeling entered into the matter; but in a case I have heard of it is possible that an element of superstition mixed itself with the mere sense of ownership. I was told years ago that an ancient burial urn had accidentally been exposed partially to sight, but that the owner could not be persuaded to allow it to be carried away to a museum. At the same time he would do nothing to protect it from being damaged by boys shying stones at it or from other dangers. Here there may have been a superstitious fear of removing anything supposed to be connected with the dead. At all events, it will serve to illustrate one of the grave difficulties which those have to face who want to see the relics of antiquity brought to places of safety.

This leads me to mention the last "Report of the Manx Museum and Ancient Monuments," which lies before me, dated March 6, 1906, signed by the chairman, Mr. Moore, and the hon. secretary, Mr. Kermode. It shows very clearly how far the trustees have got with their scheme, and what its objects are. These, as the title suggests, are two—the safe keeping of the ancient monuments, and the exhibition of them for the education of the Manx people, or rather of a wider public still; for nobody can, for instance, be said to have completed his study of runic crosses and Scandinavian epigraphy without visiting the series in the Isle of Man, the most central spot in the British Isles, and one most easily accessible from Liverpool and the north of England. Under the first heading a "Scheme for the Better Preservation of the Manx Sculptured and Inscribed Stones" has been adopted by the trustees, subject, of course, to alteration in detail where found necessary, and to the consent of the rectors and vicars of the parishes concerned. This scheme seems really to consist of so many separate schemes as there are parish churches with important monuments of antiquity near them. Even had there been a spacious museum ready to receive all the stone monuments of the island, no Manxman would probably entertain the notion of removing thither the more important runic crosses such as the group at Kirkmichael. So the arrangement which finds favour is that of constructing sheltered places for them near or within the churchyards where they stand. The work has been done already in some instances, and it may all be expected to be completed in the course of the summer. The Tynwald Court has unanimously voted, for the carrying of it out, 250*l.*, and 150*l.* more are expected from voluntary contributions.

Thus far of the protection of the larger of the ancient monuments in their respective localities. The smaller objects of antiquarian interest ought to find their safe keeping in a museum, but to meet this want less progress has been made. It is now some ten years since the trustees adopted a memorandum to the effect that the Manx Museum should consist of local objects to illustrate fully the archæology and natural history of the island, and the buildings requisite for the purpose should have a minimum area (including galleries) of 5000 square feet, and cost no less than 5000*l.* They also agreed that such an institution, being purely national, not municipal, should be provided partly by public subscription, partly by a grant from the revenue, and partly by the rates of the town in which the museum was to be established. The town, they thought, should be Douglas, and the cost of maintenance, estimated at 250*l.* per annum, should come out of the revenue, not out of the rates. The question of ways and means was in due time discussed, but nothing seems to have been done even by the town of Douglas, which was at one time eager to have the museum. In the meantime Governor Henniker placed a portion of Castle Rushen, at Castletown, at the disposal of the trustees for the purpose of a temporary museum. In fact, the nucleus of a collection had been stored there since the time of Governor Loch. Other articles, however, had been stored at the Government Office in Douglas and in Peel Castle; but the former have been added since to the Castle Rushen collection, which has been still further increased by the generosity of benefactors, especially Canon Savage.

So for the present Castle Rushen, a famous mediæval fortress, is the insular museum, and it is curious to read that the banqueting hall, that had witnessed scenes "of revelry by night," has the fine and very perfect example of the "Irish elk" from Poortown standing in the middle of the floor—it is, if I am not mistaken, not the only "Irish elk" found in the island; I have heard it said that one was presented by one of the Scottish kings of Man to Edinburgh. Among contents on a less colossal stage are the valuable casts of the early sculptured stones and inscribed monuments found in the island, a hundred and twelve in all—and the casts are already too few, for at least two more cross slabs have been discovered since the drafting of the report. In fact, this is one of the most encouraging aspects of the whole business. The collection is steadily increasing as the result of gifts, purchases, or loans, as the catalogue testifies. But here comes the difficulty, for, as the trustees point out, even for the purposes of a local archæological collection making any approach to completeness the space is insufficient for the methodical exhibition of it to the best advantage. This leaves out of consideration other aspects of the museum question, for the trustees are forced to add that though they are very willing to receive and store geological and local natural history objects, they are at present unable to exhibit them. Manx archæologists are only just in time to save the crosses of the island, but every year much is being lost for ever for the want of a museum, and the loss is not only that of Man, but of the archæology of the British archipelago as a whole.

But how is the museum to be provided? There seems to be no prospect of the island setting one up, even at the modest expense of 5000*l.*, and as to that figure I should guess that the bare building required would cost that sum, not to mention the furnishing, which would probably cost another 5000*l.* Before all I ought to have mentioned the site, for which, if it is to be at Douglas, I would rather not indicate any sum. Suffice it to say that the money difficulties are such that I can only make one suggestion, and that is, that the Imperial Government should take the matter in hand. What it has done for the island of late besides affording it and its herring fleet general protection I know not; but it is understood that the island, besides paying the expenses of its own Government, pays direct to the imperial exchequer 10,000*l.* annually, besides a very large income from royalties and other sources of revenue which discharge perennially into the coffers of the Crown. Having alluded to these disbursements, it is needless to point the moral. All lovers of fair play will agree with me that it would be but reasonable for the central Government to come to the help of the Manx people in the matter of its antiquities and natural history, and the sooner the better.

JOHN RHYS.

THE SOUTH AFRICAN MEDAL OF THE BRITISH ASSOCIATION.

WHEN the members of the British Association were in South Africa last August and September, it occurred to someone of the party that it would be well to commemorate our visit by founding a medal for South African students. I am sorry that I cannot remember to whom the credit of this admirable suggestion is due, but the officers at once adopted it with enthusiasm. Papers explaining the proposal were first circulated through the special trains on our way from Durban to Johannesburg, and a substantial sum was promised in a very short time. The proposal was subsequently laid before those who did not happen to be travelling in the special trains, and ultimately before all the members of the British Association.

On our return to England, a meeting of the subscribers was summoned, and a committee was appointed to consider the manner in which the fund should be applied. It was resolved that the South African Association for the Advancement of Science should be asked to accept the trusteeship and administration of the fund, and to undertake the annual award of the medal which was to be struck.

Mr. Frank Bowcher's Designs for the South African Medal of the British Association.

The income of the fund was to be in aid of scientific research among South African students, and it was thought that the medal would commemorate appropriately the fact that the recipient of the award was of such promise as to have been deemed worthy of the confidence placed in him.

The South African Association has cordially accepted the duties in question, and a medal, shown in the illustration, and to be struck in bronze, has been designed by Mr. Frank Bowcher.

The total sum subscribed by the members of the British Association amounts to 859*l*., but the fund will receive a further substantial augmentation, as I shall now explain.

Before the meeting of last year, the several South African colonies subscribed a large sum in aid of the expenses of the members intending to come out to South Africa, and this sum was supplemented, although on a less liberal scale, by a subscription in England. The total of this special South African fund was a little more than 9000*l*. It is expected that, when all the accounts are settled, the unexpended balance will come to about 500*l*. It is clear that this balance ought to be returned to South Africa in some way, and a resolution has been passed by the council of the association that the unexpended balance shall be devoted to the augmentation of the medal fund. The expenses attendant on the design of the medal have amounted to about 100*l*., and it is hoped that more than 1200*l*. will remain for transmission to South Africa. As a higher rate of interest on safe investments is obtainable there than here, a substantial annual sum will be provided in aid of research.

The cordiality of our reception in South Africa surpassed all that could possibly have been foreseen, and we in England are glad to be able to establish this small foundation as a memorial of the most remarkable of the many annual meetings of the British Association.

G. H. DARWIN.

THE EARTHQUAKE IN SOUTH WALES.

THE earthquake which occurred in South Wales on June 27 at about 9.45 a.m. ranks among the strongest shocks of which we have had any experience in this country. It was felt over the whole of Wales, and throughout the greater part of the west and south-west of England. Judging from the accounts which I have already received, the disturbed area must extend some distance to the north of Liverpool; towards the east it includes Northampton and Maidenhead, and approaches to within about twenty miles of London, while the southern boundary lies in the English Channel to the south of Dorset, Devon, and Cornwall. I have not yet obtained any observations from Ireland, but there can be little doubt that the shock was sensible over most of the counties of Wicklow and Wexford. A first rough estimate makes the disturbed area nearly circular in form, about 280 miles in diameter, and about 60,000 square miles in area.

The shock, which affected a region greater than the combined areas of England and Wales, was naturally of considerable strength within the central district. It is too early to make any estimate of the total damage to buildings, but the first reports show that a very large number of chimneys were thrown down, especially in Swansea, where the number is said to amount to several hundred. From Kidwelly on the west to beyond Neath on the east, and from Glanamman on the north to beyond Swansea on the south, it will probably be found that few towns and villages have escaped some injury. The isoseismal line of intensity 8, or the curve which bounds the area of slight damage to buildings, seems to be roughly elliptical in form, about twenty-eight miles from east to west and eighteen to twenty miles from north to south, or a little more than 100 square miles in area.

Nearly all the strongest British earthquakes belong to the class which have been called "twin" earthquakes. They originate within two foci, which are nearly or quite detached, with their centres, as a rule, about eight or ten miles apart. But the chief peculiarity about them is that the two impulses which cause them take place almost simultaneously, or, if not quite so, that the second impulse occurs before the vibrations from the first focus have time to reach the other, the two impulses being thus due to a single generative effort.

From the descriptions which have been given there can, I think, be no doubt that the recent shock was a typical twin earthquake. Many hundreds of observations will be required to determine the positions of the twin foci, and to ascertain which focus was first in action. But, so far as the evidence already collected allows us to judge, the foci appear to have been situated along a nearly east and west line, and are probably coincident with an east and west fault, passing close to Llanelly, Swansea, and Neath. It would be useless at present to attempt a more exact definition of the originating fault, but it is clearly connected with the great Armorican system of crust-movements, which attain their maximum in Brittany and mid-Devon, and, as they enter South Wales, begin to die away. In this district, as Mr. Aubrey Strahan remarked in his address at the Cambridge meeting of the British Association, the chief disturbances are of post-Carboniferous age. That they are still occasionally continued, though on a much smaller scale, the recent shock bears ample testimony.

It is evident from the above account that the earthquake presents several features of considerable interest to geologists. The district is also one that affords unusual opportunities for the study of the nature and effects of the shock in deep mines, and it is to be hoped that our somewhat scanty knowledge will be advanced in this respect.

I take this opportunity of stating how greatly my investigation of the earthquake would be assisted by the contribution of records from different places, and especially from the workings in the mining districts. The points on which I wish to obtain information will be found in many local newspapers, but I shall be glad to send forms on which descriptions may be conveniently entered if application is made to me at 16 Manor Road, Edgbaston, Birmingham.

CHARLES DAVISON.

PROFS. N. S. SHALER AND I. C. RUSSELL.

GEOLOGICAL science, and America in particular, has suffered a severe loss in the deaths of two university professors, N. S. Shaler, of Harvard, and I. C. Russell, of Michigan.

Prof. Nathaniel Southgate Shaler, who was born in Newport, Kentucky, on February 20, 1841, graduated at Harvard University, and served two years as an artillery officer in the Union Army during the Civil War. Subsequently he pursued the study of natural science, to which he had been attracted at the Lawrence Scientific School in Cambridge, took the degree of Sc.D. in 1865, and became in 1868 instructor in zoology and geology in that school, and also professor of palæontology in Harvard University. While retaining this professorship, he was in 1873 appointed director of the second Kentucky Geological Survey, a post he held until 1880; and in 1887 he became professor of geology in Harvard University, and occupied the chair until his death this year at the age of sixty-five. When little more than twenty years of age he discussed the age of the rocks in Anticosti, in a paper read before the Boston Society of Natural History, and in 1865 and following years he brought before the same society his views on the elevation of continental masses, arguing that sea-bottoms on which sedimentation was taking place were areas of depression, and that prominent lands undergoing denudation were areas of uplift. He discussed the formation of mountain chains (1866), and maintained that while the continental folds were corrugations of the mass of the earth's crust, the mountain chains were folds only of the outer portion of the crust caused by contraction of its underlying part, and that the formation of mountain chains would be promoted by the subsidence of the ocean's floors, fractures and dislocations being thereby produced along their borders (see G. P. Merrill's "Contributions to the History of American Geology," 1906). In a subsequent paper (1875) Shaler suggested that the transfer of weight to the land by the accumulation of an ice-sheet would influence terrestrial movements. He also discussed the possibility of the Japan current flowing at the close of the Glacial period over what is now land about Bering's Strait, and thus modifying the climatic conditions. He issued memoirs and reports on the geology of Kentucky (1876, &c.), and in later years dealt with a great variety of subjects, scientific and practical, including the classification of lavas, the fossil brachiopods of the Ohio valley, soils, the geological history of harbours, peat-deposits, road-stones, the features of the earth and moon, &c. He was author of important reports on the geology of Cape Cod district (1898); (with J. B. Woodworth) geology of the Richmond Basin, Virginia (1899); and (with A. F. Foerste) geology of the Narragansett Basin (1899). He wrote also "Outlines of the Earth's History" (1898); "Sea and Land: Features of Coasts and Oceans, with Special Reference to the Life of Man" (1895); "Study of Life and Death" (1900), and other works of a more or less popular character.

Prof. Israel Cook Russell, whose death occurred at the age of fifty-three, was born at Garrattsville, in New York State, on December 10, 1852. He graduated at the University of New York in 1872, and after further study at the School of Mines, Columbia, was appointed a member of the U.S. expedition to New Zealand (1874–5) to observe the transit of Venus. His attention, however, was given mainly to the study of physical geology. On his return from New Zealand he became assistant professor of geology at the Columbia School of Mines, and in 1878 was appointed assistant geologist on the U.S. geographical and geological survey west of the one hundredth meridian. From 1880 to 1892 he served as geologist on the U.S. Geological Survey, and in 1892 he became professor of geology in the University of Michigan. His earlier papers (1878) dealt with the physical history of the Trias in New Jersey, and with the intrusive nature of the eruptive rocks, in which he recorded the presence of a solid hydrocarbon. One of his more important works was a sketch of the geological history of the former Lake Lahontan, which in Quaternary times occupied an area of nearly 8500 square miles in N.W. Nevada (1883); he wrote also on the glaciers of Mount Rainier (1898), and on the geology of the Cascade Mountains (1900). Of later papers mention may be made of his observations on the Snake River plains, on the water-bearing strata of Idaho and Oregon, and on the volcanic eruptions of Martinique and St. Vincent. He was author of separate and more popular works on the lakes, glaciers, volcanoes, and rivers of North America.

NOTES.

ONLY a few names familiar in the scientific world occur in the long list of honours announced on Friday last in celebration of the King's birthday. Lieut.-Colonel D. Prain, F.R.S., director of the Royal Gardens, Kew, and late director of the Botanical Survey of India, has been appointed a Companion of the Order of the Indian Empire. Sir Christopher Nixon, ex-president of the Royal College of Physicians, Ireland, and the author of various papers on diseases of the heart and nervous system, has received the honour of a baronetcy. Among the thirty new knights are Mr. T. Digby Pigott, Emeritus Prof. A. R. Simpson, and Dr. A. E. Wright. Sir John Brunner, a member of the great firm of alkali manufacturers, Brunner, Mond and Co., has been made a privy councillor.

BRITISH merchants and manufacturers anticipated a great development of our trade in the Far East at the close of the Russo-Japanese War last year; but it appears from a special inquiry instituted by the *Daily Mail* that their expectations have not been realised. There has been a noteworthy expansion of trade since peace was concluded last August, but the Japanese have taken care that the chief advantages of it shall be to themselves. They have not only secured the Far Eastern market, but, according to our contemporary, the Japanese Government is laying plans for becoming our rivals as an exporter of goods to India. "The fault," we read, "is chiefly our own. Our Government neither knows what is going on nor takes any measures to protect our interests. It is quite natural that Japan should seek to take the current when it serves, but we, too, ought to have our share of the flood that leads on to fortune, and if the Far Eastern department of the Foreign Office will kindly wake up we may secure it yet." It is evident that the Japanese, with their scientific knowledge and methods, will be as strong in peace as they have proved themselves in war. This is an age when science and system are essential to progress, and the nation that realises it is best equipped for survival in the struggle for commercial supremacy. Only by insisting that the scientific spirit which permeates Japanese education and policy shall be possessed by our own statesmen can our commercial position be made secure against attack or progress be assured, either now or in the future.

IN the House of Lords last week, Lord Onslow asked whether His Majesty's Government proposed to continue to take part, after next year, in the international investigations of North Sea fisheries, and made some observations by way of criticism of the methods of investigation which the International Council has adopted. The gravamen of Lord Onslow's objection to the scheme appears to be that, whilst in his opinion the most promising method of attacking fishery problems is by the collection of statistical information from the commercial fishing vessels and at the ports of landing, in the international scheme the carrying out of accurate investigations at sea by men of scientific education and training on board specially equipped research steamers is regarded as essential to an adequate study of the very complicated problems which present themselves to those responsible for the regulation of the fisheries. The value of such collections of statistical data as Lord Onslow suggests, as an adjunct to work carried out by special research steamers, cannot be doubted, and, judging from the reports already published, appears to be fully recognised by the International Council. But no one with experience of the fundamental necessity of accurate observation and scientific method in dealing with practical problems of this character will, we imagine, for a moment be able to agree with the suggestion that such collections of miscellaneous information, the trustworthiness of which must necessarily vary greatly in different cases, can adequately supersede the observations and experiments of skilled investigators. The results already foreshadowed by the International Council seem to be of a promising character, and Lord Carrington, who replied for the Government, was well advised in postponing the consideration of the question of the continued participation of this country in the investigations until after the full reports have been received.

A MEETING was held on June 27 in support of the National Association for the Establishment of Sanatoria for Workers suffering from Tuberculosis. The secretary announced that the association is receiving the active cooperation of friendly societies. At the present time twenty-eight beds have been bespoken for the General Post Office, fifteen for the Hospital Saturday Fund, and five for the Hearts of Oak Benefit Society. Donations have been received from representatives of the participating classes, and this willingness of the ordinary public to assist men of science in their endeavours to eliminate a dreadful disease will greatly lighten their task. Mr. Chamberlain, in a speech supporting the scheme, pointed out that science has already done a good deal, and, without being too optimistic, it is likely that, from further discoveries and continued exertions of distinguished men engaged in medical research, perhaps in the near future the discovery of some definite specific remedy for the disease will be made. Cholera, diphtheria, and other diseases no longer have their terrors, and consumption may cease to be what it is at the present time. Mr. Chamberlain went on to say that he wished he could make his voice reach some of those who have, not merely too much wealth, but wealth beyond the dreams of avarice, which the possessors themselves recognise they cannot make any possible use of. He urged upon the men of great wealth that there is no possible thing they can do which will bring greater benefit to humanity at large, and give them greater satisfaction, than to endow further great schemes for medical research. While sympathising with the desire to see our millionaires emulating the example of American men of wealth in their support of scientific research, our statesmen should not lose sight of the fact that it is as much their duty to see to the protection of the people from disease as from foreign foes. The endowment of scientific and medical research is as necessary a form of national defence as a battleship, and to postpone the organisation of a State-aided campaign against a scourge like consumption until the generosity of millionaires has been developed is unstatesmanlike and a dereliction of duty on the part of Governments.

THE death of Señor Manuel Garcia in London on Sunday has deprived the worlds of science and music of a man whose work will be remembered so long as the human voice is used and studied. While the throat is capable of emitting musical sounds, and is liable to disease, the laryngoscope invented by Manuel Garcia will hold its unique place among vocalists and laryngologists. Garcia was born in Madrid on March 17, 1805, and the enthusiastic celebration of his centenary last year was described in NATURE at the time (March 23, 1905, vol. lxxi., p. 491). The King invested him with the insignia of Commander of the Royal Victorian Order, and many other tributes to his great services to mankind were presented to him. While a teacher of singing in Paris, about 1840, Garcia devoted attention to the scientific study of the problems of his art, including the anatomy and physiology of the larynx. The epoch-making paper in which he laid the foundation of the experimental study of the voice was read before our Royal Society in 1855, after he had settled in London and invented the laryngoscope. Intra-laryngeal medication and surgery, says the *Times*, soon followed the discovery of the diagnostic properties of this instrument, and its principles were extended to the elucidation and treatment of diseases of the parts situated between the nose and throat. The importance of the invention was not recognised until two years later, when the attention of the whole world was directed to the laryngoscope. Compensation for the indifference first shown by the medical profession to Garcia's discovery, was amply afforded by the centenary celebration last year, when public institutions and societies from every quarter of the globe united to honour the great teacher and investigator.

THE Longstaff medal of the Chemical Society has been awarded to Prof. W. N. Hartley, F.R.S., in recognition of his spectrochemical investigations; the presentation will be made at the first meeting of next session, October 18.

THE death is announced of M. Rayet, director of the Observatory of Bordeaux-Floirac. M. Rayet was also professor of astronomical physics at the University of Bordeaux.

THE council of the Institution of Mechanical Engineers has appointed the president of the institution, Mr. E. P. Martin, as one of its representatives upon the main committee of the Engineering Standards Committee in succession to Mr. E. Windsor Richards, past-president of the Institution of Mechanical Engineers, who has retired.

MR. G. MONTEFIORE-LEVI, of Brussels, formerly a member of the Belgian Senate, and president of the Association of Engineers, has bequeathed a portion, probably exceeding 100,000*l.* in value, of his residuary estate, to be applied for the prevention of consumption.

THE Geologists' Association has arranged a long excursion to the Yorkshire coast, extending from July 21 to July 28. The object of the excursion is to visit the Lias and Oolite sections from Robin Hood's Bay to Saltburn. Members wishing to take part should communicate at once with Mr. H. Kidner, 78 Gladstone Road, Watford. The party leaves King's Cross at 11.30 a.m. on July 21.

AT the annual general meeting held on June 28, the following were elected Fellows of the British Academy:—the Rev. R. H. Charles, Mr. W. J. Courthope, C.B., Mr. J. Fitzmaurice-Kelly, Mr. Andrew Lang, Prof. A. A. Macdonell, Dr. J. E. McTaggart, Canon Edward Moore, and Dr. G. F. Warner. The number of fellows is thus brought up to ninety-four, out of a maximum of 100 allowed by Order of Council.

AFTER the ceremony on June 25, when Mr. Haldane opened the electrical laboratory of the National Physical Laboratory, Sir John Brunner very generously placed the sum of 5000*l.* at the disposal of the committee toward the completion and equipment of the additional buildings for engineering, metrology, and metallurgy, now in course of erection.

THE past week will long be remembered by electrical engineers on account of the international meeting referred to in our last number (p. 207). We have had among us representatives of the electrical industries of France, the United States, Italy, Germany, Switzerland, and Canada, and have been enabled to return in some part the hospitality they have in past years extended to us. A good and varied programme was arranged, and our leading firms assisted by giving free access to their works and in entertaining the visitors. We trust that our guests will look back upon their visit here as no less delightful than those which many of our own electrical engineers still remember with gratitude to their respective countries.

A RAINSTORM of exceptional severity was experienced over the whole of the south-east of England during the night of Thursday, June 28, and the morning of the following day. The rainfall in and around London was as heavy as anywhere. The downpour commenced shortly after midnight, and continued without intermission for eight or nine hours. At Kew the measurement amounted to 2·36 inches, at Camden Town to 2·27 inches, and at the observing station of the Meteorological Office, in St. James's Park, to 2·07 inches. At Greenwich the measurement was 1·85 inches. Other stations reporting heavy falls were Cambridge, with an aggregate measurement of 2·3 inches; Rothamsted, 2·2 inches; Hielington, in Norfolk, and Epsom, 1·8 inches; and Oxford, 1·7 inches. Previous records only show so heavy a fall in twenty-four hours for London on three occasions during the last fifty years. This severe rainstorm was due to the passage of a shallow cyclonic disturbance across the southern portion of England, and in places the force of a moderate to fresh gale was experienced. At Greenwich the pressure of the wind was 10 lb. on the square foot, at 9 a.m., on June 29. The type of weather was peculiarly characteristic of thunderstorms, but it was only in a few isolated places that thunder and lightning occurred.

ARRANGEMENTS have now been completed for the erection of a commodious laboratory for the study of marine biology at Cullercoats, on the Northumberland coast. A much smaller laboratory, which had been provided by the munificence of Alderman Dent, the chairman of the County Council's fisheries committee, was accidentally burnt down some few years ago, and the proposed building is designed to carry out, not only fishery research, but also general biological studies. The gift of the site and the cost of erection of the building will be borne in a very generous way by Mr. Wilfrid Hudleston, F.R.S., the management being under the control of the Armstrong College at Newcastle. It is hoped that the new building will be ready for use at an early period of the next collegiate session, and that students will in this way obtain a further means of valuable training in practical biology. Cullercoats is, of course, classical ground to the marine biologist, having been the source of much of the material upon which Alder and Hancock's great work on the nudibranchiate mollusca was based.

A CORRESPONDENT writes asking for information as to self-recording instruments of the variations in the direction of the wind, and suggests that no such self-registering wind vanes are well known to the public. The information required may be found in any good text-book of meteorology, and the letter asking for it is characteristic of the general lack of knowledge with regard to meteorological matters. There are, of course, many recording anemographs which give wind direction, and our correspondent should apply to instrument makers, such as Messrs. Lander and Smith, of Canterbury, or Messrs. Negretti and Zambra, of Holborn Viaduct, E.C., for a price-list. Recording direction anemographs can be seen at work at many observing stations, such as Greenwich, Kew, Oxford, Falmouth, Fleetwood, Holyhead, Manchester, Stonyhurst, and other places.

MANY men of science will be glad to learn that it is proposed to establish some permanent memorial of the late Prof. W. F. R. Weldon, not only of the man himself, but also of the movement with which his name is especially associated, the application, that is, of exact methods of statistical inquiry to the study of variation and kindred problems in zoology. It has been suggested that the memorial should consist of a portrait—medallion or bust—in the museum at Oxford, a cast of which might be placed in University College, London, and of a prize to be awarded periodically to the author of the most valuable biometric publication of recent date. The committee will arrange that subscribers may eventually purchase a reproduction of the portrait. Contributions may be sent to Dr. G. C. Bourne, Savile House, Oxford; Dr. G. H. Fowler, 58 Bedford Gardens, W.; Prof. Karl Pearson, F.R.S., University College, W.C.; Mr. Adam Sedgwick, F.R.S., Trinity College, Cambridge; or to the Weldon Memorial Account, at the Old Bank, Oxford.

A ROYAL Commission has been appointed to consider certain questions affecting the erosion of the coasts of the United Kingdom. The commission is to inquire and report:—(a) As to the encroachment of the sea on various parts of the coast of the United Kingdom and the damage which has been, or is likely to be, caused thereby, and what measures are desirable for the prevention of such damage. (b) Whether any further powers should be conferred upon local authorities and owners of property with a view to the adoption of effective and systematic schemes for the protection of the coast and the banks of tidal rivers. (c) Whether any alteration of the law is desirable as regards the management and control of the foreshore. (d) Whether further facilities should be given for the reclamation of tidal lands. Science is represented upon the commission by Dr. T. J. Jehu, lecturer in geology at the University of St. Andrews.

A LIST of Paraguay locusts (Acrididæ), with descriptions of new species, by Mr. L. Bruner, forms the subject of No. 1461 of the Proceedings of the U.S. National Museum.

WE have received copies of two papers, by Mr. H. H. Bloomer, on the anatomy of certain species of Solenidæ, reprinted from vol. xii. of the *Journal of Malacology*. We note that the familiar name *Solen ensis* is replaced by *Ensis ensis*.

THE articles in the June issue of the *Zoologist* are all devoted to birds, Mr. E. Selous discussing sexual selection, as exemplified by the breeding-habits of the ruff, while Mr. Wesché contributes notes on the habits of cage-birds, and Mr. G. W. Kerr continues his notes on the birds of the Staines district.

AN interesting report on the leading zoological gardens of Europe has been issued by the Egyptian Department of Public Works as the result of a mission undertaken last year by Captain Stanley Flower with the view of obtaining information and hints which might prove of use in the establishment under his charge at Giza. While avoiding invidious comparisons, the author has pointed out some features in connection with buildings where particular menageries excel their fellows, and has likewise published lists of some of the more notable animals which came under his observation.

SCHIZOPOD crustaceans from the Atlantic slope, by Messrs. Holt and Tattersall, and fishes from the Atlantic slope, by Messrs. Holt and Byrne, form the subjects of the latest issues of Scientific Investigations, Fisheries, Ireland (1904, v., and 1905, ii.), both published this year. The former adds five species to the British list, of which one is new. Although, as the authors remark, the addition of new species of deep-sea fishes to the British fauna is a matter of no real importance, they are enabled to increase the list by no less than sixteen species, of which one is new. The most interesting among these is the salmonid *Bathylagus atlanticus*, previously known only by a single specimen taken off Patagonia by the *Challenger*.

Trudui St. Peterburghs. Obshch. (*Trav. Soc. Imp. Nat. St. Pétersbourg*) for March and April (vol. xxxvii., part i.) contains an illustrated account, by Mr. D. D. Pedaschenk, of a wonderful new pelagic cœlenterate from Java, for which the name *Dogielia malayana* is proposed. Measuring only from one to one and a half millimetres in length, the organism is remarkable for the possession of a complex system of paired branching outgrowths. It is considered to be a highly-specialised member of the Ctenophora. The other papers include notes on glaciation in the western Urals, on a case of artificial formation of sillimanite, and on regeneration in the polychæte worm *Spirographis spallanzanii*.

IN addition to an obituary notice, with portrait, of the late Dr. Max Kaeck, and a report on the museum and gardens for the past year, the contents of the *Boletim do Museu Goeldi* (Para) include a continuation of Dr. J. Huber's account of the Brazilian flora, a synopsis by the same author of the plants of the genus Hevea, a supplement by Mr. A. Ducke to his papers on the social wasps of Para, and a paper by Dr. E. Goeldi on the chelonians of Brazil. Exclusive of the marine forms, the author recognises twenty-one species of the latter as indigenous to the country, all but four of these belonging to the Pleurodira. Perhaps the most important part of this paper is an account of the habits of the great arrau turtle (*Podocnemis expansa*) of the Amazon, from observations made by Major J. M. da Silva Coutinho in 1868.

WITH its second (June) number, of which we have received a copy, the *Haslemere Museum Gazette* has changed its title to the *Museum Gazette*. There are several excellent illustrations in this part, among them figures of the two common British snakes and a reproduction of a photograph of the historical department in the Haslemere Museum, and a number of short articles, dealing chiefly with natural history subjects from an educational point of view. Certain items in these will be read with some surprise by naturalists. We are told, for instance, on p. 65, that "all the gnus are South African, and would appear to bear the same relation to the buffaloes of that continent that the North American bison does to the American buffalo"; while on the preceding page we are informed that "the camels and llamas form transition species between horses and oxen (ruminants and solid ungulates)." Almost equally original pieces of information occur on other pages.

In the Bulletin (May) of the Department of Agriculture, Jamaica, a new epiphytic fern, allied to the rare *Polypodium Fawcettii* and *Polypodium dendricolum*, is described by Mr. W. R. Maxon under the name of *Polypodium nesioticum*. Reference is made to a weevil attacking the camphor trees at Cinchona that has been identified as *Hilipus elegans*, a species abundant in Central America, whence it has been probably imported to Jamaica. The Bulletin also contains a note on the coagulation of Castilloa rubber, as well as an article recommending the plantation of Castilloa trees in Nicaragua in preference to Hevea.

The investigation of the fungi that prey upon scale-insects has its practical aspect, as already some of these fungi have been successfully employed in the United States as remedies against scale-pests. They are probably unimportant in temperate regions, but in the tropics they are widely spread, as may be gathered from an account contributed by Mr. J. Parkin to the Annals of the Royal Botanic Gardens, Ceylon, vol. iii., part i., reviewing the subject generally and making special reference to Ceylon forms. All the fungi so far determined fall under the Ascomycetes, and most of them belong to the Hypocreales, the best-known genus being Nectria. Other genera are classed with the *fungi imperfecti*, although they are probably conidial stages of the Hypocreales.

In accordance with the announcement that papers on systematic botany and monographs concerned with Philippine plants will be published as supplements to the Philippine Journal of Science, a supplement to the first volume contains a list of plants collected in that portion of the island of Luzon lying upon the north-west side of Manila Bay known as the Lamao forest reserve, where it is intended to investigate various forestry problems. The compilation has been prepared by Mr. E. D. Merrill, with assistance from specialists, from material recently obtained by different collectors. Out of the total of a thousand species of phanerogams, representing more than six hundred genera, 45 per cent. are classed as endemic and 54 per cent. as trees. Obviously there are few genera with many species, Ficus and Eugenia being two exceptions.

In the *Bulletin de la Société d'Encouragement* (vol. cviii., No. 4) there is an illustrated description of a remarkable testing machine of 270 tons constructed for the University of Illinois. It is 11 metres high, and will test for compression pieces $7\frac{1}{2}$ metres long, and for tension pieces 6·6 metres long, provided that the elongation does not exceed 20 per cent. There are also dimensioned drawings of the 10,000 horse-power turbine at Snoqualmie Falls. It weighs about 86 tons, and has an efficiency of 84 per cent.

The three latest Bulletins of the admirable series issued by the Peruvian Corps of Mining Engineers have been received. In Boletin No. 32 Mr. F. Malaga Santolalla describes the ore deposits and coalfields of the province of Celendin, one of the smallest but richest of the department of Cajamarca. The ore deposits are numerous, but little exploration has been carried out owing to difficulties of transport. In Boletin No. 33 Messrs. C. W. Sutton, J. J. Bravo, and J. I. Adams describe the geology of the province of Callao. An account is also given of the triangulation of the province. The base line of $2\frac{1}{2}$ kilometres at Playa Brava was measured with a 100-metre steel band, and the angles were measured with an 8-inch theodolite reading to two seconds. In Boletin No. 34 Mr. H. C. Hurd submits a report on the possibility of increasing the quantity of water available for irrigation in the valley of the Chili, in the department of Arequipa.

The current issue of the Records of the Geological Survey of India (vol. xxxiii., part iii.) is a number of more than ordinary interest. Mr. L. Leigh Fermor gives some notes on the petrology and manganese ore desposits of the Sausar Tahsil, Chhindwara district, Central Provinces, in which he puts on record petrological descriptions of certain types of rocks, chiefly of the metamorphic and crystalline series, and gives an account of the eleven manganese ore deposits known to occur in this area. Several of them are of economic importance. Six beautifully reproduced plates of rock photomicrographs accompany the paper. Mr. P. N. Datta describes the geology of parts of the valley of the Kanhan River, Central Provinces, and gives a geological map of the area. Mr. L. Leigh Fermor describes a specimen of manganite from the Sandur Hills, Madras Presidency, which is of special interest inasmuch as the occurrence of this ore in India has previously been recorded but twice. In the miscellaneous notes the occurrence of gypsum in the Vindhyan series at Satna is recorded, and accounts are given of ores of antimony, copper, and lead from the Northern Shan States; of gems from the Tinnevelli district, Madras; and of cassiterite-granulite from the Hazaribagh district, Bengal. The great increase in the exports of manganese ore from India is also noted, brought about by failure in the Russian supplies following the internal disturbances. The manganese ore exported from India in 1905 amounted to 281,735 tons, against 154,829 tons in 1904.

We have received from Prof. J. A. Pollock and Mr. S. H. Barraclough, of the University of Sydney, a reprint of an interesting paper read by them before the Royal Society of New South Wales on a hollow lightning conductor crushed by the discharge. The tube, 1·8 cm. in outer diameter, made of copper 0·1 cm. thick, was crushed in a symmetrical manner, showing the characteristic appearance of a tube which had collapsed under external pressure. The crushing appears to have been due to the electrodynamic action of the current. The material of the tube was probably plastic at the time of collapse. If so, the current is calculated to have been one of about 20,000 amperes; if not, the current would have been one of about 100,000 amperes.

Himmel und Erde for April contains an interesting article by W. Gallenkamp, of Munich, on the results of recent rainfall investigations. This paper does not deal with statistics in the usual manner, but refers to experiments by Lenard and Defant on the determination of the size of raindrops and on the velocity with which they fall. The size is determined by measuring the wet patch made on blotting paper, assuming that a drop of a given size will always produce a similar patch. The result arrived at is that the weights or volumes of the drops have a definite proportion to each other, *e.g.* if unity is taken as representing the smallest drops, the weights of the other drops are found to be 2, 3, 4, 6, &c., times that weight. *Generally speaking*, the absolute size of the drops exhibits very small differences; the smallest weigh about 0·11 mg., and the weights of the others are multiples of that value, as explained above. In a lasting downpour the largest drops weigh about 1 mg. With respect to the velocity at which the drops fall, the rate is not at all proportional to the weight; those of 0·11 mg. to 1 mg. fall at the rate of 2·7 metres to 4·4 metres per second, while those of exceptional weight, say 65 mg., only fall at the rate of about 8 metres per second. These rates only hold good during calm air; in an ascending current of 2·7 metres per second the smallest drops would remain suspended. The latter part of the article deals with Mr. Wilson's experiments on the ionisation of the atmosphere as the probable prime cause of the formation of rain. A note on the size of raindrops will also be found in vol. xviii., p. 242, of the Quarterly Journal of the Royal Meteorological Society.

An interesting contribution to the study of the nature of solution and of osmotic pressure is contained in a paper by Mr. C. S. Hudson in the *Physical Review* (vol. xxii., No. 5). The conception of Prof. Hulett that the low vapour-pressure of solutions indicates that these solutions are under a negative pressure is extended to explain the depression of the freezing point of water by the addition of a dissolved substance. It would appear at first sight that a negative pressure would occasion a rise in the freezing point, because an increase of pressure causes a lowering of the melting point of ice; but this reasoning is not correct, because the ice which freezes from a solution is under atmospheric pressure, not negative pressure, and only the solution may be regarded as being subjected to the negative pressure. By using Prof. Poynting's calculation of the change of freezing point caused by an increase in the pressure on the ice alone, it is shown that the molecular depression of the freezing point of water caused by the addition of a dissolved substance is exactly equal to that corresponding with a negative pressure exerted on the solvent, and equal in magnitude to the osmotic pressure. The osmotic pressure thus corresponds with a positive tension exerted on the liquid by the dissolved solid. A general thermodynamic investigation of the process of freezing is also contained in the paper.

A fourth edition of Mr. C. F. Townsend's "Chemistry for Photographers" has been published by Messrs. Dawbarn and Ward, Ltd.

OUR ASTRONOMICAL COLUMN.

Search-ephemeris for Finlay's Comet.—In No. 4100 of the *Astronomische Nachrichten* M. L. Schulhof publishes an approximate daily ephemeris for the coming apparition of Finlay's comet. The time of perihelion passage is taken as September 8, and the ephemeris covers the period June 18 to August 1; two contracted ephemerides are also given for T = September 4·0 and T = September 12·0. Owing to its expected close approach to the earth, the comet should be in an excellent position for observing later in the year.

The perturbations since the last apparition of this comet have not been taken into account in the present ephemeris, but a more accurate ephemeris is promised in an early publication. According to that now published, the comet is at present (July 5) apparently near to δ Aquarii, which rises about 11 p.m., but by the end of the month it will have passed into Cetus, and will be about half-way between θ and Mira Ceti.

Stereoscopic Measurement of Proper Motions.—A detailed description of the stereo-comparator method of determining the proper motions of stars is given by Prof. Max Wolf in No. 4101 of the *Astronomische Nachrichten*, where he also gives and describes the first results obtained by the method. A pair of photographs, arranged for the stereoscope, which accompany the paper show the effect of proper motion beautifully, for a star which has moved 19 seconds of arc in fourteen years appears to be considerably behind the general plane of the surrounding stars. With an especially constructed micrometer, the observer is able to determine the amount of the proper motion in right ascension and declination.

Prof. Wolf shows in a table the values measured and the results obtained for ten stars of about the tenth magnitude, and also for two other stars, Nos. 75 and 74 in Prof. Kobold's list. Comparing the meridian-observation results for the latter with the stereo-comparator values, he shows the trustworthiness of the new method thus:—

	Kobold 75 Proper motion (in secs. of arc)	Position angle	Kobold 74 Proper motion in secs. of arc)	Position angle
		°		°
Meridian circle ...	2·23 ...	162·0	0·88 ..	199·3
Stereo-comparator	2·21 ...	157·1	0·91 ...	183·2

This is very satisfactory, especially when one remembers that on the scale of Prof. Wolf's plates 1 second of arc is represented by only 0·004 mm.

Radiative Power of the Sun's Disc.—In No. 4, vol. xxiii., of the *Astrophysical Journal*, Prof. Julius describes a new method for determining the radiative power of the different parts of the solar disc. Briefly, the method consists in recording the intensity of the solar radiation at definite intervals during the progress of a total solar eclipse. Then every increment (either positive or negative) of the intensity is solely due to the radiation coming from that strip of the disc through which the limb of the moon has appeared to move during the corresponding interval. As the geometrical form of each of the strips is easily determined, the amount of each of the concentric zones (into which the disc is previously divided) contained in any one strip may be found. The total radiation from each zone is then determined by a suitable mathematical solution. This method was tried at Burgos during the last eclipse, and, despite the unfavourable meteorological conditions, the results lead Prof. Julius to hope that under suitable conditions it may be found very satisfactory.

New Forms of Astrographic Object Glasses.—In No. 4100 of the *Astronomische Nachrichten* M. Emil Schaer describes a novel method of constructing a short-focus astrographic objective. Two lenses of the usual crown and dense flint glasses are employed; the crown is placed in front of the flint, and the back surface of the latter is silvered, so that the photographic plate has to be placed in front of the combination at the combined focal distance. M. Schaer has tried this method with two discs of 280 mm. (about 11 inches) aperture, made for him by M. Mantois, and, by suitably figuring the back surface of the flint before silvering it, has obtained an objective of 89 cm. focal length which is practically free from aberration effects, and has a large light-gathering power. To obviate unnecessary reflections, the two lenses were stuck together.

Another innovation in the construction of objectives is announced in No. 597 of *Science*, where it is stated that a Hungarian chemist, after many years' experimental work, has succeeded in manufacturing perfectly satisfactory fluid lenses. The fluid is hermetically sealed between two hard glass surfaces, similar to watch crystals, the glass being chosen so that the combination is achromatic.

The inventor claims that an objective, equal in practice to any yet made, of 1·50 metres aperture can be made in a few weeks at a cost of 2000 or 3000 marks (*i.e.* about 150*l*.).

These lenses are already being manufactured, and are giving satisfactory results, in Austria, and patents are being taken out in other countries where they are soon to be introduced.

THE GREAT TYPHOON IN THE PHILIPPINE ISLANDS IN SEPTEMBER, 1905.

THE Bulletin of the Manila Observatory for September, 1905, prepared under the direction of the Rev. J. Algué, S.J., affords a striking example of the way in which any abnormal features of the weather are completely masked in monthly, or even shorter, mean values. An inspection of the latter would lead to the conclusion that the month of September was quite normal notwithstanding the occurrence of the terrible typhoon on September 25–26, which was probably the most violent of any yet experienced, not even excepting that of November 5, 1882, the worst previously on record. We gave a brief note of the storm soon after its occurrence, taken from newspaper reports, but the following further particulars from a discussion by the Rev. M. S. Mata, S.J., assistant director, may be of interest.

The disturbance appears to have originated in long. 142° E. and between lat. 11° and 12° N. on September 22, and its path over the Pacific was approximately from east to west; it reached the land on the evening of September 25, and swept across the archipelago in a south-easterly to north-westerly direction, reaching Hainan, in the China Sea, on the evening of September 28. The breadth of the storm was about 100 miles, the centre passing about twenty-four miles south of Manila; the average velocity of translation was 13·5 miles an hour. The first indication of its approach at Manila was on the morning of September 25, when the barometer registered a notable fall of pressure. On the previous day the readings were very high; an anticyclone so well defined had rarely been observed over the Philippines. On the morning of September 26 (at which time telegraphic communication to the south-eastward was already interrupted) the fall became alarming, and continued until 2h. p.m., at which time the minimum (29·21 inches) was reached, the mercury having fallen about 0·7 inch since 9h. p.m. of the previous evening; after a short pause the mercury rose again very rapidly. Between noon and 3h. p.m. the gusts of wind attained a rate of about 103 miles an hour. The rainfall in twenty-four hours amounted to $4\frac{1}{4}$ inches, of which 2·3 inches fell between 3h. and 5h. p.m., after the passage of the vortex, the wind changing from east-north-east to south-east, with rapidly rising barometer.

FIG. 1.—Meteorological Station of Legaspi, after the typhoon of September 25–26, 1905.

The s.s. *Pathfinder* was overtaken by the storm in San Bonifacio (lat. 12° 10′ N., long. 125° 30′ E.), and recorded some notable oscillations of the barometer; at 8h. a.m. on September 25 the reading was 29·78 inches, and the mercury fell rapidly until 7h. 37m. p.m., when the minimum of 27·17 inches was registered. There was a comparative lull in the wind for three or four minutes, and then it blew more fiercely than ever, with a rapid change of direction from north-by-west to west, and drove the ship ashore; in a few minutes the wind shifted to south, and by midnight the barometer had again risen to 29·61 inches. Immense damage was caused by sea and land, especially at the eastern stations. We reproduce an illustration of the destruction of the observatory at Legaspi (lat. 13° 9′, long. 123° 45′); the sea, which had not risen so high for thirty years, rushed into the town with extraordinary force, some parts being submerged to a depth of $2\frac{1}{2}$ feet to 5 feet. At many other places not a single building was left uninjured, and some of the largest trees, which had withstood all previous storms, were uprooted.

THE NEW BUILDINGS OF ARMSTRONG COLLEGE, NEWCASTLE-ON-TYNE.

THE new buildings of Armstrong College, to be opened by the King on Wednesday next, July 11, consist of the front wing of the college, together with the large public hall immediately behind the front. The imposing front block of buildings, about 100 yards in length, faces nearly west, and is on the border of the open space known as the Castle Leazes. In the middle of the college front, rising to a height of 120 feet, is the handsome Sir Lowthian Bell tower. The chief entrance is at the base of the tower, and gives access to a spacious vestibule which communicates with the north-east and south-west wings, the principal staircase, and the large public hall to be used for lectures, meetings, and examinations.

The front wing consists of four floors. On the ground floor to the north of the entrance are the principal's room, the council room, the staff common room, and a large common room for men students. To the south of the entrance are the secretary's office, the college office with strong room, and the electrical engineering department. This last consists of a lecture room, and a spacious laboratory with wide gallery on one side. On this gallery is the main electrical distribution board, to which leads are brought from every part of the building. There is a second laboratory of the same size in the basement beneath. Outside the college, on the basement level, is built a house for storage cells. Over the ground-floor corridor, in connection with this department, is a large photometric room fitted up with suitable appliances for carrying out tests in a complete manner. Access to this room is obtained from the gallery of the ground-floor laboratory.

On the first floor is the library, with a photographic dark-room adjoining, which is used for lantern-slide and other photographic work. Accommodation is also provided on this floor for the mathematics, the naval architecture, the literature, and the education departments, with their several lecture and private rooms. On the second floor there is provision for the botanical department, consisting of an elementary laboratory, an advanced laboratory, a research laboratory, lecture and preparation rooms with dark-room, and the professor's private room. There are also on this floor lecture rooms for philosophy, modern history, classics, and modern languages, as well as private rooms for the several heads of departments in these subjects. On the third floor is the zoological department, which contains a large room more than 70 feet long, one half of which, towards the front, is used as a zoological museum, and the other half as an elementary laboratory, and also advanced and research laboratories, lecture room, and professor's private room. In addition, this department has the use of the flat roof over a portion of the floor below. This open space will be utilised for maceration and similar purposes. Associated with the zoological department is the marine laboratory which is about to be erected at Cullercoats, on the coast just north of Tynemouth (see p. 228).

The ventilation of the front wing is provided for by two electrically-driven fans in the tower, which exhaust from the rooms on the several floors. The heating is by means of steam on the new so-called atmospheric system, and the lighting is by 240-volt electric lamps, which can either be supplied from the college central station or from the town supply. Electric arc lanterns are provided in several of the lecture rooms.

The large public hall, in which the chief portion of the opening ceremony is to take place, will accommodate, with the gallery at the south-west end, an audience of about 800.

The foundation-stone of the new buildings was laid by Mr. T. G. Gibson, a member of council and the most generous supporter of the college, on May 2, 1904, and the buildings have been erected to the designs and under the supervision of Mr. W. H. Knowles, of Newcastle.

FIG. 1.—New front wing (facing west) of Armstrong College, to be opened by the King on July 11. In the centre is the Sir Lowthian Bell tower.

The cost of the new buildings, together with the fittings, has been nearly 80,000*l*. The funds have been provided by public subscription, and since the buildings are intended as a memorial to the first Lord Armstrong, one of Newcastle's most distinguished citizens and benefactors, the name of the college was in 1904 changed from the Durham College of Science to Armstrong College in the University of Durham. The area of the grounds within which the college stands is between five and six acres. The present buildings occupy about two acres, and more than two acres, excluding roads, &c., are available for the extensions that are being projected. The accompanying photograph shows the front of the college, which forms the west wing.

The number of day students attending the college last session was 539, and in addition about 1100 students attended the evening and special Saturday classes. The college forms an important part of the University of the North of England. The degrees of Durham in science and letters, and its diplomas in agriculture, engineering, and mining are open to students of the college. The Warden of the University (the Dean of Durham) is the president of Armstrong College, Sir Isambard Owen is the principal, and Mr. F. H. Pruen is the secretary.

INTERNATIONAL SCIENCE.[1]

THE pursuit of science has always joined in sympathy men of different nationalities, and, even before the day of rapid letter-post and quick travelling, intercourse, especially by correspondence, exercised a considerable influence on scientific activity. Such intercourse was, however, of a personal and purely stimulating character, and only quite exceptionally was there any direct attempt to organise investigations which required a combination of workers in different localities. Within the last century, however, many problems became urgent which could not be solved without some international agreement, and special organisations came into life which have rendered a service the importance of which cannot be exaggerated.

At present we are confronted with a new difficulty. International combination has become so necessary, and organisations have in consequence increased to such an extent, that they begin to overlap, and there has been some danger of mutual interference. Fear has also been expressed that any attempt to advance knowledge by an organised combination of workers might discourage private efforts, and therefore do mischief rather than good. It must be acknowledged that this danger exists. The proper function of combination must be clearly separated from that of private enterprise, and some general regulating control is therefore called for. The time seems ripe for a general review of the situation.

We may distinguish between three types of international organisations. The first aims simply at collecting information, the second is intended to fix fundamental units or to initiate agreements on matters in which uniformity is desirable, while by the third type of organisation a more direct advance of knowledge is aimed at, and research is carried out according to a combined scheme. Generally, an international association does not entirely fall within any single one of these divisions, but it is useful to draw the distinction and classify the associations according to the main object which they are intended to serve.

The best example of an organisation formed for the purpose of collecting information is furnished by the great undertaking initiated by our Royal Society, and having for its object the systematic cataloguing of the scientific literature of the world, both according to subjects and authors. Twenty-nine countries (counting the four Australian colonies separately) are actively participating in this work by furnishing slips containing the entries which form the basis of the catalogue. A still larger number of countries assist by subscribing to the annual volumes.

The subjects included in the catalogue are classified according to seventeen branches of science as follows :—

A Mathematics	G Mineralogy	N Zoology
B Mechanics	H Geology	O Anatomy
C Physics	J Geography	P Anthropology
D Chemistry	K Palæontology	Q Physiology
E Astronomy	L Biology	R Bacteriology
F Meteorology	M Botany	

Subscribers may either obtain complete sets or any of the separate volumes. The relative popularity of the different subjects is illustrated by the following table, which gives in the different columns for each science the volumes approximately required by each country. The figures are, of course, subject to variations from year to year. The first column shows the number of complete sets subscribed

[1] Discourse delivered at the Royal Institution on Friday, May 18, by Prof. Arthur Schuster, F.R.S.

for, in addition to the separate volumes; these presumably find their way into the university or public libraries.

The popularity of the special botanical catalogue is remarkable.

We may obtain a rough idea of the scientific activity of different countries by comparing the number of slips received from them during a certain interval. The numbers given in the report published by the International Convention held in London last summer, and referring to all slips received, are shown in the following table:—

	Slips received	Number of journals	Average number of slips per journal
Austria	13,186	535	25
Belgium	2,272	174	13
Canada	537	45	12
Denmark	2,584	40	64
Finland	1,828	33	55
France	60,401	930	65
Germany	213.545	1,397	153
Holland	9,861	70	141
Hungary	2,605	35	75
India and Ceylon	2,699	31	87
Italy	21,238	300	71
Japan	3.043	42	72
New South Wales	2,049	8	256
New Zealand	440	1	440
Norway	2 017	36	56
Poland	5,830	65	90
Russia	25 741	457	56
South Africa	1,872	15	125
South Australia	159	6	26
Sweden	1,939	63	31
Switzerland	5,140	126	41
United Kingdom	56,382	488	116
United States of America	66 671	588	112
Victoria (Australia)	2,858	23	124
Total	504 297	5,508	90

The total number up to March, 1906, has increased to 700,000.

The catalogue begins with the year 1901, but some countries send in their slips rather earlier than others, so that the time interval covered by the investigations to which the table refers is not quite the same for all. Nevertheless, the numbers shown in the table possess a certain interest. I have given in the last two columns the number of journals which different countries take into account, and the ratio of the number of slips to the number of publications. Here again it is difficult to estimate accurately how much value is to be attached to the figures, as there is no uniformity of selection as to what should and what should not be included in the catalogue. Journals which may only very seldom contain any paper which is to be included may unduly diminish the numbers in the last column, which are also affected by the interpretation given as to what is purely technical, and therefore to be excluded. Nevertheless, the comparison between the United Kingdom and France gives the somewhat striking result that, while France is slightly ahead in the number of separate entries it contributes to the catalogue, it takes account of nearly double the number of journals, and the ratio showing the number of entries per journal is therefore very small. In the case of Belgium and Canada, we find also a large number of publications as compared with the slips received. Regard must, however, be had to the fact that in the subject catalogue the same paper may furnish several entries. Especially is this the case in the biological subjects, where several species may be described, for each of which a separate slip must be written out. Hence in any country active chiefly in the discovery of new species the ratio given in the last column of the table would be abnormally large. This is probably the explanation of the figures given for New Zealand. In the opinion of the director of the Central Bureau, the standards adopted by different countries are drawing nearer together as the work proceeds, and before long we may therefore expect to obtain valuable statistical information on the scientific activity in different countries. But this is only an incidental result of the undertaking. It may reasonably be argued that the scientific investigator ought not, before he begins a research, to trouble too much about what may have been done by others in the same direction, but there is no doubt that before publication he should have made himself acquainted with the literature of his subject. A well-arranged catalogue then becomes a necessity, though its value as a means of helping students differs considerably in different subjects.

The governing body of the catalogue is an International Council composed of one representative from each of the countries taking part in the scheme. This council has appointed an executive committee, of which Prof. Armstrong is the chairman.

The Central Bureau for the publication of the catalogue is in London, under the direction of Dr. Henry Forster Morley, who has a staff of thirteen workers under him. There are, in addition, nineteen experts or referees representing the different sciences. The annual office expenses, including salaries, amount to about 2200*l.*; while the expenditure on printing, binding, and publication in the year ending March 1, 1905, amounted to nearly 4000*l.* The two items are just covered by the guarantees of the different countries, which, as already mentioned, take the form of subscriptions for copies of the catalogue, so that it may be said that the central office is self-supporting. After so short a time of working, this success must be a source of considerable satisfaction to Prof. Armstrong and those who have helped to initiate the work; but the expenses incurred in London only represent a fraction of the total cost of the work. Most of the countries establish regional bureaux, which prepare the slips and forward them to London. This really constitutes the most serious part of the work. In Germany, for instance, the Regional Bureau is under the direction of Prof. Uhlworm, one of the university librarians, who is helped by six assistants, and devotes his whole time to the work.

I pass on to an undertaking of a very different kind, but still one which must be included in the class which primarily aims at cataloguing. The accurate determination of the positions of the stars for a particular period is a work which must precede all exact investigations of their proper motions. Hence it constitutes a fundamental problem of astronomy. The multitude of stars seen on a bright night is bewildering to the casual observer. They are described in poetical writings as innumerable, but when an actual count is made, it is found that their number is really moderate, and it is doubtful if more than two thousand stars have ever been visible to the naked eye at the same time. The use of the telescope considerably increases this number, according to the size of the object-glass or reflecting mirror used. Thus Argelander in his great star catalogue included nearly 324,200 stars which he observed through his telescope of four inches aperture. The advent of photography and the manufacture of suitable lenses to be used in connection with photography increased the astronomical output of a fine night to such an extent that it became possible to make a further and very substantial advance. The International Star Catalogue which is at present being constructed owes its origin chiefly to the hard work of Admiral Mouchez, who was at the time director of the Paris Observatory, and who became converted to the feasibility of the plan by the excellent results obtained by the Brothers Henry, the pioneers in star photography. He was assisted by the energetic support of Sir David Gill, to whom the first suggestion was due. The programme of work was determined upon at an International Conference which met at Paris in the year 1887. Eighteen observatories were to take part in the work, the telescopes to be used were to have an aperture of thirteen inches, and such a focal length that a millimetre on the plate corresponded to one minute of arc. Each observatory had a certain region of the sky assigned to it, and undertook to cover this region four times, twice with plates of short exposure, twice with plates of long exposure, and to measure all the stars appearing on the short-exposure photographs. The long exposures were intended for reproduction in the form of charts, and are only taken by some of the observatories. As there are about 400 stars on each plate, and it takes about 600 plates to cover the share of one observatory once, this means that each observatory has to measure nearly half a million star places, and that the complete catalogue will give the positions of nearly $4\frac{1}{2}$ million stars. This includes all stars down to the eleventh magnitude.

The following is a list of observatories taking part in the work:—For the northern hemisphere, Greenwich, Oxford, Paris, Bordeaux, Toulouse, Potsdam, Helsingfors, Rome, Catania, Algiers. For the southern hemisphere, San Fernando, Tacubaya, Santiago de Chile, Cordoba, Cape of Good Hope, Perth (W. Australia), Sydney, Melbourne.

The work connected with the ultimate completion of the catalogue, and especially the reproduction of the star maps, requires a considerable expenditure. Each country has to make its own arrangements, which in the British Empire usually means that each body concerned has to pay its own expenses. There was, however, in this case some official help. The Astronomer Royal obtained a contribution of 5000*l.* from the Government for the reproduction of charts, and in the case of the Cape of Good Hope the necessary expenses have been met from Imperial funds. Prof. Turner, of Oxford, has obtained a grant of 1000*l.* from the Government grant of the Royal Society, and a further sum of 2000*l.* for publication from the Treasury and the University of Oxford jointly; but the Australian colonies are much hampered by the want of funds, and their work will be delayed in consequence. The four French observatories, on the other hand, are well supported. Each of them has received a Government contribution of 25,700*l.*, making a total of well over 100,000*l.* More than half this goes towards the reproductions of the long-exposure photographs as a series of charts, which, however, have proved to be so costly that they will probably never be completed. Indeed, if completed, their utility may to some extent be impaired by the difficulty of storing them in an accessible manner. Prof. Turner calculates that the series of maps will form a pile of paper 30 feet high, weighing about two tons.

I now pass on to those undertakings which are intended to fix standards of measurement, or to establish a general agreement on matters in which uniformity is desirable. The foremost place in this division must be given to the Bureau International des Poids et Mesures, which was established in the year 1873 at Sèvres, near Paris. This bureau was the outcome of an International Commission constituted in 1869, which had for its object the scientific construction of a series of international metric standards. By a convention entered into by the different countries at a diplomatic conference held at Paris in March and April, 1875, means were created for carrying out the work of verifying standards under a new International Metric Committee, and for the purpose of enabling the committee to execute its duties effectually, as well as of securing the future custody and preservation of new metric prototypes and instruments, the Permanent Metric Bureau was founded. The original cost of the bureau was 20,000*l.*, and the annual budget was fixed at 3000*l.* for the period during which the prototypes were being prepared, after which time it was expected that the expenditure could be reduced to 2000*l.* In 1901, however, it reached 4000*l.*, the maximum to which, by the terms of the convention, the annual budget could be raised. Great Britain did not join the convention until 1884, when it declared its adhesion. A first payment of 1787*l.* was made as entrance fee, and the annual contribution now ranges between 200*l.* and 300*l.* Major MacMahon, to whom I owe the above details, is at present the British representative on the International Committee.

The work carried out at Sèvres is not confined to the reproduction of metric standards, but measurements of precision in various directions have been made with conspicuous success. Scientific thermometry owes much to the International Bureau, and in some respects it may be said that exact thermometry was created there. Prof. Michelson's work, in which the length of the metre was compared directly with the length of a wave of red light, is another classical investigation carried on in the laboratories of the International Bureau. More recently Mr. Guillaume examined the physical properties of alloys, notably those of nickel steel, and proved the possibility of manufacturing a material which shows no sensible expansion with rise of temperature. The importance of metallic rods the length of which does not depend on temperature is obvious, provided they prove to be of sufficient permanence.

Time does not allow me to give an account of the conference and conventions which have led to a general agreement on the standards of electric measurements, but it is a satisfaction to know that these standards are essentially those proposed and first constructed by the British Association. The old British Association ohm no doubt was found to be wrong by more than 1 per cent., but it has remained the prototype of the present international unit, and in principle the old ohm, volt, and unit of current stand as they were given to us by the original committee.[1]

While in the case of scientific units complete agreement is absolutely essential, uniformity is desirable in other cases. There are matters of nomenclature in which confusion has arisen purely from want of general agreement. Thus the great recent improvement in the optical power of telescopes has led to the discovery of many details on the surface of the moon. Small craters or other distinctive features named by one observer were not correctly identified by another, so that at the present time the same name is applied to quite different things by different observers. It is quite clear that an international agreement in lunar nomenclature is called for.

There are other deficiencies of uniformity which perhaps appear trivial, but which yet lead to the waste of a good deal of time. Such, for instance, is the position of the index in scientific books. The index is placed sometimes at the beginning, sometimes at the end, and sometimes neither at the beginning nor at the end. Some books have no index,

[1] The original committee was appointed in 1861, and consisted of Profs. A. Williamson, C. Wheatstone, W. Thomson (Lord Kelvin), W. H. Miller, Dr. A. Matthiessen, and Mr. F. Jenkins. In the following year, Messrs. C. Varley, Balfour Stewart, C. W. (Sir William) Siemens, Prof. Clerk Maxwell, Dr. Joule, Dr. Esselbach, and Sir Charles Bright were added to the committee.

some have two, one for the subject-matter and one for names of authors. The loss of time which arises from one's ignorance as to where to look for the index cannot be estimated simply by what is spent on the search, but must include the time necessary to regain the placidity of thought which is essential to scientific work.

It is time we turned to the more serious aspect of those international associations which directly aim at an advance of knowledge. Mathematicians have drawn interesting conclusions from the contemplation of ideal beings who are confined to live on a surface and have no knowledge of anything that goes on outside that surface. Our Euclidean geometry would be unknown to them, and spiritualistic tricks could be performed by anyone possessing, even to a minute extent, the power of controlling a third dimension. It is, I think, worth while investigating the extent of the direct knowledge of a third dimension, which makes us so infinitely superior to the two-dimensional beings. We are able, no doubt, through our eyes, to penetrate the depths of space, but we should be unable to interpret the impressions of our sight if we had not some tangible knowledge of three dimensions, and had not learned to bring the sense of sight and the sense of touch into harmony. But our sense of touch is confined to a very small distance from the ground on which we stand, and independently of artificial means of raising ourselves above the surface of the earth, a layer 6 feet or 7 feet thick represents the extent of our three-dimensional knowledge. Compared with the radius of the earth, the thickness of such a layer is small enough, for it would represent only the thickness of a sheet of paper on a sphere having a radius of 250 metres; compared with the solar system, and even more so with stellar distance, a thickness of layer of 8 feet seems infinitesimal. Yet the infinitesimal is essentially different from the zero, and even were our bodies much smaller than they are we should continue to have the power to interpret three dimensions. These considerations show how important it is for us to increase our knowledge of the earth itself, and to extend it so far as possible to the depth below our feet and the height above our heads.

In passing from the arbitrary units to which we refer our terrestrial measurements of length, to the scale on which we measure the dimensions of the solar system, and from them to stellar distances, the magnitude of the earth's radius or circumference forms an all-important intermediate quantity. One of the first acts of the French Academy of Sciences, founded in 1666, consisted in organising the work of accurately measuring the dimensions of the earth, and this at once enabled Newton to confirm his celebrated theory of universal gravitation. As improvements in the methods of measuring kept pace with the work actually accomplished our knowledge steadily increased, but we are still improving on it. New problems have arisen requiring more minute study, and the measurements of the shape and size of the earth still remain a question of the first importance. The actual surveys and triangulation required for the purpose are of necessity left to the initiative of individual States or to the combination of the States primarily concerned, but the general discussion of results, so far as they apply to the earth as a whole, is entrusted to an International Geodetic Association, which at present consists of twenty-one States. These, together with their annual contributions to the general fund, are entered in the following table:—

	£		£
Belgium	80	Austria	300
Denmark	40	Portugal	80
Germany	300	Roumania	80
France	300	Russia	300
Greece	40	Sweden	40
Great Britain	300	Switzerland	40
Italy	300	Servia	40
Japan	300	Spain	150
Mexico	150	Hungary	150
The Colonies of the Netherlands	40	United States of America	300
Norway	40		

The Central Bureau of this association is attached to the Royal Geodetic Institute of Potsdam, which is under the distinguished direction of Prof. Helmert, who acts as secretary to the association.

The question of measuring the size of the earth depends to a great extent on the measurement of arcs of meridian. So long as we were confined to Europe for the measurements of these arcs they remained necessarily short, but larger and larger portions of our globe have become accessible to the theodolite, and there is especially one arc which is distinguished by the fact that it is the longest possible which can be traced along the land covering the earth's surface. It runs about 30° east of Greenwich, and a large portion of it passes through Africa. Owing to the great energy and enterprise of Sir David Gill, the work of measuring this arc is well in hand, though at the present moment want of funds threatens to endanger its completion. The Egyptian Survey entrusted to Captain Lyons will no doubt receive continued support, and by an arrangement entered into between representatives of the German Government and Sir David Gill at a conference held in Berlin in 1896, Germany undertook to carry out the triangulation through her territory in South-West Africa. I understand this work has been done, and the triangulation of the Transvaal and the Orange River Colony is also complete. There is still a gap in the southern part of Rhodesia, but there is every hope that this will soon be bridged over. The British South African Company has spent 36,000*l.* on the work and thus has very materially assisted an important enterprise. When the African arc is complete it will be connected with the Russian and Roumanian arcs so as to form a continuous chain of 105° extending from 70° north to 35° south latitude. I have to point out, however, that, in the opinion of those best able to judge, the completion of the South African arc is not the only undertaking to which this country is called upon to pay attention. The triangulation of our own island, excellent as it was when first made, has fallen below the accuracy required in modern geodetic work. Until our fundamental triangulation has been repeated, the sums which at present are being spent on the detailed survey might find a better use.

The main result of the recent work has been that, so far as present measurements allow us to judge, the surface of the ocean can be well represented by a surface of revolution, and it is not necessary to assume a more complicated shape. The mean radius of the earth is determined to about 100 metres, which means a possibility of doubt amounting to about 1 part in 60,000.

Geodetic work is, however, not confined to measurements of length, for important information may be derived from an exact knowledge of the acceleration of gravity over its surface. The introduction of the pendulum of short length intended for relative and not for absolute measurement has greatly facilitated this work, and it is hoped that these pendulum observations may be carried out over still more extended regions. India is setting a good example. It has measured two arcs of meridian, and the gravitational work carried out by Captain Burrard, and recently published by the Royal Society, is of primary importance. But otherwise English colonies require encouragement to do more. I am assured that measurements of the gravitational constant in Canada would be of the greatest importance.

The bearing of such work on our knowledge of the earth may perhaps be illustrated by one example. It has often been a matter of wonder how mountain chains such as the Himalayas could rest on the lower strata of the earth without crushing them and forcing them in by the pure power of their weight, and the most plausible theory to account for this was found in the idea first suggested by Pratt, that the mountain chains must not be compared with a large weight resting on an under-structure, but rather with a lighter body partially immersed in a heavier one. Mountains, according to this theory, float in the body of the earth very much like icebergs float in water. The truth of this theory can only be tested by accurate measurement of the gravitational force, from which information may be derived on the distribution of density in the earth's strata near the surface. On the whole, the measurements so far available have confirmed Pratt's hypothesis.

More recently another problem has occupied the attention of the International Geodetic Association, and, owing to its immediate interest, has absorbed the greater portion of its funds. The astronomical world was surprised by the announcement of Prof. Chandler that he was able to demonstrate from existing observations that the earth's pole describes a closed curve taking about fourteen months to complete a revolution. The possibility of a periodic shift of the earth's axis was foreseen by Euler, who calculated the time of revolution to be ten months; but observations did not show a sensible period of that duration. No one apparently before Chandler tried to see whether another period beyond a small annual one existed. The discrepancy between the calculated ten and the observed fourteen months was cleared up by Prof. Newcomb, who pointed out that Euler's calculation was based on the supposition that the earth is an absolutely rigid body. Any yielding would increase the length of the period; in fact, the earth must be more rigid than steel in order that the period should be as short as fourteen months. This shows how indirect information on the physical properties of the earth may be obtained sometimes in an unexpected manner, the periodic revolution of the pole leading to an estimate of the average rigidity of the interior of the earth. The total displacement of the pole of the earth from its average position is small, never amounting to more than 8 metres. The accuracy with which that displacement can be measured is a testimony to the excellence of our astronomical observations. It is a type of work in which cooperation is absolutely necessary. The subject has received additional interest through the suggestion made by Prof. Milne in his recent Bakerian lecture that seismic disturbances may be caused by the changes in the position of the earth's axis. Considering that the distortions in the earth are sufficient to increase the periodic revolution of the pole from ten to fourteen months, this suggestion is well worth investigation, and the 300*l.* per annum spent by this country in support of the work of the Geodetic Association will be well employed if it allows the vagaries of our pole to be more closely studied and all the dimensional quantities of the surface of the earth to become more accurately known.

The contributions received by the Central Bureau of this association from the participating States amount to about 3000*l.*, and there is a balance which at the end of 1904 amounted to more than 5000*l.* The expenditure during 1905 was nearly 5000*l.*, reducing the balance by 2000*l.* The principal items of the expenditure were formed by contributions towards the maintenance of six stations in the northern and two stations in the southern hemisphere for carrying out the observations relating to the changes of the position of the earth's axis. The whole cost of this service is about 4450*l.* The honorarium of the secretary is 250*l.*, which, together with the cost of printing, postage, and a small item for grants toward special scientific work, makes up the expenditure. No charges are made for office expenses, which are defrayed by the Prussian Government.

The geodetic work indirectly gives us valuable, though only partial, information on the interior of the earth, but it confines itself in the main to the surface of the globe; the investigation of our atmosphere carries us beyond.

(*To be continued.*)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

DR. J. P. HILL has been appointed to the Jodrell chair of zoology at University College, London.

AT King's College, London, Dr. C. S. Myers has been appointed professor of psychology (including experimental psychology), and Mr. H. S. Allen senior lecturer in physics.

THE Rev. T. C. Fitzpatrick, dean and supernumerary fellow of Christ's College, has been elected president of Queens' College, Cambridge, in succession to the Bishop of Ely.

A COURSE of five free public lectures is to be given, in accordance with the will of Mr. Brown, in the physiological laboratory of the University of London on July 9, 11, 13, 16, and 18, by Prof. T. G. Brodie, F.R.S., on the "Secretion of Urine under Normal and under Pathological Conditions."

THE trustees of the Brooklyn Polytechnic Institute have, we learn from *Science*, subscribed 160,000*l.* toward the 400,000*l.* necessary to endow the proposed extension of the institute, affording facilities for more advanced work. In addition to this handsome provision for higher education, our contemporary announces that Mr. and Mrs. Jacob Turtellout, of Minneapolis, have offered to give 80,000*l.* to build and endow an academy for the town of Thompson, Conn., and that Dr. Henry M. Saunders, of New York, a trustee of Vassar College, has given 15,000*l.* for the erection of a building as a memorial to his wife.

THE current number of *Macmillan's Magazine* contains an article by Mr. A. C. Passmore on technical education, in which some of the weaknesses of systems of instruction of this type are summarised. The need is insisted upon for adequate preliminary training of a suitable kind for students beginning courses of technology. It is urged that instead of being in such a hurry to provide technical schools it would be worth while to consider the qualifications and fitness of the teachers. The examination system is cited as one of the chief causes conspiring to make British technical education unsatisfactory. But the author appears to be unacquainted with the work being done in many of the great municipal technical schools, and to have ceased his educational observations some ten or fifteen years ago. Conditions at present are better than Mr. Passmore paints them.

AMONG the bequests made by Mr. F. W. Webb, who died on June 4, we notice the following:—2000*l.* to Owens College, Manchester, to establish for the benefit of employees and sons of employees of the London and North-Western Railway a "Webb" scholarship tenable at Owens College, Manchester; 2000*l.* to the University College of Liverpool for a similar purpose there as defined for Owens College, Manchester; 1000*l.* to the Institute of Civil Engineers for providing annually a "Webb Medal," and a premium of books to be awarded for the best paper on railway machinery.

THE annual assembly and prize distribution at University College, London, on Tuesday, July 3, was of more than usual interest from the fact that the friends of Prof. Carey Foster had taken the opportunity of then presenting to the college the portrait of Prof. Foster which has been painted by Mr. Augustus John. The presentation was made by Prof. F. T. Trouton, who recalled the fact that Prof. Foster was the first to introduce practical laboratory teaching in physics into England. Many of the methods devised by him in the development of his laboratory courses are to-day recognised as standard ones. For instance, every student has to go through and know his Carey-Foster Bridge as surely and regularly as at school he has to pass the fifth proposition of the first book of Euclid. The example set by Foster was followed in laboratory after laboratory, until to-day there is not a town without its course of experimental physics. Prof. Trouton concluded by hoping that though the portrait represented its subject as an older man than he really is, yet his useful life might be spared until the portrait may become that of a much younger man. The Right Hon. Lord Reay, G.C.S.I., who received the portrait on behalf of the college, referred to the great impetus which the study of physics had received by his work and writings, which are characterised by great clearness and lucidity. More especially he referred to the debt owed to Prof. Foster by the college, of which he became the first principal at a time at which great tact and knowledge were required in connection with the delicate negotiations leading to the incorporation of the college in the University of London. His lordship concluded by presenting a replica of the portrait to Mrs. Carey Foster. Prof. Foster, in acknowledging the presentations, alluded to the interval of fifty-three years since he was first present at a ceremony of the same kind. In one respect the present ceremony was of historical interest, inasmuch as it was the last ceremony to be held by the college before its incorporation. He looked forward to the advantages arising from this incorporation. The prominent defect in the higher teaching in London is the dispersion of the large resources amongst various organisations which are in some respects rivals. Principal Rücker had recently said that "any organisation to be visible must be on a grand scale." It is only by combination that the colleges of London can hope to attract the support which is so urgently needed.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 8.—"The Microscopic Changes in the Nervous System in a Case of Chronic Dourine or Mal de Coit, and Comparison of the Same with Those found in Sleeping Sickness." By Dr. F. W. **Mott,** F.R.S. (From the Pathological Laboratory of the London County Asylums.)

The author describes the changes in the central nervous system of an Arab stallion, which acquired the disease by infective coitus. After exhibiting 156 characteristic cutaneous plaques, together with marked symptoms of paraplegia, it died $27\frac{1}{2}$ months after infection. The material was forwarded by Dr. Lingard, director of the Imperial Bacteriological Laboratory of India, who has written an interesting monograph on dourine. A full description of the etiology and clinical symptoms of this disease is contained in this monograph, and an account in detail of this particular case.

Dourine is due to a specific form of trypanosome, affects equines, and is transmitted, like syphilis, by coitus. This is of especial interest, since the *Spirochaeta pallida* has been shown to be the infecting agent in syphilis.

A comparative examination of the tissues of the central nervous system in this disease and in sleeping sickness, experimental and human, appears to show that prolonged trypanosome infection results in a chronic lymphadenitis, followed later by a chronic interstitial inflammation of the lymphatic structures of the nervous system. The morbid process in the case of dourine starts in one seat of primary infection, extends to the inguinal glands, and thence (presumably by the pelvic lymphatics) spreads by the lumbosacral nerves to the posterior spinal ganglia, where it may set up an intense inflammatory process with destructive atrophy of the cells. This destruction of the trophic sensory centres which was found in this case of dourine would account for the cutaneous eruption which occurred during life. It would account also for the marked degeneration of the posterior roots and the sclerosis in the posterior columns, especially in the root zones. The lesion in some respects therefore resembled locomotor ataxy, and it is of interest to note that cases of dourine have occurred in which fractures and dislocations have been observed—due probably to neurotrophic changes. Moreover, there were other signs of chronic irritation observed elsewhere in the spinal cord and nervous system, viz. subpial and septal proliferation of the glia tissue. Marek has described the disease as an infective polyneuritis; there were reasons, however, in this case, for supposing that the motor nerves were not affected by a degenerative change in the same way as the posterior roots.

March 22.—"A Note on the Theory of Directive Antennæ or Unsymmetrical Hertzian Oscillators." By Prof. J. A. **Fleming,** F.R.S.

This paper deals with the theory of bent or unsymmetrical Hertzian oscillators. As is well known, a straight linear oscillator radiates equally in all directions around the axis. It has been found, however, by Mr. Marconi that if an antenna for electric-wave telegraphy is bent so that a short part of its length, rising from the earth, is vertical, and the greater part horizontal, and therefore parallel to the earth, such an oscillator radiates less in the direction in which the free end points than in the opposite direction.[1] This is of great practical importance, and the writer accordingly investigated mathematically the behaviour of a simple case of an unsymmetrical oscillator consisting of three simple oscillators of equal electric moment ϕ superimposed so as to make a doubly bent oscillator of the shape $\sqsubset$.

If V denotes the scalar potential at a point in the field at a distance r large compared with the dimensions of the oscillator, and F, G, and H the components of vector potential, then it is shown in the paper that

$$\mathrm{V} = -\frac{\phi}{k}\frac{d\Pi}{dz} + \frac{1}{2}\frac{\phi}{k}\frac{d^2\Pi}{dydz}\delta y - \frac{\phi}{k}\frac{d^2\Pi}{dzdy}dz,$$

$$\mathrm{F} = 0,\ \mathrm{G} = \phi\frac{d^2\Pi}{dzdt}\delta z,\ \mathrm{H} = \phi\frac{d\Pi}{dt} - \frac{1}{2}\phi\frac{d^2\Pi}{dydt}\delta y,$$

where $\Pi = \sin(mr - nt)/r$, and from these expressions the electric (E) and magnetic (H) force at various points in the field can be obtained. The final result is to give expressions for these forces normal to the radius vector drawn in the equatorial plane of symmetry as follows:

$$\mathrm{H} = \frac{1}{r^3}\left[\left(\phi v m^2 r^2\right)^2 + \left(\phi v m r - \frac{\mathrm{M}}{z} m^2 r^2 \cos\theta\right)^2\right]^{\frac{1}{2}},$$

$$\mathrm{E} = \frac{1}{kr^3}\left[\left(\phi(m^2r^2 - 1) + \frac{3}{2}\frac{\mathrm{M}}{v}\frac{\cos\theta}{mr}\right)^2 + \left(\phi mr - \frac{\mathrm{M}}{2v}\left(m^2r^2 + 3\right)\cos\theta\right)^2\right]^{\frac{1}{2}},$$

where $\cos\theta$ is the azimuthal angle the radius vector makes with the axis of the oscillator reckoned from the direction in which the free ends point. These expressions show that as θ increases from 0° to 180° the values of E and H vary, and are greater when $\theta = 180°$ than when $\theta = 0°$.

Hence there is an unsymmetrical radiation by such an oscillator, greatest in the direction opposite to that in which the free ends point.

Such an oscillator may also be regarded as the combination of a completely closed conductive circuit or *magnetic* oscillator with a straight or open *electric* oscillator. The field of the magnetic oscillator was investigated by the late Prof. G. F. Fitzgerald (see his scientific writings, edited by Prof. J. Larmor, Sec.R.S., p. 128) prior to the date of Hertz's discoveries, and in the discussion at the Royal Society on March 22 on Mr. Marconi's paper, *loc. cit.*, it was pointed out by Prof. J. Larmor that a bent oscillator of the kind above discussed was equivalent in electromagnetic action to a magnetic *plus* an electric oscillator.

May 3.—"On a Static Method of Comparing the Densities of Gases." By R. **Threlfall,** F.R.S.

Since it is a simple matter to make a manometer showing differences of gas pressure of a few centimetres of water, accurate to between 1/100 mm. and 1/1000 mm., according to the construction, it is possible to determine the relative densities of gases by a method similar to the one employed by Regnault in determining the temperature-density variation of mercury.

It is shown that, using gas columns 20 metres long, the difference of density of "chemical" and "atmospheric" nitrogen should be capable of observation. The author has employed the method in a comparison of the densities of producer gas and air, using gas columns about 20 metres in height. The two columns of gas and air respectively were contained in composition pipes twisted together and immersed in water in an outer iron pipe through which a stream of water passed.

In two experiments on two different samples of gas differences of pressure of 0·3458 cm. and 0·3550 cm. of water respectively were observed, and producer-gas densities accurate to about 1 5000th part in terms of the density of air were deduced. The commercial micromanometer made by the Cambridge Scientific Instrument Co. to the author's designs was employed in these comparisons, and, since it is possible to construct an instrument say five times as sensitive, and to use columns of gas at least twice as long without inconvenience, the method should yield values of relative density correct to 1 part in 10,000 without difficulty.

[1] See Proc. Roy. Soc., vol. lxxvii. p. 413, 1906. G. Marconi, "On Methods whereby the Radiation of Electric Waves may be mainly confined to certain Directions, and whereby the Receptivity of a Receiver may be restricted to Electric Waves emanating from certain Directions."

June 7.—"Effects of Self-induction in an Iron Cylinder." By Prof. Ernest **Wilson**. Communicated by Sir William H. Preece, K.C.B., F.R.S.

An iron cylinder 10 inches (25.4 cm.) in diameter is traversed in the direction of its axis of figure by an electric current, which is allowed to become steady. Under the action of a sufficiently large potential difference and non-inductive resistance the *total* current is suddenly reversed and maintained constant, and its propagation to the centre of the cylinder is investigated by aid of embedded exploring coils. The results show that a current of about 500 amperes takes two minutes to become steady over the whole section of the cylinder. The delay is caused by the opposing electromotive forces induced in the mass by the change of the magnetic fluxes produced by the currents interior to the successive annuli. When the total current is small, the induced E.M.F.'s at the centre, for example, occur at once, and then die away. With currents of about 300 amperes a second maximum is developed after about eighty seconds. For gradually increased total currents the second maximum occurs at shorter intervals of time after reversal, and becomes the most prominent feature of the phenomenon.

The results obtained can be applied to cylinders of other diameters than the one experimented upon, and an estimate is made of the time taken fully to make use of the whole section of an iron telegraph wire and steel rails as used in alternate-current traction.

Mineralogical Society, June 12.—Prof. H. A. Miers, F.R.S., president, in the chair.—Sartorite from the Binnenthal: Dr. C. O. **Trechmann**. This mineral has hitherto been held to crystallise in the orthorhombic system, and full descriptions have appeared from the pens of vom Rath and Baumhauer. Solly, later, assigns it to the monoclinic system, without, however, publishing details. Two very perfect crystals, originally attached to each other, were examined and compared with other crystals and with the results of the above-named authors. Both crystals exhibit conspicuous monoclinic habit, and one is a distinct twin. The elements of vom Rath are $a:b:c = 0.539:1:0.619$. The elements arrived at now are $a:b:c = 1.27552:1:1.19487$ with β 77° 48′, in which $a:b:c$ correspond with $c:b:a$ of vom Rath. The twin and composition plane is $a = (100)$, and the twinned crystal is a juxtaposition twin on this face. Further evidence of the twinned structure is afforded by many narrow, twin lamellæ on the above law. Baumhauer records fifty-nine observed forms on this mineral, including thirteen pyramids. On the above two crystals eighty-seven forms were observed, including thirty-five pyramids. There is little agreement in the angles and forms with those of the other five crystals, or with previous observations. In the zone of the prisms (brachydomes of vom Rath), however, there is a close agreement, sufficient to make it very probable that all the examined crystals belong to the mineral sartorite. Further research is necessary on the scarce material in order to show whether two or more morphotropically related minerals may not be involved here.—The occurrence of axinite in the area south of Bodmin, in Cornwall: G. **Barrow**.—Cassiterite pseudomorphs from Bolivia: R. **Pearce**. The frequent occurrence of cindery and cellular cassiterite in Bolivia suggested that the pseudomorphs might be after a sulphostannate, but this is not borne out by the crystallographic examination made by Mr. L. J. Spencer.—Notes on skiodroms and isogyres: Dr. J. W. **Evans**. The author referred to Prof. Becke's paper on the subject, and showed that the derivation of the forms and movements of isogyres (the loci in convergent polarised light of vibrations extinguished under crossed nicols) from the skiodroms (the curves expressing the directions of such vibrations) are simplified when a microscope with revolving nicols is employed, instead of one with a revolving stage.—A pseudomorph of quartz after apophyllite: H. **Hartley** and N. Garrod **Thomas**.—A heating stage for the Dick microscope: H. **Hartley**.—Mr. J. P. **De Castro** exhibited a large crystal of tantalite from Western Australia, and Mr. R. **Pearce** specimens of axinite from St. Ives, Cornwall.

Faraday Society, June 12.—Mr. W. Murray Morrison in the chair.—The electrolytic deposition of zinc, using rotating electrodes: Dr. T. Slater **Price** and G. H. B. **Judge**. An improved form of apparatus for the electrolytic deposition of metals, using a rotating kathode, is described. The ordinary beaker is replaced by a tap funnel of about 100 c.c. capacity, so that the electrolyte can be run off at the end of the experiment, thus obviating the use of a siphon.—A simple form of rotating kathode for electrochemical analysis: Dr. F. Mollwo **Perkin**. The kathode consists of a spiral of platinum wire, or, better, iridio-platinum wire. Nickel wire may be substituted for platinum, and the author recommends its employment in place of the more expensive metal. Attention is also directed to the solubility of platinum anodes, with heavy currents 0.0016 grm. being dissolved in a cyanide solution in thirty-five minutes.—The electrolysis of solutions of thiocyanates in pyridine and in acetone: S. **Binning** and Dr. F. Mollwo **Perkin**. On oxidation of thiocyanates with chlorine, persulphates, &c., a yellow colouring matter—canarine—is obtained. By electrolysis of aqueous acidified solutions of thiocyanates an apparently similar product, which was originally described in 1884 by Lurdow, is obtained. The authors consider that this substance is not identical with the canarine obtained by chemical means, because it shows certain reactions not given by the oxidation product.

Geological Society, June 13.—Sir Archibald Geikie, Sec.R.S., president, in the chair.—Recumbent folds produced as a result of flow: Prof. W. J. **Sollas**. Prof. Lugeon has described a series of recumbent folds so greatly exceeding in horizontal extension their vertical thickness that they are spoken of as sheets; they lie flat one on the other, and those higher in the series extend farther to the front than those below, a feature referred to as "*déferlement*." The roots of the lower folds are visible in the high Alps adjacent, but the roots of the higher must be sought in the zone of Mont Blanc and the Briançonnais. Thus some of the uppermost folds may have surmounted the obstacle presented by Mont Blanc on their way to the front in the pre-Alps. The features presented by recumbent folds are more suggestive of flowing than bending. Experiments have been made with pitch-glaciers (*poissiers*) in which an obstruction was placed. Folds were produced, one of which was like the Morcles fold behind the Diablerets, another like the Pilatus, and yet another like the Sentis, and the fourth compared with the overslide of the Bavarian front; all four exhibit *déferlement*. The lower limb of each fold is adjacent to the similar limb of its neighbours; but, in another experiment, in which two obstacles were used, the results were nearer to those seen in the mountains, where the lower limb of a superior fold reposes on the upper limb of the fold immediately beneath it.—The Crag of Iceland—an intercalation in the basalt-formation: Dr. Helgi **Pjetursson**. The existence of fossiliferous deposits on the west coast of Tjörnes, N. Iceland, has been known for 160 years. Mörch enumerates sixty-one species of Mollusca, and concludes that the temperature must have been much milder than at present. From the shells, it has been considered that the deposit could not be younger than Middle Reg Crag. Dr. Thoroddsen thinks that these Crags are younger than the Old Basalts of Tjörnes. The author finds, however, that, about 500 feet above the sea, they are overlain by the Eastern Basalts. Thus there is a fossiliferous intercalation occupying part of the great gap between the Tertiary and the Pleistocene rocks. The basal layer of the Pleistocene series is fossiliferous, and has yielded twenty-two species of Mollusca, twenty of which represent a highly Arctic fauna. Certain of the larger basalt-dykes are cut off at the base of the Crag. The absence of the Crag-deposits from other localities is explained by the erosion of the coast-line.

Paris.

Academy of Sciences, June 18.—M. H. Poincaré in the chair.—Researches on the direct synthesis of nitric acid and nitrates from their elements at the ordinary temperature: M. **Berthelot**. Nitrogen and oxygen were caused to combine at the ordinary temperature under the action of the silent discharge, care being taken that no visible sparks were produced in the apparatus. In some experiments a confined volume of the mixed gases was used; in others a current of gas was slowly circulated through the apparatus for a period of several hours. In all cases nitric acid was the sole product, and this whether the oxygen or nitrogen was in excess. Oxides of nitrogen, nitrous acid, and ammonia were looked for, but were invariably absent, even when the reaction took place in the presence of potash solution.—The application of the telephone and the Claude-Driencourt astrolabe to the determination of the longitude of Brest: E. **Guyou.** Two chronometers, beating half-seconds, were used for the transmission of time, one being regulated to mean time, the other to sidereal time, in order to allow of the application of the method of coincidences. A microphone placed on the glass of each chronometer enabled the beat to be heard in the telephone at the distant station, two observers furnished with receivers working at each station. It was found that the deviations between the comparisons obtained at the same place by two different observations were generally less than 0·01 second, these deviations being indifferently positive and negative, showing the freedom from an appreciable personal error. The results obtained at both ends are of the same accuracy as those obtained at a single station, showing that there is no advantage in working from both ends.—The action of carbon monoxide at a red heat upon steam, and of hydrogen upon carbon dioxide. The application of these reactions to the study of volcanic phenomena: Armand **Gautier.** At a full red heat (1200° C. to 1300° C.) carbon dioxide is reduced by hydrogen, the reaction being limited when the volume of carbon monoxide produced is half that of the hydrogen remaining. The inverse reaction between carbon monoxide and steam was also studied, the composition of the gas mixture being represented by the equation

$$3CO+2H_2O=2CO_2+2H_2+CO.$$

The bearing of this reaction upon volcanic phenomena is discussed.—Some new properties of malt extract: L. **Maquenne** and Eugène **Roux.** The activity of malt extract, prepared rapidly in the cold, increases on standing, and the advantageous influence exercised by acids is due to the fact that they are favourable to the establishment of this new state of equilibrium.—Some Patagonian fossils. Study of a portion of the Antarctic region: Albert **Gaudry.** —The use of metallic oxides as catalysers in oxidation: Paul **Sabatier** and Alphonse **Mailhe.** If a mixture of a paraffin with oxygen is passed over a column of copper oxide heated to a temperature of about 200° C., the oxide glows, and the reaction continues without further heating of the tube being necessary. The greater part of the hydrocarbon is burnt to carbon dioxide and water, but small quantities of aldehydes and acids are found condensed in the water produced in the reaction.—The experimental production of transmissible varieties of the tubercle bacillus and of anti-tuberculous vaccine: S. **Arloing.** A modified human tubercle bacillus has been obtained, the acquired properties being fixed after the eighth generation. It differs from the original bacillus only in that its pathogenic effects are reduced in intensity. This bacillus has been successfully used since 1902 for anti-tuberculous vaccination of calves.—M. Edmund Weiss was elected correspondant in the section of astronomy in the place of M. Struve.—The coal basin of Sarrebrück and its continuation in French Lorraine: Jules **Bergeron** and Paul **Weiss.**—The deformation of certain tetrahedral surfaces: G. **Tzitzeica.**—Differential equations the general integral of which is uniform: M. **Gambier.**—The equation of Laplace with two variables: Georges **Lery.**—The photography of the infra-red spectrum: G. **Millochau.** In addition to the use of screens proposed by Stefanik, the author makes use of the well-known property of the infra-red rays of destroying the photographic action on an exposed plate. As the effect produced during the preliminary exposure to the actinic rays penetrates further into the film than the reversing effect of the red rays, very thin films of emulsion, coloured red or yellow, were found to give the best results.—A new method for the photography of coins: Eug. **Demole.**—The presence of gold and silver in the Trias of Meurthe-et-Moselle: Francis **Laur.** Analyses of rocks from various parts of this region show traces of both gold and silver. In one case, a limestone grit from a depth of 582 metres, the gold amounted to 39 grams, and silver to 245 grams, per ton.—The reduction of antimony selenide: P. **Chrétien.**—Oxidations with air. The problem of the comparison of velocities: André **Job.**—Heterogeneous equilibria. The formation of phosphonium chloride, ammonium carbamate, and sulphhydrate: E. **Briner.**—The osmotic pressure in colloidal ferric chloride: G. **Malfitano.**—Researches on copper steels: Pierre **Breuil.**—Melezitose and turanose: Georges **Tanret.** Turanose gives glucose and levulose in equimolecular proportions on hydrolysis, and not two molecules of glucose, as usually accepted.—The true nature of the leucins and glucoproteins obtained by P. Schutzenberger in the splitting up of proteid materials: MM. **Hugounenq** and A. **Morel.**—The influence of chocolate and coffee on the excretion of uric acid: Pierre **Fauvel.** The methylxanthines of chocolate and coffee increase the urinary purins, but not the uric acid. They prevent the precipitation of the latter by acids.—The law of increase of volume in trees: François **Kövessi.**—The spectroscopic study of the green pigments of ripe seeds: W. **Lubimenko.**—The structure of the different gall nuts in the Euphorbiaceæ: C. **Houard.**—The larval biology and metamorphoses of *Siphona Cristata.* A new case of internal ectoparasitism: E. **Roubaud.**—The influence of phosphoric acid and of mono- and trisodium phosphates on the nutritive exchanges: Mlle. Bl. **Guende.**—The influence of the ovary on nutrition: MM. **Charrin** and **Jardry.**—The characteristics of the stem of *Adelophyton Jutieri*: Paul **Bertrand.** —The rapidity of torrential erosion: E. A. **Martel.**—The polarisation of the sky during eclipses of the sun: N. **Piltschikoff.**

PHYSICAL CHEMISTRY APPLIED TO CHEMISTRY AND BIOLOGY.

Cours de Chimie physique suivi d'Applications à la Chimie et à la Biologie. By Victor Henri. Cours libre professê à la Faculté des Sciences de Paris. Premier Fascicule. Pp. xii+336 et seq. (Paris: A. Hermann, 1906.) Price 15 francs.

THIS volume forms a portion of the first part of a treatise on physical chemistry and its applications to chemistry and biology, evidently intended for readers commencing the specialised study of physical chemistry, but possessing some considerable knowledge of chemistry and biology.

The subjects described in the thirteen chapters of this first part are as follows:—General conditions of equilibrium in solutions; electrical conductivity of solutions; ionic theory; conductivity in non-aqueous solutions; osmosis and osmotic pressure; diffusion; cryoscopy; vapour pressure and boiling-point of solutions; absorption and solution; solubility and coefficient of distribution in solution; surface tension and viscosity of solutions; optical properties of solutions; electrical phenomena in solutions, study of galvanic and concentration cells (incomplete).

The general scheme of treatment which the author outlines in his preface consists in describing in each case (1) the methods of measurement used in studying the particular phenomenon under consideration, (2) the experimental results obtained, and (3) the hypotheses and general theories which make it possible to connect together the experimental results and also others obtained by different experimental methods. This method of presenting experimental results apart from the theory which may have given birth to the observations, or have formed a connecting link for correlating them with other known facts, may be most philosophical, and occasionally most desirable, in order to impress upon the mind of the student that the observed facts exist apart from any theory, as has been most ably done by the present author, for example, in chapters i., ii., and iii. of his treatise. At the same time it can and does become a most cumbrous and space-robbing form of description, and much beauty is lost by not placing the facts at once in the appropriate setting of the theory which lead the mind to the planning of the experimental work which established the facts.

It is no doubt quite possible that a mathematical treatise might be written without the use of any symbols or any conventions of any type, or that a treatise on chemistry might be written consisting of bare, dry experimental facts without any reference to the atomic theory. Such treatises would be most interesting as monuments of human perseverance and industry, and would be literary curiosities of the highest order; but it is questionable if they would be very intelligible, and certainly they would be very lengthy, and most unstimulating to the student or worker, who could not proceed a step further with their aid alone in the way of advance, but would at once have to proceed to formulate a theory if it were desired to carry out an experiment differing in type from any in such a non-theoretical treatise. Without a theory in advance there can be no such thing as intelligent experimentation; after experimentation, the theory must be adapted where necessary to experimental results, or, if necessary, a new theory formulated which will lead to further experimentation.

It is therefore a relief to find that after the first three chapters the author somewhat alters his plan, accepts the ionic theory, and speaks boldly of ions. Some of the aspects in which the ionic theory, as at present held, fails to account for experimental facts are pointed out in the book, and those many experimental observations which are accounted for, and correlated, by the theory are justly held up for well-deserved admiration.

The author is also to be congratulated upon not having too thoroughly carried out the intention expressed in his preface of making the mathematics of physical chemistry problems easy for the non-mathematical reader.

The authors who invent and perpetuate this style of mathematics made easy surely forget that a reader who has not a rudimentary notion of how to apply the calculus probably has not learnt his more elementary mathematics well enough to follow the solution of their long and involved series and equations, and if he ever did has probably forgotten it long ago, and therefore skips the proof and accepts the conclusion much as he would have done had the proof been given in the shorter way.

As stated above, anything which can be put or proven in mathematical symbols could also be equally put or proven in ordinary words, provided patience and perseverance could be provided on the part of the author to write it, and of the reader laboriously to wade through it; but when there is a better method, surely it is much better for the non-mathematical reader to accept his mathematics ready made for him, or, if he objects to doing this, take up the study of mathematics a little longer and then turn to its applications.

It is accordingly a relief to find that the author does not carry his threat of making mathematics easy too far, and employs the calculus where necessary.

Regarding the subjects treated in the first part so far as they are contained in the present volume, it may be said that on the whole the style of treatment is most interesting, and the information usually full and carried well up to the present date.

Occasionally it would have been well, as the work is obviously intended specially for biological students interested in physical chemistry, if the biological aspects had been treated at greater length, as, for example, in the section on the theory of indicators on p. 110, and that on the study of the fluids of the organism, p. 114; but it is possible that the author may intend to return to these subjects at a later part of the work.

The descriptions of how to carry out experimental work given in the volume are clearly intended to enable the student to carry on experiments, for the precautions to prevent experimental errors are often given in considerable detail, as, for example, in regard to freezing-point determinations and conductivity measurements; yet if this be the intention of these descriptions they are singularly incomplete in other respects. For example, in describing the determination of the freezing point the only thing said about the thermometer to be used is that it may have either a fixed or a variable zero. We venture to think that some description of the Beckmann thermometer and the method of using it would have been of service here.

Benjamin Moore.

THE MAKING OF ROCKS.

Petrogenesis. By Dr. C. Doelter. Pp. xii+262. (Brunswick: Vieweg und Sohn, 1906.) Price 7 marks.

In this work, which would be valued highly for its references to current literature alone, the author brings together what is known as to the origin of various types of rocks. Its outlook is that of the mineralogist and not of the physical geographer; but this enables the author, though far too modestly, to bring his researches on the construction of minerals and rocks to bear upon broad geological problems. As a treatise, the book is elementary and yet satisfying; in the series of which it forms a part, "Sammlung naturwissenschaftlicher und mathematischer Monographien," it exactly fills its place as an exposition of prevalent, if not necessarily established, views. Very often these views are subjected to criticism that shows how far we are from finality and conclusions; but the lucidity of discussion and absence of bias displayed by Dr. Doelter make us grateful to him as a guide. The history of the struggle for the Rhine in no way affects his scientific judgment; and once again we feel that Austria holds the balance in the geological controversies of our time.

When we say that the book is elementary, we mean this in the best of senses. It goes to the root of a question, and compels the reader to understand it. As an example of the large amount of valuable matter that may be compressed into one paragraph, we may take the following (p. 80), from a discussion on differentiation in igneous magmas:—

"Attempts have been made, as we have seen, to connect differentiation fundamentally with the existence of magmas which will not mix with one another. But this is an improbable supposition, since every magma can dissolve any other, as I have shown experimentally. The solubility of one mineral in another depends only on the temperature; and at a temperature varying with each case, the critical temperature of solution, the products of fusion are soluble in one another. Experiment also proves to us that no separation takes place in the fluids so long as they are stirred; it occurs first as cooling goes on; where there is no movement, separation can take place according to specific gravity, even in the fluid state."

The book opens with a discussion of the causes of fluidity of magmas within the earth, and their occasional appearance at the surface is attributed primarily to tectonic movements. When relief from pressure comes, the magma becomes fluid, and corrodes the surrounding rocks. The gases contained in it operate "like a blowpipe-flame." The results of such corrosion are treated later (p. 116, &c.), and Dr. Doelter remarks, following Daly's recent papers, that basic lavas, coming quickly up broad cracks, reach us in a state of greater purity than acid ones, which move more slowly, and have greater opportunities for affecting the walls that bound them. The acid masses "exhibit traces of the country-rocks, but not necessarily near the contact-zone, since, in the case of deep-seated rocks, the absorbed fragments may become distributed in the interior of the mass."

The author's remarks on the potency of mineralising agents during the consolidation of igneous rocks are based upon his own well-known experiments. Mica thus seems always to require the presence of fluorine. While water is the greatest mineraliser, we are reminded that we are not dealing with pure water in the earth, but with water containing chlorides, hydrochloric acid, boric acid, and so forth (p. 24). Certain minerals decompose in their own products of fusion, and give rise to other minerals, or mere glass, on consolidation. In such cases, the crystalline condition remains stable only at a lower temperature than that of fusion, and the function of a mineraliser or "crystalliser" is to reduce the temperature at which the substance crystallises out again. If the right point is reached, the original mineral is recovered in its crystalline form. Thus, in the much-debated case of quartz, the mineral, at ordinary pressure, will not separate from its product of fusion at temperatures above 950°. Below this temperature its crystals are stable. Above it they are unstable, although their melting-point is not reached until 1600° or 1700°. The common minerals that require the help of mineralisers for their formation are albite, orthoclase, quartz, garnet, haüyne, epidote, wollastonite, hornblende, and mica. Hence an acid crystalline rock cannot arise without mineralisers, and the frequent presence of tourmaline, fluorspar, scheelite, and so forth, in granite, indicating boric acid, fluorine, tungstic acid, chlorides, &c., bears out in nature the results of synthetic laboratory work.

On p. 65 it is interestingly pointed out that the different items in the chemical analysis of a rock, as written down, possess very different values, and that too large deductions must not be based on small differences in the quantities of magnesia, soda, or potash stated to be present. Exactitude in these determinations is not obtainable with the same degree of success as in the case of silica and alumina, and the alkalies, unfortunately, usually appear as small numbers, in which the second place of decimals becomes of importance for comparison. The American school, by the by, has made such headway that the word "salisch" slips in naturally on p. 44.

We cannot dwell on all the important considerations here put forward as to the processes that go on during the cooling of igneous rocks. Among these, the description of "Unterkühlung" on p. 137 strikes us as of especial interest. The retention of a mineral in a state of fusion below its ordinary melting-point may allow of the previous crystallisation of another, which cannot sustain such conditions, and thus the normal order of crystallisation may be reversed. This fact is used to explain the crystallisation of augite before the felspar in basic rocks, which, in normal circumstances, so frequently show ophitic structure.

All through the book the influence of personal experiment remains manifest, and we must not complain if the genesis of the sedimentary rocks is treated in a somewhat rapid fashion. Flints thus receive far less than their due (p. 232), considering how much they have been discussed. Guppy's observations on silicified corals in the Fiji Islands raise, for instance, new questions in themselves. But references to recent work, such as Linck's on the separation of calcium carbonate from sea-water, will lead the reader forward; and we turn back contentedly from these scantier pages to the fine account of the problems of contact-metamorphism, and thank the author again and again for his clear and stimulating treatise.

As is natural in so wide a field, we miss mention of some memorable work, such as that of Harker on mixed rocks in the Inner Hebrides; on the other hand, we hail with delight the name of MacGregory (p. 31), who appears to be Prof. J. W. Gregory in the glory of a Scottish title.

GRENVILLE A. J. COLE.

STRUCTURES AND MATERIALS.

Theory of Structures and Strength of Materials. By Prof. Henry T. Bovey. Fourth edition. Pp. xiii+968. (New York: John Wiley and Sons; London: Chapman and Hall, 1905.) Price 1*l.* 11*s.* 6*d.* net.

THIS well-known text-book has been largely rewritten and enlarged for the present fourth edition. In the preface Prof. Bovey states that a number of fresh examples, mostly drawn from actual practice, have been added to the various chapters, and that all tables of strengths, elasticities, and weights of materials have been brought up to date.

In chap. i. a description of Bow's method of notation is given, and the author has now adopted this system throughout the book when dealing with stresses developed in framed structures. The treatment of the three-hinged braced arch for station roofs and for sheds of wide span is a new piece of work in this chapter. In chap. ii. there is a new series of paragraphs dealing with the graphical determination of the maximum bending moment at any point of an arbitrarily loaded girder, and several examples illustrating the author's methods are worked out in full. Chap. iii. of the older editions has wisely been broken up into two chapters, one (chap. iii.) dealing with momentum, energy, and balancing, and the other (chap. iv.) with stress, strain, and elasticity. In the older editions this chapter was a very difficult one for the student to follow, and the author, in rewriting and dividing it, has brought the various steps of the work into their true relation one with the other. The whole of the material in chap. x. of the older editions, which dealt with thick-walled, hollow cylinders, has now been incorporated into chap. v., which treats of the more difficult work on stress and strain, and undoubtedly it follows more naturally in this position after the discussion of the general equations of stress.

In chap. vii., in dealing with the relation of the neutral plane to the stress at any point in a beam, Prof. Bovey has incorporated the results of his own experimental work, which was carried out with the view of determining within the limits of elasticity the changes of fibre length at different depths of a beam when loaded transversely. In this chapter there are also additional paragraphs dealing with the design of reinforced concrete beams, the position of the neutral axis, and the strength of such beams; additional graphical methods are given for determining the slope and deflection in loaded beams, and in connection with the theory of continuous girders fresh matter has been introduced.

In chap. viii., which deals with the theory and the bending of struts, the results of the most recent experiments have been incorporated, and, as the chapter has been rearranged, it is now much more useful to engineers engaged in the difficult problem of strut design. In chap. ix. the stresses in non-circular shafts are discussed, and there is also much new matter in the paragraphs on the efficiency of shafting and the whirling of shafting, and open coil springs are dealt with, as well as the ordinary helical springs. Chap. x., which is devoted to bridges, has been entirely rewritten and greatly improved. Graphical methods are used throughout for the determination of stresses in the piers, and the most recent types of bridges are discussed and explained. Excellent tables are given of the loads upon, and the weights of, bridges, and several examples of fairly large bridges are worked out in complete detail. This chapter is now a most valuable one for those who are concerned with the design of bridges of all classes, and the examples have been made thoroughly practical. We have no hesitation in saying that Prof. Bovey in thus practically rewriting his book has considerably improved its value both to the engineering student and to the civil engineer engaged in the design of all classes of structures in steel and iron.

T. H. B.

RATIONAL DAIRYING.

Dairy Chemistry. By Harry Snyder. Pp. x+190. (London: Macmillan and Co., Ltd.; New York: The Macmillan Co., 1906.) Price 4*s.* 6*d.* net.

PROF. SNYDER'S work as agricultural chemist in the University of Minnesota is well known. This State, with a population less than that of Kent and Essex, possesses a University Agricultural Department in which are 800 students most of whom are attending a three years' course. The majority are students who during the summer months have to work for a living, and at the close of their academic training return to rural employment. Thus Minnesota, in common with other States of the Middle West, is year by year producing an army of workers who have learnt to base their work on scientific principles and to look to the results of scientific research for the future development of their industry.

The success of the American agricultural colleges in turning out trained craftsmen (they are not, perhaps, equally successful in producing highly-trained scientific experts) is to be traced to the intimate association of the practical and the scientific teaching. On the one hand science is taught, but the mind of the student is constantly being directed to its industrial applications; on the other hand the industry is taught, but with constant reference to underlying scientific principles. Prof. Snyder's book is a capital example of the method of industrial teaching. It is a text-book of dairying, but there is no rule-of-thumb; an appeal is made to reason; processes are advocated because found by experiment to be sound; the impression left on the student's mind is, "This is the best to-day; there may be a better to-morrow."

To take from the book two examples of the effect of this method of training on industrial development:—The advantages of the cold curing of Cheddar cheese were established by Babcock and Russell at the Wisconsin Experiment Station. It is a rational process based on recent investigations on the action of the natural enzymes in milk. The results were only published in 1901, but already cold-curing factories have risen throughout Ontario and the cheese-producing States of the Union, showing a readiness to accept the results of scientific investigation, although involving a large capital outlay, to which it is difficult to find a parallel in British agriculture. As the second illustration, take the percentage of fat and total solids in milk, $3\frac{1}{2}$ and 12 respectively, enforced as the legal standard in Minnesota. To obtain such milk, cattle must be bred up to this high standard. The agricultural community is far-sighted enough to see that, although it may involve hardship on individuals, the high standard is an advantage to a State where butter and cheese production is an important industry.

The book should prove almost as useful to dairymen in this country as in America. There are few Americanisms either in spelling or phraseology, and throughout there is an insistence on the importance of proper hygienic conditions in dairying, with several useful suggestions as to how cleanliness can be secured, which should be invaluable, for it is on account of the neglect of such conditions in this country that dairymen's troubles are generally due. The method of calculating dividends in dairying is also worthy of particular attention here. There are, unfortunately, a few misprints and inaccuracies, together with curious repetitions of the same statements, suggesting that the book has been edited from lecture notes compiled in card-catalogue form. As usual in American works, the whole of the nitrogen compounds in foods are considered as proteids. The bibliography containing references to American, German, and British scientific papers is an excellent feature.

T. S. D.

OUR BOOK SHELF.

Gedanken über Vererbung. Dr. Alexander Petrunkewitsch. Pp. 83. (Freiburg, i. B.: Speyer and Kaerner, 1904.) Price 1.80 marks.

THE author thinks that clearness is gained if we regard the organism as a continually changing mechanical system with a life-cycle extending from the arbitrarily chosen moment of oogenesis to the post-mortem death of the last scrap of decaying tissue. An acquired character is the result of a reaction of the system to external influences, and presupposes a definite heritable structure capable of reacting, so that there is no sharp boundary between acquired and inherited characters. What is called a heritable character may be due to a coincidence of successive reactions. The concept of heredity strictly applies only to the germ-cells; it is simply "the process which leads to the formation of germ-cells whose structure is the same as or like the parental germ-cells." Development is the expression of this structure, and the formative causes of development lie in the relation between the system and its environment. An animate system can only exist in definite conditions, which can only oscillate within definite limits. Life is an adjustment between the amplitudes of variation in the animate system and in the environment, and involves a progressive limitation of the organismal variability. Those variations the causes of which lie in the oscillations of the germ-cell structure may be called gametogenous or endogenous as contrasted with exogenous variations (modifications) which are acquired in the course of life. This distinction will hold even if we abandon the theory of the continuity of the germ-plasm, and simply suppose that the germ-cells are those cells which through chemical reactions have attained the same structure as the parental germ-cells. When this sameness is not attained variations result, the amplitude of which may be trivial or fatal, or it may be that a new pattern of system results which we call a mutation. So far as we can see, the author simply re-states familiar facts and ideas in a slightly novel way, and we do not share his confidence that clearness is gained by so doing.

J. A. T.

Giordano Bruno. In Memoriam of the 17th February, 1600. By Alois Riehl. Translated by Agnes Fry. Pp. 112. (Edinburgh and London: T. N. Foulis, 1905.) Price 2s. 6d. net.

THE life of Giordano Bruno is not altogether unfamiliar to readers of reviews in NATURE. A larger volume on this subject was reviewed about two years ago (March 31, 1904, vol. lxix., p. 505). Still earlier, in May, 1900, the original of the present translation was reviewed, and the reviewer expressed the wish that Prof. Alois Riehl's essay could be presented in English. This suggestion has led to the appearance of the present volume.

The first account of Giordano Bruno coming from the pen of Prof. Alois Riehl dates from 1889, the year in which the present monument was erected to Bruno on the site of his martyrdom. The tercentenary of Bruno's death on February 17, 1900, formed the occasion for a second edition, in which the account of Bruno's philosophy was revised. Without entering into minute detail, the present translation bears the impress of being a good one, and when the small size of the book is taken into account the description of Bruno's life will be found to be as full and complete as could be possibly expected.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Geological Survey of Canada.

IN the issue of NATURE of June 21 is a letter from Mr. A. P. Low. This communication is liable to be misleading, and I shall be greatly obliged if you will allow me to correct the misstatement which it contain, namely, that "at the same time, Dr. R. Bell simply returned to his former position of assistant-director and chief geologist, to which he had been appointed in 1892."

I was not appointed chief geologist in 1892. This office did not then exist. It was created on March 27 last, and I was appointed to it by a formal Order-in-Council on that date, a large increase being made to my salary at the same time. ROBERT BELL.

Office of the Canadian High Commissioner, London, July 9.

I HAVE taken some trouble to inquire into the extraordinary appointment to the Geological Survey of Canada concerning which you published a paragraph on April 26 (vol. lxxiii., p. 613) and a letter on June 21 (p. 175). I send you my results in case you would care to continue the correspondence.

Report states that the Premier informed Dr. Bell that the Government, for its own reasons, was going to make certain changes in the administration of the department, but that wishing Dr. Bell to be quite contented with these changes, he asked him to state the conditions which would be agreeable to him. I have also learned that the Premier transferred Dr. Bell's letter for action to the Minister of the Interior, who is at the head of the Geological Survey Department. Owing to the great pressure of the business of the session of Parliament, the matter has not yet been considered, and further changes are probable, but for the present Dr. Bell has been promoted to be chief geologist of Canada, and allowed to devote his time entirely to scientific matters. He attains at least equal rank, and receives a substantial addition to his salary, with a promise of further increase in the near future. In connection with the above change, Sir Wilfrid Laurier spoke in Parliament in the highest terms of Dr. Bell's ability and of the great scientific services he had already rendered the Dominion.

If these are facts, then Mr. Low's letter (p. 175) appears to be inaccurate. The office of chief geologist was, it seems, newly created for Dr. Bell last March, and he was not appointed to it, as Mr. Low asserts, in 1892.

Mr. Low, I find, is quite unknown in the geological world, whereas Dr. Robert Bell's name has long been familiar throughout Europe and America. He is now in his fiftieth year of service to the Government of Canada in connection with its Geological Survey, and as practical head of that department for the last five years he has maintained its high reputation and administered all its affairs with credit. He is a Fellow of the Royal Society of London, a Doctor of Science of Cambridge, a Doctor of Medicine of McGill, a Doctor of Laws, &c., and has been honoured by the King with the companionship of the Imperial Service Order.

During his administration of the business affairs of the Canadian Survey, it is generally recognised that he has improved its efficiency in many ways, and has increased the number of its officers, the extent of its operations, the Government grant, the library, the extent of its premises, &c. He has sent to the field an average of more than thirty parties every year, as compared with less than half that number in the time of his various predecessors. Surely this is a good record, for the sooner a country is surveyed the better it is for all economic purposes.

The above matters and many others are clearly described by Dr. Bell in his annual summary reports of the survey for the past five years. He had previously caused to be carried on very extensive topographical surveys in all sections of the vast Dominion, taking the leading part himself in this work. It was for these valuable services to geography that the Royal Geographical Society this year awarded him the patron's gold medal, with the approval of the King.

It is clear, I think, that although the interests of science have not been wholly sacrificed, party politics and not geology have been in question in regard to Mr. Low's appointment. F. R. S.

July 7.

Osmotic Pressure.

THE gravamen of our criticism of Prof. Kahlenberg's paper is directed against his statement that "indirect measurements of osmotic pressures involve the assumption that the gas laws hold for solutions." In vol. lxxvii., Proc. Roy. Soc., we deduce a relation between the osmotic and vapour pressures of a solution which is independent of the gas laws "holding for solutions." Prof. Kahlenberg, in his recent letter, does not attempt to show that this relation is unsound; we may therefore take it that he accepts the theory, but is dissatisfied with the experimental evidence which we adduced to corroborate it. Perhaps the following will help to convince him.

In a paper read before the Royal Society, June 7, we give the results of the direct and indirect measurements of the osmotic pressures of some aqueous solutions of cane sugar.

Concentration	Direct O.P. at 0° C.	Indirect O.P. (from V.P. at 0° C.)
540 grs. per lit. sol.	67·51	69·4
660 ,, ,,	100·78	101·9
750 ,, ,,	133·74	136·0

Since reading this paper we have found that aqueous solutions of dextrose and galactose give similarly concordant results. As regards the last paragraph of Prof. Kahlenberg's letter (p. 222), we would point out that he gives no experimental evidence for the assumption that the sugar that had passed through the rubber membrane was sugar from which, so to speak, the solvent had been filtered off. Until such evidence is forthcoming, it seems to us that the criticism we levelled at his work is legitimate, and suggests a simple explanation of the low results he obtained. BERKELEY.

Foxcombe, near Oxford. E. G. J. HARTLEY.

Family Diseases and Temperaments.

MAY I appeal through your columns to those of your readers who are interested in the tendency of certain diseases and temperaments to run in particular families to aid me in an investigation I am at present making? The schedules now being issued contain space for a great deal of information, but it is rare for any single recorder to be able to supply all of it. What is wanted is a perfectly frank statement of what the recorder knows or can find out without much trouble. The only request made is that if the recorder feels unable to state certain facts not to the family credit, as well as those which indicate a sound, successful stock, no attempt should be made to fill in the schedule. At the same time, *no names are required*, the recorder may select any family he pleases for record, and the name of the recorder is only required in case it is needful to ask for explanation of any entry, and as a general sign of good faith.

I am fully aware of the labour involved in giving a fairly full family record, and my gratitude for aid in the matter is very great. At the same time, it is, I think, not unjustifiable to hope that among the readers of NATURE there will be some ready to help in an inquiry which if completed will be of considerable scientific value. There exists at present no ample data from which we can determine the inter-relationship of disease, temperament, and success in life. We know comparatively little the extent to which these factors are associated together or persist in certain families. After some considerable labour, about 200 records have been obtained, some of them very full and excellent, and the majority of considerable value. But the number must be extended, if possible to 1000, before the work of reduction is begun. May I ask for further aid in the matter? I shall be glad to send two or more schedules to anyone who will help to get a faithful record.

KARL PEARSON.

University College, London, W.C.

Thermodynamics of Diffusion.

IN applying the principles of thermodynamics to diffusion of gases, several pitfalls have to be guarded against.

In the first place, if we adopt the old definition of entropy in terms of integrals of the form $\int dQ/T$, we are almost certain to go wrong when we come to deal with diffusion. If we imagine diffusion to take place between two of the ideal "perfect gases" of our text-books at constant pressure, volume and temperature, and without gain or loss of heat, no quantity of the nature of dQ appears to be associated with the phenomenon, and it is easy to rush to the conclusion that no change of entropy takes place. This danger is avoided if we adopt Mr. Swinburne's plan of defining entropy in terms of "waste" or unavailable energy relative to an assumed auxiliary medium. By "auxiliary medium" is here meant a medium at uniform temperature T_0 which can be used indefinitely as a refrigerator in thermodynamic operations, and any change in the amount of *unavailable* energy under such conditions, when divided by the temperature T_0, gives the corresponding change of entropy.

If this definition is adopted we see that the phenomenon of mixing the gases does not in itself suffice to determine the changes of entropy associated with it. The matter can only be decided by an appeal to experience as to the means whereby the gases can be separated or mixed reversibly. The case of an ideal "perfect gas" forms no exception to this statement.

The proper inference is, not that the diffusion involves no change of entropy, but that the change of entropy, if it exist, cannot be expressed as a sum of differentials of the form dQ/T.

The second pitfall occurs when we take the well-known expression for the entropy of a perfect gas in terms of pressure (or volume) and temperature, and try by this means to connect the entropy of the mixture with the entropies of the components. Where we are likely to get into trouble is by ignoring the integration constants in the expressions for the entropy. There is no evidence from mere thermodynamic reasoning that the constant does not change in the process of diffusion. All we can infer is that the change of entropy associated with the mixing of gases at uniform pressure and temperature is constant, *i.e.* independent of pressure and temperature.

To sum up, then, even when we have defined an ideal perfect gas in the ordinary way, and assumed the property that two such gases can mix in a closed vessel without change of pressure and temperature, thermodynamical considerations still give us no information whatever as to the change of entropy accompanying diffusion, and on this point a further appeal to experience is necessary.

This amounts to saying that our definition of perfect gases is still incomplete. What further property shall we assume in order to complete it? If we regard a "perfect gas" as a mere invention on paper, the most *useful* plan is to take some simple property which is approximately satisfied in the case of actual gases and assume that this property is accurately satisfied by our perfect gases. Now, actual gases may be separated and re-mixed either by diffusion through a membrane or by liquefying, or, if preferred, freezing one of the constituents.

Taking either of these processes, and making suitable assumptions which would render that process perfectly reversible, we are led to the inference that the whole entropy of a mixture of perfect gases should be taken to be equal to the sum of the whole entropies of its components at the same temperature and partial pressure, *i.e.* if each component occupied the same volume as the final mixture.

According to this view, when diffusion takes place at constant temperature and *pressure*, there is a gain of entropy and a loss of available energy equal in amount to that which would be incurred if each of the constituents were to expand by rushing into a vacuum until it occupied the same volume as the final mixture.

There is another way of partially separating the constituents of a gas mixture. If the mixture be introduced into a field of force such as that due to the earth's attraction, or if we imagine it to be whirled in a centrifuge, the denser gases will predominate in the lower parts of the atmosphere or where the potential is greatest, and the lighter gases will predominate in the upper regions or where the potential is least. In this case the partial separation is effected at the expense of work done by the field of force.

This note does not purport to deal in full detail with the thermodynamics of diffusion, but merely to direct attention to certain points which are easily overlooked. One of the most important of these points is that the possibility of producing mechanical work by the diffusion of gases through a membrane at constant temperature is not necessarily inconsistent with the principles of thermodynamics or the ordinary definitions of a perfect gas.

If any physicist should claim to have discovered Maxwell's demons in connection with the diffusion of gases, the first questions we should ask him are:—

(1) Can he, without the performance of external work, separate the gases in a mixture in such a way that the temperature is the same at the end as at the beginning, and the separated constituents each occupy volumes smaller than that of the original mixture?

(2) Can he obtain external work by the mixing of two gases without change of temperature if the initial volume of each gas is not less than the final volume of the mixture?

(3) Are his claims based on new experimental evidence?

G. H. BRYAN.

Early Meteors of the Perseid Shower.

THE moon being new on July 21 this year renders the conditions favourable for observing the earlier members of the great Perseid display. A few of these are usually visible on July 15, and probably just before that night, and it would be interesting if multiple observations of supposed Perseids could be obtained so that their radiants might be definitely assigned without the risk of error.

A single record of a meteor-flight only permits an assumption to be made as to the apparent radiant, and mistakes frequently result. For example, if a streak-leaving meteor, seen at the July–August epoch, happens to be directed from the northern part of Perseus it will certainly be attributed to the Perseid swarm, though it may quite possibly have had its origin in a different shower from Cassiopeia, Andromeda, Aries, Camelopardus or Auriga. To avoid such errors of allocation it is proposed to maintain simultaneous watches this year between July 15 and 28 from 10 to 12 p.m., and the writer would be glad to hear particulars of any observations for comparison with similar results obtained at Bristol.

The mean height of the Perseid meteors has already been satisfactorily deduced, but it seems desirable further to investigate the position and motion of the radiant, especially during the last half of July. Such meteors as appear amongst the stars of Perseus or bordering constellations are the best for indicating the exact place of the radiant, and bright meteors should always be carefully registered, as they are very likely to have been noticed elsewhere. The centre of radiation travels from near ϕ Andromedæ at the middle of July to a few degrees south of the star-cluster at χ Persei at the end, the ephemeris places (*Monthly Notices*, lxii., 160) being as under:—

Date	R.A. °	Dec. °	Date	R.A. °	Dec. °
July 15	15·3	+48·9	July 25	24·9	+52·5

Bishopston, Bristol.

W. F. DENNING.

WESTERN AND CENTRAL ABYSSINIA.[1]

IT is with no desire to depreciate the work under review, or any other of the books published on the subject of Abyssinia since the great work of James Bruce (more than a hundred years ago), if the present reviewer ventures to remark that no modern work on the subject of Abyssinia has yet been written which is at all commensurate with the importance of that marvellously interesting African State. Possibly such a work might have been finally compiled had Baron Carlo von Erlanger lived to write it. In his posthumous "Forschungsreise dürch Süd-Schoa, Galla und die Somali-Länder," he treats of a fragment of Abyssinia in a way which, if it had been applied to the whole of that region, would have illustrated effectively for the first time to the man of science, as well as to the more general reader, the most interesting part of Africa.

A little reflection will convince those who have not thought on the subject that Abyssinia *is* from every point of view the most interesting portion of the Dark Continent. Here the fauna and flora of the Mediterranean region meet those of tropical Africa. Here the lofty, snow-capped mountains retain a wild goat (the most southerly occurrence of the Caprine subfamily in the African continent). Here also is a peculiar and aberrant dog *Canis simensis*. In the western lowlands of Abyssinia there is a true wild boar—*Sus sennaarensis*. Several of the antelopes and two or three species of monkeys are peculiar to Abyssinia in their range, as are numerous birds, a few fish, two or three reptiles, and a great many plants. Some of the fish are closely related to species in North Africa or Syria. The human races are of varied types and widely different origins, speaking a variety of languages, some of which are unclassified. In the extreme south-west of Abyssinia there are Negro types which have been classified as Bantu, and others which resemble either the Congo or the Bushman pygmies. In the south-east and south, and thence almost to the centre of the country, the population is mainly of the handsome Gala-Hamitic type or of the kindred Somali stock. In the west there are Nilotic Negroes, and in the north, centre, and east races that are compounded of Hamite and Semite, with traces here and there of ancient Greek or Egyptian colonies, while there are dark-skinned Jews whose origin would seem to antedate by many centuries the destruction of Jerusalem.

In this country has been developed the strangest and most debased type of Christianity, and there are forms of devil worship or belief in demoniac possession of great interest to the student of religions. Abyssinia has a history, more or less credible, going back to a thousand years before Christ, while its records from the first impact of the Portuguese in the sixteenth century down to the present day have been part of the world's history, linked on to the records of civilised Europe, Asia, and North Africa. Whereas nearly all Africa south of the Sahara, with the exception of the Upper Niger and a narrow fringe along the west and east coasts, only came within the domain of written history a hundred years ago, Abyssinia has as much formed part of the record of Caucasian civilisation as Britain or Morocco.

The author of the book under review gives within the compass of 315 pages an excellent general description of western and central Abyssinia, and the book contains a number of good photographic illustrations. In his preface, and in one or two passages in the body of the book, the author hints with some ominousness at future trouble which is coming on the Sudan from the direction of Abyssinia. It would be out of place in NATURE to discuss international politics, nor do the readers of this Journal tend to take the point of view that what is quite permissible to Great Britain in the way of political pushfulness is almost criminal when forming part of the policy of a sister European or American nation. But apart from the warnings which are given by Mr. Hayes as to the growth of German or American influence in

FIG. 1.—Market day at Zegi. From "The Source of the Blue Nile.

[1] "The Source of the Blue Nile. A Record of a Journey through the Sudan to Lake Tsana in Western Abyssinia, and of the Return to Egypt by the Valley of the Atbara, with a note on the Religion, Customs, &c., of Abyssinia" By Arthur J. Hayes; and an Entomological Appendix by Prof E. B. Poulton, F.R.S. Pp. xi+315. (London: Smith, Elder and Co., 1905.) Price 10s. 6d. net.

Abyssinia, he seems to indicate, and with much more probability, political dangers from the effervescence of the Abyssinians themselves. Before long the adjacent regions of the Egyptian Sudan promise to become exceedingly prosperous with their fertile soil and accessibility through British-made railroads or river navigation. Mr. Hayes seems to anticipate that this coming prosperity may be a source of temptation to the reckless mountaineers of western Abyssinia, who can reach the Sudan so much more easily than the Sudan can vanquish Abyssinia.

In his desire to give an accurate picture of Abyssinia, both at the present day and at previous periods, the author quotes extensively from earlier writers, with acknowledgment, and, where the works are recent, by direct permission. These extracts, coupled with his own shrewd and accurate observations, make up a most readable and, perhaps it may be said, valuable description of Abyssinia. There is a good deal of new information about Abyssinian Christianity, coupled with some admirable photographs of frescoes in the interior of churches. The author's remarks on pp. 56 and 59 on the soil created by the work of the white ant, and the washing of this soil down from the highlands of Abyssinia to the lowlands of Egypt and the Sudan, are distinctly interesting. There are one or two trifling mistakes which should be corrected; for instance, in the text and illustration on p. 184, a fine specimen of a reedbuck antelope is described as a "hartebeest." It is interesting to note that, so far north as the valley of the Atbara, such a typical specimen of the reedbuck should be found.

The author and the authorities whom he quotes somewhat extensively give an interesting description of the Falashas, the so-called black Jews of central Abyssinia, the region round Lake Tsana. The Falashas are undoubtedly Jews in religion, and have been for many centuries; but great caution should be exercised by people who desire to write with scientific accuracy in identifying these people of Semitic origin with the ancient Israelites of Palestine. It is alleged that the traditions of these Falashas would make them the descendants of a branch of the Jewish people which had never known Palestine, but had migrated to Abyssinia direct from Egypt. Such theories as this are hardly worth discussing by the scientific ethnologist. The Children of Israel were undoubtedly an Arab tribe that originated in the region between Syria and Egypt. Their monotheistic religion spread far and wide through the centuries into Arabia, Abyssinia, and North Africa; and, elsewhere, in the form of Christianity. The Jewish people that were expelled from Palestine by the Romans were a very composite race, containing a good deal of Armenian blood. It is possible that the Falashas, like other tribes of "black Jews" elsewhere, adopted the Jewish religion at some period before the spread of Christianity or of Islam, but are not directly descended from any section of the original Jews.

H. H. JOHNSTON.

OPSONINS AND TUBERCULOSIS.[1]

WHEN the scientific researches of Durham, working in Gruber's laboratory, revealed in 1895 the presence of agglutinins in the blood, the discovery was soon put to practical use in clinical medicine by Widal and Grünbaum, who showed what valuable aids these substances were in the diagnosis of typhoid fever; further, and this does not seem to have been so generally recognised, they have been shown to be of service in the prognosis of that disease. A similar and no less important practical use in the diagnosis of tubercular infections was made by Wright and Douglas (Proc. Roy. Soc., vol. lxxiv.), and is here further developed by the former in conjunction with Staff-surgeon Reid. The method employed is the estimation of the opsonic power of the serum; and the technique is that described by Drs. Wright and Douglas in a previous paper (Proc. Roy. Soc., vol. lxxii.). This briefly consists in incubating for fifteen minutes at body temperature a mixture of equal volumes of washed blood corpuscles, bacterial suspension, and the serum under investigation. Blood films of this mixture are prepared and appropriately stained, and the phagocytic count is estimated and compared with the result attained by conducting the same experiment with normal serum, such serum being obtained by pooling the blood of a number of healthy individuals. The phagocytic count of the experiment conducted with normal serum is taken as unity, and the result of the other count as compared with this gives the opsonic index of the serum under investigation.

In the recent paper the authors first give the result of a large number of blood examinations in generalised and localised tubercular infections. Two very important facts are the outcome of this work:—

(*a*) That in localised tubercular infections the opsonic index is uniformly low.

(*b*) That in cases of tuberculosis associated with constitutional disturbances the index is continually varying, the patient living a "life of alternating negative and positive phases," that is to say, the resistance of the blood is reduced as an immediate effect of the bacterial poison and then increased above the normal in response to the infection.

Further, ample evidence has accumulated substantiating the fact already enunciated that normal sera do not vary more than ten per cent. on either side of unity.

Applying these principles to the practical diagnosis of tubercular infections, it will be obvious that much value will accrue from a series of examinations of the blood, and to a less extent from a single examination. Where a series of measurements of the opsonic power of the blood reveals a persistently low opsonic power with respect to the tubercle bacillus, it may be inferred, in the case when there is evidence of a localised bacterial infection which suggests tuberculosis, that the infection in question is tubercular in character. A continually fluctuating index would point to a tuberculous infection associated with constitutional disturbances, whilst an index which never varied on either side of the normal to a greater extent than ten per cent. would be taken as evidence against a tubercular infection.

If only one examination of the blood is possible and the index is found to be low, then according to the evidence in the case under investigation of a local bacterial infection or of constitutional disturbances, it may be inferred with probability that the infection is of a tuberculous nature. A high index would be taken as evidence of a systemic tuberculous infection which is active or has recently been active. But no inference at all, either positive or negative, is warranted if on a single occasion the tuberculo-opsonic index be found to be within normal limits. In this case, however, it is possible by employing a further test to arrive at a diagnosis. This consists in repeating the experiment after having heated the serum for

[1] "On the Diagnosis of Tubercle by the Examination of the Blood, and on Spontaneous Phagocytosis." By Dr. A. E. Wright and Staff-Surgeon Reid, R.N. (Proc. Roy. Soc., B., vol. lxxvii., 1906.)

"On Spontaneous Phagocytosis, and on the Phagocytosis which is obtained with the Heated Serum of Patients who have responded to Tubercular Infection, or, as the case may be, to the Inoculation of a Tubercle Vaccine." (*Ibid.*)

ten minutes at 60° C. This method of testing is based upon the fact that if normal serum is heated it no longer incites phagocytosis, whilst in cases suffering from tuberculous infection "incitor elements" have been elaborated in the organism in response to the infection, and the serum is found, after heating, to retain a considerable measure of its power of inciting phagocytosis. In a series of experiments with normal heated sera the index varied between 0.00 and 0.125; whilst in experiments conducted with the heated sera of patients with tubercular infections the index ranged from 0.09 to 1.7. These figures are obtained by comparison of their phagocytic count with that obtained with unheated pooled blood of healthy men.

In a previous paper (Roy. Soc. Proc., vol. lxxiv., p. 157), Dr. Wright suggested that the fact that the actual focus of infection had a lowered "bacteriotropic pressure" as regards the offending microorganism might be employed in the diagnosis of abscesses or effusions of a doubtful nature, the inference being that the fluid has washed over these bacteria at the site of infection, and has thus been deprived of its antibacterial substances. In this paper an interesting and convincing series of cases is given showing the practical value of this method of diagnosis of tubercle. Further justification for this would seem to be furnished in the proof of the "specificity" of opsonins for given bacteria as demonstrated by Dr. Bulloch in a recent number of the Proceedings of the Royal Society.

The same number of the Proceedings of the Royal Society contains a further paper by the same authors on "Spontaneous Phagocytosis," and on the phagocytosis which is obtained with the heated serum of patients who have responded to tubercular infection. Under the first heading the authors investigate the question of the phagocytosis which occurs in the absence of serum; under the second, the question as to the nature of the "incitor element" referred to above as being present in the heated blood derived from patients who have responded to the tubercular infection, or, as the case may be, to the inoculation of a tubercle vaccine.

As the result of searching experiments, the authors conclude that the "incitor element" is not a "stimulin" which affects the white blood corpuscles, but an opsonin which enters into combination with bacteria. They further conclude in this matter, in agreement with the previous work of Dr. Dean (Proc. Roy. Soc., B., vol. lxxvi.), that the substance in question does not differ with respect to its resistance to heat and sunlight from that which is found in the unheated normal serum.

That the opsonins are eminently heliolabile is also of great practical import, for a blood allowed to lie in the sunlight preparatory to its examination for opsonins is entirely spoilt, as is shown by experiment in the present paper.

As regards spontaneous phagocytosis an important fact was arrived at, namely, that it is in the lowest salt concentrations (0.6 per cent. NaCl) that phagocytic activity is greatest, whilst it is practically abolished by a concentration of more than 1.2 per cent.

Another experiment of practical moment is worthy of mention. When dealing with heated sera, which, as we saw above, may be used as aids to diagnosis, it is very important that the same conditions should exist in every case, for the phagocytosis occurring after the serum had been exposed to various temperatures for varying periods was found to differ considerably. Thus a fixed temperature (60° C.) for a fixed period (10 minutes) should always be employed in the exploitation of this method of diagnosis.

NOTES.

The Mackinnon studentships for the year 1906-1907 have been awarded by the Royal Society to Mr. W. G. Duffield, "for the study of arc spectra of metals under high pressures"; and to Dr. F. H. Scott, "for the continuation of studies on the nature of the process of excitation of nerve cells."

The arrangements for the international celebration of the jubilee of the coal-tar industry to which attention has been directed in these columns are now well advanced, and a very representative gathering of foreign chemists will assemble in London on July 26–27 in honour of Dr. Perkin and his work. As might have been expected in view of the great development of the industry in Germany, that country will send a very strong body of delegates. Among those who have already accepted invitations are Prof. Emil Fischer, representing the German Chemical Society; Drs. Duisberg and Delbrück, representing the "Verein Deutscher Chemiker"; Drs. Böttinger (Elberfeld), H. Caro (Mannheim), Ehrhardt (Badische Co.), Kallé (Biebrich), Klingemann (Cassella and Co.), H. Erdmann (Charlottenburg Technical High School), Kremers, Lepsius (Griesheim), Raschig (Ludwigshafen), Möhlau (Dresden), Gustav Schultz (Münich); and Drs. Bablich, Liebert, de Ridder, Albrecht Schmidt, and Ullrich, representing the Höchst colour works. It is probable that Prof. Liebermann and Drs. v. Martius and Bernthsen will also be present. From France, M. Gautier, president of the Chemical Society of Paris, and Prof. Haller will represent their society. Profs. Étard, Moureu, and Guyot will also attend as representatives of France. Holland will be represented by Profs. Holleman and van Romburgh, Austria by Prof. Friedländer, and Switzerland by Prof. Hans Rupe. America, as already announced, proposes to have an independent celebration in the autumn, but will also participate in the general international movement. The American delegates have not yet been nominated. At the banquet on July 26 all the foreign delegates will be present as guests, and it is hoped that the chemists of this country will attend in large numbers. At the meeting at the Royal Institution on July 26 Dr. Perkin will receive the Hofmann medal of the German Chemical Society and the Lavoisier medal of the Chemical Society of Paris, besides numerous addresses from the learned and technical societies. Among the names of officials and public men who have so far responded to the invitation to attend the banquet are Lords Kelvin, Rayleigh, and Alverstone, the German Ambassador, the Right Hon. R. B. Haldane, Mr. Justice Buckley, Sir Wm. Broadbent and Sir Arthur Rücker. All applications for tickets for the dinner and other functions should be addressed to Dr. J. C. Cain, 28 Pembury Road, Clapton, N.E. As the gathering is expected to be a very large one, it is desirable that those proposing to be present should communicate at once with Dr. Cain so that the necessary arrangements for their accommodation may be made.

There are now on exhibition at the London Hippodrome three microcephalic girls stated to have come from Mexico. Like the famous Maximo and Bartola, who toured the world some fifty years ago and were described to the Ethnological Society by Sir Richard Owen. The present specimens are said to be members of an almost extinct race closely allied to simians; but microcephaly is not associated with any particular race, and the information was probably suggested by the statements made as to the origin of the earlier pair. Although they are often monkey-like, the microcephalics are not technically simian in their characteristics; in some cases they have a small vocabulary, in others they are mute so far as real language is concerned. The skull capacity has been known to fall as low as 270 cm., but the present immature specimens are said to have brains only one-seventh the normal size.

In connection with the third International Colliery Exhibition recently held at the Royal Agricultural Hall, a representative gathering of delegates from mining and allied institutions in different parts of the world was entertained at luncheon by Mr. H. Greville Montgomery, M.P. It was unanimously resolved by the assembly to hold an International Mining Conference in connection with the fourth International Colliery Exhibition in 1908. An organising committee was elected, and among its members are:—Mr. J. C. Cadman, Prof. S. Herbert Cox, Mr. W. Cullen, Prof. Dunstan, F.R.S., Mr. W. B. Esson, Prof. W. Gowland, Mr. E. M. Hann, Mr. T. H. Holland, F.R.S., Mr. J. H. Marr, Mr. T. W. Mitchell, Mr. W. H. Patchell, Mr. H. M. Ridge, Mr. W. Rowley, and Mr. W. Russell, C.B., with Mr. H. Greville Montgomery, M.P., as chairman, and Mr. Allan Greenwell as secretary. All communications should be addressed to the secretary at the offices (provisional) of the conference, 30–31 Furnival Street, Holborn, London, E.C.

The committee of bibliography and of astronomical sciences of the Royal Observatory of Belgium has undertaken to publish a list of the observatories and astronomers of the whole world. A request for information, in the form of a list of questions, with a model reply relating to the astronomical service at the Uccle Observatory, Belgium, has been addressed to directors of observatories. In addition, the list will include such astronomers (university professors, amateurs, &c.) who are not attached to any observatory, but are nevertheless actively engaged in astronomical research. The information already sent will enable the committee to draw up, not only a list of observatories, with their geographical coordinates and the members of the staff, but also a table showing the astronomical activity of the whole world, based upon the information given as to the instruments at the disposal of each institution, the researches undertaken, and the papers published. Directors of observatories who have not received the question-form, or have not yet forwarded a reply, as well as unattached astronomers, are requested to send the information desired, or to repair any omissions, as soon as possible to the chairman of the committee, Prof. P. Stroobant, astronomer at the Royal Observatory of Belgium, Uccle, Belgium.

Through the death of Prof. H. A. Ward, who was struck down by a motor car on July 5 in Buffalo, U.S.A., a figure well known to every museum and mineral dealer in Europe and America has passed away. Prof. Ward was born at Rochester, N.Y., in 1834. For a short period he assisted Prof. Agassiz at Harvard Scientific School; in 1855 he went to Paris for a course of study, and travelled thence widely over Europe; from 1860 to 1865 he was professor of natural science in Rochester University. From that period until his death, most of his time was spent in travelling for the purpose of forming collections of mineralogical and geological specimens, which are well known as "Ward's Cabinets." To geological literature Prof. Ward contributed little of importance, but as a collector he did valuable service. He had built up the most complete private collection of meteorites in existence; in extending it he spared neither time nor money; though more than seventy years of age, he passed through London last year on his way to cross Europe, searching for new specimens with the ardour of a boy.

With the Earl of Grey, G.C.M.G., Governor-General of Canada, as patron, and Sir L. A. Jetté, Lieutenant-Governor of Quebec, as honorary president, the fifteenth International Congress of Americanists will meet at Quebec from Monday, September 10, to Saturday, September 15. The work of the congress will have reference to:—(1) The native races of America, their origin, geographical distribution, history, physical characters, languages, civilisation, mythology, religions, morals and habits. (2) The indigenous monuments and the archæology of America. (3) The history of the discovery and European occupancy of the New World. The committee of organisation is as follows:—President: Dr. Robert Bell, F.R.S., director of the Geological Survey of Canada, Ottawa. Vice-Presidents: Mgr. J. C. K. Laflamme, Dean of the Faculty of Arts, Laval University, Quebec; Hon. R. A. Pyne, Minister of Education of the Province of Ontario, Toronto; Dr. D. Boyle, Department of Education, Toronto. General Secretary: Dr. N. E. Dionne, librarian, Legislative Assembly. Treasurer: Mr. Alp. Gagnon, Department of Public Works, Quebec.

In a long and interesting article in the *Times* of July 9 on the commercial application of wireless telegraphy, the writer deals very fully with the history of wireless telegraphy and with the various systems now being worked on a commercial basis. The claims of the various systems are clearly put forward, and should prove of interest to the non-technical readers who are mostly inclined to the opinion that the words "wireless telegraphy" and "Marconi" are synonymous. Among the many systems which have been developed since Mr. Marconi achieved success, may there not be one or more which is entitled to an equal consideration by the authorities? This is one of the chief points raised by the *Times* correspondent, and it is one which in the interests of the nation should be fully recognised. So long as one company is granted a monopoly, the cost for commercial use is likely to remain high, and any improvements which might be made through fair competition are unlikely to be developed in the same proportion. In Germany a combination of the various systems has been made, and any new improvement brought out is thus welcomed and given the fullest consideration. In this manner the highest efficiency is obtained, and if some similar arrangement could be arrived at in this country it would surely be to the benefit of the country at large. As to whether it would be more to the interests of the nation for the Government to own and work the wireless telegraph stations, when, by a fair trial, the best system or combinations of systems has been established, is a matter which wants the fullest consideration, and before any further licences are granted to any company or companies, this aspect of the situation should be one of the first points to be decided by the authorities in whose charge the welfare of the country is placed.

Prof. Hönnann, professor of mining in the Berlin Technical High School, died on June 30 in his seventy-first year.

The twenty-third annual congress of the Royal Sanitary Institute was opened at Bristol on Monday under the presidency of Sir Edward Fry, F.R.S.

Prof. Walther von Lingelsheim, director of the hygiene station in Beuthen, Upper Silesia, has been appointed director of the newly founded hygiene institute in the same town.

Dr. Wilhelm Bode, departmental director of the Emperor Frederick Museum in Berlin, has been appointed

Director-General of the Berlin Royal Museums, with the rank of Wirklicher Geheimer Oberregierungsrath.

THE Berufsgenossenschaft der chemischen Industrie held its twenty-second ordinary meeting in Detmold on June 28, and sanctioned the spending of half a million marks for the erection of the society's business premises.

DR. THEODOR MEYER, whose work on the commercial preparation of sulphuric acid has given him a high place among technical chemists, has been appointed director of the installations bureau for the German chemical industry, in Berlin, Kurfürstendamm 139, in succession to the late Dr. H. H. Niedenführ.

PROF. HUGO VON GILM died in Vienna on June 21, in his seventy-sixth year. Born in Innsbruck, he studied at the university under Prof. Hlasiwetz, whose assistant and co-worker in several pieces of research in organic chemistry he subsequently became. From 1863 to 1895 he was first lecturer, and ultimately professor of chemistry and chemical technology in the Vienna Landesoberreal- und höheren Gewerbeschule.

PROF. EMIL JACOBSEN celebrated his seventieth birthday on July 3 in Charlottenburg, where he has lived for many years. He was horn in Danzig, and studied as a pharmaceutical student in Breslau and Berlin. In 1862 he opened an analytical laboratory in Berlin, in which he made a number of valuable observations and discoveries. Dr. Jacobson is the originator and editor of several successful periodicals. From 1862 to 1903 he issued an annual publication under the title of the *Chemisch-technisches Repertorium*, and from 1864 to 1894 the weekly paper *Industrie Blätter*, while from 1878 to 1895 he was the director of the *Chemische Industrie*.

AN earthquake shock was felt at Manstrac, Alva, and Blairlogie, in Perthshire, about 3.45 on July 4. The tremor, which passed from west to east, lasted about two seconds, and was accompanied by sounds as of distant explosions.

THE annual exhibition of antiquities connected with the Institute of Archæology, University of Liverpool, will be held in the Lord Derby Museum, Public Museums, Liverpool, from July 11 to July 26 inclusive. The exhibits include prehistoric remains from Hierakonpolis; examples of provincial art from Esna, of Hyksos period and later; scarabs, ornaments, and inscriptions from Abydos, of 2000 to 1200 B.C.; pottery and other remains of primitive man, from Kostamneh in Nubia, recently discovered by Mr. John Garstang and Mr. E. Harold Jones.

FROM the ashes of the monthly magazine of current scientific investigation, *Science Progress*, which came to an end in 1898 through lack of support, has arisen a quarterly review under the same title, edited, with the assistance of a strong advisory committee, by Dr. N. H. Alcock and Mr. W. G. Freeman, and published by Mr. John Murray. The periodical has much the same appearance as its predecessor, and the contributions to it are of the same character. There are twelve articles in which methods and results of work in several departments of science are described by writers actively engaged in scientific investigation. The contributions are thus trustworthy statements of the position and progress of important subjects of scientific study, the biological sciences being given particular attention. In the first number the endeavour of the new periodical is stated to be "to present summaries, as far as possible of a non-technical character, of important recent work in any branch of science, to show the progress achieved, and if possible to indicate something of the line along which further advance is to be made towards the desired end. The chemist, to take an example, will describe for the botanist recent advances in chemistry, the botanist will do the same service for the chemist, often, it is hoped, to the advantage and assistance of both." These intentions are, of course, admirable, and the only difficulty to be anticipated is in their application. Scientific work is so minutely specialised that the vocabulary common to all investigators is somewhat limited; and the greatest trouble the editors will have will be to obtain authoritative articles on subjects of prime importance written in a style that can be read with ease and interest by the world of science in general, while at the same time they appeal to the wants of students of special branches of scientific inquiry. We trust that the new review will be successful in its attempt to provide a common meeting-ground for men of science, where workers in biological and physical sciences can lead one another to appreciate the significance of progress made in their respective departments of natural knowledge.

WE have received a copy of an illustrated prospectus of the new edition of the "Systematisches Conchylien-Cabinet" of Martini and Chemnitz, now in course of issue by Messrs. Bauer and Raspe, of Nürnberg, under the editorship of Dr. W. Kobelt.

FROM the University of Wisconsin we have just received a copy of No. 115 of the Bulletin of that institution bearing the date of September, 1905. It is devoted to a review of the rise and progress of the study of anatomy in the United States, drawn up by Prof. C. R. Bardeen, and delivered as an inaugural address on his assumption of the chair of anatomy in the University. The discourse includes a reference to the early history of anatomy. In the University of Wisconsin a special department has been recently established for the study of human and comparative anatomy, neurology, histology, and embryology.

"NOTES on Malayan Pigs" is the title of an illustrated paper by Mr. G. S. Miller forming No. 1466 of the Proceedings of the U.S. National Museum. As the author has had the advantage of studying large series of specimens in the museums of Washington, London, Berlin, Leyden, and Berne, it may be hoped that this communication will do much towards settling the vexed question as to the number of distinguishable representatives of the genus Sus inhabiting the Malay area, although it is possible that what Mr. Miller regards as "groups" other naturalists may consider "species." Several new forms are named.

No. 1468 of the Proceedings of the U.S. National Museum is devoted to a collection of fishes from Ecuador and Peru, the new forms described by the author, Mr. E. C. Starks, including several cat-fishes (Siluridæ). In No. 1470 of the same serial Messrs. Jordan and Snyder describe two giant bass from Japan, namely, *Stereolypis ischinagi* and *Erilepis zonifer*, both of which have been long known to science, although imperfectly represented in collections. Despite the fact of both being commonly known as "bass," the two species are referable to distinct families. One example of the former was about 6 feet in length, while a specimen of the latter measured 57 inches, and other specimens are stated to weigh as much as 200lb.

BOTANY is the main subject in the June number of the *American Naturalist*, the "notes" being entirely devoted to that subject, while Dr. K. M. Wieland discourses at considerable length on the causes of the pressure and flow of sap in the maple. Osmosis from one living cell to another is, in Dr. Wieland's opinion, the only *vera causa* for the latter phenomenon. "Only by flow through the cell from one reservoir to another, due to the unequal osmotic permeability at the two ends, does it seem possible to obtain pressure by this method. . . . The pith-ray cells seem the only ones in the wood in position to fulfil the above requirements. The most probable explanation at present is that the pith-ray cells, stimulated by the rising temperature, become unequally permeable, thus setting up a current and accompanying pressure from the pith towards the bark." Two shorter articles, one by Mr. R. C. Osburn and the other by Mr. A. S. Pearse, respectively deal with the existence of dragon-fly larvæ in brackish water and with the reactions to chemical and other stimuli of the hydroid polyps of the genus Tubularia.

THE June issue (vol. vii., No. 3) of the Journal of the Marine Biological Association of the United Kingdom opens with an obituary notice of the late Prof. Weldon, who was one of the oldest workers at the laboratories, and one of the most earnest and enthusiastic supporters of that institution. This is followed by an illustrated paper on certain British nudibranchiate molluscs. A report is appended on the work of the council in connection with the International Fishery Investigations. In order to carry out efficiently the work in the North Sea, it was found advisable to establish a laboratory at Lowestoft. The experiments with marked plaice have proved the occurrence of extensive migrations on the part of that species. Very noteworthy are some of the hydrographical results, especially in relation to the fact that the waters of the North Sea and the English Channel have, respectively, different origins, according to the season of the year. It would appear, for instance, that during the summer and early autumn of 1903, the Channel waters were largely derived from the Irish Sea, while during the remainder of the year they were chiefly drawn from the Bay of Biscay, as indicated by their excessive saltness. The issue closes with the report of the working of the laboratory, &c., during 1904-5.

AN important communication on the morphology of fishes appears in the June issue of the *Quarterly Journal of Microscopical Science*, in which Mr. E. S. Goodrich discusses the development, structure, and origin of the median and paired fins. It is shown that the mode of development of the dorsal fins is essentially the same as that of the paired fins, both arising as longitudinal folds, into which grow buds from the myotomes, these being subsequently affected by concentration and fusion. The careful and detailed observations of the author practically give the death-blow to the theory that the paired fins of fishes (and consequently the limbs of vertebrates generally) are derived from modified gill-arches, for, as is mentioned in the text, that theory gives no explanation of this remarkable structural resemblance of the paired to the median fins. On such a theory the resemblance is in truth absolutely inexplicable, whereas on the lateral (and median) fold-theory such a resemblance is not only easy of explanation, but is precisely what we should expect to occur. Mr. Goodrich has done good service in brushing aside collateral issues and putting the *crux* of the problem plainly before his readers, and it may be hoped that his efforts will result in the general acceptance of the lateral fold-theory. The contents of the above-named issue of the *Quarterly Journal of Microscopical Science* also include a continuation of Dr. Woodcock's review of the hæmoflagellates, and a preliminary account, by Miss R. M. Harrison, of a newly-discovered organ (consisting of a glandular body between the fifth and sixth abdominal ganglia) in the cockroach.

NOT for the first time American botanists are extending their sphere of operations to British colonies in undertaking an investigation of plants in the Bahama Islands. The collections gathered hitherto by various American botanists have been of a somewhat meagre character, so that Drs. N. L. Britton and C. F. Millspaugh, with the consent of the British botanists concerned, have planned a botanical survey of the group. Under the title "Prænunciæ Bahamenses," Dr. Millspaugh, in vol. ii., No. 3, of the botanical series of the Publications of the Field Columbian Museum, Chicago, treats the orders Amarantaceæ, Euphorbiaceæ, Rubiaceæ, and Verbenaceæ. Under the Verbenaceæ two new genera, Nashia, allied to Lantana, and Pseudocarpidium, allied to Vitex, are founded.

THE systematic articles in the recent part of the Kew Bulletin, No. 4, include a decade of new orchids described by Mr. R. A. Rolfe, and a series of "Diagnoses Africanæ" contributed by Mr. N. E. Brown, among which are several plants collected by the Hon. Mrs. E. Cecil in Rhodesia and Portuguese East Africa. The nature and uses of Chinese wood oil, generally known as t'ung oil, are discussed by Mr. J. M. Hillier, and the tree yielding it is referred by Mr. Botting Hemsley to *Aleurites Fordii*. A number of new species of Indian fungi are recorded by Mr. Massee, who also writes a note wherein he advances arguments proving that potato-disease and potato leaf-curl are more often perpetuated by hibernating mycelium than by diffusion of spores.

THE exhibit organised by the Meteorological Office for the International Exhibition, Christchurch, N.Z., 1906–7, was, by permission of Dr. Shaw, viewed on July 6 by many persons interested in meteorology. The exhibits were intended to illustrate the methods adopted by the Office and by the institutions associated with it, and the results obtained on land and sea. For this purpose instruments, published works, and specially prepared diagrams were arranged according to the branches into which the operations of the Office are divided. Perhaps the most imposing display was in connection with maritime meteorology; many beautiful specimen sheets of monthly charts for the various oceans testified to the care and skill bestowed on this important part of the work of the Office. Among the many objects of interest was a meteorological log contributed by the Prince of Wales when in command of H.M.S. *Thrush*. The details connected with the preparation of weather forecasts and the issue of storm warnings were well represented. Among the most attractive charts may be mentioned one showing the portions of the globe for which daily weather reports are published, with isobaric lines drawn for December 21, 1905, from the charts received; maps showing passages of cyclonic depressions across the British Isles and the prevalence of gales on our coasts. In the section dealing with climatological statistics maps were exhibited showing the stations under the control of the English and Scottish Meteorological Societies and the British Rainfall Organisation. Dr. Shaw contributed some carefully drawn diagrams showing the apparent relation between the yield of wheat and rainfall; meteorological sequences—dry autumn followed by wet spring and *vice versâ*—and the meteorological relations of widely distant regions. Although somewhat of a tentative character, the results were very striking, and led to the conviction that a great step in the right direction had been made in grappling with the multitudinous details at the disposal of the Office. The department dealing with automatic recording apparatus took also a prominent position in the exhibit; some excellent drawings were shown illustrating the mounting and working of the instruments at the first order observatories. Among the instruments exhibited by some of the principal opticians was a Beckley's anemometer with Whipple's improvements, by which the direction of the vane could be read at any time by pressing the electric button of an indicator placed in any convenient room in the observer's apartments. Another interesting feature was some carefully drawn diagrams illustrating the wind circulation at the South Pole (results of the *Discovery* observations) for each month, both at the surface and in the higher regions of the atmosphere. Mr. Dines exhibited a model of a kite and a meteorograph used for the investigation of the upper air.

THE *Physikalische Zeitschrift* for June 15 contains a description by Prof. Simon, illustrated by plans and photographs, of the new buildings and equipment of the institute for applied electricity in the University of Göttingen. A historical sketch is given of the steady development of the teaching of electrotechnics at Göttingen during the past twelve years, with particulars of the funds available during this period and of the circumstances which have led to the creation of the new "institute."

AN attempt to ascertain the cause of the explosion which sometimes occurs of sealed glass tubes containing radium bromide is described by Mr. Paul L. Mercanton in No. 11 of the *Physikalische Zeitschrift*. Such an explosion might possibly be due to the pressure set up within the tube by some gas being gradually produced by the radium. A glass tube containing 15 mg. of radium bromide, which had been kept sealed during more than three years, was accordingly opened under such conditions as would permit of the measurement of any increase of pressure, and of the examination of any gas liberated from the tube. It was found, however, that no increase of pressure could be observed, nor could the presence of helium be detected.

THE fourth edition of Prof. J. E. V. Boas's "Lehrbuch der Zoologie für Studierende," which has just been published by Mr. Gustav Fischer, Jena, contains much new matter, both in the text and illustrations. There were 378 figures in the first German edition of this work, reviewed in NATURE of January 22, 1891 (vol. xliii., p. 268), and this number has now been increased to 577; while both the general and special parts of the text have been thoroughly revised by the author, with the assistance of Prof. J. W. Spengel, professor of zoology at Giessen.

A SECOND edition, revised and enlarged, of Prof. C. Moureu's "Notions fondamentales de Chimie organique" has been published by Messrs. Gauthier-Villars, Paris. The book is a synopsis of the facts and theories of organic chemistry, and is intended to be an introduction to the study of this science.

OUR ASTRONOMICAL COLUMN.

FINLAY'S COMET.—Writing to the editor of the *Astronomische Nachrichten* (No. 4102), Herr L. Schulhof states that the Jupiter perturbations of Finlay's comet bring the time of perihelion passage forward by about twelve hours, thereby making it September 7·5 instead of September 8·0 as given originally. The uncertainty of the elements is probably not greater than a quarter of a day, so that the perihelion time may now be taken as lying between September 7·25 and September 7·75. On June this comet was twice as bright as when discovered in 1886, and its apparent brightness will steadily increase until the end of August; the observation of the comet is, therefore, very probable.

THE RADIANTS OF THE PERSEID SHOWER.—From a number of observations made at Dorpat during 1901 and 1902, M. Wwedenski, under the direction of Prof. Pokrowski, has determined the following radiants of the Perseid meteors:—

Date of observation.	No. of meteors observed.	Chief radiant point. α	δ
		°	°
1901 Aug. 10	23	40	+57
,, ,, 11	37	47	+58
,, ,, 12	17	47	+56
1902 Aug. 10	17	43	+60
,, ,, 11	27	35	+55

Another set of observations made on August 10 and 11, 1901, gave $40° + 57°$ (24 meteors) and $44° + 57°$ (43 meteors) respectively (*Astronomische Nachrichten*, No. 4098).

MAGNITUDE OBSERVATIONS OF NOVA AQUILÆ NO. 2.—The magnitude of Nova Aquilæ No. 2 was observed at the Bothkamp Observatory on seventy-seven occasions between September 5 and December 10, 1905, and the results are given and discussed in No. 4098 of the *Astronomische Nachrichten*. On analysing these results, Dr. Guthnick found that the curve showing the diminution of magnitude was not a straight line, but a parabola of the following form:—

$$m = 10{\cdot}96 + 0{\cdot}0272t - 0{\cdot}000095t^2,$$

where m = the Nova's magnitude at the time of observation, 10·96 its magnitude on September 5, 1905, and t the number of days which elapsed between September 5 and the time of observation. The departure of the observed values from those computed, for the same epoch, from the curve are given in the table accompanying the results.

AN OBJECTIVE-PRISM COMPARISON SPECTROGRAPH.—In No. 5, vol. xxiii., of the *Astrophysical Journal*, Mr. de Lisle Stewart, of the Cincinnati Observatory, proposes a new form of objective-prism spectrograph which might be employed for the determination of stellar radial velocities. Instead of making two exposures with the one instrument, as has been proposed in previous suggestions to this end, Mr. Stewart proposes to employ two similar spectrographs mounted rigidly on one equatorial mounting and having the prism bases adjacent. This would bring the two spectra of each star near together on the plate, and would, presumably, eliminate, at least to some extent, the differential effects of flexure and temperature changes. Various details as to the inclination of the two tubes to each other, the inclination of the plate, the positions of auxiliary telescopes, &c., are given in the paper. Prof. Frost estimates that the probable error of radial velocities so determined would not be less than 20 km., but Mr. Stewart suggests that practical experience would remove the outstanding obstacles to more trustworthy determinations.

RUSSIAN ASTRONOMICAL OBSERVATIONS.—We have recently received five Bulletins of the St. Petersburg Imperial Academy of Sciences, each of which contains one or more papers of astronomical interest. Thus No. 5, vol. xvii. (1902), includes a paper, in French, by Prof. Brédikhine on the *rôle* of Jupiter in the formation of simple radiants, and in vol. xviii. (1903) MM. Donitch and Jaegermann have articles on the solar envelopes during the last minimum and on the production of comets' tails respectively. Vol. xix. (1903) contains several astronomical papers, including one on the observations of the chromosphere outside eclipses (M. Donitch), and another on comet forms (M. Jaegermann). Vol. xx. (1904) is largely astronomical, and includes articles on the Pulkowa spectrograph, the repulsive force of the sun, the solar activity, and the International Catalogue; whilst vol. xxi. (1904) contains papers by Prof. Belopolsky dealing with radial-velocity problems.

A NEW OBSERVATORY FOR HAMBURG.—From *Himmel und Erde* (No. 8, 1906) we learn that a new observatory is to be erected near Hamburg. The senate and council of that town have voted one million marks towards its erection and equipment. Among the other instruments which it is proposed to instal in the new building, the following are the chief:—A meridian circle of 18 cm. (7 inches) aperture, a 60 cm. (23 inches) refractor, a double telescope for photographic purposes, and a reflector having a mirror of 1 metre diameter.

STAR TRANSITS BY PHOTOGRAPHY.[1]

THE annoyance that arises from the effects of a "magnitude equation" in transit observations has led to various suggestions for its detection or removal. Screens in front of the object-glass so as to reduce the light of bright stars have been employed with advantage, and various photographic devices arranged with the view of eliminating personal peculiarities have been adopted. But while ingenuity has been active in proposing practical applications and methods, the numerical results have been few. Recently, Prof. S. Hirayama, of the astronomical observatory at Tokyo, has put in practice a contrivance similar to that employed by the Rev. Father Hagen in photographing a star in the focus of the transit telescope. In this method the exposure and occultation of a star is alternately effected by means of a bar, moved in obedience to a clock, so as to give rise to a series of dots along the star trail.

The Tokyo transit was for this purpose provided with a triple object-glass, reducing the secondary spectrum, and specially corrected for photographic rays. The aperture was 13·5 cm., and the focal length 211 cm. The range of magnitude to which the telescope was applicable depended, of course, upon the time of exposure permitted by the occulting bar. As a matter of fact, with a full second's exposure, equatorial stars of the fifth magnitude gave a measurable image. For stars of greater declination than 73° the exposure of one second was too short to divide distinctly the successive impressions from each other. The limitations of the method are thus clearly indicated. For fainter stars it seems necessary to consider the possibility of moving the photographic plate at the same rate as the star, and imprinting on the plate the image of a fixed reticule at known times. The simpler method adopted by Prof. Hirayama recommended itself to him, since the apparatus could be constructed in the workshops belonging to the observatory.

This apparatus consisted of a camera containing the reticule, occulting bar, and the dark slide, which could be inserted in the place ordinarily occupied by the wires and eye-piece. The reticule consists of seven fine lines ruled upon a microscope cover-glass, firmly cemented to a rectangular frame which carries the dark slide. These lines are interrupted for a short distance in the middle of the field so that they shall not interfere with the star images. The centre of the field is marked by two horizontal wires in the ordinary manner. The occulting bar (Fig. 1) is a

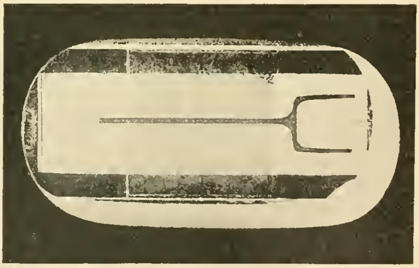

FIG. 1.—Showing the bar at rest, in the centre of the field.

thin metal slip about 8 cm. long with a square opening at one end, so as to allow the observer to see the star enter the field, and to permit him to adjust the instrument so that the transit shall take place behind the bar when in its stationary position. The end of this bar is soldered to the armature of an electromagnetic coil. Whenever the electric circuit is established the bar is lifted up and the star exposed. This circuit is made and broken automatically by contact springs in the standard sidereal clock. The bar consequently operates as an exposing shutter, permitting the cone of light from the star to fall for a longer or shorter period upon the sensitised plate, the period being decided by the contact springs.

The sensitive plate when inserted in the dark slide comes within 0·2 mm. of the lines of the reticule, so that these lines and the image of the star are practically in the same focus. Evidently this distance must be made as small as possible to reduce any error arising from photographic parallax, but the plate can be shifted in its own plane, so that five separate exposures can be made upon the same plate. The advantage thus secured of taking

FIG. 2.—The bar removed, showing the transit of a star; slightly enlarged.

five stars on the same plate is somewhat discounted by the fact that no proper adjustment can be made for developing the plates according to the different actinic intensity of the stars.

The method of observation will be easily apprehended from the description of the apparatus and the character of the results obtained (Fig. 2). The measurement of the plates is not so simple. It is distinctly admitted that to measure a negative is more laborious than to read the fractions of a second from a chronographic sheet. Theoretically, the beginning of each "break" made by the clock is the exact point to which the reading should refer; but owing to the difficulty of measuring the edges of the dots, due to the want of sharp definition, this plan could not be adopted. The middle of the "break" to the middle of the "make" has been taken as the full second. This arrangement, or conventional rule, has probably got over the difficulty arising from the photographic spread, for it seems not impossible but that the want of definition at the edges of the dot, or the distance between two dots, is dependent upon the brightness of the star. But if this source of error is eliminated the author has to regret that the length of the dot depends upon the battery, the spring, the friction, and the moving parts of the apparatus as affected by the variable component of the force of gravity. "The weakening of the battery has been constantly provided for, but at present I see no way of escape from all the other disadvantages."

This admission seems to deprive this peculiar method of observation of much practical benefit. The question that has to be solved is not so much one of relative accuracy as it is of the possibility of eliminating systematic errors, inherent in older and more familiar methods. Looked at as a simple matter of determining the position of a star on a plate at any required moment, the results leave nothing to be desired. In an example worked out in detail it is shown that the error in a single pair of measures is $\pm 0{\cdot}017$s., and the mean error of thirty-two pairs, or what may be regarded as equivalent to a complete transit, $\pm 0{\cdot}002$s. The results of the measures of 140 stars, made when the plate was moved with, and against, the direction of diurnal motion, gave for the average value of personal equation $+0{\cdot}027$s., the positive sign implying that the time of transit was longer when the plates were measured along the diurnal motion than when measured against it.

But such measures leave the question of a possible error dependent upon magnitude untouched. Unfortunately, the limited range of magnitude and the small number of observations do not permit any very definite conclusion to be drawn. The author presents a table of forty-six stars in which the photographic magnitude varies from 1·2 mag. to 5·5 mag., and gives residuals for each night and the mean residual. The latter is less than 0·05s. in all but two cases out of the forty-six. Further, when these mean residuals are arranged for each star in the order of photographic magnitude, no relation between the two is notice-

[1] "Preliminary Experiments on the Photographic Transit." By S. Hirayama. Annales de l'Observatoire astronomique de Tokyo. Tome iii., 4e fascicule. (Tokyo, 1905.)

able. Of the two errors greater than 0·05s., one is +0·072s. and the other −0·060s., and the magnitudes of the two stars are the same, and practically in the middle of the series.

But if there is no indication of a "magnitude equation" there is another circumstance which is not a little suspicious, and interesting as suggestive of the introduction of fresh sources of error. The author has referred to the fact that the mean error of observation can become comparatively large when the photographic image is poor, owing to the small altitude of the star. When the residuals are collected according to the zenith distance of the star, there is some indication of a connection between the two. "There is," says Prof. Hirayama, "a common tendency for the residual error to be least at the zenith, and to increase with the zenith distance." No stars below the pole have been observed, so that there is no means of comparing the results given by stars at small altitudes on opposite sides of the zenith. But many important questions are raised in this paper, and we notice with pleasure that Prof. Hirayama proposes to continue the inquiry. We can assure him that his investigations will be watched with interest in this country.

THE MUSEUMS ASSOCIATION.

THE seventeenth annual meeting of the Museums Association was held in Bristol on July 2–5 under the presidency of Dr. W. E. Hoyle, director of the Manchester Museum. The attendance of curators and representatives from various British museums was greater than in any previous year, foreign museums and museum workers being also represented by Geheimrat Dr. A. B. Meyer, of Dresden, Prof. Conwentz, of the Provincial Museum, Dantzig, Prof. Lehmann, of the City Museum, Altona, Mr. H. L. Brakstad, Norwegian Vice-Consul, and others.

The public conference commenced on the morning of July 3 in the Council House, a warm welcome being given to the association on behalf of the city by the Lord Mayor, High Sheriff, and museum committee, after which Dr. Hoyle gave the presidential address, taking as his subject the education of a museum curator. Briefly reviewing the varied training, or lack of training, which many curators have received, Dr. Hoyle divided museums into two great classes:—(a) museums of art, or institutions in which objects are regarded simply as material for æsthetic contemplation, where they are arranged so that each may be seen to the best advantage and minister to the cultivated enjoyment of the onlooker; and (b) museums of science, in which the object is to exhibit the state of human knowledge on one or more subjects, and to supply means of increasing that knowledge.

Confining his observations to the character of training required for curators of science museums, the president urged the necessity of a fair preliminary training in manual industry and the knowledge and use of tools, and afterwards a technical and scientific training in those subjects underlying the future work of the embryo curator. As subjects necessary to be studied because of their close relation to museum collections were enumerated the natural sciences, mineralogy, geology, biology, including in the latter term botany, zoology, anthropology, and ethnology. As sciences more nearly concerned with the acquisition, registration, preservation and exposition of museum collections were instanced the rudiments of mechanical engineering, physics, and chemistry. As a kind of post-graduate course, the necessity of visiting and studying the nature and methods of work of various museums was strongly insisted upon.

Alderman W. R. Barker, chairman of the Museum and Art Gallery committee, laid before the association a paper he had prepared tracing the rise and progress of the Bristol Museum from its inception in 1808 to the present union of museum and City Art Gallery.

Mr. H. Bolton, curator of the Bristol Museum, followed with a paper describing the general character of the collections, and the steps which had been taken to bring the mode of exhibition and usefulness of the museum contents up to modern requirements, mentioning that it was the intention of the committee to introduce a type-series of mounted specimens, an osteological series, and one in which the main structural features of the animal kingdom would be shown by prepared dissections. Work on similar lines was proceeding in other departments of the museum, and ultimately it was hoped to be able to place at the disposal of any student or visitor all that is necessary in the way of types for the full degree course of any university. Papers were also read by Mr. R. Quick, on the hanging of pictures; by Mr. F. R. Rowley, on a method of displaying coins, and on models of Protozoa; and by Mr. W. W. Watts, on the City plate and insignia.

Wednesday, July 4, was occupied with the discussion of a series of papers on museum cases and fittings, the subject being opened by Dr. A. B. Meyer, of Dresden, who outlined the result of his experiments and researches during the last thirty years upon museum cases. He strongly advocated metal and preferably iron cases, which could be made dust-proof, elegant in appearance, and not more costly than wooden cases. Dr. Meyer's remarks were followed by a paper from Mr. F. A. Lucas, of Brooklyn Museum, and one by Dr. Lehmann on a simple practical dust-proof case in the Altona Museum. Mr. Bantry White, of the Dublin Museum of Science and Art, exhibited an iron museum case built in that museum's own workshops, which was very efficient, dust-proof, and not costly.

A remarkable cabinet case, with changing trays each of which could be brought into view in turn by mechanical means, was exhibited and explained by the Rev. S. J. Ford. Mr. A. M. Rodger exhibited case fittings from the Perth Museum, and Mr. Woolnough, of Ipswich, complete models of cases it was proposed to introduce into the museum at that town. The lighting of museum cases was dealt with by Mr. Thos. White, of London. Dr. F. A. Bather explained the character of some cases in the British Museum, and illustrated his remarks, as did other speakers, by photographs and drawings. Mr. J. Osborne Smith also dealt with the same subject, and exhibited the original drawings and plans of many of the more recently made cases. Owing to the interest and importance of the subject the session was continued in the afternoon until four o'clock.

Thursday was occupied by a paper on the American Museum of Natural History, by Dr. H. C. Bumpus; by a paper on wall diagrams to illustrate prehistoric archæology, from Prof. Conwentz; a paper on the Altona room in the Arts and Crafts Exhibition, Dresden, designed to show how the form of animals is the concrete expression of adaptation to their suroundings; and one on the construction and management of museums of art, by Mr. B. Ives Gilman.

The afternoons and evenings of July 3 and 5 and the whole of Friday, July 6, were occupied by visits to the zoological gardens at Clifton, a conversazione at the Museum and Art Gallery, visits to the stone circles at Stanton Drew, the ancient British lake village near Glastonbury, the Glastonbury Museum, and the Cheddar Gorge and Caves. The meetings were well attended throughout, and a highly successful conference was brought to a close on Saturday last.

THE METEOROLOGY OF THE FREE ATMOSPHERE.

AT the request of the council of the Royal Society of Edinburgh, M. L. Teisserenc de Bort gave an address on the meteorology of the free atmosphere at the meeting of the society on May 21. Subjoined is a summary of his lecture.

The methods for sounding the atmosphere employed at the present day have been in our possession but a few years. The kite, carrying self-registering apparatus, was introduced by the Americans about fifteen years ago; the sounding balloon dates but twelve years back. The use of balloons, furnished with registering apparatus, was proposed by Lemonnier, a French physicist, at the end of the eighteenth century; but they were actually employed for the first time by the Brothers Renard, and especially by MM. Hermite and Besançon, whose first observations go back to 1893.

Observations of great interest had already been made on mountains. To these are now added observations made in air altogether free.

The distribution of the barometric pressure at a distance of several thousand metres above the ground was first examined, and maps were shown giving the isobars at 4000 metres as calculated from the pressure and temperature on the surface of the earth.

M. Teisserenc de Bort has carefully verified that the pressure in free air diminishes in accordance with the barometric formula. For that purpose he determined the heights of a large number of balloons by observing them with two theodolites. On the average the heights thus observed agree with those deduced from the barometers carried by the balloons to within 2 or 3 millimetres of barometric pressure for a height of 4000 metres. The maps of the isobars at 4000 metres show that most of the areas of high and of low pressure observed near the ground become effaced as we rise in the air, and give place to a pressure distribution of a much simpler kind, viz. a maximum of pressure all round the earth in the tropical regions, and low pressures at the poles. The average direction of cirrus clouds is in harmony with these conditions.

As regards the distribution of temperature, the following conclusions were established :—

(1) Even at a height of several thousand metres above the ground there is, contrary to what had been thought, a very sensible variation of temperature from winter to summer, the divergence of temperature between the coldest and the hottest month being 9° C. at 10 kilometres height.

(2) After it had been noticed that the rate of fall of temperature increases with the height above the ground, it was naturally supposed that temperatures at great heights in the air were extremely low. But sounding balloons dispatched from the Trappes Observatory have proved that, after a certain height, varying from 9 to 14 kilometres, the fall of temperature ceases altogether—another fact that was wholly unexpected.

(3) The zone where the temperature ceases to fall, called the "isothermal zone," is situated nearer the ground (8 to 9 kilometres in certain places) with low pressures, and further from the ground (about 12 or 13 kilometres) above high-pressure areas.

(4) As a general rule, it is colder in the upper part of an anticyclone than it is at a corresponding height above low pressures, but the contrary holds at medium heights of about 5 kilometres. The absolutely lowest temperatures are observed near high pressures. A temperature of −73° has been observed several times at Trappes, and recently as low as −80° in Austria.

(5) Balloon flights made daily for a week or more at a time, in different years and at different seasons, have shown that at intervals of a few days the atmosphere experiences variations of temperature which are much more important high up than on the ground. At a height of 11 kilometres variations of 15° to 20° are often observed at a time when variations of only 2° to 3° are found near the ground.

It is believed that the arrest of the decrease of temperature is connected with the cessation at a certain height of movements of the air having a vertical component, the air then having movements which follow the isobaric surfaces. There is no longer any temperature variation due to expansion or compression of the air.

It has been demonstrated, alike by calculation of the isobars and by the flight of balloons, that most of the depressions which appear near the ground as complete atmospheric vortices suffer deformation as the height increases, and in their northern part lose themselves in the great polar vortex; so that, at a certain height (4 to 7 kilometres), east and north-east winds are no longer found to the north of a depression, and the isobars at this height form a handle attached to the low-pressure areas of northern latitudes. On the front of a depression its characters remain distinct to the top; a sheaf of ascending air reaches the height of cirrus cloud, and then spreads over the barometric maxima to east and south-east.

M. Teisserenc de Bort exhibited his very light, compact self-registering apparatus for measuring the temperature, pressure, and humidity in the upper regions of the atmosphere. Dr. W. N. Shaw, F.R.S., expressed the indebtedness of meteorologists to M. Teisserenc de Bort, whom he had come all the way from London to hear. After referring to the main points of the address, Dr. Shaw directed attention to another important line of research for which M. Teisserenc de Bort has fitted up a fish carrier, acquired at Hull, with the aid of which he is investigating at the equator the problem of the upper trade winds.

INTERNATIONAL SCIENCE.[1]

IN an address delivered to the British Association at its Belfast meeting in 1902 I expressed the opinion that meteorology might be advanced more rapidly if all routine observations were stopped for a period of five years, the energy of observers being concentrated on the discussion of the results already obtained. I am glad to say that meteorologists have taken this remark as being meant seriously, and its echoes still reach me from distant parts of the earth. They disagree with me, but their disagreement is of the apologetic kind. I do not wish to retract or to weaken my previous statement, but merely to qualify it now to the extent that it is only to be applied to two-dimensional meteorology. There is a three-dimensional meteorology as far removed from the one that confines itself to the surface of the earth as three-dimensional space is from a flat area. Three-dimensional meteorology is a new science, which at present requires the establishment of new facts before their discussion can properly begin. The extension of our range of observations by kites and balloons is of comparatively recent origin. Mr. Archibald in this country was one of the pioneers of meteorological investigation by means of instruments attached to kites. In the United States Mr. Rotch, having established a separate observatory, succeeded in convincing scientific men of the great value of the results which could be obtained. M. L. Teisserenc de Bort, who established and maintained an observatory for dynamic meteorology at Trappes, near Paris, rendered similar services with regard to "pilot" or unmanned balloons carrying autographical instruments. The aëronautical department of the Royal Prussian Meteorological Institute, with Dr. Assmann at its head, under the direction of Prof. von Bezold, also made a number of important contributions in the early stages of the work. Prof. Hergesell, of Strassburg, similarly made numerous experiments, and chiefly through the efforts of those whose names have been mentioned, and more especially Prof. Hergesell, an international agreement has been secured by means of which kite and balloon ascents are made in several countries on the first Thursday in each month, and on three consecutive days during two months of the year. A large station for aëronautical work was recently established at Lindenberg, near Berlin, where kites or balloons are sent up daily for the purpose of securing meteorological records. The greatest height yet reached was during the ascent of November 25, 1905, when by means of several kites sent one after another on the same wire, the upper one rose to an altitude of 6430 metres, almost exactly four miles. Owing to want of funds this country could until recently only participate in this work through the individual efforts of Mr. Dines, who received, however, some assistance from the British Association and the Royal Meteorological Society. The reconstruction of the Meteorological Office has made it possible now for Mr. Dines's work to be continued as part of the regular work of the office, and further stations are being established. Mr. Cave carries out regular ascents at his own expense at Ditcham Park, and through the cooperation of the Royal Meteorological Society and the University of Manchester, assisted by a contribution for apparatus from the Royal Society Government Grant Fund, a regular kite station is being established on the Derbyshire moors.

The International Committee which collates the observations is a commission appointed by a union voluntarily formed between the directors of meteorological observatories and institutes of countries in which regular observations are taken. The meeting of directors discusses schemes of observations and encourages uniformity.

If I mention a few of the difficulties which stand in the way of a homogeneous system extending over Europe, I

[1] Discourse delivered at the Royal Institution on Friday, May 18, by Prof. Arthur Schuster, F.R.S. (Continued from p. 237.)

do it in the hope that it may perhaps ultimately assist in removing some of them. It is obviously desirable that the charts, which are intended to show the distribution of pressure and temperature, should be derived from observations made at the same hour. Germany observes at eight o'clock of central European time, and France observes simultaneously (or nearly so) by choosing seven o'clock Paris time for its readings. We observe at eight o'clock Greenwich time, which is an hour later. It is the great desire of Continental meteorologists that our standard hour should be seven o'clock; and what prevents it from being so? Chiefly and absolutely the additional cost which the Post Office must claim for the transmission of telegrams; because messages transmitted before eight o'clock are subject to an additional charge of one shilling, which may be claimed by the postmaster, the claim being possibly increased to two shillings when the postmaster and telegraphist are different persons. This is prohibitive, but it does not exhaust the inconvenience of the additional charge. For the purpose of weather forecasting it is clearly necessary that telegrams should be received as early as possible by the Meteorological Office. But the eight o'clock rule delays telegrams from some Irish stations, because eight o'clock by Dublin time is 8.25 by Greenwich time, and therefore Irish telegrams may have to wait until nearly half-past eight if they are to be transmitted without extra charge.

While the international organisation of meteorology is well on its way, though difficulties such as those I have mentioned may temporarily retard it, another question not altogether disconnected with it has been raised by Sir John Eliot. This is the establishment of an institution devoted to the collective study of meteorological problems affecting all parts of the British Dominions. It is true, not only in this, but also in other matters, that in order to take our proper position in international work it is necessary that we should set our own house in order, and we must give Sir John Eliot's proposals our hearty support. If I do not enter further into this question it is because I am to-day dealing more especially with problems which go beyond the limits of the Empire. I assume the existence of a national organisation, but lay stress on the insufficiency of this limitation.

The importance of the subject, however, may be my justification if I direct your attention for a moment to the meteorological question as it presents itself in India. We all know and realise the vital importance of the rainy season, and the benefit which the native population would derive if it were possible to predict, even if only imperfectly, the setting in of the monsoon. It appears that Dr. Walker, the present director of observatories in India, recently obtained very encouraging results in this respect. According to his investigations, a forecast of the monsoon may be derived from a knowledge of the weather during preceding months in different parts of the world. Thus a heavy rainfall in Zanzibar in May is followed by a weak monsoon, while a pressure deficiency in Siberia during the month of March indicates a probable deficiency of rain in India during the following August. I need not insist on the importance of these results, which at present are purely empirical, and require further confirmation; but it is quite clear that for the successful prosecution of these inquiries political boundaries must be disregarded, and a system of intercommunication organised between the countries chiefly concerned. Dr. Walker informs me that he has successfully arranged for telegraphic reports to be sent to him at the beginning of June from six different stations in Siberia. It is hoped that this cooperation, which was unavoidably discontinued during the late war, may now be re-established.

The course of international organisations does not always run smoothly. The efforts made toward cooperation in earthquake records have unfortunately led to differences of opinion, which have hitherto prevented a truly international system being formed; and if I give a short historical account of the circumstances which have led up to these differences it is only in the hope that this may help to remove them. The scientific investigation of earthquakes may be said to have begun when British professors of physics, engineering, and geology were appointed at the Imperial College of Engineering in Tokio. Some of them, on returning home, succeeded in interesting the British Association in the subject. Ever since 1880 that association has been an active supporter of seismic investigations. The much disturbed region of the Japanese island was naturally the first to be studied; but in 1895 Prof. Milne, as one of the secretaries of the committee, issued a circular directing attention to the desirability of observing waves which have travelled great distances, and some months later, Dr. E. v. Rebeur-Paschwitz, of Strassburg, drew up suggestions for the establishment of an international system of earthquake stations. To this scheme Prof. Milne and other members of the British Association committee gave their approval. The cooperation which thus seemed so happily inaugurated was broken by the unfortunate death of its originator. Circumstances then arose which compelled the British Association committee to go its own way. Under its direction a system was established which now includes about forty stations distributed all over the world. But the needs of different countries are not, and were not meant to be, completely satisfied by this organisation.

There is always a certain number of earthquakes having purely local importance and requiring discussion from a purely local point of view. For the purpose of such discussion relating to the disturbances which chiefly affect Central Europe, the Union (so-called Kartell) of the Academies of Vienna, Munich, Leipzig, and Göttingen formed a committee and did excellent work. In the meantime Prof. Gerland, who had succeeded Dr. Rebeur-Paschwitz at Strassburg, had personally invited a number of friends interested in the subject to a conference at Strassburg with the object of forming an international association. This was followed in 1903 by a formal conference called by the German Government, at which Great Britain was represented by Sir George Darwin and Prof. Milne. This conference drew up a scheme for an international association, and a large number of countries, including Russia and Japan, joined. Strassburg was selected as the seat of the Central Bureau. The matter came up for discussion at the meeting of the International Association of Academies, which was held in London in the year 1904, and a committee was appointed for the purpose of suggesting such modifications in the constitution of the seismic organisation as might bring it into harmony with the views of the associated academies. This committee, over which I had the honour to preside, met at Frankfort, and recommended a number of important changes, which were unanimously accepted by the second seismic conference held last summer in Berlin. In consequence of this acceptance it appears that Italy and the United States joined the seismic association, while England declared its willingness to join under certain conditions, of which the simultaneous adhesion of France was one. The following summary of the States which have joined, and their population, is copied from the official report of the last meeting at Berlin:—

Country	Population	Contribution
		£
German Empire	60,000,000	160
Belgium	7,000,000	40
Bulgaria	3,700,000	20
Chili	3,000,000	20
Congo State	19,000,000	80
Spain	19,000,000	80
United States of America	76,000,000	160
Greece	2,500,000	20
Hungary	19,250,000	80
Japan	48,000,000	160
Italy	33,000,000	160
Mexico	13,600,000	80
Norway	2,300,000	20
The Colonies of the Netherlands	5,500,000	40
Portugal	5,400,000	40
Roumania	6,300,000	40
Russia	129,000,000	160
Switzerland	3,300,000	20

It was decided at the Berlin meeting that Prof. Kövesligethy, of Budapest, should be secretary, and Prof. Palazzo, of Rome, the vice-president, of the International Seismic Association. Prof. Gerland had already previously been designated as director of the Central Bureau. The office of president of the association was left vacant until the final decision of Great Britain as to its adhesion had been settled. There the matter stands for the present.

The disastrous results of recent earthquakes and volcanic eruptions have directed increased attention to the subject. Its thorough investigation is indeed likely to yield important information on the interior constitution of the earth. A hearty cooperation to obtain and circulate the material for a detailed discussion cannot fail to bear fruit, and, even though there may be legitimate grounds for dissatisfaction at the manner in which a particular scheme has been organised, I must express my own opinion that at the present moment the permanent interests of this country would be best secured by our joining the association and helping to direct its work in a manner which would assist rather than hamper the present organisation of the British Association.

Although time is running short, I am perhaps in private duty bound not altogether to pass over in silence an organisation which has its central bureau in my own laboratory at the University of Manchester. This is a union for the observation of solar phenomena. Called into being chiefly by the energy of Prof. Hale, this association is perhaps unique in two respects. It aims more directly at conducting research work than is the case with other unions, and in so far may run the danger of hampering private efforts. This danger has, I believe, been well guarded against by the constitution adopted at the first meeting of the conference held last September at Oxford. The second peculiarity referred to is that it works a central bureau, a computing bureau (under the direction of Prof. Turner), and is going to publish Transactions without any funds beyond those doled out to it by charity. Its vitality will, I hope, help it to overcome its initial troubles. Its ambitious programme includes a definite agreement on the standard of wave-length and investigations on the permanence or variability of solar radiation.

This latter question is of considerable interest to meteorologists, and comes, therefore, within the purview of the directors of meteorological observatories, who have also, under the presidency of Sir Norman Lockyer, established a commission charged with its discussion. An arrangement has been made securing cooperation between the two bodies, the Solar Union leaving out of its programme the difficult question of the relationship between sun-spot variability and meteorological phenomena.

Although an unnecessary overlapping of two separate enterprises has in this instance been avoided, such overlapping constitutes a certain danger for the future, as the problems of geo-physics—for the investigation of which international associations are specially marked out—are so intimately connected with each other that a homogeneous treatment would seem to require a central body supervising to some extent the separate associations. Such a central body may be found in the International Association of Academies, which promises to play so important a part in scientific history that a short account of its early history may be of interest. The Kartell of some of the German academies and that of Vienna has already been referred to. In discussing the utility of its deliberations, Prof. Felix Klein, of Göttingen, first mentioned to me the idea that an association of a similar nature would be likely to prove of still greater value, if formed between the scientific and literary academies all over the world. In consequence of this conversation I tried to interest the Royal Society in the subject; and in order to obtain further information Prof. Armstrong and myself attended privately, though with the knowledge and consent of the council of the Royal Society, the meeting of the Kartell which was held at Leipzig in the year 1897. In the following year the two secretaries of the Royal Society, Sir Michael Foster and Sir Arthur Rücker, together with Prof. Armstrong and myself, attended the Kartell which then met at Göttingen. The secretaries were impressed by the great possibilities of the scheme, and the council then took the initiative and approached the academies of Paris and St. Petersburg, which both returned favourable answers.

In consequence of the correspondence between these learned societies, the Royal Academy of Berlin, in conjunction with the Royal Society of London, issued invitations for a general conference to be held at Wiesbaden on October 9 and 10, in the year 1899.

The following were represented at this meeting, at which the statutes of the new association were agreed upon:—

The Royal Prussian Academy of Sciences of Berlin.
The Royal Academy of Sciences of Göttingen.
The Royal Saxon Academy of Sciences of Leipzig.
The Royal Society of London.
The Royal Bavarian Academy of Science of Munich.
The Academy of Sciences of Paris.
The Imperial Academy of Science of St. Petersburg.
The National Academy of Science of Washington.
The Imperial Academy of Sciences of Vienna.

The unanimity of the meeting may be judged from the fact that a working constitution, which subsequent experience proved to be eminently effective, was finally arrived at on the second day. Many distinguished men took part in the discussions; amongst them Prof. Simon Newcomb and the late Prof. Virchow may be specially mentioned.

Although the Berlin Academy had never joined the German Kartell, the first idea of a wider association seems to be due to a distinguished member of that body, the historian Mommsen, who, though of advanced age, was able to be present at the first regular meeting of the association, which was held at Paris on April 16–20, 1901. In addition to the societies which took part in its foundation, the following form part of the association, and were represented at Paris:—

The Royal Academy of Sciences of Amsterdam.
The Royal Belgian Academy of Sciences, Arts and Letters.
The Hungarian Academy of Sciences.
The Academy of Sciences of Christiania.
The Academy of Sciences of Copenhagen.
The Academy "des Inscriptions et Belles Lettres" of the Institut de France.
The Academy of "Sciences, Morales et Politiques" of the Institut de France.
The Royal Society "dei Lincei" of Rome.
The Royal Swedish Academy of Sciences.

This meeting is not likely to pass out of the memory of those who took part in it. Its importance was enhanced by the social functions which were held in connection with it, and which included a luncheon given by President Loubet at the Elysée, a banquet given by the Conseil Municipal, and a special performance at the Théâtre Français. The subsequent triennial meeting of the academy, which was held in London in 1904, passed off not less brilliantly. The representatives of the learned societies were received by their Majesties at Windsor, and the Lord Mayor invited them to dinner at the Mansion House. Social entertainments, though welcome as marking the importance of the occasion, are not allowed to interfere with the very substantial work which is being done at these meetings. The list of subjects which were included in the discussion of the London assembly may give an idea of the range of activity of the association. A permanent committee is charged with the investigation of the functions of the brain, others deal with questions of atmospheric electricity, and of the measurement of magnetic elements at sea. An important proposal to carry out an exact magnetic survey along a complete circle of latitude is under discussion. The section of letters dealt with the mutual arrangements between libraries regarding the interchange of manuscripts, approved the intended edition of the Mahabharata, and considered a proposal to construct a new Thesaurus of Ancient Greek. The association also took cognisance of and received reports on independent international undertakings, such as the Catalogue of Scientific Literature, the Geodetic Association, and the Geological Congress.

The association meets every three years. To these meetings each constituent academy may send as many delegates as may be found convenient. For the discussion of special questions the assembly divides itself into a scientific section and a literary section.

In each of these sections, as well as in the plenary meetings comprising both sections, each academy has only one vote. At each triennial assembly the next meeting place is chosen. In the intervals between the meetings the affairs of the association are placed in the hands of a council on which each academy is represented by two members or one, according as it comprises both a literary and scientific section or only one of them. The resolutions passed by the association are not binding on the constituent academies, who maintain their liberty of adopting or rejecting them.

The Association of Academies suffers unavoidably from a certain want of homogeneity, owing to differences in the constitution of its component bodies. Most Continental academies contain both literary and scientific sections, and at the organising meeting held at Wiesbaden, marked attention was directed to the fact that there was no body in England that could be considered as representative of literary studies. If matters had been left as they stood then, this country would have been altogether unrepresented as regards half the activity of the association. Efforts were made in consequence to take a more liberal view of the branches of knowledge coming within the range of the Royal Society, and to include literary subjects. Very unfortunately, in my opinion, these efforts failed, and a charter was granted to the British Academy, which has now been included as a separate body among the list of academies forming part of the association. While in this respect we have been at a certain disadvantage, the constitution of the Royal Society has the great advantage of being truly representative of the Empire. In France, on the other hand, no one can belong to the Academy of Sciences who is not domiciled in Paris. Similarly, although Germany possesses four Royal academies (Berlin, Göttingen, Leipzig, Munich), each of them is confined, as regards ordinary members, to its own locality, so that a professor of the Universities of Bonn or Heidelberg, however eminent he may be, could not become a member of any of these academies. Neither in France nor in Germany can the academy therefore be called truly representative. The disadvantages which may arise from this defect have been minimised by adopting a rule that the International Association of Academies may appoint committees for the discussion of special questions, and that members of these committees need not be members of any of the constituent academies. This to a large degree obviates what would otherwise be a considerable difficulty. Nevertheless, I believe that the circumstances to which I have directed attention form the only impediment in the way of handing over to the Association of Academies the ultimate control of every new international undertaking, and even the charge of some of those already established. It is highly desirable that we should work towards this end. An energetic enthusiast may easily start a new enterprise, and Governments are appealed to from different sides for help and support. There ought to be some authoritative body to whom the Governments could apply for advice. Overlapping and waste would thus be avoided.

It is not my desire to disguise the difficulties which have sometimes been encountered in providing for joint undertakings on a large scale. Whether national or international, combined work between men of different temperaments always requires some suppression of personality. Even stronger feelings may be involved when a central office or bureau has to be selected which specially distinguishes one locality. The advantage gained by the locality is often one of appearance rather than of reality, for these central offices should be the servants rather than the masters of the undertaking. In order to prevent national feeling being aroused by any preference given to one nation, it has been customary in some cases to have a president who belongs to a different country from that of the director of the Central Bureau; there are also a vice-president and a secretary, all belonging to different nations. It is thought that such a distribution of office may assist in preserving harmony. I believe that this is the case, but sometimes at the risk of impaired efficiency. It cannot be denied, however, that the seat of the central office of an important undertaking confers a certain dignity, and it is quite natural that a country should feel some pride in the distinction.

England on the whole has not done so badly. We should not forget that in a great portion of the world all clocks strike the same minutes and seconds. Before long all civilised countries (except Ireland) will have adopted the Greenwich meridian for their standard of time, and we may rightly, therefore, call Greenwich the central bureau of universal time.

The offices of the International Catalogue and both the central and computing bureaux of the Solar Union are situated in this country, and if we have not secured an even larger share of the onerous but honourable duties incumbent on such offices the fault is our own. The questions which at the present moment more especially require combined treatment are those of geo-physics, a subject for which very inadequate provision has been made in England. Our earthquake observations almost entirely depend on the self-devotion of one man, and the Meteorological Office, which might reasonably be expected to take charge of certain portions of the work, such as atmospheric electricity, is kept in a state of chronic poverty, and has to restrict itself to work of the most pressing necessity.

Germany, having a large number of well-equipped stations for geodetic, magnetic, and aëronautic work, naturally reaps the reward when the offices of an international undertaking have to be chosen which shall be attached to flourishing institutions in charge of men possessing the leisure and qualifications for the work.

No serious advance will be made in our own country in this respect until our universities pay more attention to the subject of terrestrial physics. This would involve the establishment by the universities of separate laboratories or institutions, to which their present funds could not be applied. The matter wants consideration in detail, and should be carried out according to a homogeneous scheme which would prevent wasteful repetition in different places. But I feel certain that until we have trained up a number of students who possess an adequate knowledge of questions of meteorology, geodetics, terrestrial magnetism, and seismology, the position which this country will take in international organisation cannot be a leading one, though it may be, and, indeed, owing to private efforts, is at the present moment, one of which we need not be ashamed.

Finally, I must lay stress on one aspect of the question which I hope may induce us to attach still greater importance to international undertakings. The cooperation of different nations in the joint investigation of the constitution of the terrestrial globe, of the phenomena which take place at its surface, and of the celestial bodies which shine equally upon all, directs attention to our common interests and exposes the artificial nature of political boundaries. The meetings in common discussion of earnest workers in the fields of knowledge tend to obliterate the superficial distinctions of manner and outward bearing which so often get exaggerated until they are mistaken for deep-seated national characteristics.

I am afraid I have only given a very inadequate account of the serious interests which are already involved in international scientific investigations. But if I may point once more to Indian meteorology, and remind you of the vital importance of an effective study of the conditions which rule the monsoon, you will, I think, realise how impossible it is to separate scientific and national interests. The solution of this particular problem requires an intimate cooperation with Central Asia and Siberia—a cooperation which has been easily secured. I do not wish to exaggerate the civilising value of scientific investigation, but the great problems of creation link all humanity together, and it may yet come to pass that when diplomacy fails—and it often comes perilously near failure—it will fall to the men of science and learning to preserve the peace of the world.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The Technical High School of Prague will celebrate its hundredth anniversary in November next. Prof. Wilhelm Gintl has been appointed rector for the year 1906-7.

On July 4, the honorary degree of Sc.D. of Dublin University was conferred upon Colonel David Bruce, C.B., Mr. E. T. Whittaker, F.R.S., Astronomer Royal of Ireland, and Sir A. E. Wright, F.R.S.

Prof. C. Graebe has tendered his resignation of the professorship of inorganic, organic, and technical chemistry in Geneva University, to take effect from October 1, after which date Prof. Graebe will be an honorary professor of the University.

The cost of the new metallurgical institute now being erected in connection with the Technical High School at Aachen will be met chiefly by the voluntary contributions of the Rhine and Westphalian metallurgical industries; the sum set apart for the actual buildings is 500,000 marks. At the recent laying of the foundation stone, General-director Springomm, as president of the Verein deutscher Eisenhüttenleute, expressed the sympathy and best wishes of the society with the undertaking.

Mr. F. C. Forth, principal of the Municipal Technical Institute, Belfast, has sent us a copy of an interesting article on the compilation of technical students' records reprinted from the Journal of the Department of Agriculture and Technical Instruction for Ireland (vol. vi., No. 3). The system advocated of chronicling for ready reference data relative to students' attendances, marks, and successes has been devised to meet the requirements of a large technical institute, and as it has now stood the test of two years' working, the description of it should prove a valuable guide to other technical institutions.

Scarcely a week passes without an announcement in the American papers of some handsome contribution to higher education from public-spirited citizens. In the last issue of *Science* received we notice that at the commencement of Brown University it was announced that 32,400*l.* had been subscribed for the John Hay Memorial Library, thus securing the additional gift of 30,000*l.* by Mr. Andrew Carnegie. Mr. D. W. Goodspeed, secretary of the board of trustees of the University of Chicago, has announced a gift of 52,000*l.* from Mr. John D. Rockefeller for current expenses for the year beginning July 1. At the recent commencement of Olivet College gifts aggregating 53,000*l.* were announced. Of this amount 43,000*l.* applies toward the Carnegie endowment, leaving only 7000*l.* to be raised to ensure receiving Mr. Carnegie's gift of 50,000*l.* By the will of the late Prof. George A. Wentworth, of Phillips Exeter Academy, 2000*l.* is bequeathed to the academy.

The new Code of regulations for public elementary schools marks a great advance on similar publications of a few years ago. The detailed schedules of former years, with their minute instructions as to the work of separate standards, are discontinued. Great prominence is given to a few broad educational principles, on which all successful school practice must be based. The new code, in fact, supplemented by the recently published excellent suggestions for teachers, provides just that necessary official guidance which should suffice to enable properly trained teachers to adapt their procedure and curriculum to local conditions and requirements. The tendency exhibited by the central authority to give efficient teachers a freer hand is satisfactory, and we welcome it. A new scheme of arithmetic is included in the Code, and it reflects the movement started by the British Association to eliminate from school arithmetic all fanciful problems of little everyday use, and to introduce practical measurements at an early stage. The scheme in the new Code puts such measurements in the Fifth Standard work, but omits to state definitely in the same section that such practical work with a scale of inches and tenths, or centimetres and millimetres, is the most satisfactory and natural introduction to decimals. Decimals are, of course, included in the scheme, but the apparent omission referred to makes it appear that the study of decimals is to be postponed until vulgar fractions and mensuration have been mastered. Though the formal study of decimals may be deferred until the Sixth Standard is reached, the use of a decimally-divided scale for measurements should certainly form part of the work in the Fifth Standard at least, if not at an earlier stage. Mensuration without decimals is an anachronism; and the Board of Education ought to state, through its inspectors or otherwise, that use should be made of scales divided into tenths, in the measurements of rectangles and rectangular solids, and of triangles, included in the course prescribed.

SOCIETIES AND ACADEMIES.

London.

Royal Society, December 14, 1905.—"An Investigation into the Structure of the Lumbo-sacral-coccygeal Cord of the Macaque Monkey (*Macacus sinicus*)." By Mabel Purefoy **FitzGerald.** Communicated by Prof. Francis Gotch, F.R.S.

From the examination of the cross-sections of the lumbo-sacral-coccygeal cord of the Macaque monkey (*Macacus sinicus*), it is seen that:—

(1) The maximum section area of the cord, of the white substance as a whole, as well as of the dorsal and the ventro-lateral columns, is found in the fourth lumbar region.

(2) The maximum section area of the grey substance as a whole, and of the dorsal and the ventral horns, is found in the fifth lumbar region.

(3) Reckoning the cross-sectional area of the cord as 100, the maximum percentage of the white substance as a whole, and of the dorsal and the ventro-lateral columns, is found in the first lumbar region.

(4) The maximum percentage of the grey substance is reached in the first coccygeal region.

(5) Reckoning the total area of the grey substance in each cross-section of the cord as 100, the maximum percentage of the dorsal horns is found in the third coccygeal region, and that of the ventral horns in the fifth lumbar region.

January 18.—"Observations on the Life-history of Leucocytes." By C. E. **Walker.** Communicated by Prof. C. S. Sherrington, F.R.S.

January 25.—"On the Origin of the Sertoli, or Foot-cells of the Testis." By C. E. **Walker** and Miss Alice L. **Embleton**. Communicated by Prof. C. S. Sherrington, F.R.S.

In animals, those cells set aside to produce definite sexual elements go through two divisions, the first and second maiotic (heterotype and homotype) divisions, and are then, without any further division, converted directly into spermatozoa. The same thing happens in the maturation of the ovum. No post-maiotic (post-homotype) divisions have hitherto been recorded.

In plants, on the other hand, after the second maiotic division has occurred, an apparently unlimited number of generations may be produced of cells that have gone through the maiotic phase, and consequently possess only half the somatic number of chromosomes. In the first of the above papers, the occurrence of maiotic phenomena is recorded among the leucocytes and the cells which are their immediate ancestors. According to these observations, after the first and second maiotic divisions have occurred, they are followed by an indefinite number of generations of cells possessing only half the somatic complement of chromosomes. The first maiotic division is preceded by amitosis and mitosis of the somatic character, just as happens in the testes of many animals, if not in all. It must be remembered that in certain plants only a few of the cells which have gone through the maiotic phase ever become sex cells. The others may form tissues having somatic characters and functions. This parallel between certain vegetable cells and leucocytes is carried further by the observations recorded in the second of the above papers.

Here it is stated that at an early stage in the development of the testis, before the tubules or pockets are formed, it is impossible to discriminate between the cells destined to become foot-cells and the leucocytes or their immediate ancestors in the same animal.

Among these cells, also, divisions are seen where the chromosome number is half what is found in the somatic cells. The conclusion drawn from this is that the undifferentiated cells which surround the male ova, and which eventually form both the foot-cells and the walls of the pockets or tubules of the testis, are derived from leucocytes or have immediately common ancestors. If these observations be correct, we have, therefore, animal cells which, though reduced, form tissues possessing somatic characters and functions known to happen in plants.

The bearing of these observations upon the cancer problem is obvious when the fusion between leucocytes and tissue cells recorded elsewhere is borne in mind.

May 17.—"Some Physical Constants of Ammonia: a Study of the Effect of Change of Temperature and Pressure on an Easily Condensible Gas." By Dr. E. P. **Perman** and J. H. **Davies.** Communicated by Principal E. H. Griffiths, F.R.S.

(1) The vapour density of ammonia at 0° has been found to be 0·77085 (mass of 1 litre in grams at latitude 45°), previous results being 0·7708 by Guye and 0·7719 by Le Duc.

(2) When the ammonia and the glass vessel were thoroughly dried no appreciable adsorption of ammonia by glass, or condensation of ammonia on the surface of glass, was found to take place.

(3) From density determinations at different temperatures, the coefficient of expansion of ammonia has been deduced as 0·003914 between 0° and −20°, and 0·003847 between 0° and 100°.

(4) From Rayleigh's determination of the compressibility of ammonia and our own value for the density, the molecular weight of ammonia has been calculated as 17·030, and the atomic weight of nitrogen as 14·007.

(5) Incidentally, the density of air free from water vapour *and carbon dioxide* has been determined as 1·2920 (lat. 45°).

(6) The deviation from Dalton's law for a mixture of approximately equal volumes of air and ammonia has been found to be about 1 part in 1000.

(7) The pressure-coefficient of ammonia has been determined, the pressure being atmospheric at 15°. Between 0° and −20° the coefficient was 0·004003, and between 0° and 98° it was 0·003802.

The determination of the vapour-pressure of liquid ammonia was repeated at some of the lower temperatures, using *pure* ammonia, in order to obtain an accurate value for its boiling point. From the results, the boiling point of liquid ammonia at 760 mm. pressure was found to be −33°·5 C.

June 7.—"On the Osmotic Pressures of some Concentrated Aqueous Solutions." By the Earl of **Berkeley** and E. G. J. **Hartley.** Communicated by W. C. D. Whetham, F.R.S.

This communication gives an account of measurements of osmotic pressures of aqueous solutions of cane sugar, dextrose, galactose, and mannite. The method adopted is that briefly outlined by us in vol. lxxiii., Roy. Soc. Proc. A gradually increasing pressure is placed upon the solution (which is separated from the solvent by a semipermeable membrane) until the solvent, which at first flows into the solution, reverses its direction, and is squeezed out. The pressure, when there is no movement of the solvent, is considered to be the osmotic pressure. Owing to the difficulty of determining the exact point at which no movement takes place, and for other reasons, the experiments are carried out so as to enable an observation to be made of the rate of movement of the solvent, both when the pressure on the solution is just below and when just above the turning-point pressure. The osmotic pressure is deduced from these rates. The range of pressures covered by the experiments is from 12 to 135 atmospheres.

A description is also given of the methods adopted for making the copper ferrocyanide membranes, and it is pointed out that with the best membranes, in most cases, a small quantity of solution comes through during the experiment. It is shown that even a small leak causes a considerable lowering of the observed pressure, hence the final results accepted are those where the leak was least.

Attention is directed to the fact that the osmotic pressures of cane-sugar solutions, when measured directly and when calculated from their vapour pressures, agree to within 3 per cent.

Zoological Society, June 19.—Sir Edmund G. Loder, Bart., vice-president, in the chair.—The nudibranchs of southern India and Ceylon, with special reference to the collections and drawings preserved in the Hancock Museum at Newcastle-on-Tyne: Sir Charles **Eliot.** This paper was an attempt to settle the synonymy of various Nudibranchiata of the Indo-Pacific with the help of Kelaart's drawings and the collections made by him and Walter Elliot, and now preserved at Newcastle. It also contained some new information as to the anatomy of several species (particularly *Platydoris formosa*, *P. papillata*, *Doriopsilla miniata*, *Kalinga ornata*, and several Pleurophyllidiidæ).—An account of the Entomostraca taken during a bathymetrical survey of the New Zealand lakes, and a comparison of this fauna with that of the English lakes: Dr. G. S. **Brady.**—A paper dealing with the higher Crustacea obtained during the above-mentioned survey: Prof. C. **Chilton.**—A classification of the Selachian fishes: C. T. **Regan.** The author stated that the Selachii were regarded as entitled to rank, at least, as a well-marked subclass, and he divided them into two principal groups, viz. Trematopnea and Chasmatopnea, the latter including the single order Holocephali.—An account of the polyclad Turbellaria from the Cape Verde Islands collected by Mr. C. Crossland: F. F. **Laidlaw.** The collection shows that, on the whole, the fauna of this region of the Atlantic agrees closely with that of the Mediterranean so far as the polyclads are concerned. The most interesting of the sixteen or seventeen species represented in the collection are, perhaps, a species of Anonymus (of which several specimens were taken) and *Traunfelsia elongata*, gen. et sp. nov. The latter is an elongated form remarkable for the possession of marginal tentacles, which are not usually associated with a long, narrow body in this class. A unique feature in this genus is the presence of a pair of alveolar glands, each with a long duct opening on either side of antrum masculinum. The genus is referred to the Diposthiidæ of Woodworth.—A large unknown marine animal observed off the coast of Brazil during a cruise in the Earl of Crawford's yacht the *Valhalla*: E. G. B. **Meade-Waldo** and M. J. **Nicoll** (see p. 202).

Royal Microscopical Society, June 20.—Dr. Dukinfield H. Scott, F.R.S., president, in the chair.—The structure of some Carboniferous ferns: Dr. D. H. **Scott.** The author pointed out the change which had taken place during the last three years in our conception of the Carboniferous ferns. So many examples of fern-like plants were now known to have borne seeds, or were suspected of having been seed bearers, that comparatively few undoubted ferns were left, and it was questioned whether, at least in the Lower Carboniferous, true ferns existed. One family, the Botryopterideæ, was admitted to be well represented in Lower as well as Upper Carboniferous times, and Mr. Newell Arbor had proposed to establish a group of Primofilices to include this and other primitive ferns of the Palæozoic age. The object of the communication was to give a few illustrations of this ancient race of ferns. The Botryopterideæ were first described, beginning with the type-genus Botryopteris. The genus Zygopteris was next considered. A new genus from the Lower Coal-measures of Lancashire, for which the name of Botrychioxylon was proposed, was then described. Two or three other examples of the family having been noticed, Dr. Scott described certain annulate fern sporangia. The germination of spores within a sporangium was demonstrated, and this sporangium had quite recently been identified as belonging to *Stauropteris Oldhamia*.

Chemical Society, June 21.—Prof. R. Meldola, F.R.S., president, in the chair.—The Cleve memorial lecture: Prof. T. E. **Thorpe**.—The constituents of the essential oil from the fruit of *Pittosporum undulatum*: F. B. **Power** and F. **Tutin**. The results show that the oil contains *d*-pinene, *d*-limonene, esters of valeric, formic and other acids, a sesquiterpene, palmitic acid, and a phenol.—Mobility of substituents in derivatives of β-naphthol: J. T. **Hewitt** and H. V. **Mitchell**.—The decomposition of nitrocellulose: O. **Silberrad** and R. C. **Farmer**. The decomposition products are ethyl nitrate, ethyl nitrite, ethyl alcohol, nitric and nitrous acids, ammonia, formic, acetic, butyric, dihydroxybutyric, oxalic, tartaric, *iso*saccharinic, and hydroxypyruvic acids. Carbohydrates were also present.—Note on gunpowder and bullets made about 1641, recently discovered in Durham Castle: O. **Silberrad** and W. S. **Simpson**. The gunpowder was found to approximate closely in composition to the black powder now used in this country. The ingredients had been merely ground and mixed together. It seems probable that this powder was of Prussian origin.—The constitution of acetone: Miss M. **Taylor**. The results prove that acetone does not behave either towards sodium or Grignard's reagent as *iso*-propenylalcohol, $CH_3.C(OH):CH_2$.—Diazo-derivatives of the mixed aliphatic aromatic ω-benzene-sulphonylaminobenzyl amines: G. T. **Morgan** and Miss F. M. G. **Micklethwait**.—Influence of substitution on the formation of diazoamines and aminoazo-compounds, part v.—*s*-Dimethyl-4:6-diamino-*m*-xylene: G. T. **Morgan** and A. **Clayton**.—Improved apparatus for the determination of molecular weights: P. **Blackman**.

Linnean Society, June 21.—Dr. A. Smith Woodward, F.R.S., vice-president, in the chair.—A contribution to the botany of southern Rhodesia: Miss L. S. **Gibbs**. The collections on which the report was based were obtained in August to October, 1905, at the end of the dry season. The air is dry and the sun's rays very strong, temperature from 80° to 90°, so that the country presented a burnt-up aspect, and the trees were bare, except a few evergreens. The veld is systematically burnt, to promote young growth for cattle-food, to the detriment or destruction of trees and shrubs. Distribution of species is wide, and the present paper tends to a confirmation, with many new records. Twenty-three new species are described, amongst the more interesting being the grass *Erianthus teretifolius*, Stapf, and a characteristic Elephantorhiza.—The authentic portraits of Linnæus: W. **Carruthers**. The author recalled the fact that in 1889 he made the subject the chief topic of his address at the anniversary meeting on May 24 of that year; he subsequently visited Sweden, Germany, and the Netherlands to inspect the originals, and read a paper detailing his results at the general meeting held on November 19, 1891; a transcript of his remarks had been prepared, but did not satisfy him, and nothing was published. The approaching bicentenary celebration of the birthday of Linnæus, for which the Swedes have been making extensive preparations, had induced him to revise his old transcript, and add some recently ascertained facts, which he now submitted to the society.—Plantæ novæ Daweanæ in Uganda lectæ: Dr. Otto **Stapf**. Mr. M. T. Dawe, officer in charge of the Forestry and Scientific Department of the Uganda Protectorate, made an expedition from Entebbe, through Buddu and the western and Nile provinces of that territory. His collections were transmitted from time to time to Kew, and his report was issued as a Blue-book (1906, Cd. 2904) last April; it gave an account of his journey, with some rough illustrations of specially noteworthy plants. Much new light is thrown on distribution, and new species are described, amongst them the new genus of Rutaceæ, Balsamocitrus, Stapf, and a new species of Warburgia (Canellaceæ). As an appendix, Mr. Dawe gives a summary of his report on the vegetation of the country traversed.—The genitalia of Diptera: J. **Hopkinson**. The structure of bamboo leaves: Sir Dietrich **Brandis**.

Physical Society, June 22.—Prof. J. Perry, F.R.S., president, in the chair.—The effect of radium in facilitating the visible electric discharge *in vacuo*: A. A. C. **Swinton**. It has been shown by Edison, Fleming, and others that the passage of the electric discharge *in vacuo* is much facilitated by heating the kathode. More recently it has been shown that the passage of the discharge is still further facilitated by coating the heated kathode with oxides of the alkaline metals. It is generally held that the efficacy of the hot oxides in this direction is due to their giving off negatively-charged ions or corpuscles. The author therefore decided to ascertain whether similar effects could be obtained by painting the kathode with radium, and as radium gives off corpuscles when cold, it was anticipated that it might not be necessary to heat the kathode. Using a continuous current up to 400 volts pressure, this was found not to be the case, the radium having no appreciable effect in producing a visible discharge. When the radium-coated kathode was heated to redness, the radium was found to have a very marked action in facilitating the production of a luminous discharge. Experiments were made which proved that the mere presence of radium in the tube was insufficient to produce the effect, and, furthermore, it was found that the tube would only allow visible discharges to pass in the direction that made the radium-treated electrode the kathode, the tube acting as a unidirectional valve in the same way as do tubes with kathodes coated with oxides.—The effect of the electric spark on the actinity of metals: T. A. **Vaughton**. It has been pointed out by several observers that some metals, such as aluminium, cadmium, zinc, magnesium, &c., although not radio-active in the ordinary sense of the word, yet have the power of affecting a photographic plate. The electric spark has a remarkable influence on this "actinity," in some cases causing an increase, and in others apparently diminishing it. The alteration is not merely momentary, but remains for months. It is, however, quite superficial, and may be removed by slightly rubbing the surface of the metal with emery-paper. In the case of aluminium sparked with gold, the direction of the current does not make much difference in the actinity of the sparked plate, but in the case of other couples the difference is very marked. For example, if a cadmium strip is sparked with antimony, the cadmium being connected with the positive terminal, the cadmium becomes very active photographically, not only on the spot sparked, but all over its surface. If, however, the cadmium is connected with the negative terminal and sparked with a positive terminal of antimony, the cadmium remains very slightly more active than if not sparked at all.—The dielectric strength of thin liquid films: Dr. P. E. **Shaw**. The range of voltage used in the experiments is from 25 to 400, and the corresponding spark-lengths vary from about 0·15 μ to 6·0 μ (μ = 0·001 mm.) for the insulating liquids used. The apparatus employed for measuring length is the micrometer designed by the author for measuring gauges (Proc. Roy. Soc., April). The substances used were olive oil, castor oil, linseed oil, rape oil, turpentine, fusel oil, oil of resin, cod-liver oil, neat's-foot oil, paraffin, transformer oil, the homologous series C_5H_{12}, C_6H_{14}, C_7H_{16}, C_8H_{18}, and armacell, ohmaline, and Sterling varnishes. The best insulators are paraffin and transformer oil, though for these, as for all commercial oils, great care was taken to remove water and acid by prolonged heating to 110° C., and treating with potassium carbonate. No simple connection can be traced between specific inductive capacity and dielectric strength.—The effect of electrical oscillations on iron in a magnetic field: Dr. W. H. **Eccles**. In attempting to make precise measurements of the effect of high-frequency oscillations on iron held magnetised by a magnetic field, two main difficulties are met. The one is that arising from the fact that the oscillatory currents induced on the surface of the iron investigated shield the inner layers, and thus make the mass of iron affected a variable quantity. The other difficulty arises in the matter of producing oscillations of determinate and invariable character. The author has endeavoured to meet the first difficulty by using oscillations so feeble that they affected only the outermost layers of the iron wires employed, and these even only slightly. The second difficulty has been met by using the oscillations produced in an open insulated solenoid by a single small measurable spark passed to one end of the solenoid.

EDINBURGH.

Royal Society, June 18.—Dr. Munro, vice-president, in the chair.—A study of the dietaries of students' residences in Edinburgh: Dr. Isabella **Cameron.** The objects of the investigation were to compare the dietary of the middle classes with that of the working classes, which had already been carefully studied, to ascertain how far this diet conformed to the various standard diets, and to investigate the question of the reduction of cost through combination. The dietaries of four men's residences and one women's residency were studied for one week, which was equivalent to 1129 men for one day. The average amount consumed per man per diem was: proteids, 143 grams; fats, 138 grams; carbohydrates, 511 grams; fuel value, 3973 calories. The expenditure came to fully 1*s.* 2*d.* per day per man, nearly double the cost of the average labouring man's diet. When compared with similar institutions in America, the Edinburgh residences were found to consume more proteid and carbohydrate, but less fat. There was also less waste.—The theory of epidemics: Dr. John **Brownlee.** The growth and decay of an epidemic seemed to depend on the acquisition of a high degree of infectivity at the start, this infectivity being then lost at a rate expressible mathematically as an exponential. This truth was realised by Dr. Farr, but the subject did not seem to have been pursued with any definite scientific aim. Dr. Brownlee had subjected various epidemic statistics to mathematical analysis, and had found that the curves representing their growth and decay could be well represented by Prof. Karl Pearson's curve of type iv. The correspondence was very close, except in the neighbourhood of the vertex. The general conclusion was that the condition of the germ had much more to do with the causation of an epidemic than the constitutional peculiarity of the persons affected at the moment. There was no evidence in favour of the idea that the epidemic ended because of the lack of susceptible persons.—The plant remains in the Scottish peat mosses, part ii.: Francis J. **Lewis.** This part had to do with the Scottish Highlands, the preceding part having discussed the peats of the Lowland Uplands. These Highland peat mosses began later than the Lowland mosses, and did not show the intercalated Arctic condition after the retreat of the ice-sheet. The bottom layers in the mosses in Caithness and Inverness had Arctic plants, but these were lacking in the Skye mosses, which accordingly were shown to have begun still later. The succession of layers was broadly similar to the succession already made out in the Lowland mosses, but in the Highland peats of recent age there were two distinct dry woodland mosses full of trunks of *Pinus sylvestris*, separated by a layer of sphagnum moss. The peat deposits over Scotland thus showed a definite succession of changes which could be correlated with the later stages of the Glacial epoch.

PARIS.

Academy of Sciences, June 25.—M. H. Poincaré in the chair.—The formation of endothermic compounds at high temperatures: M. **Berthelot.** According to the current thermodynamical theories, endothermic compounds can be formed and are stable at high temperatures. The author criticises the experimental observations adduced in support of this view, and concludes that no exact observation has been brought forward establishing, either in principle or in fact, that very high temperatures can cause a reversal of chemical affinity by directly forming endothermic compounds by simple heating.—The generalised problem of Dirichlet and Fredholm's equation: Émile **Picard.**—The radio-activity of gases evolved from the water of thermal springs: P. **Curie** and A. **Laborde.** The data given in a previous paper are corrected, and some additional determinations given for some new springs.—The action of steam upon sulphides at a red heat. The production of native metals: Armand **Gautier.** The sulphides of iron give rise to magnetic iron oxide, sulphuretted hydrogen and hydrogen. In the case of lead sulphide, taken as a type of the sulphide of a metal which does not decompose water, the primary products would appear to be lead, sulphuretted hydrogen and sulphur dioxide, the two latter substances reacting to give free sulphur. Copper sulphide gave copper, sulphur dioxide, and hydrogen. These experimental facts are applied to the consideration of volcanic phenomena. The condensation of $\beta\beta$-dimethylglycidic ester with sodio-malonic ester. Syntheses of terebic and pyroterebic acids: A. **Haller** and G. **Blanc.** Dimethyl-glycidic ester, heated on the water bath with sodio-malonic ester, gives 4-methyl-2:3-dicarboxyl-pentanolide-4, and this, boiled with hydrochloric acid, gives terebic acid, the latter being characterised by its conversion into isocaprolactone and pyroterebic acid. The external work created by the statical and dynamical actions of the internal work of the motor muscle: A. **Chauveau.** The treatment of pulmonary tuberculosis by serotherapy: MM. **Lannelongue, Achard,** and **Gaillard.** The identification of pathogenic Trypanosomes: attempts at diagnosis: A. **Laveran** and F. **Mesnil.** The serum of an animal which has acquired immunity against a particular trypanosome frequently possesses to a high degree specific properties which can be utilised for the identification of trypanosomes. The authors give a detailed account of experiments made in this connection, and show that the application of this method is not without difficulties. The indication for the anti-tuberculous vaccination of young ruminants by the alimentary canal: S. **Arloing.** Details of experiments on young goats are given from which the author concludes that complete immunisation can be effected by the aid of human or bovine tubercle bacilli, suitably modified, introduced into the alimentary canal.—M. Gernez was elected a member in the section of physics in the place of the late M. Pierre Curie.—The deformation of certain tetrahedral surfaces: G. **Tzitzéica.** A theorem of algebraic surfaces of the *n*th order: G. B. **Guccia.**—Differential equations of the second order and first degree the general integral of which is uniform: M. **Gambier.**—Diminution of velocity and change of trim of ships by the reflex action of water on the bottom: E. **Fournier.**—A simplified study of the effects of capacity of alternating current cables: A. **Blondel.**—Interferential photography: the variation of the incidence: polarised light: M. **Ponsot.**—An arrangement permitting of placing simultaneously several prisms in the position of minimum deviation: P. **Lambert.**—A simple method for the study of the movements of metallic vapours in the oscillating spark: G. A. **Hemsalech.** The sparks are blown on one side by a current of air of known velocity, resulting in curved lines in the spectrum, from measurements of which the tangential velocities of the metallic vapours can be determined.—The methods of photographing the absorption lines of the colouring matters of the blood: Louis **Lewin,** A. **Miethe,** and E. **Stenger.** Details of the apparatus used are given. The present note contains no results.—The heat of formation of carbonyl-hydroferrocyanic acid: J. A. **Muller.** The heat of combustion, determined in the calorimetric bomb, was 3444 calories per gram, from which the heat of formation was calculated as −122 cal.—The kathodic phosphorescence of europium diluted with lime. Study of the ternary system lime-gadolina-europia: G. **Urbain.**—The refractive index of substances dissolved in other solvents than water: C. **Chéneveau.** Results are given for solutions of lithium chloride in water, methyl and ethyl alcohols, and in glycerol.—The variations in state undergone by amorphous carbon under the influence of a sudden variation of temperature: O. **Manville.** The variation in state was measured by the alteration in the temperature at which the carbon commenced to give carbon dioxide in a current of oxygen.—The double sulphate of iridium and potassium, $Ir_2(SO_4)_3 \cdot 3K_2SO_4$: Marcel **Delépine.**—The properties of the substances formed by the action of hydrochloric acid upon certain metallic silicides: M. **Boudouard.** These substances contain hydrogen, and may be regarded as mixtures in variable proportions of silicoformic anhydride and silico-oxalic hydrate.—The crystallography of iron: F. **Osmond** and G. **Cartaud.**—The action of oxygen on rubidium-ammonia: E. **Rengade.** The three metals potassium, cæsium, and rubidium, dissolved in liquid ammonia, give in presence of oxygen a white dioxide and a yellow tetroxide. Potassium and cæsium give in addition a dark trioxide, but there is no evidence of the formation of an analogous oxide of rubidium.—Researches on the pyrazolones: new methods of synthesis: Ch. **Moureu** and J. **Lazennec.** The reaction between the arylpropiolic esters and hydrazine, forming pyrazolones has been extended to the alkylpropiolic esters. The pyrazolones can also be obtained when the ester is replaced by the amide or by the β-oxyalkylacrylic esters obtained from the acetylene compounds by a method described in a previous paper. The theory of the reactions is discussed.—Phenyl migrations in the halohydrins and in the α-glycols: M. **Tiffeneau**. Cinnamenyl-paraconic acid: J. **Bougault**.—Researches on the relations of functional groups in distant positions: cyclic amines: E. E. **Blaise** and M. **Houillon**. Octamethylene diamine chlorhydrate gives by the action of heat an unsaturated hydrocarbon and a secondary cyclic base. This has been proved to be identical with a synthetically prepared specimen of butylpyrrolidene.—The basicity of the xanthyl oxygen: R. **Fosse** and L. **Lesage**. A description of a series of double salts, of which xanthyl-lead bromide, $CH(C_6H_4)_2O.Br+2PbBr_2$, may be given as a type.—The production of Ascidia by traumatisms: L. **Blaringhem**.—The origin of the materials utilised by the ovary: Jean **Friedel**. The assimilating power possessed by the green carpels of many plants is well known. From experiments on *Ranunculus acris* the author concludes that the ovary utilises both its own products of assimilation and the reserves of the peduncle. If the conditions in which it is placed suppress one of these two modes of nutrition, the ovary can arrive at complete development from the other.—The longevity of seeds: Paul **Becquerel**. Experiments were carried out on 550 species belonging to fifty families, the age of which varied from twenty-five to 135 years. The only seeds preserving their vitality for more than eighty years were those protected by a thick skin and possessing slightly oxidisable reserves.—A disease of the plane tree due to *Gnomonia veneta*: J. **Beauverie**.—Some new Madagascan Asclepiadaceæ producing caoutchouc; J. **Costantin** and I. **Gallaud**.—The biology of the Virgularia: Ch. **Gravier**.—A new form of operculated Cirripede, *Pyrgopsis Annandalei*: A. **Gruvel**.—Prehistoric remains in the neighbourhood of Kayes, Soudan: Fr. **de Zeltner**. The deposits of stone instruments are large, and formed out of rocks still existing in the district. The instruments cannot be classified with any of the usual European types, are highly polished, and show considerable skill in their manufacture. It is impossible at present to fix their age.—A method of isolating the hæmatablasts of the blood in a state of purity: L. Le **Sourd** and Ph. **Pagniez**.—Researches on animal electricity: MM. **Girard** and Victor **Henri**. The *rôle* of the cellular elements in the transformation of certain carbohydrates by the intestinal juice: H. **Bierry** and A. **Frouin**.—The problem of statical work: Ernest **Solvay**. A criticism on a paper of M. Chauveau on the same subject.—The sensibility of the retina for luminous radiations: Milan **Štefánik**. Using a spectroscope with glass prisms and a suitable coloured screen the red end of the spectrum is visible with sufficient clearness for measuring the lines down to λ 3830. The photographic results obtained by M. Millochau with the same apparatus give the same limit. It follows that the retina is sensible for all the radiations which pass the spectroscope.—The use of sodium chloride in the histological impregnation of tissues by silver: Ch. **Achard** and M. **Aynaud**. An experimental proof of the view recently put forward by M. Quinton that the results are due to the presence of sodium chloride in the intercellular spaces, the chloride of silver thus formed darkening in the light.—A method of detecting iron in living tissues: A. **Mouneyrat**.—Study of the transmissibility of tuberculosis by alimentary casein: Marcel **Guédras**. Food products for infants containing dried casein as a base may transmit tuberculosis. Casein dried at a low temperature may still contain the tubercle bacillus.—The extension of the marine invasion of the upper Sparnacian in the neighbourhood of Paris: Paul **Combes**, jun.—The existence of the Cretacean in the Oran schists: MM. **Ficheur** and **Doumergue**.—The Yprés clays of the department of Aisne and the climatic conditions at the Lutetian epoch: Paul **Fritel**.—The trajectory of electric corpuscles in space under the influence of terrestrial magnetism, with applications to the aurora borealis and to magnetic disturbances: Carl **Störmer**.—Two relief maps of Paringu and Soarbele (Southern Carpathians) executed from unpublished topographical sketches: E. **de Martonne**.

Calcutta.

Asiatic Society of Bengal, June 6.—Indian meteorites recently acquired by the Geological Survey: L. L. **Fermor**. The crusts of some of them show interesting flow-structures.—(1) Notes on a rare Indo-Pacific barnacle. Remarks on *Conchoderma hunteri*, Owen, which the author, agreeing with Hoek, regards as a variety of *C. virgatum* (Spengler). (2) Contributions to Oriental herpetology. No. 4. Notes on the Indian tortoises. Remarks on some obscure species, with a list of the Indian Chelonia. (3) Notes on the common Hydra of Bengal: Dr. N. **Annandale**. The systematic position of *Hydra orientalis* is discussed, with a description of its anatomy. As the result of two years' investigation, the author concludes that the species is diœcious, but that sexual reproduction plays an unimportant part in the life cycle.—Rawāts and Merāts of Rajputana: R. C. **Bramley**.—An old reference to the Bhotias: H. **Beveridge**.—Parasites from the Gharial (*Gavialis gangeticus*, Géoffr.): Dr. **von Linstow**. Two new nematodes, each representing a new genus, and a new linguatulid are described. The former were found in the stomach and on the mesentery; the latter in the lungs and trachea.

New South Wales.

Royal Society, May 2.—Mr. H. A. Lenehan, president, in the chair.—Annual general meeting. An address was delivered by the president.—A specimen of diamond in the matrix: E. F. **Pittman**. The specimen was found by Messrs. Pike and O'Donnell in their claim at Oakey Creek, near Inverell. The diamond is a small one, weighing about one-third carat, and the material in which it is embedded is an igneous rock known as dolerite. The dolerite occurs at Oakey Creek as a pipe or dyke, and the specimen is of special interest as throwing some light upon the question of the origin of the diamond.

CONTENTS. PAGE

THURSDAY, JULY 19, 1906.

SOME RECENT MATHEMATICAL WORKS.

Correspondance d'Hermite et de Stieltjes. Edited by B. Baillaud and H. Bourget. Vol. ii. Pp. viii+404. (Paris: Gauthier-Villars, 1905.) Price 16 francs.

G. Lejeune Dirichlet's Vorlesungen über die Lehre von den einfachen und mehrfachen bestimmten Integralen. By G. Arendt. Pp. xxiv+476. (Brunswick: Friedrich Vieweg and Son, 1904.) Price 12 marks.

Le Calcul des Résidus et ses Applications à la Théorie des Fonctions. By Ernst Lindelöf. Pp. viii+144. (Paris: Gauthier-Villars, 1905.) Price 3.50 francs.

Les Principes des Mathématiques. By Louis Couturat. Pp. viii+342. (Paris: Félix Alcan, 1905.)

Méthodes de Calcul graphique. By Frederico Oom. Pp. 26; with 4 plates. (Lisbon: Imprimerie nationale, 1905.)

Volume and Surface Integrals used in Physics. By J. G. Leathem. Pp. 48. (Cambridge: University Press, 1905.) Price 2s. 6d. net.

Recherche sur les Champs de Force hydrodynamiques. By V. Bjerknes. Reprinted from *Acta Mathematica*, vol. xxx. Pp. 146.

Sur la Recherche des Solutions particulières des Systèmes différentiels et sur les Mouvements stationnaires. By T. Levi Civita. Pp. 40. (Warsaw: J. Sikorskiego, 1906.)

ONE of the most noticeable features of recent times has been the increasing interest taken in the history of mathematics. That two international congresses—the historical and the mathematical—have devoted separate sections to this study is, let us hope, a stepping-stone towards the realisation of the resolutions passed at both congresses in favour of the establishment of chairs of mathematical history in the leading universities of the Continent and America, and possibly even Great Britain.

Reference has previously been made to the first volume of the interesting correspondence between Hermite and Stieltjes. The second volume, covering the period 1889–1894, is no less delightful reading than the first. Every letter fills up some gap in the reader's mathematical knowledge, either by introducing him to some little-known proposition or by presenting some well-known result in a new aspect. An appendix contains four letters addressed by Stieltjes to Prof. Mittag-Leffler in 1885–1887 dealing with Riemann's Zeta function. These letters afford a striking insight into the difficulties experienced by Stieltjes in his efforts to master Riemann's works and his ingenuity in devising alternative methods. The present volume contains a portrait of Hermite and the facsimile of a manuscript by Stieltjes.

The historic spirit has further shown itself in Prof. Arendt's issue of the nearest possible approach to a verbatim report of the lectures on definite integrals as given by Dirichlet at Berlin in 1854. It is true, as the author points out, that the lectures which Dirichlet gave on the same subject at Göttingen four years later formed the basis of the well-known treatise by Gustav Ferdinand Meyer, but it appears that the notes on which Meyer's account was based were far from complete, and it was necessary to spend considerable time in filling up the gaps in the reasoning, and, moreover, the object was to give a complete treatment of the subject rather than an exact account of the lectures. Prof. Arendt, on the other hand, has compiled the present work from a set of notes mostly transcribed on the actual dates of the lectures. The course covers a branch of mathematics well known to the average student, namely, the definition of an integral and its connection with summation, the theorems on change of limits and differentiation of integrals, the evaluation of the ordinary well-known definite integrals, the Beta and Gamma functions, transformation of multiple integrals, the attractions of ellipsoids, and applications to harmonic and hypergeometric series. The notes at the end afford evidence of the care with which the original manuscript has been followed; where any divergence has been necessary the changes are carefully pointed out; the only important innovation, however, is the introduction of the modern notation $|a|$, which greatly simplifies certain formulæ. At the present time these lectures of Dirichlet make an excellent text-book, and an interesting historical comparison may be made between the present course and Kronecker's lectures delivered at the same university about thirty years later.

Another prominent place among the "classics" must be assigned to Prof. Ernst Lindelöf's charming exposition of Cauchy's calculus of "residues." This is the eighth of a series of monographs on the theory of functions appearing under the editorship of Prof. Émile Borel. In Prof. Lindelöf, Cauchy's ideas have found an able exponent, and from a detailed study of a number of papers, including some of Cauchy's little-known writings lent for the purpose by Prof. Mittag-Leffler, the author has produced a treatise in which the simplicity and perfection of this important method of analysis are well shown. Of the applications, those in the second chapter are mainly due to Cauchy. The third shows how certain formulæ of summation can be immediately deduced from the same principle, while in the fourth it is shown how this method of treatment greatly simplifies the study of the Gamma function and of Riemann's function. Of the importance of the latter application the difficulties of Stieltjes already referred to give sufficient proof, and on the other hand the name of Stieltjes figures conspicuously in the discussion of Stirling's series, in connection with which Prof. Lindelöf contributes several new results and proofs. Finally we have a general account of certain modern results relating to functions defined by Taylor's series, thus bringing into one small volume a general survey of the recent as well as the original developments of Cauchy's method. The book includes new matter for which the author is himself responsible as regards methods of treatment no less than as regards results.

A second line of modern mathematical development consists in the attempt to probe ever deeper and deeper into the foundations of mathematics. In France, where everything mathematical is as popular as it is unpopular in England, the philosophy of mathematics has taken such hold of public thought that the multiplication of books on the subject has in a small way resembled the multiplication of school geometries with us. But a philosophical treatise stands on a very different level from a mere examination text-book, and if we have been somewhat severe in the past in our criticisms of the work of isolated writers in France, it was felt that what was wanted was something more than a number of isolated writings, each, from the nature of the case, presenting the views of one individual without much reference to the subject and its literature considered as a whole. The opening words of M. Couturat's preface, "The present book has no pretension to originality, and this is precisely what ought to recommend it to the reader," show that the author has been at great pains to fill the want. His book is to a large extent based on Mr. Bertrand Russell's English treatise with the same title, and is intended to provide a *résumé* of our present knowledge on the philosophy of mathematics. It is somewhat remarkable that up to the middle of last century logic and mathematics were regarded as essentially distinct, and it was largely the result of the labours of Boole, Peano, Cantor, and others that led to the gap being filled and to the opening out of what has proved to be one of the most fertile regions of modern thought. The complete rapprochement owes its existence very largely to the symbolical logic or "logistic" of Peano, and leads to the conclusion that mathematics is entirely and exclusively founded on the principles of logic. This view is, as M. Couturat shows, diametrically opposed to the philosophy of Kant of which a summary has been given in the appendix. It need hardly be said that Russell's treatment is in many places closely followed, and it is the author's hope that the book will induce French writers to contribute to our knowledge of mathematical philosophy in a way that has not been done hitherto.

A perusal of Mr. Oom's pamphlet will convince any reader that however much has been done elsewhere in facilitating calculations by the introduction of graphical methods, the observatory of Lisbon under the directorship of Vice-Admiral Campos Rodrigues has made a number of very distinct advances. For the correction of level and deviation error diagrams are used, as also for the corrections due to precession, and a still happier thought is the construction of slide rules for the performance of addition operations other than the addition of logarithms performed by the ordinary slide rule. Thus, for example, a slide rule graduated in reciprocals is used to work out relations between the conjugate foci of a lens; another, graduated in squares, is applicable to quantities connected by the relation between the sides of a right-angled triangle, and is particularly useful for calculations of probable error, and so on. Possibly some reader of NATURE will write and say that these slide rules have been in existence previously. In any case they are worthy of note, and M. Rodrigues appears to have devised them "off his own bat."

The issue of a series of "Cambridge Tracts in Mathematics and Mathematical Physics" under the able editorship of Messrs. Leathem and Whittaker affords evidence of the activity of the younger generation of Cambridge mathematicians. The idea is a good one. Many people have ideas about the best methods of treating some particular piece of work, which do not cover a sufficiently wide range to form a book, and are unsuitable for publishing and possibly burying in a volume of transactions. So much is this the case that we should not be surprised if Mr. Leathem finds himself besieged by tracts submitted for publication. His own contribution deals with an important point. Many physicists in the solution of problems have had to transform volume and surface integrals in a way that they either have known or ought to have known was not perfectly rigorous, but with the knowledge that the results would be all right; this particularly applies to integrals extending to infinity, and we have here in a convenient form a study of these transformations in their mathematical aspect. In discussing the application of infinitesimal analysis to potential properties of bodies of discontinuous structure, Mr. Leathem introduces the notion of *physical smallness*. The term is, perhaps, not altogether a happy one, as physics concerns itself not only with bodies of finite size, but with molecules which are of a higher order of smallness than the elements contemplated. The important point is that the applications of differential equations are based on the consideration of elements which for purposes of analysis may be regarded as infinitesimal, but which may be regarded, on the other hand, as infinitely great compared with the dimensions of molecular structure. It would be better to call such elements "differential elements" since they represent the $dx\ dy\ dz$ of the formulæ. The careful discussion of the legitimacy of the assumptions involved, as given by Mr. Leathem, is important, as we often find unscientific writers announcing as a great discovery the view that there is no such thing as temperature, quite forgetting that the notion of "temperature at a point" stands on much the same footing as that of "density at a point" or, indeed, many other similar concepts without which the study of mathematical physics would not have made the progress that it has made.

The series of papers and books by C. A. Bjerknes the father and V. Bjerknes the son well illustrate the proper spirit of scientific inquiry as opposed to the spirit of the unscientific faddist whose rejected addresses give so much trouble to reviewers. The discussion of the fields produced by bodies moving in fluids, if it has not given us a new theory of matter has certainly greatly helped us to understand the lines on which such theories should be laid down. The elder Bjerknes confined his attention to solid spheres moving in liquid; in the present instance, "bodies" are represented by portions of fluid differing from the remainder by the fact that in the latter the equations take a simple form. But is not this merely the vortex atom theory? It is true that on pp. 134–7 Prof. Bjerknes compares his results with those of von Helmholtz and Lord Kelvin, and points out the differences in his method of treatment, but all these investigations are only different developments of the same fundamental ideas.

In recent years, Prof. Levi Civita has published a number of papers in the *Atti dei Lincei* dealing with particular solutions of the equations of dynamics, and in especial with stationary motions. At the invitation of Prof. Dickstein he has now prepared a simplified account of these researches for the transactions of the "Prac matematyczno fizyczynych," published at Warsaw. The original starting point of the investigation was the method of ignoration of coordinates, but the conclusions have now been shown to be results of a general principle applicable to any system of ordinary differential equations. They form a development of the work of Routh, and the stationary motions investigated by the author of "Rigid Dynamics" are shown to belong to a particular class to which Prof. Levi Civita gives the name of "mouvements à la Routh." G. H. B.

A TREATISE ON CHEMISTRY.

A *Treatise on Chemistry*. By Sir H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S. Vol. i. The Non-Metallic Elements. New edition, completely revised by Sir H. E. Roscoe. Pp. xii+931. (London: Macmillan and Co., Ltd., 1905.) Price 21s. net.

SIR HENRY ROSCOE is to be heartily congratulated by all chemists on the appearance of a new edition of the first volume of Roscoe and Schorlemmer's "Treatise on Chemistry." This volume deals chiefly with the non-metallic elements, and is now in its third edition.

Many chemists remember the interest which the first appearance of this volume excited in 1877. Printed in large, clear type, with excellent illustrations, it was recognised both here and on the Continent as a clear and readable account of the facts relating to the chemistry of the non-metallic elements. If the student failed to find in it any new light on the obscurities of chemical theory, he at any rate was put in possession, not merely of the facts, but of the facts stated with a due regard for the history of their discovery which was then and is still foreign to the ordinary "handbook." There were, moreover, many experimental details of service to workers in the laboratory recorded in the volume which were at that time not easily accessible to the ordinary student. During the nearly thirty years which have elapsed since the first edition appeared, many treatises have been published in other languages, notably in German, but the treatise of Roscoe and Schorlemmer still retains a certain individuality for which it will be valued.

In preparing this edition Sir Henry Roscoe has had the valuable assistance of several collaborators with special knowledge, and their handiwork is to some extent evident in the different literary treatment which may be discerned in various sections of the book.

The first section of the volume relates to the general principles of the science, including a description of the properties of gases and liquids, and a very intelligible account of the development of the atomic theory. A clear sketch is given of the theory of electrolytic dissociation. This portion of the volume would have been improved by some concrete illustrations of the methods of determining atomic weights. As it is, the reader must be very much at sea in understanding what this constant actually means, apart from the implications of the atomic theory.

The remainder of the book is occupied with an account of the properties and modes of preparation of each of the non-metallic elements and their chief compounds. The history of each element is succinctly and well described, and important industrial applications are also alluded to. There is an excellent account of the modern manufacture of illuminating gas and of acetylene, as well as of the commercial processes adopted for the production of a number of the elements and their compounds which find industrial uses.

There is also a very complete account of the preparation and properties of the new gases of the atmosphere, argon, &c., which, while interesting, does not throw any new light on the obscure chemical relationships of these elements. In this connection the absence of an account of the periodic classification under the general principles of the science is specially felt. It would have been better to have included in the first part of this volume a complete consideration of the general principles of chemistry, including the determination atomic weights, instead of reserving the discussion of the periodic classification and other matters of principle for the subsequent volume relating to the metals.

When the first edition of this volume appeared, many of the lecture experiments described were new, and were of interest and value to the teacher. A number of these are now generally familiar, whilst some of those still described have since been improved upon. This feature is indeed no longer a striking one in the book. Very few new lecture or laboratory experiments are included. The teaching of chemistry is, however, no longer conducted on the old lines, and perhaps the teacher would not now look to a treatise of this kind for this information. The fact that in some sections of the work pains are taken to describe fully striking lecture experiments whilst in other and newer sections this aspect is entirely neglected is a defect in the general plan of the book which might be remedied in future editions.

This raises the question as to the characters which such a work as this should possess to be of real utility at the present day. Handbooks and text-books of chemistry for the teacher abound, many of them excellent as practical guides to the work of the lecture room and laboratory. Then there are more ambitious works purporting to be of the nature of treatises. These, however, are too often ill-assorted and ill-considered collections of the facts and theories of chemistry utterly lacking in those literary qualities without which no work of the kind can expect to appeal to the general reader or to take any permanent place in the literature of the science. There is still room for a treatise in the broad sense of the word, in which the facts and doctrines of modern chemistry are expounded in a lucid manner free from the details and technicalities which are essential in a handbook or text-book. Such a work should appeal to the teacher and to the student as a work of reference, and also to the outsider, it may be a worker in another department of science, who wishes to understand what the science of chemistry now is without being confronted with all the bewildering and conflicting details of the subject, such as the advanced student may find in Watts's Dictionary or in many German works on chemistry.

Such a treatise, perfect as a broad and general description and discussion of the science of chemistry, has not yet been written in English. Roscoe and Schorlemmer's treatise, however, still remains the nearest approach to the ideal.

POPULAR EVOLUTIONARY THEORY.

Darwinism and the Problems of Life; a Study of Familiar Animal Life. By Prof. Conrad Guenther. Translated by Joseph McCabe. Pp. 436. (London: A. Owen and Co., 1906.) Price 12s. 6d. net.

THIS is a disappointing book. The idea of using the common sights and sounds of nature which are open to general observation as material for building up a detailed comprehension of evolutionary theory is a good one; there is much to be said for the inductive system of instruction as a supplement to the deductive methods more often employed. But in this particular instance the errors in matters of fact are so prominent and so numerous as to overshadow such merit as the plan of the work possesses. Some of these mistakes must be laid to the charge of the translator, who obviously is but imperfectly acquainted with the subject-matter of his original, and whose want of due care appears in the occurrence of such phrases as "the grouping of their elements is different from in dead albumen," "Pentastomum has little of the characteristics of a spider, to which it really belongs," and of such unwonted forms as "terrestial," "adaption," "caracoid," "strepsitera"—the last two being found more than once. "Sexually," on p. 301, is clearly intended for "non-sexually." "An example of a genius under the generic title" is capable of easy emendation, but "weel" (p. 220) almost baffles conjecture. Can it be meant for "valve"?

The "processionary butterfly" is, of course, a moth; the "tentacles" of the stag-beetle (p. 91) are apparently its mandibles; we hear for the first time of the "bones" of articulates, and that our muscles are "secretory products." It is implied on p. 143 that the adder is not poisonous. This is surprising until we find from other passages that the author's "adder" is not an adder at all, but the harmless ringed snake. A sentence on p. 226 is absolutely unintelligible, unless we may conjecture that the word "falls" is an attempt to render the German "Fälle," here obviously used in the sense of "cases."

It is charitable to the author to suppose that not he but his translator is responsible for the statement that "in the case of moths and grasshoppers there is not a very great difference in habits between the larva and the imago." But when we find it stated that "in the grasshoppers the front extremities have become a powerful leaping apparatus"; that an insect is covered with "dust" by the "stigma" of a flower; that "if we take two beetles that seem absolutely like each other and only differ in size" they are of different species; that "the frogs have only one chamber to the heart"; and that "iron is always found combined with sulphur," it is difficult to avoid the conclusion that the author has to answer for mistakes of his own.

There are advantages in using the popular names of natural objects in a book intended mainly for the unlearned. But a protest must be entered against the slovenly habit, too common with translators, of contenting themselves with a literal rendering of such names into another language. How, for example, is the English reader to identify the "small nocturnal peacock's eye"? If the scientific name be disallowed, at least the recognised English popular title should be given.

Many of the author's conclusions on the main subject are sound enough. It is the more to be regretted that his statements of fact are so often open to adverse criticism, and that he has been, on the whole, so badly served by his translator. F. A. D.

OUR BOOK SHELF.

Aufnahme und Analyse von Wechselstromkurven. By Dr. Ernst Orlich. Pp. viii+117. (Brunswick: F. Vieweg and Son, 1906.) Price 3.50 marks.

IN the usual handbooks on alternating currents the methods of study of the wave-form of the alternations and the analysis of the curves of E.M.F. and current obtained are usually treated very scantily. Recently, however, the subject has attracted considerable attention, and its importance to a station engineer, who wishes to make alternators not identical in design run well in parallel, is now recognised.

Prof. Orlich, of the Reichsanstalt, has endeavoured in this little book to present a clear account of what is known on the subject. It begins by definitions and a short mathematical introduction to the use of Fourier series, &c. Then follow descriptions of various methods of taking curves by the point-to-point process, and of the apparatus of Rosa, of Callendar, and of Hospitalier's "Ondographe."

The Braun tube is described and illustrated, but no mention is made of the fact that owing to the kathode-ray bundle not being composed of rays of the same magnetic deflectability, and the consequent lack of sharpness of the moving image, its use for the study of alternating currents is limited rather to qualitative than to quantitative work. The next chapter deals with oscillographs in their various forms. Their theory is discussed, and the advantages of the different patterns of moving needle and bifilar instruments pointed out.

The recent experiments on telephony of Mr. Duddell, and the wonderful curves shown by him at his recent lecture at the Royal Institution on the analysis and transmission of sounds, show that substantial advances have recently been made in the construction of very sensitive oscillographs of his pattern, the curves of currents furnished by an ordinary microphone being readily shown to a large audience.

After a chapter on the phenomena of resonance, the concluding portion of the book deals with the analysis of curves, with descriptions of the best-known forms of harmonic analysers, including those of Henrici, and the machine devised by Michelson and Stratton for their analysis of visibility curves of interference fringes.

The information given in the book seems, on the whole, fairly complete and accurate. The word "periode" seems used in a loose sense, sometimes as "time of a single oscillation" and sometimes as "frequency." J. A. HARKER.

Cultures du Midi de l'Algérie et de la Tunisie. By C. Rivière and H. Lecq. Pp. xii+511. (Paris: J. B. Baillière et Fils, 1906.) Price 5 francs.

IN view of the fact that inside the British Empire agriculture is being practised under all sorts of tropical and semi-tropical conditions, there is a singular paucity of books in the English language dealing with the cultivation of exotic plants. The book before us, one of the "Encyclopédie agricole" series, reviews briefly the whole range of plants which are cultivated economically in the Mediterranean region belonging to France, *i.e.* in Provence, Algeria, and Tunis. This is a very special district possessing a characteristic flora adapted to its well-marked climatic conditions of insufficient rainfall which falls mainly in the winter, great heat and dryness in the summer, excessive radiation resulting in extreme variations of temperature, with sharp frosts in the winter, incessant wind, and an all-pervading sun. Under these conditions many forms of agriculture are only possible where irrigation water is obtainable, and much of the country is little better than bare rock or sand; there are, however, many important cultures, special to the district, which have been brought to a high state of perfection by the inhabitants of the Côte d'Azur.

The most distinctive example is perhaps the growth of plants for scent and essences which has its centre at Grasse, but which has been extended into both Algeria and Tunis; the rose, the orange-flower, the tuber rose, the violet, and the jasmine being the most important of the flowers thus cultivated. The olive, that most distinctive feature of all Mediterranean landscapes, is losing ground, we learn, being displaced by the competition of oils like cotton-seed and sesame; in Provence, also, the land is wanted for more intensive forms of cultivation, such as the production of early vegetables and cut flowers.

The book of MM. Rivière and Lecq suffers somewhat from the very extensive ground it has to cover; the accounts of each plant in cultivation have to be so curtailed that the details are insufficient for the needs of the practical man, who will, however, find an excellent series of references to more special books and articles on each subject. The book may be of considerable service to many of our colonists living in semi-arid countries and looking round for suitable and remunerative crops to grow; from it they can obtain both ideas as to possible introductions and such economic information as to the labour required and the probable value of the returns as may enable them to embark on the experiment with some prospect of success.

Tabulae Botanicae. (Part i., containing plates i. and ii.) Edited by E. Baur and E. Jahn. (Berlin: Gebrüder Borntraeger, n.d.) Price per plate: paper, 7 marks; cloth, 10 marks. Series of five, 25 marks.

UNDER this title the publishers announce a series of coloured illustrations of plants intended for lecture purposes, and arranged in sets for each subject, order, or class. The two diagrams received illustrate the Myxobacteriaceæ, the one representing successive stages in the life-history of *Polyangium fuscum*, selected as a general type, the other depicting the fructification, spores, &c., of Myxococcus and Chondromyces as special details. So far as one can judge from these specimens, the drawing entrusted to Ehrlich, of Berlin, promises to combine correct representation and artistic treatment, and the publisher's name is sufficient guarantee for good reproduction; the paper selected is not strong enough to withstand wear and tear, but at a somewhat higher price the plates may be obtained backed with linen and attached to rollers. The size of the diagrams, about 5 feet by 3 feet, is sufficiently large for most practical purposes. The short prospectus prefixed to the accompanying text provides little information, except to say that the plates will be designed two, three, or more to each subject, that the series will cover the whole field of the anatomy and the life-histories of plants, and that the lower plants will receive especially full treatment.

Reports of the Expedition to the Congo, 1903–5. Liverpool School of Tropical Medicine, Memoir xviii. Pp. 74. (London: Williams and Norgate.) Price 7*s.* 6*d.* net.

IN this report, the late Mr. Dutton and Dr. Todd contribute an important paper on gland-palpation in human trypanosomiasis, in which they show that most early cases of trypanosomiasis have enlarged glands, and can therefore be detected by gland-palpation. A second paper by the same authors discusses the distribution and spread of sleeping sickness in the Congo Free State. This is illustrated by four maps, which demonstrate very clearly the enormous extent of territory in which this terrible disease is now met with compared with twenty years ago. This is in great measure accounted for by the increase in travel following the opening up of the country. Two new Dermanyssid Acarids from monkeys' lungs are described by Mr. Newstead and Dr. Todd, and Dr. Stephens and Mr. Newstead contribute a paper on the anatomy of the proboscis of biting flies. It will thus be seen that the report contains matter of considerable interest, and the general "get up" leaves nothing to be desired.

Ten Years' Record of the Treatment of Cancer without Operation. By Dr. Robert Bell. Pp. 107. (London: Dean and Son, Ltd., 1906.) Price 2*s.* 6*d.* net.

IT is difficult to understand the *raison d'être* of this book, which consists mainly of a diatribe against the modern surgical treatment of cancer, and a veiled recommendation of the author's method of treatment by medicinal and hygienic measures. As regards any "record" of ten years' treatment by the author's methods we find little evidence—"several cases" eventually got quite well (p. 42), a case "recovered completely" (p. 43), a case in which "the tumour quite disappeared" (p. 63), three cases in which "recovery was complete" (p. 71). This constitutes the "record"; can the author be surprised if his views and methods be received with scepticism?

R. T. H.

The Opal Sea. By John C. Van Dyke. Pp. xvi+262. (London: T: Werner Laurie, 1906.) Price 6*s.* net.

PROF. VAN DYKE provides in these pages a readable account of many branches of modern oceanography expressed in a literary form too seldom found in works dealing with scientific subjects. As one would expect, the romance and poetry of science are given great prominence, and the attractive word-pictures reveal the fascinating nature of the work of the man of science. Many readers of these essays will be encouraged to undertake a more precise study of the physical geography of the sea from formal treatises.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Stability of Submarines.

SIR WILLIAM WHITE, in his paper in the Roy. Soc. Proceedings (vol. lxxvii. A., p. 528), discusses the hydrostatic forces tending to stability or instability of a submarine at the surface of the water. When the vessel is in motion, hydrodynamical forces come into play from the stream-line action of the water, and these also will affect the stability of the vessel. Sir W. White insists that these forces can only be examined experimentally, and has no data to give as to their magnitude. Although it is obviously impossible to obtain an exact calculation of the magnitude of these hydrodynamical forces, yet it may be worth noticing that a very simple calculation will give an approximation to their value, which at least is of importance in that it suggests that the question is one of extreme gravity.

The principle involved is, of course, the well-known principle by which an ellipsoid moving through still water tends to turn so that its smallest axis is in the direction of motion.

We may obtain a first approximation to the stream-line action by treating the submarine as a cigar-shaped spheroid, and assuming it to be completely immersed in an infinite ocean. Let a, b denote the semi-axes of the spheroid, and let it be moving with velocity V, its major axis making a small angle θ with the horizontal. The couple tending to decrease θ is known to be

$$\tfrac{1}{2}V^2 \sin 2\theta \left(\frac{\alpha}{2-\alpha} - \frac{\beta}{2-\beta}\right)D,$$

where

$$\alpha = -2ab^2\left\{\frac{1}{(a^2-b^2)^{\frac{3}{2}}}\log\frac{a-\sqrt{a^2-b^2}}{b} + \frac{1}{a(a^2-b^2)}\right\},$$

$$\beta = ab^2\left\{\frac{1}{(a^2-b^2)^{\frac{3}{2}}}\log\frac{a-\sqrt{a^2-b^2}}{b} + \frac{a}{b^2(a^2-b^2)}\right\},$$

and D is the displacement of the vessel.

The figures given by Sir William White for an actual submarine are—length 150 feet, breadth 12·2 feet. If we take $a/b = 12{\cdot}3$ in our spheroid, we obtain

$$\frac{\alpha}{2-\alpha} - \frac{\beta}{2-\beta} = -0{\cdot}95.$$

Thus, for a displacement through a small angle θ from the horizontal, the stream-line couple produced by a velocity V through the water is

$$0{\cdot}95\, V^2 D\theta,$$

tending to turn the vessel further from the horizontal.

If h is the metacentric height for longitudinal displacement, the hydrostatic righting couple is

$$ghD\theta.$$

Thus the effective righting couple is

$$gD\theta\left\{h - \frac{0{\cdot}95V^2}{g}\right\},$$

so that the metacentric height is diminished by the motion of the submarine by an amount $0{\cdot}95\, V^2/g$. This factor does not appear to depend much on the shape of the submarine; clearly, if its shape had been that of a thin long stick, we should merely have to replace 0·95 by 1·00, whereas if the ratio a/b had had only half of its present value, the numerical factor would still be about 0·9.

Sir William White gives as the metacentric height of an actual submarine 37 feet when awash on an even keel, and only 45 per cent. of this, say $16\frac{1}{2}$ feet, when trimmed to an angle of 4 degrees. The value of V^2/g when V = 10 knots, is about $9\frac{1}{2}$ feet, so that the effective metacentric height would be reduced to about 28 feet on an even keel, and to $7\frac{1}{2}$ feet when trimmed 4 degrees by the stern. So far as can be judged from a diagram given by Sir William White (Fig. 7 in his paper), the metacentric height would vanish altogether for a trim of about 7 degrees.

Thus a submarine moving ahead at 10 knots, even under perfect conditions, might apparently be expected to founder if its inclination at any time reached as much as 7 degrees.

Sir William White mentions that in the case of the submarine A8, the hydrostatic metacentric height had been reduced, at the time the accident occurred, to $8\frac{1}{2}$ feet. The further diminution in this height produced by a headway of 8 knots is about 6 feet—by a headway of 9 knots is about $7\frac{1}{2}$ feet, leaving only about 1 foot of effective metacentric height as the margin of safety.

Obviously these rough calculations ignore a great number of factors which ought to be taken into account before accurate knowledge can be obtained. The most important of these factors is probably the proximity of the surface and the consequent formation of surface-waves. A calculation which omits a factor of this kind cannot lay claim to any value as advancing exact knowledge, but may serve the humbler purpose of suggesting possible, and even probable, dangers, and of emphasising the need for experimental knowledge, before this is forced on us by a catastrophe. J. H. JEANS.

Trinity College, Cambridge.

THE mathematical investigation which Mr. Jeans puts forward is of great interest, but avowedly rests on the assumption of the complete immersion of a submarine in an infinite ocean. The concluding paragraph of his letter indicates that a great number of factors, which ought to be taken into account, are not represented in the mathematical investigation, the most important being near proximity to the surface and the consequent formation of surface-waves. It will suffice, therefore, for me to say that my insistence on the necessity for direct experiment, rather than mathematical investigation, had relation to the case where the submarine was moving at the surface with a small reserve of buoyancy. The slides which I exhibited at the Royal Society reproduced photographs taken in these circumstances, and showed the singular and irregular character of the surface-waves produced by the headway of submarines under these conditions. These slides furnished conclusive evidence of the impossibility of representing the conditions of practice by purely mathematical investigation, and the absolute necessity for experiments on models and full-sized submarines.

Mr. Jeans's investigation for the completely submerged vessel has, however, a great practical value, because it furnishes fresh and important reasons (in addition to those urged by myself) against the tendency to increase the under-water speeds of submarines. When submerged, the measure of stability of the vessel for all directions of inclination is found in the height of the centre of buoyancy above the centre of gravity. We are informed authoritatively that in the diving condition this height is less than 1 foot in existing types of submarines. It will be seen, therefore, that a very small value of V—less than 6 knots—might render such a vessel unstable; if the speed were increased to 10 knots no possible use of water-ballast could give such a hydrostatic stability to the vessel when at rest as would secure the maintenance of stability when she moved at full speed. The existence of superstructures on the upper portions of submarines, of course, involves a departure from the cigar-shaped spheroidal form, but cannot be accompanied by any such decrease in the moment of the couple resulting from the stream-line forces as would secure, or even add sensibly to, the safety of the submarine moving at high speed under water. W. H. WHITE.

The Action of "α" Radiation on Diamonds.

The action of the "α rays" on diamonds is of considerable interest, for while the fluorescence caused by the β and γ radiation from radium is probably similar to that caused by the X-rays, the appearance of a diamond made luminous by the impact of a stream of "α" particles suggests some considerations as to the possible action of "α" radiation on fluorescent crystals in general. The fluorescence of a fairly large stone (cut and polished) when viewed with a suitable lens shows practically nothing of the spinthariscopic action, although the stone may be brightly luminous. Instead of the familiar scintillations, the whole crystal, or at least the whole surface exposed to the rays, appears to give out a steady bluish-white light.

The thought at once occurs to one that this seemingly continuous flow may be the collective effect of the very numerous scintillations produced by a too intense stream of "α" rays; such an action is well shown on a zinc sulphide screen when there is an excessive quantity of radium used. That this action is really the collective fluorescence of scintillations is at once evident by removing the fragment of radium to a greater distance, reducing the quantity used, or increasing the magnifying power employed to view the screen. In the case of a diamond, however, this does not appear to be so. The use of a higher power to view the fluorescence still shows a seemingly steady glow, and the increase of the distance between the radium and the stone merely causes the light to become gradually fainter, while still preserving its steady character. Yet it is certain that the diamond responds readily to the "α" particles, and also that, as the quantity of radium is so very small, the action of the β and γ radiation is quite negligible. It is, of course, well known that when an "α" particle strikes a fluorescent screen, the point of impact becomes the centre of a luminous area, which is simply enormous in extent when compared with the size of the atomic projectile which causes it.

The following may perhaps be suggested as a possible explanation of this action:—When an "α" particle strikes a homogeneous fluorescent crystal (say a diamond), the energy which excites the fluorescence finds equal conduction in all directions. The fluorescence caused thus tends to fill the whole volume of the crystal. If there are many such atomic projectiles incident on the same crystal, they are all tending to do the same thing, and consequently their spheres of influence mingle with one another. As such spheres of fluorescence find equal conduction of all sides, they extend indefinitely within the limits of the crystal in question. As fluorescence is apparently a molecular property, and probably electrical in its nature, it is not difficult to imagine that such may be the case. A still pond, into which a handful of gravel is scattered, may present an approximate analogy. The ring-waves (neglecting the time they take to travel) would mingle with one another, and yet each one might be said separately to occupy the whole area of the pond. In the case of a zinc sulphide screen, or one coated with minute fragments of diamond crystals, the energy received by one crystal or fragment of a crystal is confined exclusively to the volume of that fragment. Moreover, it is impossible for an "α" particle to strike more than one crystalline fragment at a time, for it is a body of atomic dimensions compared with which the most minute fragment of the fluorescent compound would be enormous.

The whole of the available energy is thus confined to the limits of the fragment struck, and is not, apparently, extended to the neighbouring crystals, which are only in loose and indifferent contact with it. When such a crystalline fragment is of a size which is comfortably visible with the aid of a lens magnifying about 20 diameters to 30 diameters, the resulting fluorescence will be visible as a scintillation. To diminish the size of the crystals beyond a certain point in order to increase the brightness of the scintillations is apparently not advantageous, as it requires the higher powers of a compound microscope to render the areas properly visible, and there would be a corresponding loss of light.

On the analogy of the pond given above, the spinthariscopic effect may be compared to throwing a handful of gravel into a collection of small puddles. The disturbance caused in each would be strictly confined to its own area, and would be correspondingly intense within that area. With a given stream of "α" radiation, a small stone appears to give a very slight scintillating effect which is not seen in a larger stone, except at the edges and angles of the facets, where the area of fluorescence is abruptly terminated, and even here it is very faint. The above remarks would, of course, only apply to perfect crystals. If a crystal is full of flaws and imperfections, the areas or spheres of fluorescence would not find easy conduction across the faults, and would therefore become localised in their action. It may be noted that a lump of willemite (natural), which is of a semi-crystalline character, does show scintillations, though very imperfectly, while the powdered mineral answers much better. This may be explained on the assumption that the areas of conduction are restricted to the size of the particles. C. W. R.

June 20.

The Day of Week for any Date.

The following method for finding the day of the week for any given date (new or Gregorian style) may interest your readers. We assign a number for each month in accordance with the *old* style, beginning with March, so that the last four months are numbered according to their Latin names, as follows:—

January, 0; February or March, 1; April, 2; May, 3; June, 4; July, 5; August, 6; September, 7; October, 8; November, 9; December, 10; next January, 11; next February, 12.

For a Leap Year, January and February must count as 11 and 12 respectively in the *preceding* year.

It is only in dealing with the month-number that anything not straightforward and obvious is involved.

The rule then runs as follows:—

A. For the *century*: divide by 4, and calculate 5 *times the remainder*.

B. For the *year*: add *to the number the quotient obtained from divisor* 4.

C. For the *month*: multiply by 4, and *negate the units digit* (*i.e.* subtract instead of adding it).

D. For the *day*: retain the number unchanged.

Then add together the results A, B, C, D (casting out *sevens*, of course, as you proceed), and the result gives the required day of the week.

The rule holds without modification, not excepting such years as 1600, 2000, &c., as well as 1700, 1800, 1900, &c.

Examples—1906, September 19.

A. For *century*: $3 \times 5 = 15$ ... ... $\equiv 1$
B. For *year*: $06 + 1 = 7$ ... ... $\equiv 0$
C. For *month*: 4×7 gives $20 - 8 = 12$ ... ... $\equiv 5$
D. For *day*: 19 ... .. $\equiv 5$

$A + B + C + D = 11 \equiv 4$, *i.e. Wednesday.*

1815, June 18 (Battle of Waterloo).

A. For *century*: $2 \times 5 = 10$ ... ... $\equiv 3$
B. For *year*: $15 + 3 = 18$ ... ... $\equiv 4$
C. For *month*: 4×4 gives $10 - 6 = 4$ ... .. $\equiv 4$
D. For *day*: 18 .. ... $\equiv 4$

$A + B + C + D = 15 \equiv 1$, *i.e. Sunday.*

1784,* January 12 (Pitt's appearance as Prime Minister).

A. For *century*: $1 \times 5 = 5$ 5
B. For *year*: $83^* + 20 = 103$ ... ... $\equiv 5$
C. For *month*: $11^* \times 4$ gives $40 - 4 = 36$ ... . $\equiv 1$
D. For *day*: 12 ... 5

* Leap year.

$A + B + C + D = 16 \equiv 2$, *i.e. Monday.*

W. E. Johnson.

King's College, Cambridge, July 11.

SOME SCIENTIFIC CENTRES.

VIII.—THE MACDONALD PHYSICS BUILDING, McGILL UNIVERSITY, MONTREAL.

WISE liberality has rarely reaped a richer and more immediate harvest than the gift by Sir William Macdonald of the Physics Building to McGill University at Montreal. This benefaction is but one instance—though a very important instance—of the fact that education, particularly scientific and technical education, is of enormous practical advantage, and that the most wealthy men in Canada and the United States recognise that it has the first claim on their generosity. In England money is given with no less lavish hand, but vast sums are devoted to objects less deserving than education, inasmuch as they afford palliatives, and not preventives, of failure, suffering, or distress.

The Physics Building, with its accompanying endowments and equipment both for instruction and research, forms but a small fraction of the total gifts of Sir William Macdonald to McGill University—gifts which exceed in value three and a half million dollars. A brief history of its growth, more particularly as a centre of research work, may be of service to those desirous of emulating a noble example.

In 1891 a chair of physics was endowed by Sir William Macdonald, to which John Cox, formerly Fellow of Trinity College, Cambridge, was appointed as the first professor. He was at once instructed to visit the best laboratories in America, and thus add to his experience of similar institutions in Europe. He received the most cordial assistance in the United States, and learnt both what to acquire and what to avoid. On his return, in conjunction with the architect, Mr. Andrew T. Taylor, he planned a building, beautiful in appearance, and so complete in every detail, that it is scarcely possible, with an intimate knowledge of the internal arrangements, to suggest any material improvements. The general scheme was to provide a building which would meet the requirements of the ensuing fifty years. The cost of the fabric was 29,000*l*., being at the rate of about elevenpence a cubic foot.

The donor further instructed Prof. Cox to prepare estimates for equipment and apparatus, and in response for a request of 5000*l*., the sum of 6000*l*. was placed at his disposal. At this point Sir William Macdonald decided to endow another chair for research in physics, and the institution was fortunate in obtaining H. L. Callendar, from Trinity College, Cambridge, as its first occupant. The equipment of the laboratory continued from 1892 to 1897, when the founder was assured that sufficient apparatus had been obtained; but the first grant had been greatly exceeded, and the total donation for this purpose was 22,000*l*. This sum has been discreetly spent, and adequate provision has been made for lecture tables, laboratories, and for all branches of physical research. Sir William Macdonald made a further gift of 30,000*l*. in order to secure an annual income of 1500*l*. to provide for the salaries of demonstrators and to defray the cost of heat, light, upkeep of apparatus, and repairs to the fabric. As educational property is not subject to taxation in Canada, the only rate payable is the water tax. In addition to the preceding gifts, the donor of the Physics Building has made special grants from time to time for the purchase of radium, for a liquid-air plant, for two large induction coils, and in particular 1000*l*. for the purchase of books for the library in the building, and 400*l*. for a special research fund. It is fortunate that such splendid munificence has been judiciously expended by Prof. Cox, and that the results obtained have been such as to win for the laboratory a place in the foremost rank.

A detailed account of the rooms in the building is unnecessary, but an important item in the establishment is the workshop, with tools and lathes driven by electric motors, sufficient to make a large proportion of the more simple apparatus required for instruction or research. A complete plant of this nature, under a competent mechanic and assistant, effects a great saving of time and money in a city where skilled labour is often scarce and always costly. It is not within the scope of this article to give an account of the purely educational uses of this building, but it is sufficient to state that the lecture theatres and laboratories are ample in size and equipment, so that all students in the faculties of arts and of science receive courses in physics suited to the requirements of their future professions. An interesting question arises as to the extent to which professors of research should devote their time to the instruction of ordinary students. On the one hand, it may be regarded as a waste of valuable time, but from the student's point of view it is a great gain to come into contact, both in laboratory and lecture room, with the best intellects in his university. A research professor must necessarily devote some of his time to the instruction of advanced students, and particularly to the assistance of research students. It is therefore undesirable that any large

FIG. 1.—Macdonald Physics Building, McGill University, Montreal.

fraction of his time should be absorbed by giving lectures to elementary students. This difficult question of the division of time appears to have been satisfactorily solved in the Physics Building.

The first research professor, H. L. Callendar, was an active and able investigator. He invented and improved his platinum thermometer with an ingenious compensation method, and applied it to various uses. In conjunction with Prof. J. S. Nicholson, of the engineering building, he solved many temperature problems connected with the steam engine. He investigated some important meteorological questions, determining the temperature at various depths in the earth—a matter of special interest during the severe winters in Canada. He also constructed a self-recording instrument which measured the difference of temperatures between the top of Mount Royal and the base near the observatory. Further results have been obtained by Prof. C. H. McLeod and Dr. H. T. Barnes, using the same instrument. The latter was also associated with Prof. Callendar in effecting some improvements in the Clark cell as a standard of electromotive force. But Prof. Callendar's most important work at McGill was the development, in conjunction with Dr. Barnes, of the continuous flow method of calorimetry. This has proved a great advance, both for simplicity and accuracy, on the older methods of calorimetry. Very exact determinations have thus been made by Dr. Barnes of the mechanical equivalent of heat, and of the specific heat of water at various temperatures. Dr. Barnes, with Dr. Coker, determined the effect of temperature on stream lines and the critical velocity. He has also made a close study of the properties and peculiarities of ice formation in Canadian rivers. Freezing does not occur merely at the surface, as in most English rivers, but, after passing rapids, water may congeal at the bottom and form "anchor ice." Still more remarkable is the formation of "frazil," consisting of minute crystals pervading the whole mass of water. The presence of ice in this state occasions serious trouble in the turbines of the power stations, and special precautions are necessary to mitigate the evil.

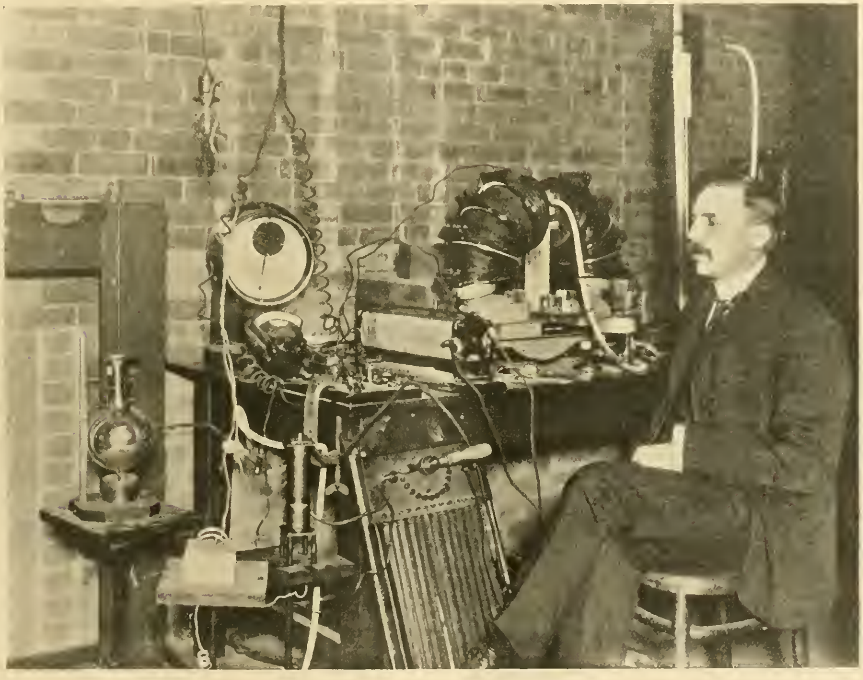

FIG. 2.—Prof. E. Rutherford, F.R.S., in his laboratory.

On the appointment of Prof. Callendar to the chair of physics at University College, London, Prof. Cox again visited the Cavendish Laboratory, and, on the advice of Prof. J. J. Thomson, he selected to fill the vacancy E. Rutherford, a young man who had already distinguished himself for originality, insight, and great capacity for work. Soon after M. Becquerel's discovery of the radiations from uranium, Rutherford had published a paper on that subject, and removed some misapprehensions as to the properties of the radiations. Moreover, he had served a most useful apprenticeship on the investigation of the properties of ions, whether produced by Röntgen rays, ultra-violet light, or by uranium. This thorough mastery of the indispensable elements served him in good stead when he continued at Montreal his researches on radio-activity. At this time Prof. H. B. Owens, of the engineering building, had noted the peculiar inconstancy of the radiations from thorium, and traced it to air currents. Prof. Rutherford then made an exhaustive examination of the phenomena, and he found that thorium emitted a gaseous substance, to which he gave the name "emanation." He also proved that the emanation had the remarkable property of making other substances active by a material surface deposit due to the emanation. Assisted by Miss Brooks, he proceeded to measure the rate of diffusion of the emanation from radium, for he then saw, and saw correctly, that the emanation was a gas and a distinct form of matter.

At this point Mr. Soddy came from Oxford to McGill University and worked with Prof. Rutherford. Together they tried the effect of varying the physical conditions, such as temperature, upon the emanating power of radio-active substances, and in the course of this work it was found that the emanation came from thorium X, a substance which could be separated from thorium. When they realised and clearly proved that the emanation was produced from thorium X, that thorium X constantly appeared from thorium, and as constantly decayed, that the curves of decay and of recovery were strictly complementary, and followed with exactitude simple exponential laws, that the rate of change was proportional to the amount of material still unchanged, then for the first time a most clear conception of the sequence of production of matter in fresh forms, with distinct chemical properties, was attained. The substances thus discovered were in quantities too minute to be detected by the balance or spectroscope. The new theory of radio-activity was published in two papers by Rutherford and Soddy in the *Philosophical Magazine* of September and November, 1902. In these papers the experimental evidence was first reviewed, and then the theory was stated that radioactivity is an atomic phenomenon accompanied by chemical changes in which new types of matter are produced, that the changes must occur within the atom, and that the radio-active substances must be undergoing transformation. This theory on its first appearance was regarded by many as a mere flight of the imagination, and efforts were made to detect a cause exterior to the atom. The theory was stoutly championed by Rutherford in the face of doubt and criticism, and it is now so thoroughly accepted by all who have investigated the subject that the initial opposition is almost forgotten. It is remarkable that a new subject should have reached the position of an exact science with such great rapidity.

Experimental research continued at McGill with speed which was almost feverish. Having established the fact that the highest temperatures obtainable had no effect on the rate of transformation of the emanation of radium, it was desired to try the effect of extreme cold. Again the good genius of the Physics Building was invoked, and a complete plant for making liquid air was presented. Within a quarter of an hour after the first 100 c.c. of liquid air were prepared the emanation had been condensed, and the material nature of this gas had been proved beyond question.

It is noteworthy that in the paper on the cause and nature of radio-activity in the *Philosophical Magazine* of November, 1902, the speculation was advanced that the presence of helium in minerals associated with uranium and thorium might be connected with their radio-activity. In 1904 this forecast was verified by the observation of the presence of helium in the spectrum of the radium emanation by Ramsay and Soddy in the laboratory of the former. In the meantime Rutherford had proved by magnetic deflection that the α particles carried a positive charge. The remarkable heating effects of radium, three-quarters of the total amount being due to the emanation, were investigated and measured. At a later date the heat generated by the γ rays was under observation and found to be very small, a result of importance in estimating the nature of the rays. In these heat determinations Prof. Rutherford was assisted by Dr. Barnes. In 1902 Mr. Soddy left McGill University, worked for a year with Sir William Ramsay, and was then appointed lecturer in physical chemistry at Glasgow University. Prof. Rutherford continued his research work with unabated energy and success. Radio-tellurium and polonium were relegated to their proper places among the products of radium, now grown to a family of six, the successive offspring of the emanation. The theory of rayless changes was advanced, and the complicated cases arising therefrom were thoroughly explored, and the results published in the Bakerian lecture delivered before the Royal Society in 1904. The brilliant work of Rutherford received recognition by the award to him of the Rumford medal. More recently he has again directed his attention to the α particles, deflecting in electric and magnetic fields the rays from radium C and other substances, thus determining the charge and mass of the particles, and endeavouring to account for their abrupt disappearance whilst their velocities are still very great.

So much work and such novel theories have naturally called forth criticism, but the discussions have always been chivalrous, buttons have been on the foils, and Rutherford's extreme care in verifying every step by thorough experimental evidence has saved him from error to a degree quite exceptional. A prominent physicist in the early days of radio-activity remarked that the subject was such a tangled skein that it was almost hopeless to unravel it. This sufficiently indicates the difficulty of the subject in the initial stages. It is fortunate that so much of the development centred in a man to whom the remarkable instinct is given of rarely following side-issues. As a result of this concentration a uniform system of nomenclature has been adopted, and experimenters are saved much time and trouble in following the work of others. Apart from such concentration, it is not difficult to imagine the state of chaos into which the whole subject would have lapsed. Rutherford's work, "Radio-activity," has passed rapidly through two editions, has kept pace with discoveries, and is the encyclopædia of the subject.

At the physics building Prof. Rutherford inspires research students with some of his own enthusiasm and energy. He follows their results closely, is ready with advice and criticism, and is as delighted with any of their discoveries as with his own. He is generosity itself in giving a full measure of credit to those who do research work under his guidance.

Reference may be made to some of the work done by research students. Miss Brooks has published several papers on various radio-active phenomena, and this lady was one of the most successful and industrious workers in the early days of the investigation of the subject. H. L. Cooke discovered penetrating rays from the earth, and made contributions on the activity of ordinary matter. R. K. McClung determined the coefficient of re-combination of ions, and worked with Rutherford on the energy required to produce an ion, and on allied problems. S. J. Allan worked at the active deposit derived from the atmosphere and from falling snow. Miss Gates ascertained the true nature of the discharge due to quinine sulphate. A. G. Grier detected the magnetic deviation of the β rays of thorium.

Others have come to Montreal from afar, attracted by the magnetic influence of Rutherford, such as Dr. Godlewski, of Lemberg, in Poland, who investigated in Montreal the products of actinium and some notable properties of actinium and uranium. From Frankfurt came Dr. Hahn, discoverer of radiothorium in the laboratory of Sir William Ramsay. Dr. Hahn, whilst working at McGill, also discovered radioactinium and a new product of thorium. Dr. Levin, from Göttingen, and Dr. Bronson, from Yale, have also done research work whilst at McGill, and the latter has increased our accurate knowledge of various radio-active constants by his modification of the electrometer giving direct and immediate readings. All these workers testify warmly to the inspiration kindled by Rutherford.

His own success as an investigator may be traced to a few well-marked characteristics. The first is the pertinacious and reiterated assault on the particular problem in hand. He does not grope in the dark for chance results, but bombards the particular point which he wishes to attack. He has also an instinctive insight which often makes his initial point of view more trustworthy than the deliberate conclusions of some befogged experimenter. He is not only an industrious, he is also a very rapid worker, but his experimental conditions are varied sufficiently to eliminate error, and his observations are repeated until he has perfect confidence in his results. Most noteworthy of all is the extreme simplicity and directness of his experimental methods. Some observers appear to grow happier as their apparatus becomes more complex. Rutherford selects some ingenious, straightforward attack, but the simplicity is supplemented by the genius which has enabled him to make such great contributions to our knowledge of the mutability of matter and of the atom in evolution.

In conclusion, the writer, who is an Englishman resident in Canada, ventures to emphasise the importance of research laboratories, so well equipped and so distributed that able men in Great Britain may not find themselves hampered through want of means and opportunity to pursue their work. The gift of the Cavendish Laboratory to the University of Cambridge by the late Duke of Devonshire has produced results which are recognised as holding the first place in recent advances in physical science. The Macdonald Physics Building has brilliantly started on its career. But there are other universities less fortunate, and there are other wealthy men.

A. S. Eve.

THE YORK MEETING OF THE BRITISH ASSOCIATION.

Provisional Programmes of the Sections.

The local arrangements for this meeting, which will be held at York from August 1 to 8, are progressing extremely satisfactorily, and a large assembly is expected, as nearly 1200 persons from a distance have already signified their intention to be present. The evening meetings will be held in the large hall of the Exhibition Building; 2200 numbered seats are already arranged, while there is space behind, making up a total accommodation of at least 5000 if necessary. All these will have a full view of the speaker, and the lantern screen, though, of course, those behind will be a considerable distance away. It will be well, therefore, for visitors to bring their opera glasses with them.

The neighbourhood of York affords many objects of interest, archæological, botanical, and geological, and many of these are more readily accessible by road than railway. Cyclists are therefore recommended to bring their machines with them, as the roads are mostly good and level. Hotel and lodging list can, as usual, be obtained of the local secretaries, Davy Hall Chambers, York. The following provisional programmes have been arranged by the committees of the various sections:

Section A (Mathematical and Physical Science).—This section will, as usual in recent years, meet in three departments. In the chief department a series of discussions has been arranged. Prof. Soddy will open one on the evolution of the elements, and a number of leading workers in radio-activity, including Sir Wm. Ramsay, are expected to follow. Mr. J. Swinburne will discuss the nature of the radiation from incandescent mantles; and Dr. H. Rubens, of Charlottenburg, will expound his views, and illustrate them experimentally. Representatives of the Chemical Section will be deputed to attend both these discussions. It is expected that they will prove of great value as well as of great interest. The Hon. R. J. Strutt has consented to give an account of his recent work on the internal structure of the earth as indicated by the phenomena of radio-activity, and Prof. J. Milne will also speak on it. It is probable that the Geological Section will collaborate in this discussion; hence it will be treated from various points of view. There will be a paper by the Earl of Berkeley on osmotic pressure, which will lead probably to renewed debate on the ever-interesting subject of the nature of solutions. Sir Wm. Ramsay and J. F. Spencer have presented a paper on chemical and electrical changes induced by ultra-violet light, which contains important new matter, as well as a summary of what is at present known on this subject.

There will also be papers by H. Stansfield on photographs of thin liquid films (with experiments); Prof. E. H. Barton and J. Penzer on photographic records of a string's vibrations and responsive motions in the air; Mr. C. E. S. Phillips on the production of an electrically conductive glass; and Prof. W. F. Barrett on entoptic vision. In the Department of Astronomy and Cosmical Physics, a joint discussion has been arranged with Section E (Geography) on the necessity for the re-measurement of the British geodetic arc. This will be opened by Major E. H. Hills, R.E. In the Department of Mathematics, Prof. A. R. Forsyth will read a paper on the different kinds of integrals of partial differential equations. Papers will also be read on a test for the convergence of multiple series, by Mr. T. J. Bromwich; on some notes on finite groups, by Harold Hilton; on Aleph numbers, by Dr. E. W. Hobson; and on the residues of hypereven numbers, by Lieut.-Colonel A. Cunningham. Prof. Henrici will open a discussion on the notation and use of vectors.

Section C (Geology).—The following are among the principal papers promised for this section: The problems of the Palæozoic glaciations of Australia and South Africa, Prof. J. W. Gregory; On a criterion of the glacial erosion of lake-basins, R. D. Oldham; Notes on recent earthquakes, Prof. J. Milne; On anthropods from the Coal-measures, Dr. Hy. Woodward; On the Jurassic flora of Yorkshire, A. C. Seward; Discussion on the origin of the trias, opened by Prof. Bonney and Mr. J. Lomas; On an artesian boring at Lincoln, Prof. Hull; On the post-Cretaceous stratigraphy of Southern Nigeria, J. Parkinson; On a peculiar variety of sodalite showing colour-change, T. H. Holland. Prof. P. F. Kendall will give a lecture on the geology of the country round York. The president's address will deal with the interglacial problem as it applies to the British Isles. A number of other papers have also been promised—relating mainly to the geology of the Yorkshire district. The following are among the number: On the limestone knolls of Craven, and on an intrusive rock near Grindleton in the West Riding, A. Wilmore; Notes on the glaciation of the Usk and Wye Valleys, Rev. W. Lower Carter; On faults as a predisposing cause of the potholes on Ingleborough, H. Brodrick; On a section in a post-glacial deposit at Hornsea, T. Sheppard.

SECTION D (ZOOLOGY).—President's address by Mr. J. J. Lister, F.R.S. *Papers.*—Conjugation of *Paramaecium caudatus*, Prof. Gary N. Calkins (Columbia Univ.); Breeding experiments in canaries—an exception to Mendel's law, Prof. Noorduijn; Preliminary note on a new conception of segregation, A. D. Darbyshire; On epigamic and aposematic scents in rhopalocera, Dr. F. A. Dixey; Outline sketch of what appears to be a periodic law in organic evolution, with a re-estimation of the cell, H. M. Bernard; Maturation of parthenogenetic eggs, L. Doncaster; The milk dentition of the primitive elephants, Dr. C. W. Andrews; Habits of galatheidæ in relation to their structure, Dr. Herbert J. Fleure and Miss E. F. Galloway; Some points of interest with reference to the mandible in mammals, and Some remarks on the manus of the dolphin, Prof. R. J. Anderson; Title not communicated, but dealing with the zoology of the Scottish Antarctic Expedition, W. F. Lanchester. *Discussions.*—Halolimnic faunas and the Tanganyika problems, J. E. S. Moore; it is hoped the following will speak: Prof. Pilseneer, Dr. Bordenger, Prof. Gregory, Mr. Cunnington, Mr. Hudleston, Dr. Calman, Mr. R. T. Gunther. Melanism in Lepidoptera, G. T. Porritt; the following will speak: Mr. J. Arkle, Dr. Dixey, Mr. W. Hewitt, and others. Prof. Gary N. Calkins will introduce a discussion on Protozoan life-histories. Spicule formation, Prof. E. A. Minchin; it is hoped the following will speak: Prof. Yves Delage, Prof. Sollas, Prof. Dendy, Mr. W. Woodland. Suggestions for the more systematic study of oceanic plankton, Dr. G. Herbert Fowler; probable speakers: Prof. Gibson (Louvain), Dr. Norris Wolffenden, Mr. Stanley Gardiner. On the relations of scientific marine investigations to practical fishery problems, Dr. E. J. Allen; it is hoped that in addition to men of science a number of persons practically interested in the fishing industry at Hull and Grimsby will take part in the discussion. On Monday morning (August 6) there will be a joint meeting with Section K (Botany) for the discussion of several cytological papers, among which will be Mr. Doncaster's (*vide supra*). There will also be two afternoon lectures illustrated with lantern slides (semi-popular), namely: The habits of tube-building worms, Arnold T. Watson; Birds and mammals of Yorkshire, Oxley Grabham (local secretary).

SECTION E (GEOGRAPHY).—*Discussions.*—Proposed measurement of geodetic arcs in Great Britain, opened by Major E. H. Hills, C.M.G., R.E.; Changes on the coast of England, especially at the mouth of the Humber, opened by Mr. Clement Reid. *Papers.*—The scientific results of the Scottish Loch survey, James Murray; The Chagos Islands, Indian Ocean, J. Stanley Gardiner; A journey across the Sahara, M. E. F. Gautier (not quite certain); The structure of Southern Nigeria, John Parkinson; The study of Social Geography, Prof. G. W. Hoke, of Ohio State Normal College; A journey in the Central Himalaya, T. G. Longstaff; The future of wheat-growing in Canada, Prof. L. W. Lyde; Geographical photography, John Thomson. *Afternoon Lectures.*—Past and present in Asia Minor, Prof. W. M. Ramsay; The visit of the Association to S. Africa, H. Yule Oldham; A tour in South-East Persia, Major P. M. Sykes.

SECTION G (ENGINEERING).—Address by Prof. J. A. Ewing, president of the Section; Modern armour and its attack, Major W. E. Edwards; The deformation and fracture of iron and steel, W. Rosenhain; Segregation in steel ingots, and its effect in modifying the mechanical properties of steel, J. E. Stead; Structural changes in nickel wire at high temperatures, H. C. H. Carpenter; Standardisation in British engineering practice, Sir John Wolfe Barry, K.C.B.; Recent advances in our knowledge of radiation phenomena, and their bearing on the optical measurement of temperature, J. B. Henderson; The removal of dust and smoke from chimney gases, S. H. Davies and F. G. Fryer; Glow lamps up-to-date, and the grading of voltages, Sir W. H. Preece, K.C.B.; The advent of single phase electric traction on railways, C. F. Jenkin; Some recent developments of the steam turbine, G. Gerald Stoney; Some recent experimental results with internal combustion engines, Prof. W. E. Dalby; A general supply of gas for heat, light, and power purposes, A. J. Martin; Experiments illustrating the balancing of engines, Prof. W. E. Dalby; An indicator for high speed engines, Prof. B. Hopkinson; A new form of transmission dynamometer, Prof. B. Hopkinson and L. G. P. Thring; The new engineering laboratories, Edinburgh University, and their equipment, Prof. T. Hudson Beare; Waterproof roads as a solution of the dust problem, Douglas Mackenzie; The central technical college lecture table testing machine, Prof. Ashcroft; The teaching of mechanics by experiment (with illustrations), C. E. Ashford.

SECTION H (ANTHROPOLOGY).—In this section the proceedings promise to prove as interesting as usual, and quite a large number of the communications are likely to give rise to considerable discussion. One of the most important items in the programme will be a discussion on the head-form of the prehistoric and early historic races in Britain which has been arranged to take place in connection with an exhibit of British crania, now in the possession of the Yorkshire Philosophical Society, and crania from Laver Hill. The discussion will be opened by Mr. J. Gray with a paper surveying the evidence, anthropological and collateral, bearing on the affinities and probable origin of the prehistoric and early historic races which have settled in Britain. Dr. F. C. Shrubsall has also promised to contribute, and Dr. W. Wright and others will take part in the discussion. In this connection considerable interest attaches to a paper on the relations between archæological and anthropographical data in the ethnology of Scotland by Dr. T. H. Bryce, and a paper by Mr. J. R. Mortimer on the relation between stature and head-form in the skeletal remains found in the round barrows of Yorkshire, based on data obtained from his own collections at Driffield. Mr. H. Brodrick will describe a skeleton recently discovered in Scoska Cave, Littondale. Two communications by Dr. W. L. H. Duckworth will deal respectively with a rare anomaly in human crania from Kawiawata Island, New Guinea, and observations on a eunuchoid subject in the Cambridge Anatomy School. Dr. C. S. Myers contributes, as an addendum to the report of the committee on anthropometric investigations among the native troops of the Egyptian Army, and notes on the distribution of cephalic and nasal indices in different provinces of Egypt.

In general ethnography communications are hardly as numerous as usual. Dr. Haddon will contribute a paper on the ethnology of South Africa, based principally on material collected during the visit of the association to South Africa last year, and Mr. S. Dornan, a South African member, sends a communication dealing with the Bushmen of Basutoland. Messrs. T. A. Joyce and E. Torday jointly will contribute a paper on the Ba-Yakka, a tribe in the Congo Free State. Among papers dealing with points of a more detailed character, Dr. Rivers offers, as a possible explanation, alternative, at least in India, of the importance of the maternal uncle among primitive races, a survival in the marriage customs of southern India, and an account of the astronomy of the Torres Straits islanders. Mr. H. A. Rose will contribute a paper on the custom of female infanticide in India, and Prof. Ridgeway will deal with the origin of the fiddle and guitar. Dr. T. H. Bryce and Mr. Newberry, of the Glasgow School of Art, will exhibit a number of examples of the "door-step" art—designs used by peasants to decorate their door-steps and dairy and kitchen floors in Scotland, which present many interesting features.

In archæology, Prof. W. M. Flinders Petrie will give an account of a Hyksos fortress and other discoveries in Egypt in 1906; Dr. R. C. Bosanquet will describe his excavations in Sparta, and a communication from Mr. J. L. Myres will deal with early traces of human types in the Ægean. Mr. D. G. Hogarth hopes to communicate an account of the treasures of the primitive Artemisia of Ephesus, should the interval before the meeting be sufficient to allow an examination of the objects from the site, which have only just arrived in England. Major P. M. Sykes will exhibit a collection of bronze weapons and implements from Persia, which are discussed in a communication by the Rev. Canon Greenwell. Dr. T. Ashby will read papers on the recent excavations in the Forum, and the excavations at Caerwent in 1904–6. Prof. R. S. Conway will contribute a paper on the Keltic weights found at Melandra, which throw considerable light on the subdivisions of the pre-Roman pound in Britain. Excavations on the interesting palæolithic site at Ipswich, of which accounts have on two occasions been presented to the section, have now brought to light a number of small implements which would appear to have been used as scrapers, and further evidence as to the relations of the implementiferous strata, which will be described by Miss Layard. Miss Layard also contributes an account of the excavation of an Anglo-Saxon cemetery at Ipswich, which has produced, among other objects, fibulæ of interesting types, rare in Great Britain. Mr. Rudler's paper on the "Red Hills" of the east coast salt-marshes will describe the low mounds of burnt earth of frequent occurrence on the estuarial marshes of Essex, which it is now proposed to examine systematically.

SECTION I (PHYSIOLOGY).—*August* 2: Address by the president, Prof. Gotch; Report of committee on The metabolic balance sheet of the tissues; Papers on physiology. *August* 3: The nitrification of sewage, Dr. George Reid; Papers on hygiene; Report of the committee for the investigation of the effect of climate upon health. *August* 5: Discussion on the physiological value of rest, opened by Dr. T. D. Acland. Dr. Rivers, Dr. Myers, Prof. McDougall are expected to take part. Papers on the special senses, psychology and electrophysiology. Dr. Bevan Lewis and Dr. Smith will give a demonstration on improved methods of studying the central nervous system, and a paper on the pericellular plexus and neuro fibrils of the cerebral cortex. *August* 6: Joint discussion with Section B (Chemistry) on the factors which determine minimum diet values, opened by Dr. F. Gowland Hopkins. This, of course, has special interest, as much sociological work has been done in York by Mr. B. Seebohm Rowntree on the limits of diet. Prof. Armstrong and other members of the chemical section will take part. Papers on pathology. *August* 7: General papers.

SECTION K (BOTANY).—At least three of the sessions of this section will be devoted to special topics of current interest, the proceedings in each opening with a general paper or address dealing with the topic as a whole, followed by more special papers and a general discussion. The three topics chosen for the present meeting are as follows:—(1) Some aspects of the present position of Palæozoic botany will be dealt with by Dr. D. H. Scott, F.R.S., and the conditions of growth of Carboniferous plants by Prof. F. E. Weiss, Miss M. C. Stopes, and others. (2) The nature of fertilisation and kindred problems, at a joint session with Section D (Zoology). Mr. V. H. Blackman will open the proceedings with a general address setting forth the present position of the subject. Prof. Farmer, F.R.S., is expected to contribute a paper on the cytological features of apospory, and Mr. Doncaster one on some cytological features of animal parthenogenesis. Several eminent foreign botanists, distinguished for their work on kindred topics, have promised to be present, among them being Prof. Tschermak, of Vienna, Prof. Johannsen and Dr. Ostenfeld, of Copenhagen, Dr. Rosenberg, of Stockholm, and Dr. Lotsy, of Leyden. (3) The phylogenetic value of the vascular system of seedlings. Mr. A. G. Tansley and Miss E. N. Thomas will open the proceedings, while Prof. Jeffrey, of Harvard, Messrs. A. W. Hill, T. G. Hill, and Miss Ethel Sargant are expected to contribute by papers or otherwise to the discussion.

Dr. T. W. Woodhead, who has been spending the last year at Zurich with Prof. Schröter, will communicate a paper on ecological work in Switzerland, Mr. C. E. Moss will give an account of survey work and mapping in Somersetshire, while Dr. Fritsch and Mr. Walker will contribute papers on algal ecology. Prof. Wyndham Dunstan, F.R.S., is expected to give a general account of his work on hydrocyanic acid in metabolism, but it is not yet certain whether this will be presented to the botanical or to the chemical section. Among other papers may be mentioned Prof. H. H. W. Pearson's on the habitats and habits of S. African cycads, communicated by Mr. A. C. Seward, F.R.S., and Mr. Hugh Richardson's on the vegetation of Teneriffe. It is hoped that Dr. Blakeslee may be able to be present and give an account of his work on sexual differentiation in the Mucorineæ, and also of his important recent discoveries of sexual differentiation in the spores of Marchantia.

SECTION L (EDUCATIONAL SCIENCE).—*August* 2: Presidential address, Prof. Michael E. Sadler; Report on health in schools, Prof. Sherrington; Medical inspection of schools and colleges, Sir Lauder Brunton, Sir Henry Craik; Physical training, Dr. Ethel Williams, Major Norman; The education of workpeople, Hugh O. Meredith. *August* 3: Curriculum of primary schools and the training of teachers in such schools; Report of committee on the courses of practical, experimental, and observational studies most suitable to elementary schools: general principles, Sir Philip Magnus, M.P., subcommittee report on arithmetic and mensuration, Prof. R. A. Gregory, subcommittee report on nature-study, Hugh Richardson. Contributions to the discussion will be made by Principal Burrell, T. S. Dymond, Prof. Green, J. C. Hudson. Training for the home duties of women. Report of subcommittee on Domestic studies, Geo. Fletcher. The following will contribute to the discussion:—Miss Mary E. Marsden, Prof. A. Smithells, Miss Maud Taylor, Prof. H. E. Armstrong, Mrs. Margaret Pillow, B. S. Rowntree, Mrs Marvin, Miss Romley Wright. *August* 6: The balance of subjects in the curriculum of the secondary school and the training of teachers for such schools, T. E. Page, Hon. and Rev. E. Lyttelton, Rev. E. C. Owen, Arthur Rowntree (Leisure pursuits), Gidley Robinson (Preparatory schools), C. M. Stuart, J. H. Leonard, Miss E. E. C. Tomes (Training), Prof. Raymont (Training); The uncertainty of educational values in the absence of scientific experiment, Dr. E. P. Culverwell; The demonstration school as a field for scientific research in school teaching, Prof. J. J. Findlay. *August* 7: Inspection and examination of schools, C. M. Stuart, J. L. Holland, Geo. Fletcher, and others; The teaching of modern languages, Prof. Wyld, Prof. Robertson; Experiments and results in elementary modern language teaching conducted since 1892, Prof. J. J. Findlay; (joint meeting with Sections A and G) The teaching of mechanics by experiment, C. E. Ashford.

NOTES.

THE death of Prof. Drude by his own hand at the early age of forty-three is a serious loss to physical science. Born at Brunswick in 1863, he made his mark first as a pupil of Voigt at Göttingen, and his series of papers in which he applied the electromagnetic theory of Maxwell, as developed by Herz, to the problems of light, stamped him as a physicist of the first rank. These appeared in *Wiedemann's Annalen* in the years 1896–9, and as more fully developed in the author's "Physics of the Ether" and his text-book of optics, have received recognition in these columns. Among them may be specially noted his theory of the magneto-optic phenomena of iron, nickel, and cobalt, 1897; the theory of anomalous dispersion, 1898; and of electric dispersion, 1899. Drude was also an experimenter, and was able to devise and carry out critical experiments to test, where necessary, fundamental points of his theory. In 1900 he succeeded Wiedemann as editor of the *Annalen der Physik*, and under his capable guidance that well-known journal has fully maintained its reputation, while only last year he was called to Berlin as professor of physics in succession to Warburg, now president of the Reichsanstalt. The physics school of the University of Berlin has suffered severely in recent years, and the loss of the brilliant physicist who had so recently joined them will be deeply felt by his friends and colleagues.

THE report on the civil hospitals and dispensaries in the United Provinces states, says the *Pioneer Mail*, that five cases of snake-bite have been successfully treated at Gorakhpur with Dr. Calmette's anti-venene and permanganate of potash. They seemed bad cases, and almost immediately recovered after the injection of the serum. Twenty-two cases were also treated in the Banda district, and in twenty-one cases the treatment was successful.

THE death of M. Edouard Piette in his eightieth year removes from the ranks of French anthropologists a tireless investigator. He began to write on prehistoric questions as long ago as 1869, and contributed numerous articles to periodicals, among which may be mentioned a supplement to *L'Anthropologie*, entitled "Les Galets coloriés du Mas d'Azil," splendidly illustrated in colours. Another work was entitled "Les Tertres funéraires d'Avezac-Prat"; but a great part of his material remains unpublished, though some of the plates illustrative of it were exhibited at the Trocadéro some years ago. He formed a magnificent collection of stone, bone, and early iron objects from Brassempouy, Mas d'Azil, and other places, and presented it about four years ago to the Museum of Saint-Germain, where it is arranged in stratigraphic order. He was an honorary fellow of many learned societies, but, his generous benefaction notwithstanding, he was neither a member of the Institute nor the recipient of a decoration.

THE death of the Rev. J. F. Blake will be felt by many British geologists as a personal loss. Prof. Blake was born in 1839. He was educated at Christ's Hospital and Caius College, Cambridge, where he was senior scholar. In the natural science tripos of 1862 he took a second class, and he was fifteenth wrangler. Following the profession of his father, the Rev. Robert P. Blake, he entered the Church, and held curacies at Lenton, near Nottingham, and at St. Mary's, Bryanston Square. Afterwards he went as mathematical master to St. Peter's School, York, a post he occupied for nine years. From 1876 to 1880 he was lecturer at Charing Cross Hospital on comparative anatomy. From 1880 to 1888 he held the chair of natural science at University College, Nottingham. In 1895 he went out to India to arrange the Baroda Museum. Prof. Blake was an active Fellow of the Geological Society of London, and in 1891-2 he was president of the Geologists' Association. His contributions to geological literature cover a wide field, but the ground he made particularly his own was the Jurassic of England. Many of his papers will be found in the Journal of the Geological Society, in the Palæontological Society's monographs, and elsewhere. A characteristic publication was the "Annals of British Geology," an excellent work, which doubtless failed through containing too fully the marks of Prof. Blake's strong critical capacity. His natural enthusiasm and integrity of character endeared him to all with whom he came really in contact.

MR. F. VICTOR DICKINS informs us that on August 21 the session of the Congrès préhistorique de France will open at Vannes, the curious old capital of the Morbihan, under the presidency of M. A. de Mortillet. All necessary information will be readily afforded by the general secretary, Dr. Marcel Baudouin, Paris, rue Linné 21. The subscription and cost of excursions are extremely moderate, and for ten francs a day, all comprised, the very best accommodation is procurable at Vannes. The session will close on August 26; and arrangements are made for a reduction of the fares on the French railways.

THE *Daily Chronicle* of July 6 publishes a Reuter telegram of the previous day from Rome announcing that the Duke of the Abruzzi had telegraphed to the King of Italy that on June 16 he reached the highest point of Mount Ruwenzori. The probable position of this peak, as deduced from a combination of the best data available, may be gathered from a paper by Lieut. T. T. Behrens, R.E., in the current number of the *Geographical Journal*. Lieut. Behrens makes use of (1) trigonometrical determinations of two tops of a summit; (2) trigonometrical rays to four other summits; (3) eight perspective views from sketches and photographs, with some magnetic bearings; (4) a map compiled from all available sources up to 1901, chiefly based on Dr. Stuhlmann's traverse and astronomical observations; and (5) information just received from Mr. A. F. R. Wollaston, a member of the zoological expedition sent out under the auspices of the Natural History Museum, who with two other members of the expedition made a number of ascents in this range during April last.

THE Country in Town Exhibition, which was opened by Princess Christian on July 5 in the Whitechapel Art Gallery, has proved in every way as successful as its promoters could have wished. The chief objects of the exhibition are to show how many interesting remnants of the country and its denizens there still remain in London, to suggest how much of the country can be brought back to town, and to indicate those places near the metropolis (which can be reached at trifling cost) where the beauties of nature can easily be enjoyed. In connection with the exhibition, a series of lectures was arranged, the first being given by Mr. Richard Kearton, on Nature at work and play. Dr. Henry, in dealing with the question of tree planting in London, showed that it was the way the trees were treated rather than the injury caused by the atmosphere which prevented them from growing. Mr. T. S. Dymond gave many useful hints in connection with the soil of London, Sir John Cockburn outlined the way in which Australian cities have been beautified by tree planting, Mr. Herrod dealt with bees, and Mrs. Dukinfield Scott showed her animated photographs of plants. The chairman of the executive committee is Mr. J. C. Medd, and the honorary secretary is Mr. Wilfred Mark Webb.

FROM a resolution published in the *Pioneer Mail* (June 15) it appears that the Government of India has had under consideration the desirability of making better provision for scientific research in connection with Indian forests. In order to provide a staff of experts who will be in a position to devote a large proportion of their time to the prosecution of scientific research connected with forest produce, as well as to give the best available training to candidates for the forest services, both of British India and of native States, the Indian Government has, with the sanction of the Secretary of State, decided to raise the status of the existing Imperial Forest School at Dehra Dun, and to add to its staff. The school will now be known as the Imperial Forest Research Institute and College, and the staff will include six officers of the Imperial Service holding the following posts:—(1) An Imperial sylviculturist, who will make sylviculture his special study. (2) An Imperial superintendent of forest working plans, who will collect and collate statistics of the results of forest management throughout India. (3) An Imperial forest zoologist, whose chief duty will be to investigate the damage caused by insects and other pests, and to suggest remedial measures. (4) An Imperial forest botanist, who will study the botany of forest plants, diseases of trees, and distribution of species. (5) An Imperial forest chemist, who will investigate the chemical properties of soils and of the produce of the forests. (6) An Imperial forest economist, who will make a special study of the best methods of rendering forest produce of all kinds available at the smallest cost to consumers, and will keep in touch with the commerce of India with the view of fostering and meeting the demand for forest products.

Communication by wireless telegraphy has just been established between the Australian continent and Tasmania by the Marconi system.

The foundation stone of the German Museum "für Meisterwerke der Technik" is to be laid in Munich about the middle of November, in the presence of the Emperor of Germany.

The Magdeburg civic authorities have decided to pay for the erection of a laboratory for the examination of food materials in connection with the new State bacteriological laboratory which is shortly to be built.

The income of the jubilee fund founded in Heidelberg in 1886, and to be awarded to teachers in the university in recognition of their scientific work, has been divided between Prof. Fr. Pockels, professor of physics, and Prof. A. Klages, professor of chemistry, to enable the latter to continue his investigations on optically active benzoyl derivatives.

Prof. K. Seubert has retired from the International Atomic Weights Subcommittee on account of over-pressure of work. His place will be taken by Prof. W. Ostwald, so that the subcommittee will now consist of Profs. T. E. Thorpe, H. Moissan, W. Ostwald, and F. W. Clarke, president.

A standing exhibition committee is to be formed in Berlin by the Zentralverband deutscher Industrieller, acting in conjunction with the Zentralstelle für Vorbereitung von Handelsverträgen and with the Bund der Industrieller. The duties of this committee will be to collect information with regard to all exhibitions of importance and to deal with questions affecting the interests of German exhibitors, both at home and abroad.

A legacy of 360,000 francs has been left to the French Academy of Sciences and a few other institutes under the will of the late Baron de Rey. To the Academy itself is bequeathed the sum of 150,000 francs, from the interest on which there is to be offered quinquennially a prize of 20,000 francs to the French investigators who, in the opinion of the Academy, have best contributed to the progress of physical science.

Pupils and friends of the late Prof. August Kekulé, who died in 1896, have handed over to the University of Bonn a sum of 31,500 marks, the yearly interest on which is to be given to a young investigator of the exact sciences, more especially chemistry and physics, on July 13 of each year, the anniversary of Kekulé's death. The first payment is to be made after the relatives of the deceased chemist have no further claim on the income of the fund as arranged.

The Deutscher Verein für öffentliche Gesundheitspflege will hold the annual general meeting this year on September 12 to 15 in Augsburg immediately before the beginning of the meeting of the Deutsche Naturforscher und Aerzte in Stuttgart which begins on September 16. The subjects to be proposed for discussion include:—(1) Precautions against hydrophobia, (2) the milk supplies of towns, with special reference to the milk supplies of young children, (3) invalid homes, (4) the dust plague in the house and on the streets, (5) the hygiene of small houses.

In No. 55 of the *Chemiker Zeitung* will be found some interesting details of the imports and exports of Germany for the year 1905; the estimated total value of the former is given as nearly 7500 million marks, and that of the latter as nearly 6000 million marks. Of these, 430 million marks are imported chemicals, including both raw and manufactured substances, and 473 million exported raw and manufactured chemicals; it is noteworthy that the imported raw stuffs for the chemical industries is put down at nearly 300 million marks in value, and the exported at 57 million.

With the view of cultivating an intelligent interest in meteorological science, the council of the Royal Meteorological Society appointed the assistant-secretary of the society, Mr. W. Marriott, last year to act in cooperation with scientific societies, institutions, and schools as a lecturer on meteorological subjects. The experiment has proved so successful that it is being continued, and a list of lectures for the coming lecture season has just been issued. Particulars can be obtained from the society, 70 Victoria Street, S.W.

An article on hybridisation and plant breeding in the July number of the *Monthly Review*, written by Mr. A. J. Bliss, affords a timely introduction to the subject that will shortly attract public notice when in the course of the month the third triennial conference on plant breeding will be held in London under the auspices of the Royal Horticultural Society. Premising that there are continuous variations and discontinuous variations, the writer proceeds to show how variations have been produced by cultivation and selection alone, as in the case of Shirley poppies, or more easily and rapidly by cross-fertilisation. To fix the type, thanks to Mendel, certain principles are being evolved for the guidance of the breeder. The elucidation of these principles and other problems will be discussed at the conference. The article concludes with some interesting details of results already obtained and future possibilities.

In their thirty-fourth annual report (for 1905) the directors of the Philadelphia Zoological Society state that they are considering a plan for lectures on animals to be given in the gardens at such times as they are most frequented by children. Special attention is directed to the valuable results attained by the introduction of a pathological laboratory. "No monkey is now placed upon exhibition unless it has successfully passed the tuberculin test, and it is hoped that by the employment of every practicable measure of prevention within the building, including prohibition of feeding by visitors, the occurrence of tuberculosis in these susceptible animals may be brought under control. A temporary result of the rigid system which has been put in practice is that the collection in the Monkey House is less complete than is usually the case. . . . Of those procured a considerable number failed to pass the tests and have not got beyond the quarantine-room."

In a paper on additions to the exhibited series of fossil vertebrates in the U.S. National Museum, published in the Proceedings (No. 1460) of that institution, Mr. C. W. Gilmore figures another specimen of a pterodactyle from Eichstatt showing the impressions of the wing-membranes, and also the skull of a new horned dinosaur of the genus Triceratops. Japanese fishes form the subject of a paper in the same serial (No. 1462) by Messrs. Jordan and Starks, while in No. 1464 the former writer reviews the sand-lances (Ammodytidæ) of Japan, and in No. 1470 he describes, in conjunction with Mr. R. C. McGregor, a new threadfin-fish of the genus Polydactylus from Japan.

Dr. Stejneger in No. 1471 describes a new tree-frog (Hyla) from Costa Rica; East African birds, by Mr. H. C. Oberholser, form the subject of No. 1469; while in No. 1472 Mr. E. S. Miller discusses mammals from Engano Island, off Sumatra. Certain American moths are described in Nos. 1463 and 1465 by Mr. A. Busck.

In a paper contributed to part iii. of vol. xxv. of Gegenbaur's *Morphologisches Jahrbuch*, Mr. J. E. V. Boas makes the startling announcement that a pleural cavity is absent in the Indian elephant. The author believes the feature to be constant, and that it will be found to hold good also for the African elephant, in which case we shall have a feature distinguishing the group from all other mammals. This paper is followed by one by Prof. G. Ruge on the shape of the thoracic cavity in the Indian elephant, and the relations thereto of the lungs. In a third paper Mr. A. Rauber contrasts the skull of Immanuel Kant with that of a member of the Neanderthal race. A striking difference between the two crania is to be found in the extreme brachycephalism of the one and the equally marked dolichocephalism of the other. If it be suggested that the shortness of the savant's skull was due to inheritance—from his ancestors in Scotland and Nürnberg—this is merely evading the main question, namely, When did the first brachycephalic man appear? It is noteworthy that if Kant's skull be plotted on the dolichocephalic lines of that of the Neanderthaler, and the Neanderthaler's cranium drawn on the brachycephalic proportions of that of Kant, the normals from a line connecting the "ophrion" with the "basion" will be very nearly the same in both cases.

The *Bio-Chemical Journal* for June (i., Nos. 6 and 7) contains several interesting papers. Prof. Moore and Messrs. Alexander, Kelly, and Roaf show that the secretion of gastric hydrochloric acid is very sensitive to any variation in general health of the body, any enfeeblement leading to decreased percentage of the acid. This reduction in acid-secreting power is much more marked in cancer than in any other condition. Prof. Moore and Mr. Wilson contribute a paper on a clinical method of hæmalkalimetry which seems to be a distinct advance on previous ones.

The longevity of *Bacillus typhosus* in natural waters and in sewage forms the subject of an important paper by Messrs. H. L. Russell and C. A. Fuller (*Journ. of Infectious Diseases*, Supp. No. 2, February, p. 40). Permeable sacs of celloidin, parchment, and agar were employed to imprison the typhoid organisms while exposed to the influence of water and sewage bacteria. When *B. typhosus* was exposed to the action of flowing lake water (Mendota), the longevity of the organism ranged from eight to ten days; when exposed directly to the action of sewage bacteria, its longevity was reduced to three to five days.

In Bulletin No. 104 of the Agricultural Experiment Station, Morgantown, West Virginia, Mr. J. L. Sheldon writes on the ripe rot or mummy disease of guavas, ascribed to the fungus *Glomerella psidii*. Brown spots appear on the ripening fruits causing them to shrivel, whence the term mummy disease; if not identical with the bitter rot of apples it is very similar, and it was found possible to inoculate apples with the fungus. Delacroix assigned the fungus to the genus Glœosperium, but on account of the ascigerous stage observed by Mr. Sheldon he refers it to the genus Glomerella.

Experiments on the tapping and preparation of rubber from Castilloa trees are in a less advanced stage than experiments with *Hevea latex*. As Castilloa promises to be more suitable for cultivation than Hevea in parts of the West Indies, considerable interest attaches to the preliminary results outlined in the West Indian Bulletin (vol. vii., part i.) by Mr. J. C. Moore for St. Lucia and Mr. J. Jones for Dominica. A variation in the semi-circumferential method of tapping is described, where, instead of a continuous cut, a series of incisions are made with a chisel. Castilloa is found to thrive on land suited to cacao, and may be grown on a shade tree for cacao; it possesses the further advantage of being able to withstand severe storms.

It is interesting to note how the trade of each of the West Indian Islands possesses its own special features. Dr. F. Watts reviews the changes that have occurred in the agricultural industries of Montserrat in the West Indian Bulletin, vol. vii., No. 1, of which the most prominent facts are the decadence of the sugar industry and the marked fluctuations in the production of lime and lime-juice. The raising of cattle and stock for export shows a steady increase, and a *papain* industry has been developed, which, however, is threatened by competitive production in the East. Cotton is regarded by Dr. Watts as the most hopeful industry for the future, but the peasant population has not, so far, taken to the cultivation. In the course of another article, Dr. Watts outlines the development of the cotton industry in the Leeward Islands since 1900, the greatest changes having been effected thereby in Nevis and Anguilla.

The completion of the Simplon Tunnel, 12¼ miles in length, at a cost of 3,100,000*l*., and at an average rate of two miles a year, has induced Mr. Lewis M. Haupt to publish in the Journal of the Franklin Institute (vol. clxi., No. 6) some comparative notes on other great tunnels. The Hoosac Tunnel, Massachusetts, five miles in length, was begun in 1854 and completed in 1876, with an average progress of 5·5 feet per day. The Mont Cenis Tunnel, eight miles in length, was begun in 1857 and completed in 1871, with an average progress of 8 feet per day. The Sutro Tunnel, Nevada, four miles in length, was begun in 1869 and completed in 1878, with an average progress of 10·24 feet per day. The St. Gothard Tunnel (1872–1881), 9¼ miles in length, was driven at the rate of 14·6 feet per day. The Arlberg Tunnel (1880–1884), 6·38 miles in length, was driven at the rate of 27·8 feet per day.

The third number of *Concrete and Constructional Engineering* (July) shows a marked improvement on the previous issues. The principal articles deal with reinforced concrete in France, reinforced concrete bridges, steel and concrete buildings in Scotland, reinforced concrete water mains, the theory of reinforced concrete, and hollow concrete blocks. The illustrations are excellent, and the articles are written by recognised authorities. An editorial note deals with the need for international standards in respect to reinforced concrete, and suggests that the International Association for Testing Materials should form a committee to collect international data. There is also a portrait and obituary notice of the octogenarian Joseph Monier, who died in Paris on March 13 last, almost unknown, almost forgotten, and in unfortunate circumstances, yet credit will always be due to him as the inventor of reinforced concrete.

The blackening of rocks in rivers has of late received some attention from geologists. Mr. A. Lucas, chief chemist to the Geological Survey in Cairo, sends us a paper on the blackened rocks of the Nile Cataract (National

Printing Department, Cairo, 1905; for the Ministry of Finance). The dark outer film is similar to that well recognised as a characteristic of stones in deserts. The desert-film has been examined separately, and Mr. Lucas agrees with Walther that "the colour is much the darker the more the silica content of the rock." "The depth of colour is dependent upon the amount of black oxide of manganese in the film, and this is conditioned first by the manganese content of the rock, and secondly by the opportunities presented for the manganese salts to be brought to the surface and oxidised." "A hot climate and a small rainfall are necessary to the formation and preservation of the film." In regard to the river-film, it is noted that certain incised stones at the First Cataract are equally black on their surface and in the hollows of the inscriptions. Silica is one of the minor constituents of the river-film, but is absent from the desert-film. Mr. Lucas, after discussing previous literature and his own analyses, concludes that the river-film arises from material in the rocks themselves, as in the case of the analogous desert-film. Dr. W. F. Hume contributes a description of the microscopic characters of the rocks examined, with the general result that no connection can be established between the surface-film and any special decomposition in the outer layers.

The June number of the *National Geographic Magazine* contains an account of a visit to Vesuvius after the eruption of April 8. The account is illustrated by a number of reproductions from photographs, of which we reproduce one showing the aspect of the cone after the eruption. The scoring of the slope of the cone is due to slipping of the loose ashes, not to stream action.

Fig. 1.—The new cone of Vesuvius from the road to the observatory, covered with white volcanic ash. From the *National Geographic Magazine*.

The current number of the *Home Counties Magazine* contains an interesting article on old pewter by Mr. H. M. Cooke. In a broad sense pewter is composed of tin alloyed in varying quantities with antimony and copper; lead, bismuth, and zinc are sometimes also employed. The variety and constant change of colour are due to the difference of alloys and to atmospheric influence. The colour is in some measure dependent on the surface being good. As a domestic article, pewter succeeded wood, and was used almost universally until earthenware became cheap. It did not come into general domestic use until the seventeenth century. On account of its fusibility pewter was used by goldsmiths to take castings of certain articles. Benvenuto Cellini is said to have used it for this purpose in connection with his work. It appears from Mr. Cooke's article that dealers nowadays, to enhance the value of their wares, often point to the small marks in shields of a lion rampant or a leopard's head crowned, and describe articles bearing these as "silver pewter." But such marks indicate no special value in the metal, and except for the infinitesimal quantity that there may be in the lead employed, it is safe to assume that old pewter contains no silver.

In a paper on the rapid measurement of geodesical bases published in part i. of the Bulletin of the French Physical Society, Dr. C. E. Guillaume gives details of the construction and use of the standards and measuring wires referred to in his article on invar (Nature, vol. lxxi., p. 138). An account is given, in particular, of the rapid, direct measurement of base lines by means of stretched wires of invariable length. This process is extremely rapid as compared with older methods; in good country, ten or twelve men can measure up 5 to 6 kilometres per day, whereas with a bimetallic scale fifty men are required, and the distance covered per day does not exceed 400 metres. Formerly the number of bases directly measured was kept as small as possible, nearly all the values being obtained by triangulation. The use of these measuring wires of invariable length affords a means of controlling the older data, and will change the character of future surveys by increasing the number of direct data at the expense of those obtained by triangulation.

The third volume of the contributions from the Jefferson Physical Laboratory of Harvard University for the year 1905 has been received. The previous volumes were described at some length in Nature for March 1 last (vol. lxxiii., p. 427). The results of the investigations published in the present volume were obtained largely by the aid of the Thomas Jefferson Coolidge fund for original research. Nine of the twelve papers have already appeared in the Proceedings of the American Academy, and most of the contributions have been dealt with already in notes published in these columns.

The *Electrician* Printing and Publishing Company, Ltd., is issuing a new series of *Electrician* primers at 3*d*. each, post free. A complete list of the primers will be sent on application. From an examination of specimens dealing with thermopiles, Röntgen rays and radiography, influence machines, the induction coil, the magnetic properties of iron and electrical units, it is clear that the series will prove of service to technical students.

The *édition de luxe* of the Great Eastern Railway Company's handbook, "Summer Holidays," by Mr. Percy Lindley, is provided with an excellent series of facsimiles of water-colour drawings of places of interest in the eastern counties. In addition to the illustrations in colour, the pen and ink drawings, the letterpress, the list of golf links, and other information provided, combine to make the publication a useful holiday guide.

OUR ASTRONOMICAL COLUMN.

REDISCOVERY OF FINLAY'S COMET (1906*d*).—A telegram from the Kiel Centralstelle announces the rediscovery of Finlay's comet by Herr Kopf on July 16. The position of the comet at 13h. 14·4m. (Königstuhl M.T.) on that date was :—

R.A. = 23h. 38·3m., dec. = 14° 3′ S.

The object is stated to be a bright one. Subjoined is an extract from the approximate ephemeris published by Herr Schulhof in No. 4100 of the *Astronomische Nachrichten* :—

12h. M.T. Paris.

1906	α (true) h. m.	δ (true) ° ′	log Δ
July 16	23 44	−13 7	9·5443
18	23 57	−12 10	9·5254
20	0 11	−11 6	9·5073
22	0 25	− 9 56	9·4902
24	0 40	− 8 40	9·4744
26	0 56	− 7 17	9·4602
28	1 13	− 5 47	9·4478
30	1 30	− 4 12	9·4376
Aug. 1	1 47	− 2 33	9·4299

A comparison of the observed and computed places on July 16 will give an approximate value for the corrections to be applied to the ephemeris positions. When rediscovered, the comet was about one degree north of ω Aquarii; at present (July 19) it is presumably about five degrees north of 2 Ceti, and is travelling in a north-easterly direction, so that it now rises above the south-east horizon at about 11.30 p.m.

THE ORBIT OF CASTOR.—An interesting paper on the quadruple system of Castor, by Dr. H. D. Curtis, appears in No. 5, vol. xxiii., of the *Astrophysical Journal.*
