CANCER AND ITS SUPPOSED CAUSES.

Induced Cell-Reproduction and Cancer. The Isolation of the Chemical Causes of Normal and of Augmented Asymmetrical Human Cell-Division. By H. C. Ross. Being the results of researches carried out by the author, with the assistance of J. W. Cropper. Pp. xxviii+291. (London: John Murray, 1910.) Price 12*s.* net.

MR. ROSS may be congratulated on having written a book singularly unlike most sober scientific treatises. He has been continually on the track of new things, and even the frontispiece, purporting to portray photographically a mitotic figure induced in a large lymphocyte, seems to have been inserted in order to embody a fresh discovery made after the rest of the book had gone to press, though whether others will attach the same significance to the photograph that Mr. Ross himself appears to do, the future will doubtless decide.

The book is written in an interesting and somewhat journalistic style, and the preface contains excellent autobiographical material designed, *inter alia,* to show how "a new method of experimentation with individual living human cells" was accidentally lighted on by the author.

Briefly, the method in question consists in concocting a jelly with agar, to which certain substances, including a dye, are added. Upon this jelly, films of blood containing living leucocytes are spread, which can thus be examined microscopically under various conditions. Ingenious devices for rapid photography are described, and considerable use is made of the photographs so taken in recording the results of observation.

A cytologist will find he has fallen into a rather strange environment when he gets immersed in Mr. Ross's book. He will have much to unlearn, and many new facts to assimilate, before he can hope to emulate the confident progress of his new leader. He will have to recognise that "the word 'nucleus' has a very vague meaning"; that chromosomes are not really of nuclear origin, but that they originate from the Altmann granules, and are formed in the cytoplasm; that the nucleus forms the spindle and the nucleolus constitutes the centrosomic apparatus. He will probably also be astonished to hear that living cells have not hitherto been studied, and consequently that his own reminiscences of observations on Ascaris and many other animals' eggs, to say nothing of plants, in all of which he will seem to remember that nuclear divisions have been followed in the living cell, must be founded on delusion. The zoological investigator will further discover that he owes a larger debt than he was aware of to his botanical colleagues, for Mr. Ross tells us that "most cytological research has been carried out with plant-cells."

Mr. Ross thinks that "from the persistent examination of dead structures, cytology has been rather led away into a maze, from which it will be difficult to extricate it." The main task which he sets himself in his book is to perform this service of extrication and to show what can be accomplished by the study of the living cell in ascertaining the causes which underlie cell division, and especially of cell proliferation. The latter process is obviously of special importance, inasmuch as it lies at the root, not only of the ordinary processes of healing, but also, when it assumes an aberrant character, of malignant disease as well.

The new engine of research, the jelly method, is fully described, and one of the main objects in its use by the author was to control the rate of diffusion of different substances into the cell. There is an excursus on the problem of diffusion, and the net outcome is embodied in formulæ for making what Mr. Ross terms "coefficient" jelly, meaning thereby a jelly in which the rate of diffusion of stain, &c., can be related to a standard in which a particular rate is accepted as unity.

This jelly is made up of a 2 per cent. solution of agar, to which certain proportions ("units") of alkalis, salts, stains (commonly Unna's polychrome methylene blue), and other substances are respectively added. The "units" of each ingredient are so fixed that a doubling of any one of them (*i.e.* two units) will double (or halve) the rate at which any particular substance, the action of which on the cell it is desired to study, will be absorbed. The method is a neat one, but it possesses obvious drawbacks, unless the separate action upon the cell of its constituents in the different strengths employed is fully known. The formulæ employed present an unfamiliar appearance, as the factors are all added together, and the inclusion amongst them of time- and heat-factors, on the basis of units composed of ten minutes and 5° C. respectively seems to assume unusual simplicity in the reactions involved.

By means of this method, however, depending largely on the entrance of the stain to the nucleus, many surprising results were obtained. The addition, for example, of various alkaloids, putrefactive products, &c., led the author to formulate far-reaching conclusions as to the causes underlying cell division, with the result that he believes himself to be justified in announcing the discovery of the main causes that bring about cell division, and induce cell proliferation. The causal agents in question are, of course, chemical, and probably most people who have paid any attention to the matter would agree with Mr. Ross that the fundamental causes of mitosis (nuclear division) are assuredly of a chemical nature. He thinks he has identified certain of these bodies, and this would constitute a most important addition to science if his views as to their action on the living cell should turn out to be as well founded as he imagines them to be.

It is, however, difficult to avoid scepticism on this very point, namely, as to whether the evidence on which the conclusions are drawn is really cogent, and whether the latter are themselves fully warranted.

The author might himself have contributed towards the solution of these crucial difficulties had he seen fit, in addition to the picturesque presentation of his results, to have subjected the foundations on which they rest to a full and wary criticism. For it is clear enough from the account actually given that the cells, even as they were being examined in the jelly, were moriturient. It is stated, over and over again, that under the conditions of the experiments it was not easy to keep them alive for more than ten minutes. It is not, after all, very surprising to learn that all sorts of movements and distortions followed on the application of drugs like atropin, but it is at least uncommon to find that a mitosis can be completely carried through in three minutes. Numerous examples of alleged "mitosis" are described, and photographs are adduced in support of the descriptions. But the photographs themselves are singularly unconvincing, and suggest fragmentation or breaking up of the cell as a whole rather than anything one would expect to see in an actual cell- or nuclear-division. We fail to find any critical guard against misinterpretation of phenomena that might be due to osmotic differences or to the poisonous action of reagents employed.

Nor is one reassured by the account of mitosis (*i.e.* nuclear-division) as referred to in the book. The treatment of the whole subject is suggestive of the enthusiastic amateur who is simply unable, owing to temperament or lack of training, critically to check and examine his own work. Of course, we do not mean positively to assert that such is really Mr. Ross's position, but anyone who puts forward statements on mitosis such as appear on pp. 148 and 149, or again on p. 166, without producing the strongest and most convincing proofs, must not complain if in other directions his views fail to command unreserved acceptance. We are not at all surprised to learn that when Mr Ross attempted to convince his friend of the soundness of his conclusions by demonstrating to them his preparations they all with one consent, as he himself avers, "began to make excuse."

It may be readily admitted that the book contains much that is interesting and valuable by way of suggestion, but we do not regard the conclusions of its author on cell-division and cell-proliferation as sufficiently well founded. J. B. F.

THE EVOLUTION OF LUNAR DETAIL.

Vergleichende Mond- und Erdkunde. By Prof. S. Günther. Pp. xi + 193. (Braunschweig: F. Vieweg und Sohn, 1911.) Price 5 marks.

THE resemblance which exists between the surface of the globe and that of the moon, as shown in the irregularities of level and the general character of the superficial formations, has long attracted attention, and much ingenious speculation has been exhibited in tracing a connection and seeking the cause. Fanciful theories exist without number, but men of the highest eminence have occupied themselves with the same theme, being led to it by the fascinating problem of the "Plurality of Worlds." This is the attraction that has induced Prof. Günther to study the subject, or, perhaps it would be more correct to say, to sift and examine what others have written about it. His book is a marvel of research and a triumph of industry. He seems to have examined all that has been written, whether in fact or fiction, bearing on the relations of earth and moon. Mr. H. G. Wells and Jules Verne represent one school of thought; Procter and Flammarion another; the highest authorities, as Darwin, Loewy, and Puiseux, form a third. Every page bristles with notes, and is encumbered by the author's commentaries on those notes. This arrangement perhaps shows greater power of collection than of assimilation. Much of the matter, if worth preserving, could have been incorporated in the text and made the book easier to read.

But however wide the outlook, whether in time or in nationality, problems connected with the physical constitution of inaccessible bodies are likely to remain unsettled, and the discussion prove barren of result. The history of this speculative inquiry is profoundly interesting, but from a philosophical and not an astronomical point of view. We are indebted to the author for the skill with which he has marshalled his facts and the enormous amount of information he has collected, but the moon seems little likely to contribute any fresh facts of importance to the main issue, since the probability in favour of similarity of structure and of evolutionary history is so great. By whatever process we suppose the genesis of the moon to have been accomplished, it would be difficult to imagine a body so near the earth not possessing the same external characteristics and passing through similar geological changes. There is some evidence to show that the actual materials that once formed part of the globe were transferred to our satellite, and this probability is strengthened by the agreement between the density of the moon and that of the superficial rocks on the earth. Indeed, as the author reminds us, there are not wanting those who can point to the exact spot where the catastrophe occurred that in times past tore from the earth the eightieth part of its mass.

The main result of the author's examination is to show the general uniformity of the conviction possessed by all students of the lunar surface that the earth and moon have passed through approximately identical processes of evolution. Prof. Günther reproduces the speculations of ancient Greek philosophers and continues the theme to modern times. Kepler's "Traum von Monde" and the observations of Galileo form connecting links, with the results derived from lunar cartography. In this newer research we start from Hevel and Cassini onwards to the exact methods of Meyer, Lohrmann, Schmidt, and Neville Neison. We are reminded of the artistic work of Nasmyth and Carpenter, of Klein, and of Weinek, and justice is done to their penetrating insight and the ingenuity with which they have pursued their researches. One does not realise how engrossing this subject has proved, how keen has been the attention and the hold it has had upon so many ardent workers, until the whole history is methodically exposed.

Another chapter is devoted to the results of photographic research, in which the pioneer work of De la Rue, Rutherford, and Draper is reviewed, and the history traced down to the admirable series of pictures issued from the Paris Observatory by MM. Loewy and Puiseux. The last four or five chapters are really the kernel of the whole. Herein are considered the formation of lunar craters, the origin of the bright streaks, the debated question of changes of the surface, sufficient in amount to be observed telescopically. The tectonic and orogenic structures here come under review, also, but without much approval, the views of Mr. G. K. Gilbert as to the possibility of the fall of meteors influencing or explaining the external features of our satellite.

SUBSTITUTION IN BENZENE.

Die direkte Einführung von Substituenten in den Benzolkern. Ein Beitrag zur Lösung des Substitutionsproblems in aromatischen Verbindungen. By Prof. A. F. Holleman. Pp. vi+516. (Leipzig: Veit and Co., 1910.) Price 20 marks.

IT is well known that the empiric rules of substitution, which have been evolved from the study of the aromatic compounds, may enable a chemist to predict roughly the result of such a process; it is equally well known that not one of these rules is free from exceptions. The absence of any rational theory underlying the process or the lack of novelty in the methods employed may have deterred chemists in recent years from following up what was formerly regarded as one of the most attractive lines of inquiry; but it is quite certain that very little in the way of systematic study, especially of a quantitative character, has been done in this field of research. Yet the process of substitution possesses not merely a theoretical significance; it has a very considerable technical value. The formation of halogen, nitro and sulphonic derivatives of aromatic compounds are among the most familiar technical operations of the colour-maker.

Though the subject has undoubtedly suffered from neglect, nevertheless a few serious students of the process are to be found. Prof. Holleman and his pupils have for many years devoted themselves to the task of systematising the scattered facts and adding new knowledge by a careful qualitative and quantitative study of these reactions. The volume before us contains not only an account of these inquiries and a critical review of methods and results, but forms at the same time a complete book of reference to all the published observations referring to benzene derivatives containing up to three substituents. It is obviously a work of immense labour, but should be invaluable to those engaged in this fundamental branch of organic chemistry. It may possibly also serve to direct more attention to a topic of so much interest. It is impossible in a limited space to give more than an outline indicating the scope of the book.

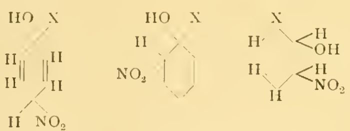
The first three chapters contain an account of substitution methods, the quantitative estimation of the products by chemical and physical means (many of which have been devised in the author's laboratory), and the nature of the di-derivatives formed.

Chapter iv. contains a compendium of results and a critical review of the rules and theories of orientation. Some of the apparent inconsistencies and contradictions in the ordinary rules may be realised from such facts as the following:—The nitration of a halogen derivative of benzene containing an atom of fluorine, chlorine, bromine, or iodine follows the ortho-para rule, yet the amount of ortho compound under similar conditions varies from 12 to 37 per cent. in the four cases. In the nitration of benzonitrile, nitrobenzene, benzoic acid and its esters, all of which are supposed to follow the meta rule, the first gives exclusively a meta compound, whereas the three latter yield an amount of ortho compound varying from 6, in the case of nitrobenzene, to 28 per cent. in that of ethyl benzoate. Whilst aniline and dimethylaniline under certain conditions give meta or meta and para compounds as chief products, dimethylaniline oxide and nitrous acid give mainly ortho and para derivatives. But perhaps the most striking case is that of acetanilide, which, when nitrated in presence of sulphuric acid, gives 80 per cent. of para, but when acted on by nitrogen pentoxide in a solution of acetic anhydride, forms almost exclusively the ortho derivative.

The empirical rules which have been drawn up at different times by Hübner, Nölting, Armstrong, Crum-Brown, and Gibson, and Vorländer, are carefully considered and rejected in turn as inconsistent with the facts, whilst the theories of Armstrong, Flürscheim, and Obermüller are shown to be fundamentally untenable or self-contradictory. The author concludes :—

"Das Endergebniss unserer theoretischen Betrachtungen ist kein erfreuliches; alle Versuche, welche bis jetzt gemacht sind, um die Gesetzmässigkeiten, welche den Ort bestimmen, wo ein zweiter Substituent im Kern eintritt, zu ergründen, sind vollkommen fehlgeschlagen; ja selbst ist es nicht möglich gewesen, die Tatsachen in einer empirischen Regel zusammenzufassen."

After discussing the position taken up by the third entrant group in chapter v., the author develops his own views on the mechanism of substitution. These views, which are published here for the first time, are so eminently simple and rational that chemists may be interested in the following brief outline. Following Kekule's idea that substitution is a succeeding phase of an additive process, Prof. Holleman considers that such a process as nitration, for example, of a compound containing a substituent X produces in the first place one or more of the following three substances :—



para ortho meta

from which the elements of water are subsequently detached. The nature of the predominating compound or compounds will be determined by the accelerating or retarding influence of the substituent X, just as addition of bromine to an olefine will be determined by the substituents already present. If X accelerates the reaction of ortho and para, substitution will be the main result, if it retards, meta substitution (where the double link is unconnected with the X complex) will be the primary effect. If X has no marked effect meta and ortho, meta and para, or all three may be formed.

A work of this kind, which, the author tells us, necessitated the careful perusal of upwards of a thousand original papers, ungrateful and laborious as the task of compilation may have been, will always remain a standard book of reference, for which chemists will feel fully grateful to the author.

J. B. C.

FERMENTS AND FERMENTATION.

Micro-Organisms and Fermentation. By A. Jörgensen. Translated by S. H. Davies. Fourth edition, completely revised. Pp. xi+489. (London: C. Griffin and Co., Ltd., 1911.) Price 15s. net.

IN this translation of the fifth German edition (dated January, 1909) of his well-known textbook, the author has incorporated the main results of investigations made since the appearance of the previous English edition about ten years ago. Although the book has been, to a considerable extent, rewritten, its original characteristics are retained.

Five of the six sections of the work have been enlarged, whilst the sixth, dealing with the pure culture of yeast on a large scale, has undergone marked reduction in volume, possibly because it forms the subject of a separate publication by the author. The illustrations have been increased in number from 83 to 101, nearly all of those found in the previous edition being again given; most of the figures are good, but those numbered 12, 13, and 51 would undoubtedly bear improvement, while Fig. 80 fails to bring out the peculiar bean- or kidney-shape of the spores of *Saccharomyces fragilis*. The bibliography has been revised and supplemented; it is, however, questionable whether a bibliography placed at the end of the book is more convenient than references given as footnotes to the text. One new feature, which will be welcomed by all readers, is the provision of an alphabetical index of subjects.

As the author is a member of the Danish school of micro-biologists, the book would naturally be expected to give, as in reality it does, a prominent place to the investigations of Hansen and his followers on the micro-organisms met with in the brewing industry. At the same time, the more important researches carried out during recent years in Germany and elsewhere are not, as a rule, lost sight of, although no reference is made to the valuable work of Slator on alcoholic fermentation, while the meagre notices given to the results obtained by Ehrlich and by Harden and Young might have been replaced profitably by more extended discussions.

The first chapter, headed "Microscopical and Physiological Examination," deals with such subjects as staining, sterilisation, antiseptics, nutritive substrata, and pure culture methods. In this section the space devoted to technique is very small, and a more detailed description of the methods employed in the author's laboratory would have been of value. In the part dealing with nutritive media, no mention is made of "eau de touraillons," which furnishes an excellent basis for such media, and is largely employed by some of the French investigators. Attention is directed to the stimulating action of small proportions of various poisons on the growth of micro-organisms, but no reference is made to the very thorough researches of Javillier on the influence of zinc on the growth of vegetable organisms, including moulds.

Chapter ii. treats of the biological examination of air and water, chiefly from the point of view of brewery requirements.

In chapter iii., the functions and conditions of growth of zymogenic bacteria are described. A paragraph is given to the nitrifying bacteria, but nothing is said of the very important class of nitrogen-fixing bacteria.

The moulds form the subject of chapter iv., which also deals incidentally with enzymes and with the influences of various external conditions on micro-organisms in general. The occurrence and life-history of most of the commoner moulds are studied, and reproductions are given of some of the excellent drawings made by Brefeld and de Bary.

The fifth chapter, occupying nearly two hundred pages, is concerned with the yeasts, and deals, in addition, with non-sporulating or Torula forms, as well as *Mycoderma vini* and *cerevisiae*. A short account is given of the history of fermentation and of the controversy respecting spontaneous generation. Then follow discussions of the biological relationships of yeasts, variations in the Saccharomycetes, morphology and anatomy of yeast-cells, spore-formation and its application to the analysis of yeasts, and a number of allied subjects. Lastly come descriptions of the more important culture and wild yeasts met with in the brewing, distilling, and wine-making industries.

The last chapter gives a brief account of the methods and apparatus employed in the preparation and transport of cultures of pure yeast for industrial purposes.

The translation has been on the whole well done, although in some cases the English is stiff and the grammar faulty. Rather ugly split infinitives occur in moderately large number, and subject and verb do not always agree in number. Use of the expression "equal molecules of dextrose and lævulose" is difficult to defend, and "sorbite," "mannite," and "albuminoid" are nowadays better termed "sorbitol," "mannitol," and "protein." Very few misprints are noticeable; *d*-methylglucoside (p. 359) obviously refers to α-methylglucoside. T. H. P.

THE FISHES OF AFRICA.

Catalogue of the Fresh-Water Fishes of Africa in the British Museum (Natural History). By G. A. Boulenger, F.R.S. Vol. ii. Pp. xii+529. (London: British Museum (Natural History), 1911.) Price *2l.* *5s.*

THE author is to be heartily congratulated on the appearance of the second volume of this great work, which succeeds its predecessor after an interval of two years, a period by no means excessive when the amount of labour involved in a task of this nature is taken into consideration. The present volume completes the account of the carp tribe (Cyprinidæ), containing the great bulk of that group, and likewise includes the whole of the cat-fishes (Siluridæ), several new genera and species being named.

Although no one regards systematic works of this class as the final aim and end of zoological science, their importance and value cannot be overestimated, since it is upon such sure foundations that all superstructures of a more far-reaching and philosophical nature must be based. That it was high time the task of bringing our knowledge of the African Cyprinidæ and Siluridæ up to date was undertaken will be evident by a comparison of the number of species of certain groups recorded in the present volume with that given in Dr. Günther's "Study of Fishes," published in 1880, and based on articles in the ninth edition of the "Encyclopædia Britannica." It is stated, for instances, in p. 573 of the "Study of Fishes" that the total number of species of cat-fishes of the exclusively African genus Synodontis is fifteen, whereas Mr. Boulenger has swelled the list to fifty-seven. Again, Dr. Günther estimated the total number of representatives of the Old World cyprinoid genus Barbus at about 200, while Mr. Boulenger gives a list (inclusive of nine additional uncatalogued species) of no fewer than 194 African members of the genus. Unfortunately comparisons cannot be extended to the total numbers of African Cyprinidæ and Siluridæ recorded by the two naturalists, as Dr. Günther enumerates only those inhabiting Africa south of the Sahara; but, even so, his lists of fifty-two Cyprinidæ and sixty-one Siluridæ (*op. cit.* p. 230) inhabiting Ethiopian Africa are altogether outclassed by Mr. Boulenger.

This great increase in the number of African representatives of the two families has, of course, a most important bearing on previous conclusions as to the place of origin of the two groups. Dr. Günther (*op. cit.* p. 225) suggested that since the majority of the groups of fresh-water fishes common to India and Africa, with the exception of the siluroid Clarias and its relatives, had more representatives in the former than in the latter area, the presumption is that they are of Asiatic origin. Although these conditions are now in many cases reversed, the conclusion will, we think, still hold good in the case of Barbus, the members of which, like many groups of antelopes with ancestral forms in India, would appear to have undergone an unparalleled development when they reached Africa. On the other hand, the abundance of siluroids in the Eocene of the Fayum, where no remains of cyprinoids have hitherto been discovered, points to the conclusion that this group is endemically African. And here it is noteworthy that the connection between the African and South American cat-fishes is now regarded as even less intimate than was the case when Dr. Günther's work was written, the two African species there referred (p. 233) to the South American Pimelodus now being assigned to a genus apart. But to pursue this interesting subject would demand more space than can be given to it in these columns.

If such space were available, we might presume to criticise some details in Mr. Boulenger's "keys"; and we cannot conclude without mentioning that the value of the work would have been increased if the dates of presentation of the specimens were added. The work appears singularly free from misprints. R. L.

THE INTERNAL-COMBUSTION ENGINE.

Gas Engines. By W. J. Marshall and Captain H. R. Sankey. Pp. xvi+278. (London: Constable and Co., Ltd., 1911.) Price 6*s.* net.

THIS book is the latest addition to Messrs. Constable and Co.'s Westminster series, and is intended to be useful to

"those who, being either purchasers or users of gas engines, wish to know the principles underlying the design or construction and the methods of diagnosing defects when they occur, and the steps to be taken to remedy such defects."

It may fairly be said to have achieved its purpose, and, for the most part, any criticism to which it lays itself open is little more than that to which almost any first edition is liable.

The book (an unusually heavy one to handle for its size) is divided into ten chapters, of which the first three deal with the theory of gas engines and with the Otto and two-stroke cycles of operation. The fourth, fifth, and sixth chapters are concerned with the water cooling of the engine parts, the various methods of ignition, and the principles of operation. Then follows a section on the arrangement of a gas-engine installation and the testing of the plant, whilst the two concluding chapters contain a good description of the various methods used for the governing of the engine and of the use of gas producers.

The book is stated on the title-page to be by the two authors mentioned in the heading to this review, and it is therefore puzzling on pp. 1, 110, and 152 to find "the author" only referred to. Possibly the book was written in sections, and this explanation appears plausible by reason of the curious contradictions that occur in it. Thus, on p. 1 it is stated that "the modern gas engine is a prime mover, perfectly reliable, cheaper in first cost, including the gas producer, than a steam engine and its boiler"; whereas on p. 21, we learn "the capital cost of the gas-engine plant is much greater than that of the steam-turbine plant," and on p. 152 that "the modern gas engine is very nearly as reliable a machine as a steam engine."

These statements should not all of them appear in one publication, as, even if explicable by some verbal modification, they tend to confuse the non-expert readers for whom this book is intended. It is this very use by the non-expert that renders slips in explaining the theory of the engine very unfortunate. On p. 5 an unlucky oversight has led to the statement appearing that if "pressure be kept constant the volume will vary as to absolute pressure." Again, the author or authors in stating (on p. 7) that "only a certain proportion of a given quantity of heat can be converted into work," neglect such a well-known fact that the heat conveyed to a gas to keep its expansion isothermal is all of it converted then and there into work.

These are matters which should be put right in a second edition, and, in view of the very thorough knowledge shown of the practical working of the engine and of the misfortunes to which it is sometimes liable, it is likely that there will be a large number of persons to whom the book will be of such value as to render a second edition a necessity. The description of the mode of working of the Clerk engine is specially good, and the letterpress is well illustrated. The authors commit themselves on p. 94 to an interesting prophecy concerning the probable future development of the gas engine.

"It seems likely," they say, "that in the future large gas-engine plants will be designed with engines working on two-stroke cycles, but, instead of each engine having its own charging pumps, a central set of independently driven pumps for gas and air will be provided"; "these pumps," they suggest, "will probably be of the turbine type, and of greater efficiency than is obtainable with pumps forming an integral part of the engine."

Finally, we welcome the book as an interesting addition to the less ambitious side of gas-engine literature, and foresee a useful place for it in the library of many persons who wish to learn something of this growingly important prime-mover.

RESINS, RUBBER, AND ESSENTIAL OILS.

Allen's Commercial Organic Analysis. A Treatise on the Properties, Modes of Assaying, and Proximate Analytical Examination of the Various Organic Chemicals and Products Employed in the Arts, Manufactures, Medicine, &c. With Concise Methods for the Detection and Estimation of their Impurities, Adulterations, and Products of Decomposition. Edited by W. A. Davis and S. S. Sadtler. Vol. iv., Resins, India-Rubber, Rubber Substitutes, and Gutta-Percha, &c. Fourth edition, entirely rewritten. By the editor and the following contributors, M. B. Blackler, E. W. Lewis, T. M. Lowry, E. C. Parry, H. Leffmann, and C. H. Lowall. Pp. viii+466. (London: J. and A. Churchill, 1911.) Price 21s. net.

THE general characters of the new issue of Allen's work have been described in the notices of earlier volumes reviewed in this journal (NATURE, vol. lxxxv., pp. 37, 365). In this connection therefore it is only necessary to remark that the present volume is notable among its fellows for the rather large proportion of theoretical and descriptive chemistry which it contains.

Many users of the book, however, will probably find this a convenience. Considerable advances have been made in the chemistry of the resins and essential oils since the publication of the earlier editions, and many of the results have not hitherto been brought together. Taken with the numerous references supplied, the articles upon the three groups of products dealt with in the book—namely, resins, india-rubber, and essential oils—form an excellent summary of the general and analytical chemistry of these products. The following are a few out of many interesting matters to be found in the volume.

Thanks largely to the work of Tschirch and his coadjutors, it is now possible to make at least a provisional attempt at a satisfactory classification of the resins. The proximate constituents of these bodies, so far as they are yet known, may be divided into (1) *Resin-esters* and their decomposition products; (2) *Resinolic* or *Resin acids;* and (3) *Resenes;* the last being oxygenated compounds with no very characteristic chemical properties beyond the attribute—a very valuable one—of resistance to the action of alkalies. In many of the resins one or other of these three classes is the preponderating constituent, whence three groups can be distinguished, namely, *ester-resins*, *acid-resins*, and *resene-resins*. The first group, for instance, includes (among others), gum benzoin, storax, "dragon's blood," ammoniacum, and asafœtida; in the second group are the coniferous resins and copaiba balsam; and in the groups of resene-resins are included myrrh, olibanum, dammar, and Manila copal. From a number of the ester-resins the alcohol of the ester has been isolated, and Tschirch distinguishes two kinds of these alcohols—*resinols* and *resinotannols*. The former are colourless, and give no reaction for tannin when tested with iron salts; the latter are coloured and give a tannin-reaction. For the general analytical examination of resins, the acid, saponification, iodine, methoxyl, and acetyl values are the determinations most frequently useful in forming a conclusion.

The chemistry of the essential oils is no doubt better and more widely known than that of the resins. Nevertheless, in the interests of readers who are not specialists in this branch of chemical work, a summary of the chief facts respecting the composition of the essentials oils may not be unprofitable. These oils, to which the characteristic odours of flowers and plants are nearly always due, are composed of some half-dozen groups of compounds, one or two of the groups predominating in any particular oil. *Terpenes* constitute the bulk of many essential oils, but are seldom the most useful portion. In fact, various so-called "terpeneless" oils are now prepared, the removal of terpenes serving in effect to concentrate the odoriferous properties of the oil in the residual constituents. *Alcohols* of various types—open-chain, aromatic, and sesquiterpene alcohols—with their corresponding *aldehydes* and *ketones,* are the important compounds in many oils. Examples are the alcohol *geraniol* in otto of rose; the aldehyde *citral* in lemon-grass oil, and the ketone *pulegone* in oil of penny-royal. Bergamot, clove, and mustard oils respectively owe their special properties to *esters, phenols,* and *sulphur compounds.* Methods by which the proportions of the various constituents may be determined, usually with a fair approach to accuracy, are described at length in the volume, which can be recommended as well worthy of its place in the series.

C. Simmonds.

MECHANICS, THEORETICAL AND TECHNICAL.

(1) *Lehrbuch der technischen Physik.* By Prof. Hans Lorenz. Dritter Band, Technische Hydromechanik. Pp. xxi+500. (Munich and Berlin: R. Oldenbourg, 1910.) Price 14 marks.

(2) *Die Theorie der Kräftepläne.* By Prof. H. E. Timerding. Pp. iv+100. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 2.50 marks.

(3) *Vibrations of Systems having One Degree of Freedom.* By Prof. B. Hopkinson. (Cambridge Engineering Tracts, No. 1.) Pp. 54. (Cambridge: University Press, 1910.) Price 2s. 6*d*. net.

(4) *Leerboek der Werktuigkunde.* By F. J. Vaes. Vol. i., pp. xii+152. Vol. ii., pp. xiv+224. (Schiedam: H. A. M. Roelants, 1910.) Price 1.40 gulden.

THERE is probably no branch of science in which such wide gaps occur between theory and practice as in the study of the motion of fluids. We have, on one hand, the mathematical theory of hydrodynamics, which is limited by the difficulty of obtaining soluble problems and building up integrals of the differential equations of motion subject to given boundary conditions. This difficulty alone restricts the scope of the investigation mainly to the study of perfect fluids, thus immediately introducing a discrepancy between theory and observation. On the other hand, we have the hydraulics of the engineering student, the object of which is mainly to enable numerical calculations to be made regarding such problems as town water supply, efficiency of turbines, pumps, propellers, and ships.

In endeavouring to produce a text-book on technical hydromechanics (1) which should be satisfactory both from a theoretical and from a technical point of view, Prof. Lorenz thus undertook a duty of enormous difficulty. It is not surprising that when he had half finished the manuscript in 1906 he was so dissatisfied with the result that he decided to start afresh, a task which he did not commence until 1908, after re-studying the subject and making a number of original investigations. That such difficulties would exist was shown not only by what he describes as the "step-motherly" treatment of this subject in technical colleges, but also by the absence of any comprehensive treatise covering the required ground. Books on hydraulics generally treated the subject entirely from Bernouilli's principle, combined with the hypothesis of parallel sections, nothing being said about Euler's equations of motion in three dimensions, much less of their modifications for viscous fluids. In one case the treatment of hydraulics was preceded by an introduction on hydrodynamics, an order of treatment likely to confuse rather than enlighten the "applied science" student. On the other hand, we have purely theoretical treatises on hydrodynamics, where practical applications are represented only by half a chapter on the hypothesis of parallel sections, and this Cambridge lecturers, at any rate formerly, told their students to omit.

The order of treatment adopted by Prof. Lorenz is probably the best that could be devised for the object in view. Starting with analytical hydrostatics (including the oscillations of floating bodies, and surface tension) the author next deals with steady, and subsequently with variable, one dimensional motion treated by the hypothesis of parallel sections. These chapters constitute hydraulics proper, and contain applications to flow over weirs and through sluices, pumps, efficiency of turbines, and propellers, long waves in canals, and tides. The extension of the investigation to three dimensional motion leads up quite naturally to Euler's equations of motion of a perfect fluid, problems in irrotational motion, both continuous and discontinuous, vortex motion, and viscosity. In addition to such problems as are commonly treated in hydrodynamics, we have discussions of the oscillations of ships, including a digression on the Schlick gyroscope, approximate theories of the turbine, and of the resistance of ships, and the equations of motion of underground waters. The latter subject might with advantage be brought more prominently than it has been before mathematical students in this country. It affords excellent examples of motion derived from a potential, and the divergence between theory and observation is probably less than in Eulerian irrotational motion. Not the least important feature is a concluding chapter on the history of hydrodynamics. A few points in the book might be improved. The proof of the permanence of irrotational motion on p. 342 scarcely appears conclusive. The equation shows that if the components of spin are ever zero their rates of change will also be zero. This does not prove *without further investigation* (*e.g.* by Stokes's method) that if the components are zero initially they always will remain zero, for a similar argument applied to uniformly accelerated motion from rest would lead to a *reductio ad absurdum.* Does not the author, however, assume this inference? Again, in dealing with flow of a viscous liquid between two parallel plates, would it not be more correct to say that Hele-Shaw first made the experiments, and Stokes subsequently showed that the results were largely due to viscosity, although it was previously thought, and perhaps even incorrectly stated, that these motions represented an actual realisation of two-dimensional flow of perfect liquids?

(2) Prof. Timerding's introduction to "Graphical Statics" contains a praiseworthy attempt to bridge over the gap which so often exists between treatises of a purely theoretical character, and text-books dealing too exclusively with technical applications. In particular the author shows clearly the equivalence which exists between the equations of equilibrium of uniplanar analytical statics and the geometrical constructions of force diagrams, funicular polygons, and stress diagrams of loaded frameworks, such as roof trusses. It is not surprising to find the author compelled to limit the scope of his book to the simplest portions of the subject. By this means he rightly claims to have produced a handbook which is accessible to students possessing a limited knowledge of mathematics (including very elementary analytical geometry but excluding calculus), but which constitutes a self-contained and connected exposition of the subject-matter of which it treats. As the author points out, the book should show to the technical worker that he can derive help and elucidation even from apparently abstract theories, while, on the other side, the mathematician will see with pleasure how densely the path of practice is strewn with the finest flowers of theory.

(3) "Vibrations of Systems having One Degree of Freedom" is a tract of a rather more elementary character than the series of "Cambridge Mathematical Tracts" which have proved so useful already. It might afford a useful supplement to existing text-books for such students of physics as have attended a suitable course of preparation in the elements of the calculus and differential equations. The equations of free and forced oscillation with one coordinate are discussed, and are applied to such problems as the rolling of ships and its measurement by the pendulum. The main difficulty is for students to find time to read such tracts when they have so much other subject-matter to study; this difficulty can probably be overcome by placing the book in the hands of the lecturer rather than of the pupil. There is certainly much to be said for requiring students to get a clear understanding of vibrations with one degree of freedom before introducing them to the more general problem where there are several coordinates. So much for the use of the book by students of pure science. As for its use for the class of students for which it appears to be primarily intended, we can only express the opinion that the book tends in exactly the same direction as the two German works above reviewed, and we hope it will be as successful as they are in making such students appreciate the value of theoretical knowledge.

(4) "Leerboek der Werktuigkunde" (=Lehrbuch der Werkzeugkunde) is a text-book on elementary statics and dynamics treated without the calculus for use in the Dutch higher schools, and by private students. Both in the methods of treatment and exposition, and in the worked-out exercises, examples and questions for examination, this book closely resembles our numerous English school books on elementary mechanics. Its contents include uniformly accelerated motion, component and resultant velocities, relations between force, mass and acceleration, composition of coplanar forces and couples, centres of gravity, ordinary examples on equilibrium of bodies resting against one another, the principle of work, circular and harmonic motion, elementary moments of inertia, impact, and the so-called mechanical powers. This course of study is so familiar to English readers that further description is unnecessary. It may be noticed that while the familiar "first and second systems of pulleys" appear in the last-named section, allowance is made for passive resistances, such as friction, which is not always done in English books. On the other hand, the author still follows old customs in trying to deal with composition of velocities without the necessary explicit references to relative velocity, which last receives somewhat meagre attention, a plan which experience shows to lead to frequent mistakes on the part of students.

G. H. B.

OUR BOOK SHELF.

History of Biology. By Dr. L. C. Miall, F.R.S. (The History of Science Series.) Pp. vii+151. (London: Watts and Co., 1911.) Price 1s. net.

This is a wise and instructive book, such as we have learned to expect from Prof. Miall. It is scholarly but restrained, so that the reader is not overwhelmed with too much learning. It is a model of terseness, yet it has that picturesqueness of illustration which is necessary if a history is to grip the ordinary mind. A book like this, which commands our warmest admiration, could not have been written except by one who had studied the history of biology for a long time, and at first hand.

After a brief reference to the biology of the ancients, the long cessation of scientific inquiry that followed, and the revival of knowledge, Dr. Miall sketches the history in five periods. The first (1530–1660) saw the fresh start of botany and zoology, the beginning of experimental physiology, the exploration of new lands. The second (1661–1740) was the period of the early microscopists, of discussions as to the meaning of fossils, of early comparative anatomy and taxonomy, and of inquiry into the sexes of flowers. The third (1741–1789) was the time of Linnæus and the Jussieus, of Réaumur, of the rise of the genetic or historical method as illustrated by the works of Montesquieu and Buffon, of inquiries into animal intelligence and instinct, the metamorphoses of plants, the function of the green leaf, and so on. The fourth period (1790–1858) is illustrated by Sprengel and the fertilisation of flowers, by Cuvier and palæontology, by Chamisso and alternation of generations, by von Baer and embryology, by the cell-theory, and by the investigation of the higher cryptogams. The fifth period is illustrated by Darwin and Pasteur.

At the end of the book there is an interesting chronological table—a good lesson in itself. There is reason for regret that students often take relatively little interest in the historical development of the science which they pursue. The excuse sometimes offered, that they have no time for "historical studies," is made impossible by a book like this, short and illuminating. It shows us, with singular success, how "Biology, which in the sixteenth century sent out only a few feeble shoots, has now become a mighty tree with innumerable fruit-laden branches. The vigour of its latest outgrowths encourages confident hopes of future expansion." J. A. T.

Catalogue of the Lepidoptera Phalænæ in the British Museum. Vol. x. Plates cxlviii–clxxiii. (London: Printed by order of the Trustees, 1911.) Price 20*s.*

VOL. x. of Sir George F. Hampson's great work on the moths of the world was issued in November, 1910, and was reviewed in NATURE for February 23, 1911 (p. 539). It was published in advance of the plates, which were not quite completed, but which appeared in May of the present year. They number twenty-six, and on each plate thirty-two species are figured, making a grand total of 842 species figured out of 1222 described (except a few described in vols. viii. and ix.) in vol. x., and if we add to this number the 214 species figured in the text, we find that only a few species are described and not figured, and even of these most are recognisably figured elsewhere. The enormous number of species of insects makes this of great importance, and the close resemblance and frequent dull colouring of many species often makes it difficult to point out their characters by description alone. With these excellent illustrations it should be easy to identify most, if not all, the species represented, and it is to be regretted that we have not yet a sufficient series of illustrated works on other orders of insects besides Lepidoptera.

The Mechanism of Weaving. By Thomas W. Fox. Pp. xxii+604. Fourth edition. (London: Macmillan and Co., Ltd., 1911.) Price 7*s.* 6*d.* net.

SINCE the first edition of this book was reviewed in NATURE on December 13, 1894 (vol. li., p. 149), 130 pages and twenty-six new illustrations have been added. Some parts of the work have been rearranged and others enlarged. The sections dealing with dobbies, Jacquards, figuring harnesses, card-cutting, picking, multiple shuttle boxes, letting off, taking up, beating up, loom adjustments, and reeds have all been extended; and those on gauze, lappets, and swivels have been rewritten. Descriptions of terry weaving, the automatic supply of weft to looms, and warp stop motions have been included in this edition, and also an ind.x.

Die Grundlehren der höheren Mathematik. By Prof. G. Helm. Pp. xvi+420. (Leipzig: Akademische Verlagsgesellschaft, 1910.) Price 13.40 marks.

THIS is much more like an English school class-book than usually reaches us from Germany. Practically it is a revision course of pure mathematics for what we should call a degree standard. There are chapters on differential and integral calculus, analytical plane and solid geometry, differential equations, interpolation, and the elementary theory of vectors. The author has had in mind the requirements of technical students, and his illustrations of theory are mainly of a practical kind. Finally, there are nearly 400 diagrams, so that the "appeal to the eye" has not been neglected. M.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Duration of Geological Time.

THERE is at the present time a great discrepancy in the numerical values given for geological time by the various methods employed. Considering the period which has elapsed since the commencement of the Cambrian, the evidence afforded by the study of radio-active minerals suggests that its length is of the order of 500 million years. Arguments derived from the study of sedimentation give, according to recent writers, a space of time for the same period not exceeding 50 million years, and the method based on the salinity of the ocean gives a similar figure. It is with regard to sedimentation that I wish here to make a few remarks.

It is evident that at the present time the volume of post-Eozoic sediments in existence is greater than ever it has been, and also that it is slowly increasing at the expense of the igneous and pre-Cambrian rocks now exposed to denudation. Knowing the rate of this denudation and the total volume of these sediments, all of which must necessarily have had their origin in igneous and pre-Cambrian rocks, the period represented by the fossiliferous strata is given by a simple process of division.

Situated as I am in Africa, without any geological literature, I can only give the most approximate estimates of the necessary factors with which to illustrate the method and arrive at the required length of time.

Sollas gives the thickness of the post-Eozoic sediments as 250,000 feet, or approximately 50 miles.

If we suppose all the sediments to be deposited at the maximum rate, they will form a regular bed along the continental shores for a distance of 35 miles seawards. Taking 100,000 miles as the average shore line of the Cambrian and subsequent periods, we arrive at the total volume of sediments—175×10^6 cubic miles. This spread over the whole globe represents a thickness of seven-eighths of a mile.

The average rate of continental denudation is probably 1 foot in 5000 years, or 1 mile in 26 million years. The continental area is 56 million square miles, one quarter of which is occupied by igneous and pre-Cambrian rocks, *i.e.* 14 million square miles. The rate of denudation of the latter is therefore 14 million cubic miles in 26 million years. The time for all the sediments to collect at that rate would be 325 million years. This figure is only an indication of the order of the time elapsed. It requires to be corrected for the following factors:—

A. Factors tending to decrease the estimate.

(1) Exposed surface of igneous and pre-Cambrian rocks may have been greater in former ages.

(2) Marine denudation of igneous and pre-Cambrian coasts.

(3) Greater density of igneous rocks than of sediments.

B. Factors tending to increase the estimate.

(1) Average land area has probably been about 0·8 that of to-day.

(2) Average continental mean height has probably been below that of to-day.

(3) Recent glaciation has laid bare many pre-Cambrian areas.

(4) Present is a volcanic period, increasing the weathering capacity of rain.

(5) Present climates are of maximum variability.

(6) Parts of land area are subject to deposition, *i.e.* negative denudation.

(7) Unconformities not represented by sediments elsewhere.

(8) Some sediments at great depths may have become igneous rocks.

It is hoped that, with the increase of accurate quantitative knowledge of former conditions, and of the processes at work in denudation and deposition, the above factors may be verified and allowed for in making an estimate of the antiquity of sediments.

The estimate here given is probably too low in the light of these corrective factors, and it is interesting to notice how much more closely it agrees with the results of the totally independent method based on radio-activity than do those deduced from the facts of sedimentation in the usual way.

Arthur Holmes.

Mosuril, Portuguese East Africa, May 6.

Breath Figures.

The two interesting letters on breath figures by Lord Rayleigh and Dr. Aitken (Nature, May 25 and June 15) seem to me to contain a statement of the cause of this phenomenon as well as the data necessary to support it.

Thus it is shown that a blow-pipe flame, burning sulphur, sulphuric acid, hydrofluoric acid, and caustic soda give these breath figures, while heat and alcohol flame give no such result. The conclusion apparent from these chemical data is that when the glass is coated with a film having an affinity for water, breath figures are formed.

Coal gas contains sulphur, and a blow-pipe flame gives sufficient sulphuric acid to form a film on glass; burning sulphur gives similar acid products, and both yield breath figures.

Sulphuric acid, hydrofluoric acid, and caustic soda are each capable of dissolving glass, which implies wetting and a certain amount of penetration; washing does not immediately remove this, and a film of acid or alkali is left capable likewise of forming breath figures.

In ammonia solution we have a strong alkali which cannot dissolve glass in the caustic soda sense; when it is allowed even to stand on a glass plate no breath figure is formed, but when it is well rubbed in a faint figure is produced.

If breath figures, from blow-pipe flames, say, be soaked in ammonia solution and washed, they may be gradually destroyed—by neutralisation of the acid in the superficial pores of the glass—until breath outlines only exist. These lines correspond to the lines of greatest acid penetration, and would be represented by charred lines on a piece of wood.

This gradual destruction of the figures on gradual neutralisation of the acid conclusively shows that these figures are neither due to cleanliness nor dust, as has been suggested.

This explanation enables one to predict that Dr. Aitken's suggested experiment of burning pure hydrogen in dustless air would give breath figures, while pure (dusty) hydrogen burning in pure (dusty) oxygen would give no figures, the reasons being that pure hydrogen burning *in air* gives sufficient nitric acid to produce figures, while pure hydrogen burning *in pure oxygen* produces no acid, and would produce no figures.

Caeteris paribus, it may be inferred that pure quartz glass would not give figures with sulphuric acid, but with hydrofluoric acid and caustic soda.

If the rays from radium can produce breath figures on glass, it constitutes another cause.

Glasgow. George Craig.

A Zenith Halo.

Will you permit me to quarrel with your correspondent for the heading "A Zenith Rainbow," attached to his letter from Bruges, published in Nature of May 11, p. 340? The phenomenon described was not a rainbow, as Mr. Gold has taken pains to point out. The heading is unfortunate, for two reasons: first, because it tends to confirm the prevalent misuse of the word "rainbow," and, secondly, because it will probably lead to the improper classification of Mr. Kreyer's letter in bibliographies.

The terminology of atmospheric optics is in a state of dire confusion, even among scientific men, but all the latter are agreed in calling the phenomenon in question a halo. Mr. Gold follows Pernter and most other writers in terming this particular halo an "arc of contact." However, this name, as well as the common alternative, "tangent arc," is objectionable, for the reason that the halo thus designated is by no means always in contact with, or tangent to, the halo of 46° (or the position which the latter would occupy if present). On this subject see M. Besson's article "Le halo du 21 décembre 1910; un arc tangent qui n'est pas tangent," in *La Nature* of March 11, 1911, p. 248. In the picture that accompanies M. Besson's article, the "tangent" arc is shown separated from the halo of 46° by an interval of about 3°.

Another common name, "circumzenithal arc," is open to the objection that this halo is but one of many that are central at the zenith.

The only accurate and distinctive name for the phenomenon is "upper quasi-tangent arc of the halo of 46°."

Statistics of the frequency of the various halo phenomena are misleading. Mr. Gold states, on the authority of Pernter, that the arc in question had been observed only about seventy times up to 1883. Besson, "Sur la théorie des halos," records 111 observations of it in ten years (1898–1907) *at Montsouris alone.* If systematic observations of halos were made all over the world, the frequency of such phenomena would doubtless be found to be far greater than is now generally supposed.

C. Fitzhugh Talman.

U.S. Weather Bureau, Washington, May 22.

Probably no one will be inclined to dispute Mr. Talman's proposition that systematic observations would largely increase the apparent frequency of the phenomenon mentioned.

With reference to the terminology, it is, as he points out, unfortunate that the terms "arc of contact," "tangent arc," should have come into general use for a bow which is not always in contact with the halo. I cannot, however, agree that Mascart's term, "quasi-tangent arc," is a satisfactory substitute. It was, I believe, intended to meet those cases when the arc is present at approximately 46° from the sun, but without the 46° halo. It does not fit cases for low or high solar altitudes when the arc is more than 46° from the sun. I think it would be better, instead of trying to indicate all the peculiarities of the phenomenon by its name, to use a term such as "auxiliary arc," if the present names are to be abandoned.

The phenomenon is described by Bravais as "un véritable arc-en-ciel," and this may account for the less appropriate use of the term "rainbow."

E. Gold.

Meteorological Office, South Kensington, London, S.W., June 2.

Jelly Rain.

On the morning of Saturday, June 24, the ground here was found to be covered with small masses of jelly about as large as a pea. There had been heavy rain on Friday night, and it was raining at 7 a.m., when, so far as I can ascertain, the phenomenon was first seen. On being examined microscopically the lumps of jelly turned out to contain numerous ova of some insect, with an advanced embryo in each. The egg itself is very minute—an elongated oval 0·04 mm. in length. Yesterday and the day before many larvæ emerged, and were obviously those of some species of Chironomus, though colourless, having no hæmoglobin, as is the case with the larvæ of *C. plumosus*. Not being an entomologist, I am at a loss to understand how these egg-masses could have appeared where they did unless they were conveyed by the rain, as it does not seem likely that the midges would have laid their eggs on pavements, gravel paths, tombstones, &c., even had they been wet; nor has any large number of adult insects been seen in the locality. It would be interesting to hear whether the same thing was observed elsewhere, and whether the phenomenon often occurs. Showers of algæ, small snails, and even frogs have been recorded from time to time, but I cannot recall a like instance to the above.

Eton, Bucks, June 30. M. D. Hill.

NOTES ON THE HISTORY OF THE SCIENCE MUSEUM.

THE recent discussions relating to the Science Museum have brought to the front several important questions connected with the utilisation of land for public purposes connected with science and the arts. They have occurred, too, at a time when the Royal Commissioners for the Exhibition of 1851, who in times past have behaved so generously in selling their land at a nominal price, have now parted with the last square yard of it which can be used for the high purposes determined upon by the late Prince Consort when it was placed at his disposal by them.

It seems desirable, therefore, to bring together as briefly as possible the facts touching the various allocations of the land which have been made from time to time. In this way we shall be able to touch upon some of the circumstances which have arisen regarding museum sites during the last half-century. Further, we shall be led to recognise the vast benefits which have been conferred upon the nation by the Commissioners' action.

The present site of the new Victoria and Albert Museum to the east of Exhibition Road was the first thus devoted in 1858, after the partnership between the Commissioners and the Government had been dissolved, chiefly to the purposes of Art, although a small Patent Museum ("the Boilers") had before that year been erected by the Government at a cost of 15,000*l*.

Next came the plot on the south face of the main square of the Commissioners' estate, facing Cromwell Road. This was the largest plot conveyed to the Government for national purposes, and its transfer was made memorable by a remarkable speech by Lord Palmerston concerning the Cabinet's decision to purchase it, and the uses to which it was proposed to apply it. In this speech (*Hansard*, June 15, 1863), Lord Palmerston, the Prime Minister, took pains to show the generous action of the Commissioners. Some extracts from this speech may be given.

"Sir, I rise to propose the Vote of which notice has been given, for the purchase of land and buildings on the site of the Exhibitions of 1851 and 1862. This City of London may, without exaggeration, be called the commercial capital of the world. It ranks high among the great political centres of civilised nations, and in point of wealth and population it may very fairly be stated to exceed any other European city. But the very circumstances which I have mentioned—the great wealth and great population of the City—have tended progressively to impair the architectural and ornamental character of the town. Our streets are narrow, our open spaces few and small, our public buildings are not many, and, respecting those which do exist, differences of opinion prevail as to their propriety of ornamentation and architectural design. We have not, in this town, what are to be found in many smaller towns upon the Continent, a great number of splendid palaces belonging to individuals. When we have mentioned Northumberland House, and, perhaps, Lansdowne House, if we are called on to enumerate other great ornamental constructions, we shall be driven to the, no doubt, very beautiful collection of apparent palaces—the clubs in Pall Mall, many of which are imitations of beautiful palaces on the Continent. In all the Italian towns, at Prague, and in most German towns, there are large piles of ornamental buildings which represent the wealth and taste of the nobility of those countries. What is the reason of that? What is the reason of the inferiority of this city as compared with other first-rate towns, in regard to the conditions of the space occupied by and the character of the buildings? The great run of the private houses of London may really be termed mean. I am not speaking of those more lately constructed, which are on a better plan; but the old red-brick houses of London are low, they are destitute of architectural ornament, and may be said to be mean in their character. What is the cause? It arises from the great value of the ground—from the immense competition which the wealth of the metropolis causes for the small spaces of ground. People are unable to buy a large quantity of ground on which to construct a house, and, having paid dearly for such a portion of the land as they require, they have smaller disposable means for the erection of ornamental and handsome structures. The price of land in London is very great. I will just mention a few instances to show the value that attaches to the surface in this great town. . . . Therefore I say that the natural progress of wealth and civilisation tends to add greatly to the value of land to be covered by buildings in the interior of towns; and admitting that there are certain requisites which are necessary for the development of the public establishments and buildings, the question arises where the land for such purposes can be acquired, and whether we should look for it in the centre of the town, where everything is covered with valuable property, or whether we should embrace the opportunity of acquiring it at certain greater distances, but still within reach for all the purposes to which it is to be applied. Well, we hold that the land held at Kensington by the Commissioners of 1851 does afford the means of providing for our immediate and prospective wants, and we are able to get land there for our immediate purposes on terms infinitely cheaper than those on which land can be acquired nearer the centre of the metropolis."

Having shown how the question was dominated by the price of land in various parts of the metropolis, Lord Palmerston passed to the then requirements of the Government. The chief of these was an expansion of the Patent Museum before referred to, and also of the British Museum.

In 1859, two years after the establishment of the Patent Office Museum, the Commissioners of Patents laid a Report before Parliament, in which the following passage occurs:—

"It is intended to make the Patent Office Museum an historical and educational institution for the benefit and instruction of the skilled workmen employed in the various factories of the kingdom, a class which largely contributes to the surplus fund of the Patent Office in fees paid upon patents granted for their valuable inventions. Exact models of machinery in subjects and series of subjects, showing the progressive steps of improvement in the machines for each branch of manufacture, are to be exhibited; for example, it is intended to show in series of exact models each important invention and improvement in steam propellers (steamboat propulsion) from the first engine that drove a boat of two tons burden to the gigantic machinery of the present day, propelling the first-rate ship of war or of commerce. The original small experimental engine that drove the boat of two tons burden, above referred to, is now in the museum."

Add to these illustrations of applied science similar illustrations of the instruments used in the advance of pure science, and we have a picture of what is required in the Science Museum of to-day.

Lord Palmerstone thus referred to the needs of this museum:—

"Now, the question is, what do we want? What are the requirements that press on the Government? In the first place, we want a Patent Museum. Anyone who considers the value of a great collection of models and inventions to those employed in the mechanical and productive arts of the country must know that it is of great importance that they should have access to a repository in which they can find everything connected with that particular department of industry to which they have devoted themselves. In America, a country not supposed to be addicted to unnecessary ornament, but where a great disposition is shown to practical improvement, there is a Patent Museum which covers eleven acres. Well, we do not propose a museum of such dimensions. I think that about three acres will be sufficient for all present needs in regard to a Museum of Patents."

He then passed on to the British Museum requirements:—

"Then we want an addition to the British Museum. The question then arises where that addition is to be found—whether the land is to be had by purchasing land in immediate contiguity to the British Museum, or by the purchase of land at Kensington, as we propose. Calculations have been made that eight acres are required, but that is, I think, more than is necessary. I think that five acres would be a nearer approximation, and three acres have been named as the smallest amount of space that is required."

Next we have a reference to the National Portrait Gallery, room for which was eventually found elsewhere:—

"We have got together, at some expense and trouble, a most interesting collection of portraits of distinguished men connected with the history of the country. They are now placed in a house where they cannot be seen, and it is urgently desirable to have a better building in which to place that Portrait Gallery, Then we have a Museum at Kensington, full of most valuable and instructive productions, and a Committee of the House of Commons that sat two or three years ago strongly recommended additions to that institution."

"Now, we calculate the cost of these various augmentations—supposing that the land were bought in the metropolis and at the rate which it now bears—as follows:—If eight acres are taken for the British Museum, the cost of land will be 390,000*l*., and the buildings 824,000*l*., making a total of 1,214,000*l*. If five acres only are required, the land will cost 240,000*l*. and the building 567,000*l*., making a total of 807,000*l*. Supposing the lowest estimate of three acres to be sufficient, the land will cost 150,000*l*. and the building 300,000*l*., making a total of 450,000*l*. I then take the Patent Museum, which will require three acres. The land is set down at 100,000*l*. and the building at 100,000*l*., making together 200,000*l*. . . . The Portrait Gallery will require half an acre, and we calculate will cost 25,000*l*. for land, and 25,000*l*. for the building, or together 50,000*l*. These sums would come to the following total:—If you take eight acres for the British Museum, the total for all these buildings will be 1,514,000*l*.; if you take five acres, 1,107,000*l*.; if three acres, 750,000*l*. Assuming that these are wants which Parliament may think it proper to meet, these would be the sums you would require if you took land now occupied by houses in any central part of town. Now, the proposal that we make is one which the Committee will see is a very economical one. By the plan which we recommend we should have much more space and at far smaller expense. The arrangement that we propose is, that the public should purchase seventeen and a half acres. (Several hon. Members: Sixteen.) No—seventeen acres of the land belonging to the Commissioners, which is now covered with the building in which the Exhibition took place. For that land the Commissioners are willing to take 120,000*l*. My hon. friend will admit that to get seventeen acres of land at about 7000*l*. per acre, for which we should pay 50,000*l*., 60,000*l*., or 70,000*l*. an acre elsewhere, is a considerable advantage."

It will be gathered from this speech what an enormous saving had been effected by paying such a low price for the land. The plot in question was sold for half its then value, thus presenting the public with 120,000*l*. In the conveyance a covenant was inserted restricting the use of the land to purposes connected with Science and the Arts.

In 1863 the only land to be obtained on these low terms was the large plot purchased from the Royal Commission of 1851, capable of containing the Patent Museum, the Natural History Museum, and other institutions; but by 1869 there was another plot available for the building of a Natural History Museum. This plot consisted of land reclaimed from the Thames near Hungerford Bridge by the construction of the Embankment. As no action had yet been taken on the Cabinet decision of 1863, referred to in Lord Palmerston's speech, concerning the Natural History Museum, it was suggested that it should be built here, and a Select Committee was appointed to inquire into the matter. Their first report was published on May 10, 1869 (Report of Select Committee on Hungerford Bridge), and this was soon followed by a second.

These reports and their accompanying plans are a mine of information, especially in relation to the then stated requirements of biologists with regard to the natural history collection.

It has already been shown that the demands for space for these collections before the Government in 1863 were three acres and eight acres, and that Lord Palmerston compromised with five acres, which were to be provided for out of the sixteen and a half acres purchased from the Royal Commission of 1851.

In the interval between 1863 and 1869 further inquiries had been made, as will be gathered from the following extracts of the evidence (second Report):—

"Examination of Prof. Owen, p. 107.

"2343. [Mr. Cowper.] Will you state, according to your present views, what area you think necessary for properly providing for the natural history collection?—Mr. Hunt, in 1863, went carefully into all those details and questions with me and ultimately embodied them in a plan, which is printed in a Parliamentary paper. He arranged the building for present actual wants on a space of three acres, and I asked for two additional acres for later additions, looking forward to the next thirty years."

"2344. Is that your present view of the subject?—It is so."

"Examination of Prof. Huxley, p. 112.

"2422. [Mr. Tite.] Probably three acres might include it all?—Yes. I reckon that five times the space now occupied by the bird-room in the British Museum (taking that space at 15,000 square feet) would suffice for the erection of a building in which the largest zoological collection that can ever be formed may be displayed and preserved in a manner most advantageous to the public and to men of science. Thus, for zoology, I ask, say, an acre and three-quarters; I should provide another 15,000 square feet for the fossils, and half as much for the mineralogical collections; and half as much for the botanical collection, if any such collection is to be taken to the new site. This makes a sum total of about two acres and a half, and half an acre for margin, offices, and residences, and the like, and I believe that ample provision will be made not only for all present, but for all future, needs of a great national natural history museum. In saying that, I think the building ought to be of only one storey, and top-lighted; I mean so far as it is devoted to museum purposes. But I think that the museum galleries might be conveniently supported on a side-lighted ground floor, which would afford ample room for the library and offices.

"2423. [Mr. Layard.] Of course, when I asked you the question about the space, I meant to include all the natural history collections, together with the collections of mineralogy, zoology, geology, osteology; in fact, everything that appertained to the department of science in the British Museum?—My first answer had reference entirely to the zoological collection; but if you wish to add the other collections I should say, speaking roughly, another couple of galleries, making, say, seven altogether, would be sufficient, but that is, of course, a mere estimate, and a very moderate one."

The plans show that the building proposed on this site covered about $3\frac{3}{4}$ acres, and there was little, if any, room for expansion, as the District Railway and wide roads had to be provided for, and it was proposed that the latter should bound the area available for museum purposes.

Ultimately this scheme was given up, and the South Kensington site was fixed upon, the building covering the same ground—$3\frac{3}{4}$ acres—as that proposed for the Hungerford Bridge site.

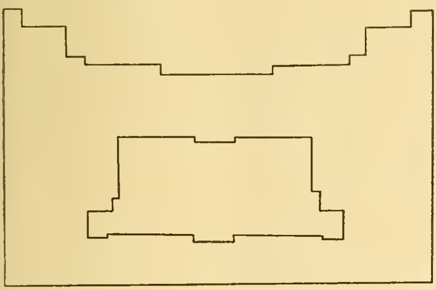


FIG. 1.—Plan of plot and building erected on it.

It would seem that between 1863 and 1869 the question of the Patent Museum had dropped into the background, for the plan ultimately adopted for the Natural History Museum was allowed to sprawl over nearly the whole of the plot as shown in the copy of the map published in the sixth Report of the Commissioners of 1851 (1879). It thus put difficulties in the way of using the unoccupied land. I give another plan, which shows that two museums of the same plan and size, say a Natural History Museum and a Patent Museum, could have been built on the land, leaving some eight acres for future extensions. Of course, if this had been carried out, any desirable change in the plan might have been made.

It would seem also that all the data collected in 1863 and 1869 had either been forgotten or shown to be worthless, for there is nothing that I know of in the shape of public documents to show, until long afterwards, of what part of the $16\frac{1}{2}$ acres bought the British Museum Trustees might consider themselves to be in possession. The land all round the museum was necessarily planted and laid out as gardens, because at the time it was not used for building purposes.

The first thought seems to have been given to this matter in 1881, after the erection of the building. A fence was erected to cut off the land to the north, and the new museum then found itself in the centre of a square containing more than $12\frac{1}{2}$ acres. Shade of Owen! shade of Huxley! The first had asked for three acres, and two more to cover the expansion of thirty years, and the latter three acres, in which "the largest zoological collection that can ever be formed may be displayed and preserved in a manner most advantageous to the public and to men of science."

The second thought was given to this subject in 1899, when a new north boundary was considered. This added one and a half acres more land, making more than fourteen acres in all.

There is no doubt that the Government *then* allocated this land for Natural History Museum purposes. In the recent "Correspondence" (Cd. 5650, p. 1) a letter of 1910 is printed, quoting a letter of 1899 "with reference to the boundary line between the ground which it was then contemplated should be allotted for the use of the Natural History Museum and that provided for the use of the Education Department (Science Museum).

"It was then arranged that a boundary should be fixed, as shown upon the plan, which was forwarded to your predecessor at that time, and it was decided that all the land to the south of that land should be regarded as ear-marked for the future of the expansion of the Natural History Museum."

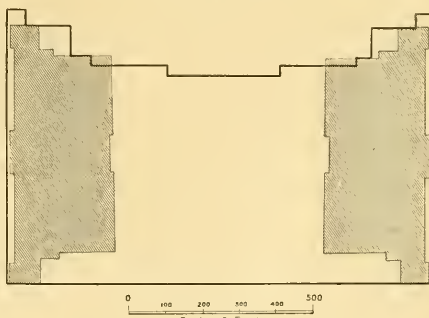

FIG. 2.—Plan showing what might have been.

As the building covers $3\frac{3}{4}$ acres, this allocation provided $10\frac{1}{4}$ acres for future expansion.

Incredible as it may seem, this is more by an acre than the area of the parent institution in Bloomsbury at the present time; an area required to garner all the collections on all subjects except natural history, made since 1753, say during a century and a half. Until 1907 it occupied seven and a half acres. In 1907 five and a half acres additional were bought, making thirteen in all.

To state this fact is to show that something had gone wrong somewhere. Had someone blundered?

This does not seem to be impossible, for the Government has recently been led to reconsider the matter. We read in the "Correspondence" referred to:—

"The Treasury and this Board [of Works] have had no desire to disturb the arrangement then [in 1899] arrived at so long as the occupation of this land by the Natural History Museum does not affect injuriously the interests of any other Department."

"The land and the Museum Buildings being vested in the Commissioners of Works, are the property of His Majesty's Government, and they are bound, therefore, in the interests of the public, as a whole, to consider without prejudice whether the time has not now arrived when some modification of that boundary [that of 1899] should be made."

The "Correspondence" goes on to say:—

"There can be no doubt that, whatever shape the new Science Museum may ultimately take, it will be necessary to build up to the boundary line, and it is probable that, in order to safeguard both the Science Museum and the Natural History Museum from fire, and to lay out the ground to the best advantage, it may be necessary to construct a road, to be used privately between the two buildings."

In later "Correspondence" (Cd. 5673, p. 3) a block plan is given in which the revised boundary is indicated by the proposed road.

This proposed road, if constructed, involves the proposed to construct the new private road for the special purposes of the Science Museum. This new road will have to run from Exhibition Road to Queen's Gate, a distance of 1170 feet, and will absorb *at least* three-quarters of an acre of ground. The architects of the Imperial Institute and the Imperial College between them absorbed three acres in their new road running between the same termini.

It must be pointed out that the proposed new road will run parallel to, and only fifty feet away from, the existing road, which has served the purposes of the Natural History Museum for the last thirty years. Curiously enough, this road is not shown on the block plan.

Even a Quartermaster-General proud of his department would scarcely recommend the construction of two parallel roads fifty feet apart, especially where every square foot of space is so precious and is being so hotly contested.

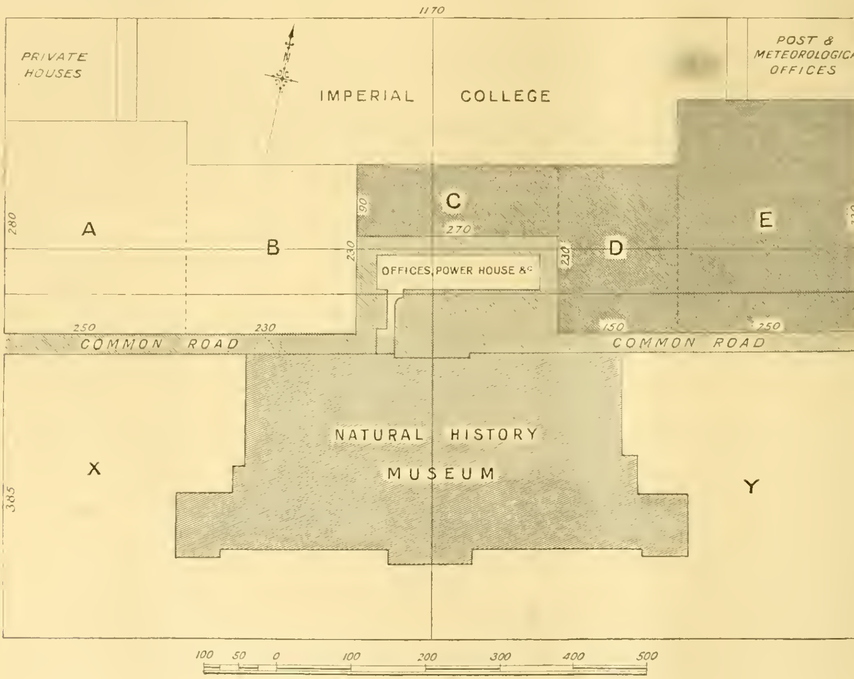

FIG. 3. Plan showing utilisation of the existing road and spirit museum building.

destruction of the building of the spirit museum. It is the inflammable nature of the contents of this building which has been objected to, and not the building itself, which might from its position be conveniently applied to many uses for one or both museums.

This action of the Government in changing the boundary has withdrawn the one and a half acres additional land included in the boundary in 1899; but that still leaves the Trustees in possession of twelve and a half acres, two and a half times what was asked for in 1869 by their responsible officer to provide for a thirty years' expansion.

The newly defined frontier is really the old line of fence erected in 1881, to the north of which it is

The question arises whether the existing road is not really the best boundary. This I referred to in my letter to *The Times* of May 30. It would serve the purposes of the two museums as regards fire precautions and other matters; no sacrifice of space for a new road, no breaking up of frontages, and no destruction of the spirit museum would be necessary.

Further, the existing road when the boundary was thus established could be made to enclose the *body* of the *spirit* museum, which might remain for use as offices, workshops, or other convenient use, in a central backyard, away from any frontage; this, as well as the road which would be carried round it, would be common to the purposes of both museums.

In the accompanying plan (Fig. 3) I have shown gardens, until they are built over, as an embellishment of the south front. I append photographs showing the present condition of the ground and how it would appear if the Science Museum were built to

FIG. 4.—Things as they are.

blocks A, B, C, D, E, which could then be used for the Science Museum; the area is six acres.

With regard to the Natural History Museum, it may be stated that with the three boundaries above referred to the included areas are as follows:—

	Feet	Acres
Boundary fixed in 1889	1170 × 530	= 14·2
Proposed road	1170 × 470	= 12·6
Existing road	1170 × 415	= 11·1

harmonise with the Victoria and Albert Museum across Exhibition Road.

In the photograph the frontage is shown broken by the road, but there is no necessity for this if for any reason it would be better to continue it for the purposes of either museum.

If the blocks C, D, E, were built on first, the combined area of the building, just over three acres, would be a little less than that of the Natural History

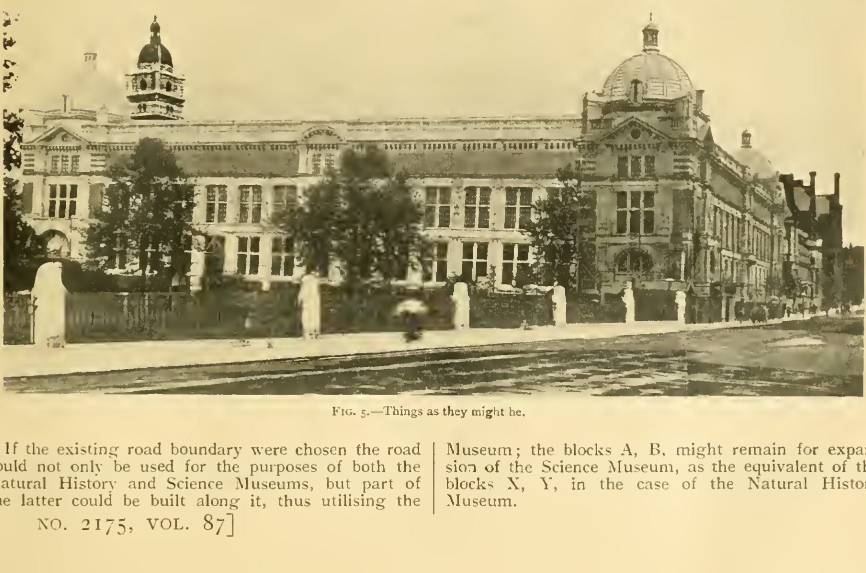

FIG. 5.—Things as they might be.

If the existing road boundary were chosen the road could not only be used for the purposes of both the Natural History and Science Museums, but part of the latter could be built along it, thus utilising the Museum; the blocks A, B, might remain for expansion of the Science Museum, as the equivalent of the blocks X, Y, in the case of the Natural History Museum.

I believe that if such a scheme as this were put forward as a compromise, those who declined to consider it as a way out of the present *impasse* would put themselves in the wrong, in the minds of straight-thinking people who know the history of the question and the requirements of science taken as a whole.

It must be remembered that these museums, to obtain their highest use, must be in close association with institutions in which teaching of the corresponding sciences is carried on, and reciprocally the institutions for higher teaching and research which are already housed at South Kensington require museums of the several sciences in the immediate neighbourhood. In view of these requirements, the removal of one or other of the museums to a distant site is not a practicable alternative. By the compromise here suggested a real Science Museum, in its widest sense, would be established, with two branches dealing respectively with the natural history and the physical and mechanical sciences, in immediate contiguity to the Imperial College. It only wants a consideration of the many memorials presented to the Government since 1858, and of the recommendations of the Duke of Devonshire's Royal Commission of 1871, to be perfectly certain that in the future the two museums will be under one master instead of two.

NORMAN LOCKYER.

EARTHQUAKES AND LUMINOUS PHENOMENA.

IN vol. xiv., No. 6, 7, and 8, of the *Bollettina della Societa Sismologica Italiana*, we find a very long paper by Dr. Ignazio Galli on the collection and classification of luminous phenomena observed at the time of earthquakes. After an introduction, he considers that which might be excluded and the difficulties first met with in the formation of a catalogue of the phenomena he discusses. The illustrations which he gives of luminosities and other strange phenomena which have appeared at or about the time of earthquakes are 148 in number. The date of the first is 89 B.C., and the last March 30, 1910. These descriptions occupy 184 pages. The various luminosities are classified under more than twelve heads, and to these are added the number of times that earthquakes have been associated with vapours, smoke, and odours of sulphur or bitumen.

Seismologists have known for years past that certain earthquakes are said to have been accompanied by appearances of the Aurora Borealis, glimmering lights in the sky, fire-balls, *ignis fatui*, lightnings, corrustations and emanations from the soil, but this is the first time so large a collection of these phenomena have been brought together for their consideration.

When resident in Japan the present writer made many experiments extending over some years on electrical and magnetic phenomena associated with seismic disturbances. He also collected material from all parts of the world which bore upon these associations. One conclusion arrived at is that it is an undoubted fact that at the time of certain large earthquakes, as, for example, the one which in 1906 destroyed Valparaiso, curious lights which, in this instance, were compared to those of chain lightning, have been seen playing across the hills in the epicentral region. Observations of this nature led the writer to make experiments at Shide, in the Isle of Wight, and at the King Edward VII. Mine at Camborne, in Cornwall. The object was to determine whether there was or was not at the time of a large earthquake a practically instantaneous transmission of energy to distant regions other than that recorded by seismographs. It was observed, and still is observed, by many persons that the face of a very large chalk pit at Shide exhibits, after dull damp days, a flaring luminosity. In a chamber at the end of a tunnel in this pit, a cylinder carrying photographic paper was installed. This cylinder was enclosed in a box, one end of which was a metal plate containing three holes. The plate touched a flat chalk surface. The cylinder took one week to turn; therefore parts of the paper before the holes were very slowly exposed to a chalk surface about 3/16th of an inch distant. On certain weeks the results were nil. Other weeks, after the development of the paper, there were three dark bands corresponding to the position of the holes, suggesting that the chalk had acted like an extremely feeble light. Another experiment was to place small pieces of photographic paper in envelopes, a certain number of which had a small glass window; these were placed against the face of the chalk. The image of the windows was frequently obtained, but nothing more than the effects of damp was found upon the others.

The conclusion arrived at was that the photographic effects were in no way connected with radio-activity, but they were probably electrical. The effects obtained in the granite of Cornwall were very marked and, like those observed in the Isle of Wight, varied in their intensity. As to the possibility of these effects being due to micro-organisms, a number of investigations were made, but there were no indications that organisms obtained from the chalk surfaces were connected with luminosity.

Whether these observations throw light upon differences in climate observed at different places, even though they may be near to each other, is a matter for conjecture, but future researches may show that the well-being of living things on the surface of our earth is more dependent upon its radiations than has hitherto been imagined.

I venture to refer to these experiments to show that the outcome of observations similar to those catalogued by Dr. Galli have not been overlooked in this country.

The 148 detailed descriptions which he has collected are used as subject-matter for twenty-six analyses. For example, did lightnings, thunderstorms, meteors, beams of light, luminous clouds, hot vapours, and other appearances precede, accompany, or were they noted after an earthquake? Dr. Galli says that sixteen of these analyses are nothing but the analytical *résumé* of the various phenomena which have been observed, and they therefore possess a real value which cannot be sensibly altered by any report that is ill-founded or untrustworthy. The remaining ten are provisional conjectures which await the judgment of physicists and seismologists. They will be confirmed or contradicted by future observations. If they fall, either partly or entirely, they will at least have the merit of having put the question as to certain probable causes of luminous phenomena connected with earthquakes. At the same time, as one heartily wishes, they may suggest hypotheses which are better, broader, and more synthetic than those the writer of the paper has brought forward.

Dr. Ignazio Galli is to be congratulated on his work, which directs attention to a neglected branch of seismology. When a face of rock 100 or more miles square is rudely pushed over another face, equal in area, it seems reasonable to suppose that such an adjustment should be accompanied by luminous and other phenomena.

JOHN MILNE.

NOTES.

THE arrangements for the meeting of the International Association of Seismology are now nearly complete. The following foreign States will be represented:—United States, France, Russia, Austria, Germany, Hungary, Belgium, Switzerland, Spain, Greece, Italy, Holland, Rumania, Servia, Bulgaria, and probably also Japan and Norway. At the opening meeting on July 18 the Lord Mayor of Manchester and the Vice-Chancellor of the University will welcome the delegates, and Prof. Schuster, as president, will deliver a short address. On the same day the Lord Mayor will hold a reception in the Town Hall. The council of the University will give a dinner, and Dr. Shaw, the director of the Meteorological Office, will invite the guests to an excursion to view the observatory at Eskdalemuir. Among British men of science, the following have signified their intention of being present:—Sir George Darwin, Dr. Milne, Prof. Perry, Prof. Lamb, Prof. Knott, Prof. Love, Mr. Oldham, Dr. Shaw, and Dr. G. W. Walker.

EARLY on the morning of Saturday, July 1, a school of cetaceans, numbering apparently between fifty and sixty head, was stranded on the beach at Mount's Bay, near Penzance. Judging from an illustration in *The Daily Mirror* of July 3, these cetaceans may be identified with the black-fish or pilot-whale (*Globicephalus melas*), which derives its name of ca'ing whale from the habit of entering bays or inlets in schools, and thus becoming stranded, as in the present instance. Although such events are not uncommon in the Faröes and Shetlands, they are rare further south, and the Mount's Bay case appears to be unique. When the tide rose several of the stranded creatures succeeded in making their escape, but those unable to get away, if not already dead, were shot. Such stranded cetaceans are, we believe, Crown property, and application was accordingly made to the Board of Trade for permission to obtain specimens for the Natural History Museum. This being granted, a taxidermist was dispatched by the night mail on Monday with instructions to prepare skeletons and make preparations of some of the viscera. The largest specimen is stated to be about 25 feet long.

THE fact that on July 3 eleven aëroplanes crossed the Channel from Calais to Dover between 4 and 5.15 a.m. without a mishap is a striking proof—if proof be now needed—of the growing trustworthiness of men, motors, and machines. Accidents rarely occur now to experienced pilots, though their experience is small compared with what is considered necessary to make a first-class motorist. The oldest European pilot now flying has barely three and a half years to his credit, while it is well known that double that time scarcely suffices to produce a racing motorist of the highest rank. The eleven aëroplanes included eight monoplanes: Morane (Védrines), two Déperdussins (Vidart and Valentine), Sommer (Kimmerling), two Blériots (Lieut. Conneau and Garros), R.E.P. (Gibert), and Train (Train); and three biplanes: two Maurice Farmans (Renaux, with a passenger, and Barra), and Bristol (Tabuteau). It is worthy of remark that all the machines had Gnome motors except those of Gibert, who used a 60 horse-power R.E.P., Barra, who had a 70 horse-power Panhard, and Renaux, who had a 60 horse-power Renault. The occasion was the seventh stage of the circuit of Europe—from Paris *via* Liége, Spa, Liége, Utrecht, Brussels, Roubaix, Calais, Hendon, Calais, back to Paris again, a total distance of about 1025 miles. At the time of writing, omitting Valentine, Train, Barra, and Tabuteau, all the above mentioned have completed all the stages up to Hendon. The total times of the first four from Paris stand at present as follows:—Conneau, 51h. 43m. 5s.; Garros, 55h. 37m. 7s.; Vidart, 67h. 47m. 57s.; and Védrines, 70h. 20m. 20s.

AN archæological discovery of some interest has been made at Corfu. Excavations carried on by M. Versakis, the local Ephor of Antiquities, on the site of the ancient city (Palæopolis) of Korkyra, at the expense of the Greek Archæological Society, have resulted in the discovery of fragmentary sculptures belonging to an early temple. The most important fragments are those of a Perseus and Medusa group, which reminds one very forcibly of the metope sculptures of Selinus. The remains of colour on them are reminiscent of the brilliant painting of the early sculptures from the Athenian Akropolis now in the Parthenon Museum. There are other fragments of sculpture, all of interest. The discovery having been made during the stay of the Emperor William at the Achilleion this year, naturally attracted the eager attention of his Majesty, who at once consulted Prof. Dörpfeld, the director of the German Archæological School at Athens, with regard to carrying on the excavations himself. This has now been arranged, and Prof. Dörpfeld will carry on M. Versakis' work at the expense of H.I.M. Prof. Dörpfeld is of opinion that the remains belong to a temple of Apollo, dating to the seventh century B.C., probably. The resemblance of the style of its sculptures to that of the Selinuntine metopes is interesting in view of the fact that both Selinus and Korkyra were colonies of Corinth.

THE International Congress of Naval Architects and Marine Engineers, which is being held in celebration of the jubilee of the Institution of Naval Architects, was opened by the Duke of Connaught on Tuesday, July 4, many delegates of foreign Ministries of Marine and foreign societies being present in the assembly. The congress was to have been held last year, but was postponed in consequence of the death of King Edward. The council of the institution, to do honour to their guests from abroad, has made the following additions to the list of honorary members:—The King of Norway, the King of Spain, the King of Sweden, Prince Henry of Prussia, the Archduke Ferdinand, the Duke of Connaught, the Duke of Genoa, Prince Roland Bonaparte, Lord Rayleigh, Admiral Dewey, Admiral Togo, and Admiral Ijuin. An account of the proceedings of the congress will appear in a subsequent issue of NATURE.

THE fortieth meeting of the French Association for the Advancement of Science will be held this year at Dijon from July 31 to August 5, when M. Charles Lallemand will be the president. The sections of the association and their presidents are as follows:—M. E. Belot, mathematics, astronomy, geodesy, mechanics; M. Galliot, navigation (civil and military), engineering; Prof. Hurion, physics; Prof. Georges Lemoine, chemistry; Prof. Violle, meteorology and physics of the globe; Prof. Collot, geology and mineralogy; Prof. Quéva, botany; Prof. Bataillon, zoology, anatomy, physiology; Dr. Henri Martin, anthropology; Dr. Paul Courmont, medical science; Dr. Delherm, medical electricity; Prof. Grimaud, odontology; M. Lucien Magnien, agriculture; M. Auguste Chevalier, geography; M. Paul Razous, political economy and statistics; Prof. Beauvisage, pedagogy and teaching; Prof. Jules Courmont, hygiene and State medicine; Dr. Simon, archæology. Inquiries may be addressed to the secretary of the association, Dr. Desgrez, 28 rue Serpente, Paris.

THE third International Congress for Sanitary Dwellings is to be held this year, on the occasion of the International Hygiene Exhibition at Dresden, on October 2–7. The congress is to be divided into nine sections, as follows:—Group A: *General.*—Section i. Town-planning (building, forms of country settlement, garden cities, width of streets, height of building). ii. Construction of buildings (planning, distribution of space, building material, foundations, basement, kitchens, lavatories, floors and ceilings, staircases, lifts and roofs). iii. Internal arrangements (lighting, heating, ventilation, furnishing). iv. Sanitation (cleaning, removal of refuse, disinfection). Group B: *Dwelling Houses.*—v. Dwelling houses in towns. vi. Dwelling houses in the country. Group C: *Special Kinds of Dwellings.*—vii. School buildings, boarding-schools, prisons, hotels, lodging-houses, hospitals, convalescent homes, baths, churches, theatres, and other public buildings. viii. Work-rooms and workshops, means of communication and transit (railways, tramways, ships, vehicles, &c.). Group D: ix. Legislation, executive, statistics, &c. Prof. Renk is the president of the congress, and Dr. Hopf the general secretary, and all inquiries should be addressed to him at Dresden, Reichsstrasse, 4. Other communications and money-orders should be addressed: Kongresskanzlei, Zimmer 156, neues Rathaus, Dresden.

So far as is at present known, no fresh cases of plague among the rats have been discovered in the last few days at the riverside wharves at Wapping and Shadwell (see NATURE, June 29, p. 592). *The Times* special correspondent in the issue of June 28 pleads for an organised inquiry into the incidence of plague among the rats in England. He points out that in East Anglia, where plague was present last September, no action had been taken by several of the rural district councils, and that in London only spasmodic attempts at rat destruction have been undertaken. He also condemns as unwise the attitude of the Local Government Board in attempting to suppress knowledge of these recurring outbreaks of plague among the rats. No other country has so much at stake as Great Britain, with her vast carrying trade, and a persistent, elaborate, and prolonged inquiry into the radius of rat-infection is urgently called for.

THE issues of *Travaux de Soc. Imp. des Naturalistes de St. Pétersbourg—C.R. des Sciences* from January to March contain several articles on various groups of invertebrates, for the most part in Russian, notably two by Mr. K. Derjugin on the scientific results of the cruise of the schooner *Alexander Kowalevsky* in the Kola-Fjord during 1908–9.

To the *Sitzungsberichte* of the Vienna Academy of Sciences for December, 1910 (vol. cxix., part i.), Mr. J. Tandler contributes an important memoir on the pectoral muscles of mammals, based on MS. left at his death by the late Dr. E. Zuckerkandl. The anatomy and relationships of these muscles are described in representatives of the various orders, from the opossum to the gorilla and man.

IN reference to the paragraph on African dinosaurs on p. 390 of NATURE of May 18, Mr. F. A. Lucas writes to say that the longest rib of a dinosaur from the western United States, described in 1904 by Riggs under the name of *Brachiosaurus altithorax*, measures 2·74 m., or somewhat longer than the corresponding bone of the African species. The length of the femur is 2·03 m., and that of the humerus 2·04 m. The latter is a little less than the length of the African humerus, but serves to show that the femur is not necessarily the longest of the limb bones. In Mr. Lucas's opinion Brachiosaurus and the African dinosaur may prove to be related.

THE migration of the godwit from eastern Siberia to New Zealand forms the subject of an article by Mr. R. W. Reid in the July number of *Chambers's Journal.* The birds leave the extreme north of New Zealand early in April, and reappear usually in the first weeks of October; and they appear to spend a couple of months in the far north, four months in travelling, and the remaining half of the year in their southern home. They thus enjoy two summers in succession. When they arrive in New Zealand the godwits are in their winter plumage, but those which remain when their fellows fly north assume the brilliant summer dress, although they never breed. These non-migrating birds thus wear a summer livery in winter. It would be interesting to ascertain whether the Antarctic affords suitable breeding-grounds for the species.

MUSK-RATS (genus Fiber) form an exclusively North American group of rodents, with a distribution extending from the neighbourhood of Bering Strait to Arizona and the Gulf of Mexico. With such a range, it is remarkable that they have not hitherto been detected in north-eastern Asia, either in the living or fossil condition. Full details of their taxonomy, distribution, habits, and commercial importance are given by Mr. N. Hollister in a memoir published by the U.S. Department of Agriculture as No. 32 of the North American Fauna. The typical species is divisible into a number of local races, but the Newfoundland musquash (*F. obscurus*) is recognised as a distinct species on account of its inferior size, relatively large hind feet, dark colour, and small and weak skull and teeth. A form from a small area on the coast of Louisiana is likewise ranked as a species (*F. rivalicius*), although it differs from the typical *F. zibethicus* mainly by its somewhat inferior dimensions, duller colour, and darker under-parts. Three extinct species are recognised. In spite of incessant pursuit for the sake of their fur, which is steadily increasing in value, musk-rats continue to hold their own, and, according to the author, will probably become in the future the chief American fur-producer.

INHERITANCE of heterostylism and colour in *Primula sinensis* have provided the subject of extensive experiments by Mr. R. P. Gregory, who presents his latest results in *The Journal of Genetics* (vol. i., No. 2). Colour has to be considered independently for the flowers and stems; when absent from the flowers they are white, and when absent from the stems they are green. Colour may also be distinguished as full or pale. Full-coloured flowers are only produced on deeply coloured stems, although in the horticultural class "Sirdar," where the petals are full-coloured but the pigment occurs in dots, the stems are green. Full colours are dominant to pale; magentas are dominant to reds, and both colours to blue; whites may be dominant or recessive to colours.

A MORE than ordinary amount of critical investigation has been undertaken by Dr. A. S. Hitchcock and Miss A. Chase in the compilation of the monograph on North American species of Panicum, published as vol. xv. of the Contributions from the United States National Herbarium, as may be surmised from the list of herbaria consulted, and is confirmed by examination of the details supplied. The authors take a restricted view of the genus, which is founded on the species *Panicum miliaceum.* In addition to the section of Eu-Panicum, under which seventy-five species are collected, a small subgenus Paurochætium with six species, and a large subgenus Dichanthelium, comprising 110 species, are segregated. The two larger sections are again subdivided into groups named after a leading species. Members of the Dichanthelium section are characterised by distinct vernal and autumnal habits.

The question having been raised whether the timber from teak plantations is as strong as that from natural forests, specimens from trees grown in Burma were subjected to a series of tests, with the results recorded by Mr. R. S. Pearson in Forest Bulletin No. 3 published by the Government of India. The samples were, of course, similar in dimensions, and care was taken to get them as uniform as possible with respect to moisture content. Only in the case of transverse strain did the timber of natural-grown teak give a higher coefficient, and then the difference was small enough to be negligible for practical purposes. Another Bulletin (No. 2), issued with the former, provides a set of diagrams and curves, prepared by Mr. F. A. Leete, to show the relation between age, girth, number of stems, and height of teak trees in fully stocked plantations. The data may be used to determine whether any given area is suitably stocked or if thinning is required.

In *La Géographie* for April M. C. Rabot summarises his own work and that of others relating to the superior limits in altitude of forest trees in Scandinavia, and comes to the conclusion that the retreat of these upper limits is to be attributed to climatic variation or, more exactly, a lowering of the summer temperature, which has been estimated at 2·5° C.

In the Transactions of the Royal Society of Canada Dr. W. Bell Dawson describes in general terms the scope of the investigations carried on by the Tidal Survey of Canada. An important portion of the work has been the establishment of local bench-marks and the determination of their relation to mean sea-level, since no general system of levels yet exists in the country. A number of these have now been fixed, and are described in a recent (1906) report of the marine department, but their connection by lines of precise levelling is still wanting.

Messrs. S. Nakamura and K. Honda contribute a lengthy paper to the Journal of the College of Science at Tokio University on seiches in some lakes of Japan. Starting with a Sarasin limnimeter, a simpler type of portable instrument was found desirable, and each of the authors produced one which was found to be well suited to the investigation in hand. Large-scale records of the curves obtained with these instruments are given in facsimile, and these show the very marked oscillations of the water set up by violent thunderstorms passing over the lake while the record was being taken.

In the *Arkiv för Matematik, Astronomi och Fysik* of Stockholm, Band 6, No. 40, Mr. O. A. Akesson puts forward a method for determining the direction of ice-drift in the neighbourhood of the Pole. Supposing such drift to be rectilinear and uniform, he utilises four altitudes of the sun taken in pairs at about six hours' interval, as long a period as practicable separating the first and last pair. The Greenwich times of the observations are supposed to be known, and, following the method employed by Prof. Charlier, the position of the first point and the direction and rate of drift are obtained. An example from the voyage of the *Fram*, when ice-bound from February, 1893, to August, 1895, is given in illustration of the method.

At a meeting of the Research Department of the Royal Geographical Society, Dr. Strahan presented the fourth report on the investigation of British rivers, which dealt with the Exe, the Creedy, and the Severn. Gauge readings and discharges had been taken frequently, and an interesting determination of the bottom-load moved by the Exe in each of the past seven years was included. The rainfall has also been studied to obtain the ratio of the run-off for the river system and for different tributaries. This most important investigation can only advance slowly on account of the lack of local observations having any considerable continuity and being satisfactorily comparable. Even under the present arrangements, it is difficult to ensure brief flood waves being adequately recorded at all stations, but the results testify the importance of the inquiry and the need for continuing it on as wide a basis as possible.

The meteorological charts for July issued by the Meteorological Committee contain, *inter alia*, timely and useful notes on the cyclonic storms of the Indian Ocean. During that month the south-west monsoon dominates the weather conditions over the Bay of Bengal and the Arabian Sea, and storms over the head of the bay are of comparatively frequent occurrence; the force of the monsoon in the Arabian Sea attains at times thirty to forty-four miles an hour. In the South Indian Ocean cyclonic storms are (so far as available observations show) practically non-existent in July; only one trustworthy storm track is shown there on the chart during a 38-year period. The interesting synoptic weather charts over the North Atlantic for June 8–14 show that a cyclonic area which was formed off Newfoundland on June 11 moved steadily eastward, and at the close of the period was beginning to influence the weather on our extreme western and south-western coasts.

An interesting contribution to *Symons's Meteorological Magazine* for June, by Mr. R. C. Mossman, now attached to the Argentine Meteorological Office, refers to the probable rainfall in the north-east of England during the present summer. On comparing the rainfall at Cordoba for the first quarter of the year for the thirty-three years 1878–1910 with that of the north-east of England for the third quarter, it is seen that the values are generally the reverse of each other, *i.e.* when the rainfall at Cordoba is in excess of the normal during the first quarter, it is in defect over the north-east of England in the third quarter, and *vice versa*. During the first quarter of this year the rainfall at Cordoba was only 46 per cent. of the normal. So far as these statistics go, therefore, there is a distinct suggestion that the present summer (July to September) will have a rainfall in excess of the normal over the north-east of England.

The summary of the weather for the first six months of the present year, which has just been issued by the Meteorological Office, shows that the mean temperature was slightly in excess of the average in all parts of the United Kingdom, taking the period as a whole. The absolute highest temperature in any district during the six months was 84°, in the north-east of England, and 80° has been exceeded in every district except in the north of Ireland and in the Channel Islands, whilst the lowest temperatures are below 20° in every district except in the Channel Islands, the absolutely lowest reading being 11°, in the east of Scotland. The largest aggregate rainfall for the six months January to June inclusive is 24·02 inches, in the north of Scotland, which is 0·58 inch more than the average; but this is the only district with an excess of rain except the east of England, where the aggregate was 10·33 inches and the excess 0·15 inch. The smallest aggregate rainfall in any district is 8·31 inches, in the Midland counties, where the deficiency for the six months amounts to 3·30 inches. The greatest deficiency is in Ireland, amounting to 3·97 inches in the north and 3·88 inches in the south. In the south-east of England, which includes the London area, the aggregate rainfall was 9·97 inches, which is 1·38 inches fewer than the average. The greatest number of rainy days is 106, in the north of Scotland, and the least 73, in the Midland counties. The total duration of sunshine was nowhere very different from the average; there was an excess in all districts except in the north-east of England, the Midland counties, and the Channel Islands, but the deficiency nowhere exceeded twenty hours. The rainfall for the first month of summer was generally in excess of the average; but the difference from the normal was nowhere very great except in the north-east of England, where the excess amounts to 2·20 inches. The duration of bright sunshine for June was generally in excess of the normal. At Greenwich the mean temperature for June was 60·8°, which is 0·5° above the average of the previous sixty years; the first half of the month was much warmer than the latter half, and the rain during the latter half was very much heavier; the aggregate for the month was 0·1 inch more than the normal, whilst the duration of bright sunshine was about twenty-five hours more than usual.

SOME interesting photographs are described by M. Flammarion in the June number of *L'Astronomie*. Apropos of Prof. R. W. Wood's recent experiments in photographing the lunar surface in ultra-violet light, M. Flammarion shows pictures of ordinary objects taken with the sun's invisible radiations, infra-red, and ultra-violet. In one set, taken in full sunlight with the less refrangible rays, white trees are seen projected against a dead-black sky, giving the appearance of a nocturnal snow scene. Another pair of photographs, one ordinary and one ultra-violet, are simultaneous photographs of a man standing; his shadow, very pronounced in the ordinary photograph, has disappeared, through lack of contrast, in the second. But perhaps the most striking pictures are a similar pair in which the camera was pointed towards a landscape so that a part of the latter is seen through a glass window. In the ultra-violet picture the window and the landscape beyond have both disappeared, the window-glass being entirely opaque to the shorter radiations solely transmitted by the screen and the quartz objective.

As a preliminary to the study of the magnetic properties of some slightly magnetic alloys, Mr. H. C. Hayes, of the Jefferson Physical Laboratory of Harvard University, has investigated the errors to which the cooling curves taken in the metallurgical study of an alloy are subject. As these errors are obviously greater the more rapid the cooling, Mr. Hayes has constructed a new crucible which allows the process to be accelerated at will. It is of steel, and to prevent contamination of the melt is lined with a thin coating of lime, which is applied in a special way. The crucible and its contents can be quickly transferred from the furnace to a tank of water. Using an Einthoven string galvanometer with thermo-junctions of copper-constantan, the author finds that with the usual arrangement of the couple in a protecting tube of, quartz or porcelain the lag of the thermo-junction behind the temperature of the melt may, during a rapid cool, exceed 400° C. By using a copper tube deposited electrolytically on the end of the constantan wire, and protecting it by means of a thin coating of lime, he finds that the lag is reduced to a very small quantity, even for the most rapid cooling curves.

A COPY of a report on the analysis of potable spirits by the Government analyst for Western Australia has reached us. Its chief feature is a table setting out in detail the analytical results obtained in the examination of eighty-seven specimens of whisky, of known origin and age, selected from distilleries and other places in Scotland. The author considers, in reference to the evidence given before the recent Royal Commission on Whisky, that there is really less difficulty than was supposed in forming analytical standards for distinguishing between various classes of whisky, namely, "pure malt, pot still" whisky, "grain, patent still" whisky, and "blended" whisky, a mixture of the two. He suggests that definitions should be based, not upon any one constituent, but upon three taken conjointly, the furfural, esters, and higher alcohols being the three chosen. Further, not only should the quantities of each of these reach a stipulated minimum, but the three should bear a certain proportional relation to one another. On these principles definitions are formulated for (1) pure malt pot-still whisky, and (2) for blends containing, respectively, not less than 75 and not less than 50 per cent. of the pure malt pot-still product. The actual figures proposed as standards presume that the particular analytical methods described are employed, and it is admitted that they would exclude some spirits from their proper classes, though the number would be few. There is nothing new in the principle of forming a judgment on the character of a spirit by considering all three of the constituents indicated; probably most alcohol analysts do it, and certainly some have done so for years past. The data now given, however, obtained as they are from a considerable number of whiskies all analysed under strictly similar conditions, will be very useful in any discussion of standard values, whether the particular limits suggested by the author are accepted or not. A similar series dealing with Irish whiskies would be valuable.

THE first part of the fifth volume of the Journal of the Institute of Metals has been received. The first section of the book, which runs to 423 pages, contains a full account of the annual meeting held on January 18 last, and reported in the issue of NATURE for January 26 (vol. lxxxv., p. 429). The report of the council for the year 1910 is included, and the presidental address by Sir Gerard A. Muntz, Bart., entitled "'The Reason Why': the Quest of the Institute of Metals," is printed in full. The second section is devoted to abstracts of papers relating to the non-ferrous metals and the industries connected therewith; while the third contains the Memorandum and Articles of Association and a list of members.

MESSRS. J. AND A. CHURCHILL have in preparation, for publication early next year, a new annual entitled "Who's Who in Science," to be edited by Mr. H. H. Stephenson, and to contain the names of leading representatives of science throughout the world, as well as statements of their chief works.

OUR ASTRONOMICAL COLUMN.

WOLF'S COMET, 1911*a*.—In No. 4508 of the *Astronomische Nachrichten* Prof. Max Wolf states that he rediscovered his comet, on June 20, on a plate taken for that purpose. The position, for 1855·0, was 18h. 43·7m., +13° 25′, at 12h. 4·9m. Königstuhl M.T., on June 19. 18h. 43·7m., +13° 25, at 12h. 4·9m. Königstuhl M.T. The object has a stellar nucleus of magnitude 15, or brighter, lying eccentrically in an extremely faint nebulosity of 20″ diameter. According to M. Kamensky's ephemeris, the positions for July 6 and 14 are 18h. 31·6m., +15° 0·5′, and 18h. 24·5m., +15° 15′, respectively.

THE RADIAL VELOCITIES OF NEBULÆ.—Prof. Campbell, writing to the *Astronomische Nachrichten* (No. 4508), urges that as many radial velocities of nebulæ should be determined as is possible.

Keeler's observations of the radial velocities of twelve planetary nebulæ show that these objects probably have very high actual velocities, something of the order of 25 km. per second. On the other hand, observations of the Orion nebula, and others, indicate that these extended nebulæ have very low radial velocities, or are at rest relatively to the stars of our system. If these facts can be accepted as a generalisation, many problems connected with stellar evolution are opened up. For example, it is suggested that the extended, amorphous nebulæ are masses of primordial substance antecedent to the stellar state, whereas the quickly moving planetary, or condensed, nebulæ are the results of collisions, or near approaches, &c., of rapidly moving aged stars. Some support is given to this suggestion by the observation that helium (early) stars show but small radial velocities (6 km.), whereas the older, reddish stars give much higher (16 or 17 km.) velocities.

THE INTERFEROMETER IN THE STUDY OF NEBULÆ.—In the June number of *The Astrophysical Journal* (vol. xxxiii., No. 5, p. 406) MM. Fabry and Buisson describe an apparatus they have employed in the spectroscopic study of nebulæ. This apparatus is compact and light, and can readily be attached to any telescope of sufficient aperture for the work. They have used it with the Marseilles refractor of 10 inches (26 cm.) aperture and 10 feet (3·1 metres) focal length, and have secured useful observations of the Orion nebula; but a reflector of large relative aperture would be much better for the work, because of its achromatism.

The method is capable of giving very accurate measures for the wave-lengths of the different nebula lines, and, therefore, using the hydrogen lines should give the radial velocity with great precision. By finding the variations of wave-length from one part of the nebula to another, the circulatory movements of the gas might be determined.

THE ROTATION OF STARS ABOUT THEIR AXES.—In a note published in No. 7, vol. lxxi., of the Monthly Notices (p. 578), Prof. George Forbes makes an interesting suggestion on the possibility of determining the rotation of stars about their axes and the direction of the axes. In the case of the sun this rotation causes a displacement of the lines in the limb spectra, which in the case of the integrated light of the stars would become a broadening of the lines. But if the star is an Algol variable the light from each limb is periodically arrested by the eclipsing satellite, and the spectral lines should then show broadening on one side only. When the other end of the bright star's equator is eclipsed, broadening on the other side of the line would result. Relatively this would amount to a periodical displacement of the lines about a mean position, such as has been observed in some cases, and a measure of the displacement might provide material from which the direction of the star's axis and the velocity of equatorial regions of the star could be approximately deduced.

THE TAILS OF COMET 1910*a*.—From Prof. K. Pokrowski, of the Dorpat Observatory, we have received an interesting monograph dealing exhaustively with the several tails of comet 1910*a*. From fifty-nine observations made by various observers—many of which were recorded in these columns—Prof. Pokrowski determines the positions of different points in the tails, and then calculates the time at which the matter forming them was ejected and the value of the repulsive force which drove them away from the nucleus. He thus finds that the chief tail conforms to Bredichin's second type, the repulsive action being about equal to the gravitational attraction; the western branch of the tail was probably ejected, under rather greater repulsive force, from the nucleus about January 18.

The second, smaller tail, belongs to the third type, being formed under a repulsive force considerably less than the gravitational repulsion by particles which left the nucleus about January 16. The anomalous tail, directed towards the sun, is likened to those of comets 1844 III., 1862 III., and 1882 II., where the particles left the nucleus with a very small velocity, in this case about 0·5 km. per second.

CONFERENCE ON EDUCATION AND TRAINING OF ENGINEERS.

THIS conference, organised by the Institution of Civil Engineers, held its meetings at the rooms of the institution on June 28 and 29, under the presidency of Mr. Alexander Siemens. The subjects were discussed under three sections, general education, scientific training, and practical training, the chairmen of these being respectively Mr. Anthony G. Lyster, Dr. W. C. Unwin, and Mr. R. Elliott-Cooper. There were very large attendances at all of the meetings.

In opening the conference, the president stated that the council of the institution had endeavoured to define the scope of discussion by declaring that its object was to consider the methods of preparation to be adopted by those who contemplate entering the engineering profession in compliance with conditions laid down by the by-laws for election into the institution. In addition to a sound general education, to a competent knowledge of science and to practical training, there is the necessity common to all professions, which Prof. Max Müller defines thus:—"... No science and no art have long prospered and flourished among us, unless they were in some way subservient to the practical interests of society ... that interest depends on the practical advantages which society at large derives from these scientific studies." This principle may be expressed by saying that a young engineer should be educated so as to become a dividend-earner for his employer, for this is the most trustworthy indication of his merit. He should possess some knowledge of business methods and of law, and he will find one or more modern languages very useful in obtaining remunerative employment. No definite resolutions would be taken on the subjects under discussion, as the object of the conference is rather to form opinion than to arrive at and to record definite conclusions.

Sir Wm. White directed attention to the danger of too much devotion to the theoretical side. At one time training in engineering science could scarcely be obtained, but there was a modern tendency to go too far in the other direction at the expense of the practical side of the engineer's training. The evils of coaching for examination purposes were also pointed out by the same speaker. Sir J. Wolfe Barry justified the introduction of admission to the institution by examination, and considered that in the engineer's course of training the general education of an accomplished gentleman should not be lost sight of.

Mr. Anthony G. Lyster considered that education, to be of real value, should not only furnish information and knowledge, but should also train and expand the intelligence and develop that type of character which fits a man to lead the best and most useful life. The demand for special training for the engineer becomes increasingly urgent, and unless he is to be debarred from our universities or public schools, it behoves the authorities to bring their educational standards into line with modern requirements. There is no desire that members of the engineering profession should be engineers and nothing else; on the contrary, every opportunity should be given to the best type of man that the university and public school can produce to start with the best intellectual equipment as an engineer.

In the general education section, Dr. James Gow, headmaster of Westminster School, opened the discussion on literary education and engineering by stating that his experience as examiner in Latin for the institution showed that Latin is seldom included in the preliminary education of an engineer, or that boys who intend to be engineers pay little attention to this subject. It is probable that, where Latin is neglected, no very close study is given to any other language. He did not contend that literary studies are of any direct or immediate use to the engineer; his work must be largely deductive and mathematical, on which a literary education has no bearing. But presumably there are occasions when he is called upon to make use of chemistry or geology, or some other deductive science, and he is not properly equipped unless he has a fair knowledge of these sciences. Now it is notorious, at least to schoolmasters, that a boy who passes from the classical side to the modern side of a school has an immense advantage in inductive science over those who have been educated entirely on modern lines. Latin, as taught with grammar and dictionary, is inductive science almost in the abstract. Again, the engineer is doubtless often called upon to command a gang of foreign workers. The sooner and the better he learns their language the more easily he will control them and direct their labour. The language may be wholly alien to any that is spoken in Europe, yet the necessary elements of language must always be the same. It is undoubtedly the business of the engineer to understand contracts, and to give and receive orders accordingly. These transactions require a careful and exact appreciation of words by whomsoever used. It is too often forgotten that the whole profession of lawyers lives, in the main, on the inability of other people either to say what they mean or to understand what is said to them. Dr. Gow suspects that the time is at hand when it will be advantageous to the engineer to mingle the *utile* with the *dulce*, to discern not only what is mathematically possible, but also what is artistically impossible, not only what is cheap, but also what is nasty. For this purpose some general culture is necessary, such as makes a man liberal in mind and sympathetic to the common run of his fellows. Dr. Gow considers that the best plan is to give a boy a general education, mainly literary, up to sixteen years of age, and at that point to watch him closely and put him to what he wants to learn. If he is clever he will be successful; if he is not clever he will, at least, be happy and proud of his calling.

Prof. Silvanus P. Thompson initiated a discussion on the extent to which mathematical and scientific subjects should share with other subjects of literate education the attention of schoolboys who intend to enter later the engineering profession. In the present chaos of secondary education, the schools of the type which chiefly furnishes boys to the engineering profession are almost wholly destitute of any organisation adapted to that end. Not one, so far as the speaker knew, has any definite educational goal to set before the majority of its boys. In general, schoolmasters devote their energies to preparing a few scholarship candidates, and have no definite educational aim whatever for the bulk of the boys. Until this hopeless state of things is radically altered, and until the goodness or badness of a school is adjudged, not by the triumphs of a few, but by the proportion of all its scholars whom it brings to a maturity test, British education will continue to be in a bad way. In all German secondary schools there is a perfectly definite goal before every boy in the school. Before he reaches the topmost class he will have to pass the Einjährige examination, or pass out disgraced. Three years later, if he passes the Abiturient examination, the way is open for him to any university and to any professional career; otherwise he is marked as unfit for professional life. Here, with us, the State (save in Scotland) has not yet organised the secondary schools. Each university wastes its energies over holding matriculations and the like. Almost all the professional bodies hold amateur matriculations or preliminary examinations of their own. The result, educationally, is muddle, waste, inefficiency. The schoolmasters, in despair at the multitude of twenty conflicting matriculations, fix upon none, and let chaos work.

Prof. Thompson is in agreement with the recommendations of the report of the committee of the Institution of Civil Engineers, given 5½ years ago, on the studentship examination. These briefly are:—(1) specialisation at school is undesirable; (2) a leaving examination for secondary schools, similar to that in existence in Scotland and in Wales, is desirable throughout the United Kingdom; (3) instruction in mathematics should be by somewhat modified methods; (4) a general knowledge of elementary physics and chemistry or natural philosophy is preferable to the pursuit in detail of some particular department in science.

At school, the first object of science teaching should be to evoke interest, not to impart the facts or data of science, still less to systematise their rediscovery. All that has its place later. Even the driest subject can be made thoroughly attractive by a live teacher who handles his subject in a human way. A bad teacher can make even electricity as dull and distasteful a subject as the conjugation of irregular verbs. One difficulty which has been explained by masters of progressive tendencies in seeking to introduce mathematical reforms such as that which has come about in the past few years has been the stupidity of inspectors, who have not yet grasped the importance of the reforms. The benumbing influence of all the older Cambridge traditions is also felt. Bad teaching is responsible more than anything else for distaste for mathematics. A really capable teacher will make his boys enthusiastic over matters that in the hands of others are deadly dull.

The greatest change which has come over the teaching of mathematics is the almost complete disappearance of Euclid. Prof. Thompson is not sure whether the loss is not greater than the gain. The teaching of Euclid was in one respect absolutely invaluable. If approached rightly, after practice in geometrical drawing, the study of Euclid constitutes an unrivalled training in methodical and cogent reasoning. But Euclid is gone, and there has been no satisfactory substitute for it. It is the opinion of Prof. Thompson that boys nowadays are less capable of following a sustained train of thought than they used to be.

In the conflict of subjects, one is apt to lose sight of the fact that training in thinking and in the correct expression of thought is more essential than the study of any particular subject. In all studies—science, mathematics, language, or literature—there should be cultivated precision in the use of words and cogency in modes of thought. These things are vastly more important in the ultimate making of a professional engineer than the acquisition of a hoard of scientific facts. The secondary school must not degenerate into a house of cram.

Sir John Wolfe Barry agreed with Dr. Gow that specialisation should not commence too early. A general training should be given in early life, as it was impossible to attain to such later. His own early training had not been directed towards engineering, and he considered that this had been to his advantage.

Mr. Theodore Reunert, of Johannesburg, hoped that the conference would lay down a definite course of training for engineers. In other professions parents could obtain definite information regarding the course of study and training through which their sons must proceed; in engineering no such information is available.

Dr. W. H. D. Rouse thought that specialisation before sixteen or seventeen was wrong. In his opinion, Prof. Thompson had not spoken too strongly in regard to the evils of examinations. Examinations were generally of an undesirable character, and their continued multiplication was a great evil. Prof. Thompson's remarks about German examinations being conducted by cooperation between the State and the teachers were of value, and he considered that such was the only way that was fair to the teachers.

Mr. W. Whitaker, F.R.S., could not confirm the view that culture could be obtained only in early life. Dr. Gow had emphasised the educational value of literature; there was nothing like leather, and he noticed that Dr. Gow was a Doctor of Literature. Mr. Whitaker agreed with Prof. Thompson's remarks on the teaching of Euclid. He believed that English was taught very badly, and that scientific men in this respect were as badly trained as the majority of people, and worse than most.

Dr. R. Mullineux Walmsley thought that the lack of a definite educational aim in England was due to defective public opinion. In this respect matters were much better in Scotland. The statement which had been made that universities had to hold matriculation examinations because they wanted the fees was true, and if the London University gave its examinations up it would be bankrupt —a scandalous state of affairs.

Prof. W. S. Abell considered Euclid to be the basis of the English system of mathematics, and that the Institution of Civil Engineers should insist on its being taught.

Colonel J. E. Capper said that a mechanic might be able to lay a railway, but an engineer, in addition, should be able to say if it was necessary to lay it at all. To answer such questions, a general literary education was necessary.

Mr. T. H. Bailey suggested that Prof. Thompson had missed the aim of public-school life, which was not to turn out professional men, but to give a general grounding and moral training.

Both Dr. Gow and Prof. Thompson in their replies agreed on the undesirability of having a rigid examination for all students. But schoolmasters certainly desired the laying down of a general course which might be available for the information of parents.

Prof. Alfred Schwartz opened the question of specialised entrance examinations for university or college courses of study in engineering, and is of opinion that a satisfactory standard of general education should be attained, and should not include specialised subjects germane to engineering science. This examination should admit to all faculties. The secondary-school training of the engineer should be on as liberal lines as possible, since his subsequent training is largely materialistic. What is wanted in the engineering courses is a supply of students with a wide mental outlook, whose faculties have been well trained and evenly developed, and any specialisation in the secondary schools at the expense of this liberal training is to be deprecated.

Mr. J. T. Jackson considered that entrance examinations should be so framed as to be capable of being passed by students of good general education only. His own experience was that men who commenced engineering at an early age were less successful generally than those who commenced at a later age.

Prof. W. C. Unwin considered that some early specialisation was desirable. Boys of eighteen, without such specialisation, had to look forward to three years of study and three years of practical work before being in a position to take responsible posts. This would bring them to twenty-four years of age before they were capable of earning a living. Not much was asked for, but he thought that a boy of eighteen might be expected to be prepared in part for his future career. He did not agree, as the result of his experience at Coopers Hill and at the Central College, with Mr. Jackson's remarks regarding non-success being due to an early start in engineering. Prof. H. J. Spooner pointed out, in regard to mathematical training, that students were now generally given courses in practical mathematics. The result is that few students now took mathematics as a regular study, necessitating much special cramming for mathematical examinations.

In closing the discussion, Mr. B. Hall Blyth said that he thought it would bear some good fruit if it resulted only in the restoration of Euclid to its old place in the schools. He agreed with the many speakers on the dangers of cramming, and thought that the institution, whose own examination was open to the charge, might take these remarks to heart.

Mr. R. Elliott-Cooper, as chairman of the section on practical training, opened the proceedings in this section by saying that it was of importance that all should be agreed, if possible, as to what practical training really means. Real and useful practical training can be obtained only under the actual or commercial conditions which cannot be found in educational establishments. The knowledge which young engineers may obtain from, say, two years in the workshops of a contractor after his college course is completed, should be supplemented by the experience to be gained in an engineer's office. Such experience would include designing, drawing, specifying, and estimating. In a few branches of the profession pupilage does not occupy its former place, but, taking the profession as a whole, inquiry shows that it still holds an important position.

Mr. Alfred F. Yarrow, in dealing with the apportionment of training between practical work and scientific study, took up the social aspect of the question, and gave some suggestions applying to apprentices in or on works far distant from their homes. He was of opinion that a sandwich system of six months in the works and six months at college was desirable. The student living at home during his college term would be under good influences and affectionate surroundings such as were impossible during a lengthy apprenticeship away from home. London colleges especially should so arrange their courses as to render this system available for their students. Further, some member of the staff in the works should be looked upon as an adviser to the apprentices. He should be accessible at all times, and should make a point of interviewing each lad at least once in three months and ascertain if he could be of service to him. He should also keep in touch with the work of lads attending evening classes by personal visits to the local technical schools. This system is of advantage both to apprentices and employers, and would enable the latter to select wisely those apprentices whom it is desirable to retain after the termination of their apprenticeship. It is a notorious fact that employers have often lost the services of many capable men through being ignorant of the talent that has passed through their works.

Mr. William H. Allen, dealing with the case of a student determining to go both to college and to works, was of the opinion that the college course should be taken first. In his experience this is the order of procedure in which will be found the best chance of success. As regards how much study should be undertaken by a pupil during the period of his practical training, Mr. Allen thought that, if a young man does his duty conscientiously in the works from 6 a.m. to 6 p.m., he will find that as much as his health can stand, without burdening it by further serious study at night. A period of training in the workshops extending over three years is desirable, and should not be specialised too greatly.

Mr. F. E. Robertson referred to the deficiencies in the knowledge of elementary science in young men trained in locomotive works who present themselves to him for examination for posts in India. Prof. Arnold said that his experience had been quite different, and cited the case of the Midland Railway, who handle the training of their apprentices in an excellent manner. Prof. Arnold regretted the modern drifting apart of the engineering side and the metallurgical side in the training of engineers. Mr. E. R. Dolby thought that too much was being attempted in the training of an engineer, and that better results would be obtained by subdivision, as is done in the architectural profession.

Mr. E. Benedict thought that people who accepted premiums should also accept responsibility, and advocated the deputing of someone to look after apprentices.

Prof. E. G. Coker regretted the loss of engineering establishments in London, and favoured a six months' sandwich system. Prof. W. E. Dalby found that teaching was much easier to workshop-trained youths than to others. The sandwich system is best if it can be worked; he had asked works to take pupils on this system, but had not always met with success. The premium question presented a difficulty.

Mr. W. B. Worthington, dealing with the question of training in the engineer's office, said that engineering as an art and profession is based upon the matter of design. However good a man's training and experience on constructional works or in the shops may be, it will not, without experience in the engineer's office, make him a civil engineer, although it may make him a good mechanic or contractor.

Dr. W. C. Unwin presided over a joint meeting of the sections on scientific and practical training, and in opening the proceedings gave a carefully considered statement of the relations between the employers and college-trained youths. This is printed in full elsewhere in the present issue.

Dealing with the relation of engineering employers and colleges from the point of view of the practical training of college students, Prof. J. E. Petavel thought that the employer can cooperate in the educational work of the university by a frank and friendly criticism of the methods adopted, and by offering to take college graduates on a six months' trial.

Mr. James W. Horne directed attention to the cases of engineering firms who have developed a keen interest in the better education of those apprentices who start at sixteen years of age. Every encouragement is given to attend evening classes, and several give facilities for attending college on one or two afternoons a week. By these means many have reached a standard of education which enables them to proceed to a college for two or three years' courses. Such apprentices are a valuable asset to the nation.

Mr. Alexander Siemens did not consider it possible to allow apprentices off on one or two afternoons a week. Mr. Hall Blyth referred to the mistaken idea which some engineering professors have that their students are ready, on leaving college, immediately to take a responsible place in the works. Sir Wm. White directed attention to the many cases of swelled-head in college graduates, a matter which interferes with their employment in a good many instances. Reference was also made in the discussion to the plan followed at Bristol, whereby unsuitable students are advised, through their parents, to withdraw from college at the earliest possible moment. (It may be said here that other colleges also follow this procedure.)

Prof. Archibald Barr advocated a six months' sandwich system, and pleaded that engineering institutions should allow a wide latitude in the systems of training that they will recognise. Prof. Henry Louis did not think that the six months' sandwich system is satisfactory, and suggested the course followed by mining students of three years' college followed by three years' practical work.

Mr. John A. Brodie had little sympathy with those who think it necessary that young engineers should work a reduced number of hours in the workshop in order to enable a greater time being given to study. If the youths of our day cannot or will not stand the strain of the severe training which has given good results in the past, they will probably have to take a position behind those who are prepared to do so. There are other lines of life in which young men can acquire both money and position more easily and quickly than in the engineering profession.

Prof. Stephen M. Dixon opened the subject of the value of a university degree in engineering science in relation to professional competence. There is a feeling in some quarters that the university graduate is rather in the way in an engineer's office. Matters, however, in this respect are improving. When engineering firms recognise the advantage of having assistants thoroughly trained in the principles underlying practice, and whose training also specially fits them for adopting new ideas rapidly, they will be only too glad to cooperate with the universities in completing the education of the engineer.

In dealing with the same subject, Prof. Charles F. Jenkin said that an engineering degree may be looked at in three lights: as a guarantee that the holder has had the best theoretical training and has profited to some extent thereby; as the final step in that type of liberal education at the universities of which England is justly proud; as a broad basis on which State recognition of the engineering profession may be founded.

Prof. Fleming attacked vigorously the whole system of degree examinations as being wrong and as liable to pass candidates whose knowledge was of a very scrappy nature, a view which was promptly controverted by another speaker, who said that he had five degree men in his London office and was entirely satisfied with the results. The same speaker had a good word to say for men who had been trained in evening classes; he was of opinion that swelled-head accounted for some failures in graduates, but that these men were of use after they had been got in hand.

Profs. Dalby, Hopkinson, and Goodman dealt with the subject of the position and uses of engineering laboratories in relation to education at college. All agree that small units are of more service in the work of education than the very large pieces of apparatus—steam engines of large power and the like—which used to find favour.

In closing the conference, Mr. Alexander Siemens suggested that schoolmasters should try to agree on a common syllabus for leaving examinations. University teaching should be scientific and wide in its scope; the training of the mind is all-essential. He was of opinion that practical training should begin by a year in the workshops to be followed by the college course, and then back to the workshops again for completion of the practical training.

TOTAL SOLAR ECLIPSE, TASMANIA, MAY, 1910.[1]

IN a short introduction the author and leader of the expedition explains his motive in publishing in full this account of a solar eclipse expedition which was, unfortunately, unsuccessful in its main object. The site chosen for the camp was in very wild, mountainous country on the southern shores of Tasmania, and in these circumstances it is evident that, going as a private party, exceptional provision had to be made for the many details of equipment, transportation, and maintenance of the observers during the period of preparation for the observations. It was with the hope of giving useful information on these questions that the author decided to present the log of his journey at length.

In chapter i. a very interesting account is given of the general preparations for the eclipse, the prospecting journeys for selection of site, that finally occupied being on Hixson Point, Port Davey. After this was settled, some time was occupied in arranging for and purchasing tents, camp equipment, food and drink, and other details necessary for nine persons during a stay of one month. At the camp, nothing was available for food except fish, wallaby, wombats, and kangaroos. A complete list is given of the details of the equipment and stores; in the case of foodstuffs, &c., both the quantities taken out and the amount unused are given, from which future pioneers in this class of work may learn wisdom; for instance, lime juice was evidently not the beverage most sought after, as out of eighteen bottles taken, thirteen are recorded as unused. A very useful item is the actual cost of the expedition, reckoned from Hobart out to Port Davey, the stay there, and back to Melbourne—347*l.*

As a more or less detailed account of the instruments taken out for the work on the eclipse has already appeared in NATURE, it is only necessary here to say that, in spite of most trying and tempestuous weather, the whole apparatus was adjusted ready for the eclipse time. Details of the work involved for each section are given, with very clear photographic illustrations of the progress and methods adopted in transporting the heavy cases over the difficult ground from the shore to the camp site. Provision had been made for obtaining photographs of the corona with telescopes of various apertures and focal lengths, and for the spectrum of the chromosphere and corona with a powerful concave grating spectrograph.

Included is a report on the observations made by J. Brooks for the determination of the astronomical position of the site, and a description of the corona photographs obtained by another party at Queenstown. After examination of these plates, on which the diameter of the moon's image is 4·4 mm., Mr. W. H. Wesley reports that the extensions of the corona were very small, in no part reaching beyond one quarter the moon's diameter from the limb. On a plate submitted by another observer, with a smaller image still, 1·5 mm., the extensions reach about one diameter. The most striking feature was a wide rift, fairly symmetrical with the South Pole, extending for nearly 50° along the limb. There was also a long ray of synclinal character on the east of this southern rift.

The form of the corona appears to be of the type associated with the period intermediate between the maximum and minimum of solar activity.

The volume is illustrated by thirty-five excellent photographic reproductions showing the interior of Port Davey Harbour, incidents in the transportation and erection of the various instruments, a scrub fire which very nearly destroyed the camp, and the photographs of the corona obtained at Queenstown by the Rev. L. S. Macdougall and Mr. J. Booton.

CHARLES P. BUTLER.

[1] Report of the Solar Eclipse Expedition to Port Davey, Tasmania, May, 1910. By F. K. McClean and others. Pp. 42+35 plates. (London: Printed by R. Clay and Sons, Ltd. Plates reproduced by A. E. Dent and Co., Ltd., 1910.)

THE CAMBRIDGE ANTHROPOLOGICAL EXPEDITION TO WESTERN AUSTRALIA.

IN the early part of last year plans were made for an anthropological expedition to Western Australia, and Mr. A. R. Brown, Fellow of Trinity College, Cambridge, who had been re-elected to the Anthony Wilkin studentship, was appointed leader, the main object of the expedition being to study the social organisation and magico-religious beliefs and observances of the natives. Mr. Brown left England at the end of July, 1910. Soon after his arrival in Perth, mainly through the instrumentality of Mrs. D. M. Bates, a donation of 1000*l.* was made to the expedition by Mr. Samuel P. Mackay of that State. This munificent gift is a notable example of public spirit, and it proves that, despite the manifold claims of a very new State on its citizens, there are individuals who have the advancement of pure science at heart. The benefaction was particularly acceptable, as Mr. Brown's modest resources consisted only of the studentship, a gift of 200*l.* from Sir John Murray, and a grant from the Royal Society of 100*l.* Field investigation is very expensive in Australia, partly owing to the great distances that have to be traversed in order to come into contact with the natives, who even then may be in very small bands.

On his first excursion Mr. Brown was accompanied by Mr. E. L. Grant Watson, of Trinity College, Cambridge, who assisted in taking photographs and measurements of natives, and by Mrs. Bates, who for some years has been employed by the Government of Western Australia to collect information concerning the aborigines of the State. Mrs. Bates has a very considerable knowledge of the natives, and her valuable MS. notes have been placed at Mr. Brown's disposal.

In the south-west corner of the State the natives are extinct; the greater portion of the western half of the State is unopened, and mainly desert country; the natives are quite wild, and it is at present almost impossible to get into touch with them. There remains a broad band of country to the east and the Kimberley gold-field district which have been opened up for pastoral purposes or for gold mining. The gold-field blacks are for the most part beggars, and suspicious and treacherous; they are constantly moving from place to place.

In the eastern part of the region, between the Fortescue and Gascoyne Rivers, there are eleven tribes which belong to one type of social organisation. They never practise circumcision or subincision; they have the usual four-class system with the kinship system commonly associated therewith, but cross-cousin marriage is prohibited, and there are specific kinship terms to distinguish own mother's brother's children from tribal mother's brother's children. The members of a clan may eat their totem, which is inherited in the male line, and ceremonies of the *Intichiuma* type are performed for the increase of the totem. Each tribe is divided into definitely circumscribed local groups, the descent of the local group being in the male line. A local group consists mainly, and perhaps in some cases entirely, of persons of the same totem. In most cases the spot at which the ceremonies for the increase of a totem are performed is within the territory of the local group of the men of that totem, but in a few cases a local group contains no totem centre, and the men of the group must journey to some neighbouring group to perform these ceremonies. The totemic groups are united into larger social divisions, for which Mr. Brown has not yet found a suitable name. During the last two or three generations many irregular marriages have taken place, which have resulted in the distribution of totems through the four classes. In such cases the children take the totem of the father, but enter the class to which they would have belonged if the mother had taken her proper husband. To the south the tribes are, on the whole, very similar to the above; to the east, north-east, and south-east circumcision and subincision are not usually practised: they have the four-class system, and in some tribes every person has several totems (as many as twelve or more), which are inherited in the male line; these may be eaten, and *Intichiuma* ceremonies are performed. Inland between Fortescue and De Gray Rivers, cross-cousin marriage is not permitted, and no distinction is made between own mother's brother's children (and own father's sister's children) and tribal mother's brother's children.

Scattered sporadically all over the area investigated are found the beliefs that children are the result of food eaten, or that they may be projected by magic into a woman. In all cases these beliefs exist side by side with ordinary totemism and entirely independent of it, and also with a perfectly clear recognition of the normal method of procreation.

Mr. Brown is at present on a six months' visit to uninvestigated tribes, mainly in the north-east of the State.

A. C. Haddon.

EXPLORATIONS IN DUTCH NEW GUINEA.

On Monday, July 3, Captain C. G. Rawling lectured before the Royal Geographical Society on the geographical results of the British expedition in Dutch New Guinea, which was organised by the British Ornithologists' Union, and was led by Mr. Goodfellow until illness compelled his return. The dense tropical jungle of the low plain between the mountains and the coast, the heavy rainfall, and the sickness which incapacitated their carriers, prevented the travellers from reaching the higher portions of the range, but the scientific results, zoological, ethnographical, and geographical, are most valuable. Captain Rawling and Dr. Marshall stayed for some time with the pygmy tribes of the lower hill ranges, and obtained much information concerning their customs, habits, and general character. Subjoined are some extracts from Captain Rawling's paper.

From inquiries made before leaving England, it was decided that the Oetakwa, the mouth of which river was known to lie due south of Carstenz peak, the greatest of the snow-peaks, should be utilised as our line of communication. Prior to our advent but two rivers on the whole of the south-eastern coast of New Guinea had been visited, the Oetakwa and the Mimika, and these had only been explored for a few miles from their mouth. Further inquiries made in Batavia induced Mr. Goodfellow to change his objective from the Oetakwa to Mimika, and this, little as we suspected it at the time, sealed our fate as to all possibility of ever reaching the Snows.

Almost coal-black in colour, and rather exceeding the average European in height, the Mimika coast native, with his splendidly developed muscles, is physically an almost perfect man. But the brutal features of his face, accentuated by the closely cropped head, makes him anything but an attractive creature. The mass of fuzzy curly hair, in which the natives of other districts take so much pride, is here cut off by means of sharpened shells, split bamboo, or an old piece of hoop iron. What remains is closely plaited in ridges. With the loss of hair nearly all love of decoration or ornament seems to have vanished, their dress consisting of a large white shell worn on the stomach, a hollow carved bamboo, or a narrow strip of tree bark beaten soft and pliable. Round the neck a few beads may be strung, while below the knees and around the biceps a narrow band of plaited grass may often be seen. As a further attempt at ornament, a few white feathers of the hornbill may be stuck into the hair, or if a fierce expression is desired, the split beak of the same bird is pushed through a hole in the septum nasi. The women are even less given to trinkets, for, besides the narrow strip of bark hanging down in front and behind, they are as bare as nature made them: poor creatures, they have little time to think of anything but work. Widows are rather favoured in this respect, for their weeds consist of a great poke bonnet, in addition to a bodice and skirt, all of grass. The instinct of self-adornment is, however, very strong, for trade articles, such as beads and cloth, were subsequently not only eagerly sought for but worn on all important occasions. Absolute nakedness was rare amongst the Wakatimi people, for girls wore some form of dress from an early age, and boys took on the garb of manhood at the age of fifteen or sixteen.

The front teeth of the men, but not the women, are in many instances sharpened to a point, a painful process, for the operation is carried out, not by filing, but by chipping the sides away with a piece of iron, or, if this is not available, a hard shell used after the manner of a chisel. The custom of sharpening the teeth is often put down as a sign of cannibalistic practices, but we have no reason to believe that the habit of eating human flesh is ever here put into practice. Certainly during our sojourn amongst these tribes we saw no signs of cannibalism, nor when examining the human bones preserved in every house, did we find any evidence pointing to such a custom. When questioned on this subject, some natives showed abhorrence, whilst others exhibited, at any rate, no great disgust at the suggestion.

Wakatimi, as we afterwards found, was but a sample of other coast villages, consisting of a long row of huts made of pandanas and palm leaves held up by poles cut from the forest. Each new-comer added on his hut to the last, at the same time removing the partition, by this means turning the village into one endless habitation, broken by their respective doorways. The floors were of sand brought from the seashore, and, with the exception of the crudest of fireplaces, other furniture there was none. Skulls and the bones of departed relatives dangled in grass bags from the roof, blackened by the smoke of the fires. Now and again a wood pillow might be seen, otherwise the interior was bare. Outside there stood, ready for instant use, a stone club, a few spears—the heads fashioned from the leg-bones of pig or human beings—or a bow and a sheaf of arrows, to which weapons they flew on the slightest provocation.

The natives of this portion of New Guinea are divided into three classes or tribes. First come the people inhabiting the low-lying ground near the coast and extending inland for about twelve miles, and known to us as the coast natives. Then comes a strip of land practically uninhabited, and above this again, on a level with the headwaters of the Mimika, a race known to us as the up-river natives. Still further north, and inhabiting the foothills, are the pygmies. These three tribes are entirely distinct from one another, having no communication in the north and south direction—even though living on the same river—but passing freely to the east and west. The dividing line is hard and fast, and is not crossed except for occasional purposes of trade.

With the latitudes of Atabo at the coast and Parimau known, and the azimuth obtained, it was easy to fix all the points in the range from Carstenz in the east to Mount Darwin in the west. The height of Carstenz, formerly assumed to be about 18,000 feet, was found to have an altitude of rather more than 16,000 feet, while to the west three more great snow-peaks were discovered, with a height of about 15,500 feet, and these we named Mount Idenburg. Beyond and between these two mountains two other great snow-peaks were visible, evidence that the ground to the north does not fall abruptly away. But more interesting than all was the discovery that the great range, stretching from Carstenz in the east to the Charles Louis mountains in the west, a distance of eighty miles, formed one immense unbroken precipice, culminating in its greater sheer height at Mount Darwin. We were never in a position to measure with the theodolite a greater sheer height of more than 6500 feet, but from many views obtained while climbing, I have no hesitation in stating that the greatest perpendicular height is, at this spot, not less than 10,500 feet, or two miles.

The snow-line is at about 14,500 feet, the glaciers on Carstenz descending lower and falling over the precipice to the south. From a letter received from Lieut. Postema, the naval officer in charge of the survey of the Dutch Expedition on the Oetakwa river, I understand that he is of like opinion that Carstenz mountain is not climbable. The extreme wetness of this district is, without doubt, due to the great altitude and proximity of these mountains, the rainfall being in excess of any other portion of New Guinea.

To sum up the final results of the expedition: large and valuable collections of birds, mammals, reptiles, butterflies, and moths had been formed, together with botanical and ethnographical specimens; a new and unknown race of pygmies discovered, studied, measured, and photographed; a range of mountains, containing the greatest precipice in the world, together with 3000 square miles of country, surveyed and mapped, new snow-mountains found, and many great rivers explored; and a long stretch of coast-line surveyed. We had accomplished the longest cross-country journey ever undertaken in Dutch New Guinea, *i.e.* eleven marches from the up-river camp, had proved the impossibility of the Mimika river as a line of advance to the Snows, and, on the other hand, the value of the great rivers to the east if the same goal is intended. From experience, and our heavy death-roll will bear me out, I have no hesitation in saying, first, that the land is an impossible one to any but a Papuan: and secondly, that, unless most carefully picked, no natives of the East Indies, with the exception of Dyaks from Borneo, are of the slightest value as carriers in South Dutch New Guinea.

WORKSHOP AND COLLEGE.[1]

It is now agreed that engineering training should include scientific instruction and practical and commercial experience. But very divergent views are held as to the relative importance of the different components of such a training and as to the order and duration of each. We must recognise at once that the field of engineering employment is a very wide one, and that different capacities are required in different parts of that field. It is therefore in no way surprising that persons, whose opportunities of observation give them every right to express a definite opinion as to what is best for one special branch of engineering, have arrived at conclusions very different from those held by others, whose field of work has been in a different branch. No system of engineering training can be arranged to meet all special demands, and it is the object of such a conference as this to find out what is most essential in all courses of training and what modifications are practically possible to meet different cases.

First of all, I think it must be assumed that the engineering education we are specially charged to consider is that of young men whose aim it is to arrive ultimately at a professional status, such a status as membership of this institution implies. Their hope is to be employed ultimately in the design and control and direction of engineering work. Of course, some of them may fail in capacity or may lack opportunity, and may drift to one of the many more commercial occupations allied to engineering; and even there the knowledge they have acquired will be a valuable asset. But at the outset a professional career is aimed at, and the system of engineering education must be arranged to meet that condition. It is probably only by educating many that the few can be found who have the capacity and character necessary to achieve considerable advances and to do work of national importance.

Now, very few young men at eighteen can foresee into what line of employment they may be driven, and consequently the first or undergraduate stage of education must be broad, so as to fit students for widely different spheres of work.

Perhaps the greatest defect of engineering education at present is the want of more provision for the higher and more specialised education of the few students of real capacity discovered in the sifting process of an undergraduate course.

In spite of the general acceptance of the view that a study of scientific principles and their application is a necessary preliminary to a practical course in field or workshop, a certain jealousy of college education is still obvious in some practical engineers. While conceding in words that some scientific education is necessary to an engineer, they would, in fact, confine it to very elementary matters. They would greatly restrict the time given to it, and they are disposed to depreciate the value of any higher teaching, and even to regard it as mischievous and likely to unfit a man for the strenuous life of the manufacturing workshop.

I believe the idea that a college course unfits a man for practical work is a wholly mistaken one. There may be students who prove unfit for practical work in spite of college education. They would equally fail if their education was purely practical. There may be college courses, I am afraid it must be said there have been college courses, badly arranged, and teachers in colleges less competent than is desirable. But such things are inevitable. Nothing is more certain than that there has been a great improvement of college teaching of applied science in the last twenty years.

An employer who takes into his works college students is, I think, often disposed to expect from them an immediate availability which is unreasonable. It is not the main object of a college course to make a student acquainted with the details of any particular business; that is the proper object of the first year or two of practical work. It is not the main object of a college course to fit students specially for such work as will fall to them

[1] Opening remarks at a Conference on Education and Training of Engineers (joint meeting of Sections II. and III., Scientific and Practical Training), held at the Institution of Civil Engineers, by Dr. W. C. Unwin, F.R.S., chairman of Section II.

while in the lowest rank of the profession. The college course must contemplate the fitting of a student for his whole career, and provide him with an intellectual equipment which will only gradually become useful as he rises to higher rank in his profession. The view of the employer who looks only to the immediate usefulness of the student is a short-sighted one.

Nevertheless, a college course is an unpractical and badly designed one if, at the end of it, a student is not more capable and useful from the first, in any type of workshop, than a lad without such a training. The college discipline is bad if he has not much more character and energy than the raw lad. His training has been a failure if he does not pick up the specialised details of any business to which he may be put far more rapidly than an untrained lad. I should like to suggest to those practical engineers who are implicitly, if not openly, hostile to college training, who would, at any rate, greatly restrict it, and who advocate lengthened periods of workshop apprenticeship, that they exaggerate the value of such workshop experience as an ordinary apprentice gets. I am not, of course, considering artisan apprentices, but young men expecting to rise to positions of trust. Here and there are works where special trouble is taken with apprentices; but in general apprentices are left to pick up what knowledge they can with very little help, and in many cases, I think, a good deal of their time is absolutely wasted. Some skill of handicraft is no doubt acquired. But the engineer works with his head, not with his hands, and manual skill is of use to him only in very exceptional cases.

I hope I do not in any way underrate the value, to mechanical engineers especially, of that kind of knowledge of materials, of tools, of processes, and of cost which can only be learned in the workshop. But I think practical engineers forget how little of this valuable knowledge really comes to the works apprentice. The engineer of higher rank who discusses matters with foremen and draughtsmen, who has responsibility for design and cost, and is, moreover, in a position to know the reason of all decisions, is learning in the workshop all his life, and naturally sets a high value on the knowledge slowly acquired by years of constant and close observation. So high a value that perhaps he ignores the importance of the scientific knowledge which was, somewhere and by someone, applied in bringing his business to a state in which it can be carried on successfully as a mere manufacture. But the knowledge which comes to those in responsible positions is not open to the ordinary apprentice, and he learns slowly, if at all, unless he brings to the works such a knowledge of principles and methods that he can interpret for himself what he sees. No system of workshop apprenticeship can, I think, be considered satisfactory unless someone is specially charged with care of the apprentices, whose duty it should be to make sure that they have opportunity of seeing a great variety of work and of helping them over their difficulties.

I believe employers will find—some of them have found already—that they owe a debt to the colleges, and that the college-trained student will prove, with a minimum of special experience, a valuable assistant, and in some cases the originator of a real advance in practice. I should like to plead that in return the employer might be a little more ready to give college students a year or two years' run of the works, either without remuneration or with a small remuneration just enough for disciplinary purposes. I do not think there would be any loss in the case of a properly trained student, and the employer would in many cases find an assistant worth keeping and promoting.

GOLD MINING IN THE TRANSVAAL.[1]

THE discovery of gold on the Witwatersrand was made in the year 1885. The growth of the field was at first slow. Some of the earliest workers believed that the auriferous gravel, exposed in shallow open workings, was a superficial deposit of the nature of the alluvial "placers" of California and Australia. The true character of the conglomerate beds was, however, soon realised by those who were fortunate enough to possess some geological knowledge, and by 1887 stamp-mills were in operation, the output from the Witwatersrand mines for that year being 81,045*l*. From 1887 onward the progress has been rapid.

Down to the permanent water-level, at a vertical depth varying from 200 to 300 feet, the conglomerate beds were "free-milling," that is to say, the iron pyrites, with which the gold is intimately associated, had been destroyed by oxidation, thus setting free the gold. Below the water-table the colour of the rock changes from red to blue: the ore becomes pyritic; and the gold is no longer so amenable to recovery by amalgamation, as is the case with the oxidised ore. This was the first difficulty that had to be overcome. Up to the year 1890 the treatment of the Rand ore had consisted of crushing in stamp-mills, and the recovery of 50 to 60 per cent. of the gold, by amalgamation on mercury-coated copper plates. The tailings received no further treatment; they were considered to be valueless, and, where the ground permitted it, were allowed to flow away.

The successful introduction of the cyanide process in 1890 inaugurated a new era in the history of Rand gold mining. It is no exaggeration to say that the great success of the Witwatersrand gold industry is a direct result of the introduction of the cyanide process. For the majority of the mines, the gold won by this process represents the difference between profit and loss, and without it the profitable working of the vast quantity of low-grade banket now being mined on the Rand would be impossible.

At first the pulp from the stamp-mills was run into retaining dams, from which the sand was afterwards dug out and conveyed in Scotch carts or in mine-trucks for treatment in the cyanide vats. On account of the slime-content, only 30 per cent. of the gold left in the pulp from the amalgamating tables was recovered, the remainder being in the untreated slimes and in the residues.

The next step was the introduction of hydraulic classifiers, by means of which a considerable proportion of the slime was eliminated and a sand product obtained, which could be run direct into leaching tanks.

A process was then evolved for the treatment of the slimes. It consisted in causing the slime, overflowing from the sand-collectors, to settle, by the addition of lime, the bulk of the water being subsequently removed by decantation. The concentrated slime so obtained was then agitated with cyanide solution, which was ultimately drawn off by decantation.

The separation of sand from slime by the old-fashioned inverted pyramidal form of hydraulic classifier, and the decantation method for the removal of water or cyanide solution from sand or slime, are now giving place to the use of diaphragm cones and vacuum filters. In the most modern plants the separation of sand and slime in a mill product is effected by feeding the mill-pulp into a cone-shaped collector or diaphragm cone; the sand is drawn off as a thickened pulp from the bottom, while the slime flows over at the periphery, and after passing through a secondary washing cone is freed from most of its remaining water on a Caldecott filter-table, which is a slowly rotating horizontal vacuum filter.

The treatment of slime has been much facilitated by the recent introduction of air-agitation tanks and vacuum-filters, which enable the enriched cyanide solution to be rapidly drawn off from the slime-residue and sent as a clear liquid to the extractor boxes. The precipitation of the gold was effected in the original MacArthur Forrest process by zinc shavings, and this method is still preferred for the rich solutions; but for weak solutions, such as are obtained in the treatment of slimes, zinc dust is employed as a precipitant.

One important result of the perfection of the slimes-treatment process has been the introduction of fine grinding in tube-mills, with consequent increased extraction and shortened treatment period. Further, the adoption of tube-mills has modified the function of the stamp-mill. Stamps are no longer employed for fine crushing, and amalgamation in the mortar-boxes has been completely abolished; and even such plate-amalgamation as took place in front of the stamp-mills has in many cases been done away with. Concurrently with the limitation of the effective range

[1] Abridged from the nineteenth "James Forrest" lecture delivered on June 28 before the Institution of Civil Engineers by Dr. F. H. Hatch, vice-president of the Institution of Mining and Metallurgy.

of the stamp-mill, the weight of individual stamps has been increased by lengthening the heads, until, with the 2000-lb. stamp of the new mill of the City Deep mine, the economic limit of the cam-lifted gravitation stamp appears to have been reached.

Underground, efforts have been made to solve the dust problem. With few exceptions, the Witwatersrand mines are dry mines, and the processes of machine-drilling, blasting, and shovelling consequently create and distribute through the air great quantities of fine dust. The inhalation of the dust-laden air causes a peculiar disease, known as miners' phthisis, a deadly complaint which is responsible for a high mortality among the white miners. By the proper application of water at the point of origin, the formation of dust can, to a large extent, be prevented; and several ingenious contrivances have been invented for catching the dust from the upward holes, into which water cannot be poured from a can, in the manner usually adopted with downward holes. The chief difficulty, however, appears to be to get the men to use the dust-arresters and to water-down the stopes and other working places after blasting. By better supervision and a stricter enforcement of regulations, such difficulties will doubtless be overcome.

In the early days of the Rand, and, indeed, up to quite recently, it has not been found necessary to employ any artificial system of ventilation, the numerous shafts and outlets to the surface of the outcrop mines having sufficed to maintain an ample supply of fresh air. But with deeper levels, fewer communications with the surface, and an increased rock-temperature, artificial ventilation is destined to play an ever more and more important part in the future. It will be impossible to work the deep levels economically without carefully thought-out schemes of ventilation, and for the success of these it will be necessary to have shafts with small frictional resistance and large air space, and to carry the air-current through special ventilating roads.

The ventilation problem has been seriously attacked on the Rand, and already ventilating fans, varying in capacity from 50,000 cubic feet per minute at 1 inch water gauge to 250,000 cubic feet at 4 inches water gauge have been installed at many of the mines. In splitting the air current, the numerous dykes of igneous rock that traverse the Witwatersrand mines in a north and south direction (*i.e.* across the strike) can be made to serve as natural brattices, since they cut up the mines into air-tight compartments. The levels which penetrate these dykes must be permanently closed, or, if used for tramming purposes, closed by double swinging-doors.

Under the changed conditions now prevailing on the Rand, due to the enormously increased size of the properties brought about by recent amalgamations, and the consequent possibility of concentrating a large output on fewer main hoisting shafts than heretofore, the evolution of an entirely new system of underground transport is being accomplished. It is becoming recognised that the rock, broken in the stopes, can only be economically dealt with by handling it on a few main haulage-levels, situated at great intervals apart and driven straight, from point to point, in the footwall of the reef. These main haulage-roads, which are intended to serve also as the intake of the fresh-air current, can, on account of their economic importance, be constructed of large dimensions. They can also be carefully graded and equipped with heavy rails.

The handling of the broken rock in the stopes is, from an economic point of view, scarcely less important than its haulage on the levels. Everything depends on the angle of dip of the reef. In many of the outcrop mines of the Central Rand the high dip of the reef permitted the rock, broken in the stopes, to find its way by gravitation to the tramming-level, where it was drawn off as required from the stope-boxes; but with the dips of from 25° to 30° obtaining in most of the deep-level mines, the broken rock requires to be assisted down the stope-floors by shovelling. Only in the extreme East Rand, where the reef lies very flat (dipping at from 8° to 10°) is it possible to fill the trucks at the stope-faces and to run them thence direct to the tramming-levels. Hand-shovelling is uneconomical, and, moreover, is detrimental to health, on account of the dust it raises. Consequently, several attempts have been made to substitute for it some conveyer system of handling the broken rock. Stope-conveyers are shaking chutes consisting of iron plates. They are suspended by short chains from the roof next to the working face of the stope, and are kept in motion by ropes attached to the upper ends of the conveyers. Many of these shaking chutes are now in use on the Rand.

In the past, the use of machine-drills for stoping has not been looked upon with much favour. For this there are several reasons: first, the machine used was the heavy drill employed for development work, and with this type it was impossible to work in narrow stopes without breaking a large amount of waste; secondly, the bands of barren quartzite, with which the payable conglomerate is often interstratified, suffered such pulverisation by reason of the large blasting charges used that often it could not afterwards be eliminated by sorting; and, thirdly, the large blasting charges were found to weaken the roof, so that a greater number of pillars had to be left for its support than was the case with hand-drilling. Only in wide stopes, on a large homogeneous reef with good walls, could these drills be used to economic advantage. The necessity for a good stoping drill for narrow reefs, however, has become more and more pressing with the extension of the mining industry, with which the supply of native labour for hand-drilling has not kept pace.

By a series of competitive trials carried out under Government supervision, it has been established that machine-drilling in moderately narrow stopes costs no more, and perhaps even less, than hand-drilling by natives. Hundreds of small drills (drilling a hole to take a ⅞-inch explosive) are already employed for stoping on the Rand, and their average duty is three-quarters of a fathom per shift. To stope very narrow and low-grade reefs hand-labour has still to be used; but it is hoped that a drill capable of doing even this class of work will eventually be evolved.

Another important problem which has recently forced itself on the notice of those responsible for the mining operations on the Rand is the support of the hanging wall. The removal of the gold-bearing conglomerate bed, which, except for its somewhat steeper dip, may be compared to a coal-seam, leaves an open space, which is not allowed to fall in, as in a coal mine worked on the long-wall retreating system, but is supported over enormous areas by pillars of unworked conglomerate in the stopes, by ribs left above and below drives, and by pillars left to ensure the safety of the shafts, supplemented in some cases by the stowing of waste rock. These methods have sufficed in the past to keep open the stopes and drives and to protect the shafts; but owing to the robbing of the stope pillars in the outcrop mines, and more especially to the increased pressure of the superincumbent rock mass in the deep levels, serious movements of the hanging wall have lately been making themselves felt, crushing the pillars in the stopes, destroying the ribs above and below the drives, and in some cases even affecting the shaft pillars.

To arrest this untoward movement, which at one time threatened the loss of the main thoroughfares of some of the mines, a system of sand-filling has been adopted. By this system the abandoned stopes and other working places in the mines are filled with sand taken from the residue dumps. The sand is mixed with sufficient water to cause it to flow down pipes in the shafts and to be discharged in the stopes prepared for its reception. Underground, the pulp is conducted by wooden launders to the stope to be filled. Barricades are used to keep the sand in place; but it drains well, and soon packs solid enough to bear the weight of a man. The effluent water is pumped back to the surface. At first it was feared that the cyanide remaining in the sand would be dangerous to the mine-workers; but a little research has eliminated this source of danger. The effluent water from the sand-packs underground shows no trace of cyanide, and no hydrocyanic acid has been found in the air of the stopes which are being filled. The filling of the worked-out stopes will also assist ventilation, since it will prevent the dissipation of the fresh-air current. The system is already in use at many mines, and there is little doubt that it will be universally adopted.

One of the most remarkable economic changes on the Rand is now being brought about by the concentration of the steaming plant at two or three centres, from which power is distributed to the mines by electric transmission or in the form of compressed air. This has largely been the work of the Victoria Falls and Transvaal Power Company. Electrically transmitted power is rapidly supplanting independent steam power for mills, winders, sinking engines, underground hoists, pumps, &c., owing to the favourable rate at which it can be purchased from the power company. The price has been fixed by agreement at 0·561 pence per unit until October, 1912, and thereafter at 0·525 pence. Transmission is effected both by overhead lines (at 40,000 volts along the Rand, and at 80,000 volts from Vereeniging, a distance of 30 miles) and by underground cables (at 20,000 volts). The length of the overhead lines is 150 miles, that of the underground cables 35 miles. A portion of the power supplied by the company is in the form of compressed air for rock-drills.

A considerable economy will be effected by this centralisation of power generation, and the consequent reduction in the number of independent steaming plants. From the price per unit at which the Victoria Falls and Transvaal Company are supplying power, the cost of a horse-power per annum, utilised continuously day and night, can be calculated: it works out at 14*l*. It is not so easy to arrive at the average cost of a horse-power year on the mines prior to electrification, but it is stated to have been 28*l*. In any case, the saving due to the substitution of electric motive-power for steam-power is undoubted, and there is, moreover, the indirect advantage of greater flexibility and more perfect control.

The present position of the industry and the progress to be expected in the future may be illustrated by a few statistics.

Since the discovery of the Field in 1886 to the end of 1910 the Rand has milled 155 million tons of ore, and produced gold to the value of 276,000,000*l*., this being an average of 35·6*s*., or 8·4 dwt. of fine gold to the ton milled. During the same period dividends amounting to 72,416,550*l*. have been distributed, equivalent to 9·3*s*. per ton milled.

During 1910 gold to the value of close on 31,000,000*l*. was produced by crushing 21,500,000 tons of ore; this is equivalent to an average yield of 28*s*. 6*d*., or 6·7 dwt. of fine gold per ton milled. The working costs averaged (from the returns of fifty-six companies) was 17*s*. 7*d*. per ton, giving an average profit of 10*s*. 9*d*. per ton milled.

Seven of the largest companies, crushing close on a quarter of the whole tonnage, are working at an average cost of 13·8*s*. This very remarkable result has been brought about by increasing, to their economic limit, the size of the units used in the various operations, such as trucks, stamps, tube-mills, vats, pumps, &c.; by the simplification of the methods of handling ore; and by replacement, so far as it is economy to do so, of hand-labour by mechanical appliances. Larger units of development and the centralisation of power plant have also contributed to this result; while the amalgamation of the properties into larger units has helped to lower working costs, by permitting a reorganisation of the transport and hoisting arrangements, and by reducing the standing charges.

Future of the Goldfield.—Working at a cost of 13·8*s*. per ton means that the cost of development, extraction, and reduction, including administration, is covered by a recovery of 3¼ dwt. of fine gold per ton. On 5 dwt. ore, therefore, this would allow of a profit of nearly 7*s*. 6*d*. per ton: and over a considerable area of the Rand the average grade of the ore-bodies is not much above 5 dwt. The inclusion of large tonnages of relatively poor reef, which formerly were considered outside the range of practical mining, has been made possible by lower operating costs. The grade of the ore crushed has fallen in consequence. This does not necessarily imply that the increased depth of the mines has (*per se*) caused a falling-off in the actual value of the ore-deposit considered as a whole.

The effect of this increased tonnage and diminished grade on the life of the Rand goldfield as a whole is an interesting subject for speculation. From the data available the production of gold to be expected from the Main Reef series, if worked down to a vertical depth of 6000 feet, may be estimated.

It figures out at 1,046,000,000*l*., which, on the basis of an average output of 30,000,000*l*. per annum, is equivalent to a life of thirty-five years, *i.e.* down to a vertical depth of 6,000 feet. But, if at still greater depths the banket should contain sufficient gold to yield a profit, after deducting the cost of working, we may rest assured that it will be worked. What, then, are the limiting factors? They are generally considered to be (1) the mechanical difficulty of raising the ore to the surface from such great depths, and (2) the effect of the temperature gradient. With regard to the mechanical question, the electrical transmission of power applied to stage-winding has so modified the mining engineer's conception of the depth from which deep hoisting is practicable, that it is now generally assumed that there are no mechanical difficulties that cannot be overcome if it pays to do so. As to the temperature question, figures based on Mr. Marriott's careful experiments, which showed that the rise is only 1° F. for every 208 feet of depth, indicate that the rock-temperature at 7000 feet would not exceed 97·5° F., and with efficient ventilation the air temperature would of course be considerably lower. It follows, therefore, that for all practical purposes the whole question turns solely on the gold content, and what that may be at a vertical depth of 7000 or 8000 feet, no one can tell. This much, however, may be said: the geological structure of the country clearly points to the continuance of the conglomerate or banket beds to still greater depths than even 7000 or 8000 feet, before the bottom of the great synclinal basin of the Witwatersrand is reached; and, beyond that point, the beds must still continue until they rise to form the southern lip of the basin known to exist beyond the Vaal River.

THE FUNDAMENTAL PROPERTIES OF THE ELEMENTS.[1]

THE mystery that enshrouds the ultimate nature of the physical universe has always stimulated the curiosity of thinking man. Of old, philosophers sought to solve the cosmic problem by abstract reasoning, but to-day we agree that the only hope of penetrating into the closely guarded secret lies in the precise estimation of that which is tangible and visible. Knowledge of the actual behaviour of material and of energy provides the only safe basis for logical inference as to the real essence of things. Faraday was deeply imbued with this conviction; and it is widely recognised as the basis of all modern experimental science. The subject of my lecture to-night concerns the methods and general results of several extended series of investigations, planned with the hope of adding a little to the foundations of human knowledge by means of careful experiment.

At the outset let me remind you of an old saying of Plato's, for it sounds the keynote of the lecture:—"If arithmetic, mensuration, and weighing be taken away from any art, that which remains will not be much."[2] In other words, the soundness of all important conclusions of mankind depends on the definiteness of the data on which they are based.

Lord Kelvin said:—"Accurate and minute measurement seems to the non-scientific imagination a less lofty and dignified work than looking for something new. But nearly all the grandest discoveries of science have been the rewards of accurate measurement and patient, long-continued labour in the minute sifting of numerical results."[3] The more subtle and complicated the conclusions to be drawn, the more exactly quantitative must be the knowledge of the facts.

Measurement is a means, not an end. Through measurement we obtain data full of precise significance, about which to reason; but indiscriminate measurement will lead nowhere. We must choose wisely the quantities to be measured, or else our time may be wasted.

Among all quantities worthy of exact measurement, the properties of the chemical elements are surely some of the most fundamental, because the elements are the vehicles of

[1] Abridged from the Faraday lecture delivered before the Chemical Society by Prof. T. W. Richards on June 14.

all the manifold phenomena within the range of our perception.

Weight is clearly one of the most significant of these properties. The eighty or more individual numbers which we call the atomic weights are perhaps the most striking of the physical records nature has given us concerning the earliest stages of the evolution of the universe. They are mute witnesses of the first beginnings of the cosmos out of the chaos, and their significance is one of the first concerns of the chemical philosopher.

Mankind is not yet in a position to predict any single atomic weight with exactness. Therefore the exact determination of atomic weights rests upon precise laboratory work; and in order to arrive at the real values of these fundamental constants, chemical methods must be improved and revised so as to free them from systematic or accidental errors.

What, now, are the most important precautions to be taken in such work? These are worthy of brief notice, because the value of the results inevitably depends upon them. Obvious although they may be, they are often disregarded.

In the first place, each portion of substance to be weighed must be free from the suspicion of containing unheeded impurities; otherwise its weight will mean little. This is an end not easily attained, for liquids often attack their containing vessels and absorb gases, crystals include and occlude solvents, precipitates carry down polluting impurities, dried substances cling to water, and solids, even at high temperatures, often fail to discharge their imprisoned contaminations.

In the next place, after an analysis has once begun, stance into the balance case.[1] Every substance must be collected and find its way in due course to the scale-pan. The trouble here lies in the difficulty in estimating, or even detecting, minute traces of substances remaining in solution, or minute losses by vaporisation at high temperatures.

In brief, "the whole truth and nothing but the truth" is the aim. The chemical side of the question is far more intricate and uncertain than the physical operation of weighing. For this reason it is neither necessary nor advisable to use extraordinarily large amounts of material; from 5 to 20 grams in each experiment is usually enough. The exclamation, "What wonderfully fine scales you must have to weigh atoms," simply indicates ignorance; the real difficulties precede the introduction of the substance into the balance case.[1] Every substance must be assumed to be impure, every reaction must be assumed to be incomplete, every measurement must be assumed to contain error, until proof to the contrary can be obtained. Only by means of the utmost care, applied with ever-watchful judgment, may the unexpected snares which always lurk in complicated processes be detected and rendered powerless for evil.

That the atomic weights may be connected by precise mathematical equations seems highly probable; but although many interesting attempts have been made to solve the problem,[2] the exact nature of such relationships has not yet been discovered. No attempt which takes liberties with the more certain of the observed values is worthy of much respect. It seems to me that the discovery of the ultimate generalisation is not likely to occur until many atomic weights have been determined with the greatest accuracy. No trouble being too great to attain this end, the Harvard work will be continued indefinitely, and attempts will be made to improve its quality, for the discovery of an exact mathematical relationship between atomic weights would afford us an immeasurably precious insight into the ultimate nature of things.

But weight is only one of the fundamental properties of an element. Volume is almost, if not quite, as important in its own way, although far more variable and confusing. All gases, indeed, approach closely to a simple relationship of volumes, defined by the law of Gay Lussac and the rule of Avogadro, and well known to you all. In the liquid and solid state, however, great irregularities are manifest, and very little system as regards volume is generally recognised.

About twelve years ago, the study of such small irregularities as exist among gases led me to the suspicion of a possible cause for the greater irregularities in liquids and solids.[1] On applying van der Waals's well-known equation to several gases, in some tentative and unpublished computations, it seemed clear that the quantity b is not really a constant quantity, but is subject to change under the influence of both pressure and temperature. This conclusion has also been reached independently by van der Waals himself.[2] But if the quantity b (supposed to be dependent upon the space actually occupied by the molecules) is changeable, are not the molecules themselves compressible?[3]

The next step in the train of thought is perhaps equally obvious. If changes in the bulk of molecules are to be inferred even from gases, may not the expansion and contraction of solids and liquids afford a much better clue to the relative expansion and contraction of these molecules?

Most physical chemists refer all changes in volume to changes in the extent of the *empty space* between the molecules. But are there, after all, any such empty spaces in solids and liquids? Solids do not behave as if the atoms were far apart within them; porosity is often conspicuous by its absence. Take, for instance, the case of glass; the careful experiments of Landolt on the conservation of weight[4] show that glass is highly impermeable to oxygen, nitrogen, and water for long periods. Such porosity as occurs in rigid, compact solids usually permits the passage only of substances which enter into the chemical structure of the solids themselves. Thus nitrogen cannot free itself from imprisonment within hot cupric oxide, although oxygen can escape;[5] again, water cannot evaporate into even the driest of atmospheres from accidental incarceration in crystals lacking water of crystallisation.[6] Palladium, on occluding hydrogen, is obliged to expand its bulk in order to make room for even this small addition to its substance. The behaviour of platinum, nickel, and iron is probably analogous, although less marked.[7] Fused quartz, impermeable when cold, allows of the passage of helium and hydrogen at high temperatures;[8] but most other gases seem to be refused admission, and very many solid substances appear to act as effective barriers to the passage of even hydrogen and helium, especially when cold. In these cases, as in so many others, the so-called "sphere of influence" of the atom is the actual boundary by which we know the atom and measure its behaviour.[9] Why not call this the actual bulk of the atom?

From another point of view, the ordinary conception of a solid has always seemed to me little short of an absurdity. A gas may very properly be imagined with moving particles far apart; but what could give the rigidity of steel to such an unstable structure? The most reasonable conclusion, from all the evidence taken together, seems to be that the interstices between atoms in solids and liquids must usually be small even in proportion to the size of the atoms themselves, if, indeed, there are any interstices at all.

Very direct and convincing evidence of another sort is at hand. The idea that atoms may be compressible

[9] Since these ideas were first advanced, Barlow and Pope have brought forward much interesting evidence concerning the significance of the volumes of solids and liquids, which supports the idea that the atoms are closely in contact with one another (Trans., 1906, lxxxix., 1675; 1907, xci., 1150; 1908, xciii., 1528; 1910, xcvii., 2308).

receives striking confirmation from a recent interesting investigation of Grüneisen[1] concerning the small effect of low temperatures on the compressibility of metals. The average compressibility of aluminium, iron, copper, silver, and platinum falls off only 7 per cent. between the temperature of the room and that of liquid air. Extrapolation of the curves indicates that at the absolute zero very little further diminution should occur. So far as we can guess, therefore, the hard metals are almost as compressible at the absolute zero as at room temperatures. But at the absolute zero all heat-vibration is supposed to stop; hence this remaining compressibility must needs be ascribed to the atoms themselves.

If the atoms are compressible, all mathematical reasoning which assumes them to be incompressible rests upon a false basis. The kinetic theory of *gases* remains unmolested by these considerations, except as they indicate the changeability of b in the equation of van der Waals, but the new views affect seriously the application of this equation to solids and liquids.

Let us proceed to trace a few of the outcomes of our hypothesis. If atoms may really be packed closely together, the volumes of solids and liquids should afford valuable knowledge concerning the relative spaces occupied by the atoms themselves under varying conditions. The densities of solids and liquids then assume a significance far more interesting to the chemical philosopher than before, because they have a more definite connection with the fundamental nature of things.

An apparent objection at once suggests itself; if the particles in condensed material are really touching one another, how can we account for heat within the material? Would such closely packed atoms be able to vibrate?

The theory of compressible atoms supplies as one of its own corollaries the immediate answer to this question. If atoms are compressible throughout their whole substance, they may contract and expand, or vibrate within themselves, even when their surfaces are prevented from moving by being closely packed together. It is thus possible to conceive of a vibrational effect, even in contiguous atoms, provided we can conceive of these atoms as being elastic throughout all their substance. Agitation sufficient to produce even the Brownian movement might easily exist in such a system.

Clearly there is nothing impossible or obviously contradictory to experimental knowledge in the notion that atoms are compressible; indeed, the old idea of small, hard particles far apart is really more arbitrary and hypothetical than the new conception. The obvious simplicity of the latter is rather in its favour than otherwise, as in Dalton's atomic theory. In general, the more simply a hypothesis interprets the phenomena of nature, the more useful the hypothesis is likely to be, provided, of course, that the interpretation is adequate. The modern philosophy of pragmatism is a good guide in such matters; a theory not obviously illogical should be judged by its usefulness. Let us, then, test the new hypothesis by applying it to other aspects of physical chemistry.

If pressure produces a change in the sizes of the atoms and molecules themselves, may not the actual volumes of liquids and solids be used as a guide to the unknown internal pressures within them? Cannot we thus discover whether or not chemical affinity exerts pressure in its action? To follow this clue, the simplest possible case was chosen at first, namely, the comparison of the contractions taking place on combining several elements in succession with a single very compressible one. The changes of volume occurring during the formation of oxides were first computed; later, chlorides and bromides were studied. According to the theory of compressible atoms, we should expect to find greater contraction in cases of greater affinity. A diagram depicting typical data concerning certain nearly related chlorides strongly supports this inference.[2] One line shows the total change of volume which occurs when a grain-molecule of chlorine combines with the equivalent weight of metal; the other gives the heat evolved during combination. The lines show distinct parallelism; that is to say, reactions evolving much heat manifest great contraction. In cases of this kind, the heat of reaction is usually not very different from the change of free energy; therefore we may infer that greater *affinity* is associated with greater contraction; and it is but a small leap in the dark to guess that the change of volume is *caused* by the pressure of affinity. Since chemical affinity holds two elements firmly together, why should it not exert pressure? And if it exerts pressure, why should not the volume of the system be diminished by this pressure?

Evidently the change of volume in any case must depend not only on the intensity of the pressure exerted by the affinity, but also, among other things, on the compressibility of the substances concerned. The greater the compressibility, the greater should be the change of volume caused by a given pressure of affinity. Before any definite conclusion can be drawn, the differences in compressibility must be taken into account.

These thoughts led to the measuring of the compressibilities of a large number of elements and simple compounds. The previously employed methods for solids and liquids being unsatisfactory, a new and highly satisfactory method was devised for the work done at Harvard. The compressibilities of thirty-five elements and many single compounds were studied by this method with sufficient care to leave no doubt as to their relative values. It became at once manifest that the formation of a compound of a compressible element was attended with greater decrease of volume than the formation of a similar compound of a less compressible element, other things being equal.[1] This is just what the theory leads us to expect, and is a fact inexplicable by any other hypothesis as yet known to me.

Another essential aspect of the theory of compressible atoms is that which concerns cohesion.[2] If the pressure of chemical affinity causes atomic compression, may not the pressure of cohesive affinity also have the same effect? Traube suggested this possibility, but looked at the whole question from a different point of view.[3] The affinity which prevents solids and liquids from vaporising is generally admitted to produce great internal pressure; must it not tend to compress the molecules into smaller space? Molecules with high cohesive affinity (those of substances hard to volatilise) should be much compressed and possess small volume, whereas molecules with a slight cohesive affinity should be more bulky. Moreover, those molecules already much compressed by their own self-affinity would naturally be but little affected by additional pressure. Thus, as regards two substances otherwise similar, the less volatile one would be less compressible, denser, and possess greater surface tension.[4] These outcomes of the theory correspond with the facts in a majority of cases thus far studied; for example, *o*-xylene is denser, less volatile, less compressible, and possesses a greater surface tension than either *m*-xylene or *p*-xylene. Differences of structure and differences of chemical nature sometimes conceal these relations; the parallelism appears most strikingly among isomeric compounds. In brief, the bulk of evidence strongly indicates that cohesiveness as well as chemical affinity exerts pressure in its action, and hence that each plays a part in determining the volumes occupied by molecules.

Thus the computation of the space occupied by either a solid or a liquid becomes a very complex matter. Not only must the various chemical affinities at work be taken into account, but also the cohesive attraction of both factors and products, and the compressibilities over a very wide range of all the substances concerned. Discoverable parallelism in volume changes is to be expected only when one alone of these forces is the chief variable.

The exact mathematical working out of the consequences

[1] E. Grüneisen, *Ann. Physik.* 1910, [iv], xxxiii., 1239. The relative values for the compressibilities recorded in this investigation are doubtless trustworthy, although the absolute magnitudes are somewhat uncertain because they depend on the rather inadequate theory of elasticity.

[2] Richards, Proc. Amer. Acad., 1902, xxxvii., 399; also especially J. Amer. Chem. Soc., 1909, xxxi., 188.

[1] Richards, Proc. Amer. Acad., 1904, xxxix., 581. [2] *Ibid.*

[3] See especially Traube, *Ann. Physik.*, 1897, [iii], lxi., 383; 1901, [iv], v., 548; 1902, viii., 267; 1907, xxii., 519; *Zeitsch. physikal. Chem.*, 1910, lxviii., 289; also Walden, *Zeitsch physikal. Chem.*, 1909, lxvi., 385 Their interpretation depends largely on the application of van der Waals's equation and the complicating assumption of a *co-volume*; however, Walden's very recent paper presents a number of interesting and important relations concerning internal pressure, which seem to demand the assumption of atomic compressibility for their explanation.

[4] Richards and Mathews, *Zeitsch. physikal. Chem.*, 1908, lxi., 449.

is very far in the distance, if, indeed, it can ever be attained. This fact does not, however, militate in the least against the plausibility of the idea. Although mankind has not yet been able to devise a method of mathematical analysis which will solve at one stroke the gravitational relations of three bodies, nature is not on that account prevented from causing three or more bodies to act on one another with the force of gravity, or astronomers from calculating as nearly as may be the consequences by a process of approximation.

Carried through to its logical conclusion, the idea that atoms are compressible gives one quite a new conception of the molecular mechanics of the universe. The influence of atomic compressibilities may be perceived everywhere, and in most cases each fact seems to fit easily and without constraint into its place in the hypothesis. Even apparent exceptions, such as the abnormal bulk of ice, may be ascribed in a reasonable fashion to superposed effects. A detailed discussion of many applications of the theory is impossible here, but a few may be suggested in order to make clearer its possibilities.

The satisfying of each valence of an atom would cause a depression on the atomic surface, owing to the pressure exerted by the affinity in that spot. The stronger the affinity, the greater should be this distortion. Evidently this conception gives a new picture of the asymmetric carbon atom, which, combined with four other different atoms, would have upon its surface depressions of four unequal magnitudes, and be twisted into an unsymmetrical tetrahedron. The combining atoms would be held on the *faces* of the tetrahedron thus formed, instead of impossibly perching upon the several peaks. According to this hypothesis, the carbon atom need not be imagined as a tetrahedron in the first place; it would assume the tetrahedral shape when combined with the other four atoms. One can easily imagine that the development of each new valence would change the affinities previously exercised, somewhat as a second depression in the side of a rubber ball will modify a forcibly caused dimple in some other part. Thus a part of the effect which each new atom has on the affinities of the other atoms already present may be explained.

Many other physico-chemical phenomena assume a new aspect when viewed from the point of view of this idea. New notions of the mechanism of the critical phenomena, surface tension, ductility, malleability, tenacity, and coefficient of expansion are gained. The peculiar relations of material and light, such as magnetic rotation, fluorescence, partial absorption, and so forth, may be referred to the modified vibrations of distorted atoms. The deviations from the exact fulfilment of many older generalisations concerning volume (such as the equation of van der Waals already cited, the comparative volumes of aqueous solutions, especially of electrolytically dissociated substances,[1] and the variations in the crystal forms of isomorphous substances) are seen to be a foregone conclusion. Moreover, the theory, although not necessarily dependent on the modern belief that atoms are built up of numbers of much smaller corpuscles, is consistent with that belief; for would not such an entity be compressible?

The more closely the actual data are studied, the more plausible the hypothesis of compressible atoms appears. Ten years' experience with its interpretations leads me to feel that the idea is highly suggestive and helpful in stimulating new search after truth and in correlating and codifying diverse facts. By such fruit are hypotheses justified.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

OXFORD.—The following is the text of the speech delivered by Prof. Love in presenting Sir W. T. Thiselton-Dyer for the degree of D.Sc., *honoris causa*, at the Encaenia on June 28:—

Adest nobis ornandus Willelmus Turner Thiselton-Dyer, vir magnam in Botanica laudem adeptus, huius Academiae olim alumnus. Qui cum Dublinii, Corinii, Londonii hanc scientiam profiteretur, docendi rationes ita novavit ut florentissimis totius Europae scholis schola Britannica par fieret. Idem postea regalibus hortis Kewensibus praefectus varia negotiorum genera ad Botanicam pertinentia promovit. Testis est India, Cinchonae Peruvianae, in medendo potentissimae, nunc ferax: testes etiam Taprobane insula et Chryse Chersonesus Heveae Brasiliensis cultrices, cuius arboris virtutes omnibus notissimae sunt. Adeo non solum saluti, sed etiam rei familiari civium hic noster sua opera inserviit.

[1] Baxter has very recently discussed this matter from the point of view of the theory of compressible atoms (J. Amer. Chem. Soc., June, 1911).

MR. J. H. PRIESTLEY, lecturer in botany at the University of Bristol, has been appointed professor of botany at the University of Leeds.

MR. JOHN BLAKEMAN, head of the mathematical department of the Leicester Technical School, has been appointed as principal of the Northampton Technical School.

AN endowment fund of 200,000*l.* has been presented to University College, Reading, with a view to enable it to apply for a charter as an independent university. Of the amount mentioned, Lady Wantage has given 50,000*l.*, Mr. and Mrs. George W. Palmer 100,000*l.*, and Mr. Alfred Palmer 50,000*l.* Mr. Alfred Palmer has, in addition, presented to the college the freehold of four acres of land contiguous to the college site, at present held and used for horticultural purposes by the college under lease from him.

WE learn from *Science* that a gift of 4000*l.* to aid general research in the study of diseases at the Yale Medical School has been announced from an old student. Further gifts of 2000*l.* toward the endowment of the University clinic, and to the Peruvian exploration fund, for the Yale expedition under Prof. Hiram Bingham, have also been announced. From the same source we find that gifts of 20,000*l.* in lands by Messrs. James B. and Benjamin N. Duke, of 10,000*l.* for a new building by Mr. James B. Duke, and of 2000*l.* by Mr. B. N. Duke for improvements, were announced recently at Trinity College, Durham, N.C.

THE General Assembly of the State of Illinois has granted to the University of Illinois for the next two years the sum of 703,860*l.* *Science* says that this is the largest grant ever made by a State legislature to a State educational institution. The General Assembly has not only recognised the immediate needs of the University, but has looked ahead and made provision for the future by levying a one mill tax for the continued support of the University. It is estimated that this tax will yield an income to the University, two years hence, of about 450,000*l.* a year. In addition, the University will receive from the Federal Government and other sources funds that will bring its income to about 400,000*l.* per annum for the next biennium.

SOCIETIES AND ACADEMIES.

LONDON.

Mineralogical Society, June 13.—Prof. W. J. Lewis, F.R.S., president, in the chair.—G. S. **Blake**: Zirkelite from Ceylon. The results of five analyses made on fragments grouped together according to their specific gravity, which ranged from 5·2 to 4·4, showed remarkable variation in the percentage composition, the densest containing about 20 per cent. thoria and little uranium, and the lightest 14 per cent. U_3O_8 and little thorium; the precise formula is uncertain. A few crystals, some simple and some twinned, were met with; they apparently belong to the hexagonal system ($cr = 53° 22'$), the observed forms being $c(0001)$, $m(10\bar{1}0)$, $r(10\bar{1}1)$, $s(20\bar{2}1)$, $d(10\bar{1}2)$, $e(20\bar{2}3)$, and r the plane of twinning; they were opaque in mass, but translucent and isotropic in splinters.—Rev. Mark **Fletcher**: Note on some crystals of artificial gypsum. The crystals, which were formed in the condensing plant of a distillery at Burton-on-Trent, were twinned about 101, and the forms 100, 110, 230, 111 were observed.—L. J.

Spencer: The larger diamonds of South Africa. Historical notes relative to the "Excelsior," "Jubilee," and "Imperial" diamonds were given, together with a tabular statement of the weights of the rough and cut stones in carats and grams, and the percentage yield of the cut brilliants from the rough.—F. H. **Butler**: Brecciation in mineral veins. In vein-breccias due to fracture *in situ* (crush-breccias) replacement of country-rock is a characteristic feature. Where the coarse fragments in a brecciated fissure-vein indicate erosion, removal of fine rock débris may be inferred. Fragments that are angular and uneroded and completely isolated by encrusting material often indicate by shape and position their former existence as a single mass. The quiet removal of such fragments into a vein-cavity after reunion, and also the banding, with concomitant contortion of adjoining soft country-rock, by their cement-substance, may be ascribed to the hydrostatic pressure and the solvent and mineralising properties of the waters which furnished that substance. The coarse constituents of breccia may have been crushed *in situ*, or forced from fissure-walls by earth movements, or detached therefrom by aqueous pressure and solution.—Arthur **Russell**: Prehnite from the Lizard district. Two distinct types of crystals, tabular and prismatic, were recently found by the author on hornblende-schist at Parc Bean Cove, Mullion, Cornwall, the former showing the forms 001, 302, 061, and the latter 100, 001, 110, 061, and the rare form 301.

Royal Meteorological Society, June 14.—A. J. **Makower**, W. **Makower**, W. M. **Gregory**, and H. **Robinson**: Investigation of the electrical state of the upper atmosphere. The object of the experiments described was to measure the electrostatic potentials at various heights above the ground and the currents that flow down an earthed kite-wire. The method adopted was to send up kites or, in still weather, balloons attached to steel wires, provision being made for detaching sections of the wire from the winding drum so that the lower end might be anchored to a long rod of ebonite in order to insulate it from the ground. When this had been done the wire could either be earthed through a galvanometer to measure the current flowing down the wire, or else be connected to an electrostatic voltmeter having a range of 100,000 volts by means of a metallic line passing through glass tubing supported on long insulators to prevent brush discharges to the surrounding air or leakage to earth. Curves are given embodying the results of a series of flights made during the month of August, 1910, the potentials and currents that were measured being plotted as functions of the heights above the ground. The values obtained for the potential gradient near the ground lie between 0·5 and 1·5 volts per centimetre, and are in agreement with those deduced from the tests of previous experimenters using water-droppers or radium collectors, but it is found that the potential gradient diminishes rapidly as the height above the ground increases. Flights are recorded up to 4000 feet above the ground, at which height the potentials ranged between 40,000 and 60,000 volts, and the currents between 40 and 100 microamperes. Measurements were also made of the time taken by the kites and balloons to attain the full potential of the surrounding air from the moment at which the wire was disconnected from earth. This rate of charging is of interest in aëronautics in connection with the devising of suitable methods of preventing dangerous electric discharges from taking place between a balloon and the surrounding medium after a sudden change of height. The tests showed that the kites and balloons, the collecting area of which was about 150 square feet, charged up according to an exponential law, the exponential coefficient having values lying between 0·1 and 0·23, showing that a potential of half the full value was reached in about 5·5 to 7 seconds. It is argued that the rate of charging up is probably proportional to the radius of the balloon, and so the rate of charging up of large passenger balloons might be deduced from the rates determined with the small balloons used in these investigations. Attempts were made by the authors to discover a connection between the electrical state of the atmosphere and the prevailing temperature, barometric pressure, humidity, and wind velocity as registered on self-recording instruments sent up at each flight, but it was found that the amount of data collected was not sufficient to make such deductions possible. It seems that such conclusions will not be able to be drawn until continuous experiments extending over a considerable period of time have been made.

Geological Society, June 14.—Prof. W. W. Watts, F.R.S., president, in the chair.—Prof. W. S. **Boulton**: A monchiquite intrusion in the Old Red Sandstone of Monmouthshire. An unrecorded monchiquite, intruded into the Upper Old Red formation of Monmouthshire, is described. The manner of its intrusion is doubtful. The disturbance and metamorphism of the contact-rocks are dealt with, as also the rounded lumps of marl and subangular chips of sandstone incorporated in the igneous rock. The monchiquite contains large phenocrysts of augite and biotite, generally much corroded. Rounded "nodules" of olivine-augite rock with chromite are also included. A second generation of augite, biotite, and decomposed olivine occurs porphyritically in the ground-mass. The ground-mass is a felt of minute elongated augite prisms, magnetite grains, and flakes of biotite. A complete analysis of the rock is given, which bears out the petrographical evidence that it is a very basic lamprophyre belonging to the monchiquite group. Its age and connection with the only other known intrusion into the Old Red Sandstone of the South Wales area are referred to.—Notes on the Culm of South Devon: Part i.—Exeter district, by F. G. **Collins**, with a report on the plant-remains by E. A. N. **Arber**, and notes on the Cephalopoda by G. C. **Crick**. The paper is to show that the fauna of the Culm Measures of South Devon proves these beds to be the equivalents of the Pendleside series of the Midlands. The actual fossiliferous localities are eighteen in number, but often the fossils are too poor for determination. It seems advisable to seek more evidence, and an attempt will be made by working due north from Waddon Barton, a point farther to the west.

British Psychological Society, June 24 (held at Manchester).—Dr. T. Graham **Brown**: Note on the perception of movement in the environment.—C. **Burt**: The experimental investigations of emotional dispositions.—Dr. H. **Watt**: A new classification of experiences.—Prof. C. S. **Sherrington**: A simple teaching apparatus for illustrating Listing's law.—Prof. J. Lorrain **Smith** and Dr. W. **Mair**: A chemical comparison of the brain substance of the child and the adult.

DUBLIN.

Royal Irish Academy, June 26.—Rev. Dr. Mahaffy, president, in the chair.—C. F. **Rousselet**: Clare Island Survey: rotifera. Mr. Rousselet collected all the rotifera except the Bdelloida, which are embodied in a special report by Mr. James Murray. The report shows that the rotifer fauna of Clare Island and the neighbouring parts of the mainland differs in no special features from that of many other parts of the British Islands. Mr. Rousselet gives a list of 103 species with their distribution. Some of these had not previously been recorded from the British Islands.—Eugène **Penard** and G. H. **Wailes**: The freshwater rhizopoda obtained during the Clare Island Survey. The first collections of the fresh-water rhizopoda of Clare Island and the neighbouring districts of the mainland of Ireland were made by Dr. E. Penard, the work being continued later by Mr. G. H. Wailes. The present report has been drawn up under the joint authorship of these two investigators. The total number of species and varieties recorded is 140, of which *Cryptodifflugia eboracensis*, *Euglypha cirrata*, *E. rotunda*, and *E. armata*, as well as several varieties, are new to science. Seven other species are new to the British Islands.—D. J. **Scourfield**: Freshwater entomostraca. In a preliminary report Mr. Scourfield states that 41 species of Cladocera, 23 species of Copepoda, and 13 species of Ostracoda have been observed on Clare Island and the neighbouring parts of the mainland. No new species have as yet been definitely identified, but a couple may eventually prove to be new to science. The great majority of the species recorded are common types in the British Islands; only a few are to be considered as rarities.—Miss A. Lorrain **Smith**: Lichens (Clare Island Survey). The lichen flora of the Clare Island district is extremely abundant, especially as regards rock and ground species. The rarity of trees renders bark species less widely distributed than usual. The present report deals with some 280 species and 40 subspecies, &c. Of these, between thirty and forty are hitherto unrecorded from Ireland, and several are new to the British Isles or only once previously found therein. A summary of previous work in the district shows that while the neighbouring county of Galway has been well explored by Larbalestier, Mayo was practically unworked until the present investigation.

PARIS.

Academy of Sciences, June 26.—M. Armand Gautier in the chair.—E. **Guyou**: Solution of problems of altitude. New tables of navigation.—J. **Boussinesq**: Calculation of the absorption in translucent crystals for plane waves, laterally undefined.—P. **Villard** and H. **Abraham**: A large electrostatic machine. A description of a specially constructed Wimshurst machine of twenty plates, capable of yielding 1 milliampere at 250,000 volts.—A. **Müntz** and E. **Lainé**: Considerations on the employment of sewage in agriculture. Analyses of the Paris sewage are given, showing its value when applied directly to various crops. It is deficient in phosphates, and to use it to the best advantage these should be added.—L. **Maquenne**: Concerning a recent communication by M. L. Cailletet (on the origin of the carbon assimilated by plants).—E. L. **Bouvier**: New observations on evolutionary mutations.—Édouard **Heckel**: The action of cold, of chloroform, and of ether on *Eupatorium triplinerve.* No odoriferous substance exists preformed in this plant, but such a substance is formed after desiccation for several hours, and much more rapidly after exposure to cold or to the action of anæsthetics.—J. Ph. **Lagrula**: A triple meteor observed at Nice.—Luigi **Giuganino**: Effect of the movement of the earth on light phenomena.—M. **Chanoz**: Images physically developed after fixing exposed gelatine-silver bromide plates.—J. **Gardner**: Apparatus for the telephonic reception of submarine signals. This consists of a microphone connected with a metal ring of carefully specified proportions, and attached to the armour of the ship. The signals can be perceived at increased distances, and their directions ascertained.—G. **Sagnac**: Movement of the earth and the optical phenomena in an entirely terrestrial system.—H. **Buisson** and Ch. **Fabry**: Measure of the intensities of the different radiations in a complex ray. The radiations from a quartz mercury vapour lamp were allowed to fall upon a thermopile after passing through various absorbing media, such as water, solution of potassium chromate, solution of quinine sulphate, solutions of oxalic acid, glass, &c., thus obtaining the amounts of energy carried by radiations of different groups of frequencies.—Georges **Meslin**: Circular polarisation.—L. **Bloch**: Some general theorems in mechanics and thermodynamics.—L. **Houllevigue**: Kathode rays produced in electric incandescent lamps. Conditions are described under which it is possible to obtain pencils of rays, easily deviable by a magnet, in the interior of incandescent lamps.—M. **Dussaud**: Economical incandescent lighting. Description of the great efficiency of a coiled filament of tungsten as compared with a carbon filament.—A. **Besson**: Action of the silent discharge on dry and damp ammonia. Small quantities of a substance which reduces copper salts are formed. This is probably hydroxylamine, produced according to the equation

$$NH_3+H_2O=H_2+NH_2OH.$$

—Paul **Pascal**: A method of optical control of magnetochemical analyses.—J. B. **Senderens** and J. **Aboulenc**: Catalytic esterification of aromatic acids in the wet way. The yield of ethyl benzoate produced in presence of sulphuric acid was found to depend upon the amount of the latter added. Acids such as the toluic acids, and salicylic acid, resemble benzoic acid in this respect, and in having the carboxyl group attached directly to the benzene nucleus; whereas such acids as phenylacetic and phenylpropionic, in which this group is not directly attached to the nucleus, do not yield increasing amounts of ester with increase in the quantity of sulphuric acid used as catalyst. The effects of potassium bisulphate and of aluminium sulphate as catalysts were also examined.—G. **André**: The diffusion of saline substances through certain organs of plants.—H. **Astruc**, A. **Couvergne**, and J. **Mahoux**: The adherence of insecticides of arsenate of lead.—V. **Balthazard**: Identification by finger-prints.—Léon **Pigeon**: Measure of the degree of strabismus.—M. **Odier**: The part played by mercury and some of its salts in certain cancers.—M. **Foveau de Courmelles**: A cause of X-ray dermatitis.—MM. **Sollaud** and **Tilho**: The presence in Lake Chad of *Palaemon niloticus*.—E. **Kayser**: The influence of humous substances on micro-organisms.—M. **Lemoigne**: Denitrifying bacteria of filter-beds.—Jean **Bielecki**: The part played by mineral matters in the formation of the protease of anthrax.—Stanislas **Meunier**: Influence of the structure of certain fossil shells on the production of a new variety of fibrous silica.—M. **Lantenois**: The advance of geological knowledge concerning Indo-China.—Henry **Hubert**: The mechanism of rains and storms in the Soudan.

CONTENTS.

THURSDAY, JULY 13, 1911.

A GREAT NATURAL PHILOSOPHER.

Life and Scientific Work of Peter Guthrie Tait. By Cargill Gilston Knott. Pp. x+379. (Cambridge: University Press, 1911.) Price 10s. 6*d.* net.

TWO large quarto volumes of Prof. Tait's collected papers were published some time ago by the Cambridge University Press, and these have now been supplemented by an exceedingly interesting account of Tait's life and work, from the pen of his pupil and friend, Dr. C. G. Knott. Every Edinburgh student must recognise the fidelity of the picture which Dr. Knott has drawn, and feel that his book is in all respects a worthy memorial of the great Edinburgh professor. The book will appeal very directly to many of the readers of NATURE, who remember the searching and trenchant reviews of books on physical mathematics, and the articles on such subjects as the physics of golf, and on questions connected with physical mathematics, which appeared in these columns from time to time, and were signed with the initials "P. G. T." Many of these less formal papers were of much scientific interest, which was not lessened by the eminently human personality of the writer, which appeared in every sentence, and the humour, a little grim at times, with which he illustrated or drove home his conclusions.

In a review of Tait's "Thermodynamics" in NATURE (January 31 and February 7, 1878, vol. xvii.) Clerk Maxwell said, "Science has enough to do to restrain the strong human nature of the author, who is at no pains to conceal his own idiosyncrasies, or to smooth down the obtrusive antinomies of a vigorous mind into the featureless consistency of a conventional philosopher." These words are a true description of Tait, the outspoken and uncompromising controversialist, the critic unsparing of error, but not without regard for the feelings of the advocates of views which he combated or denounced, the philosopher who said hard things regarding professed metaphysicians, but who thought of the foundations of dynamics and did not disdain to adduce metaphysical considerations for the justification of a fundamental principle of quaternions. Such men are rare at the present time. Everybody is superficially and laboriously polite; the old broadsword play of word and phrase is too often replaced by suggestion and innuendo. But a good knockdown blow or cut is better than a sting that empoisons the blood and festers.

Tait was a native of Dalkeith, near Edinburgh, and studied his rudiments in the grammar school of that town. At the age of ten, on the death of his father, he was brought with the family to the city in which his life-work was to be done, and became a pupil of the Edinburgh Academy, a day school which from its foundation in 1824 has always been famous for the soundness of its classical and mathematical instruction. There he had as schoolfellows Clerk Maxwell, Lewis Campbell, Fleeming Jenkin, and several others who achieved eminence or fame in after life. Maxwell was his senior by a year. It is foolish to attach very great importance to school examinations—some minds begin to mature sooner than others—but it is interesting to note that Tait, Campbell, and Maxwell seem to have been nearly equally distinguished in mathematics. All were soundly drilled in classics; the rector of the academy was an eminent classical scholar—the Ven. John Williams (curiously enough at the same time Archdeacon of Cardigan), who was chosen first rector in 1824, mainly at the instance of Sir Walter Scott. Tait had an excellent verbal memory, and used in after life to repeat much Greek and Latin poetry learned in the forms of the academy.

It is rather remarkable that at the University of Edinburgh neither Maxwell nor Tait excelled the best of their fellow-students in natural philosophy. Perhaps in music alone does early precocity precede the highest excellence in maturity; but then musical genius is much less dependent on the ripening of the logical powers. For original work in mathematics and physics a natural gift or instinct is, of course, essential.

Tait's career at Cambridge, and his initiation in the following years into experimental work in the laboratory of Dr. Andrews at Belfast, were incidents in the scheme of things which led to his return to Edinburgh in 1860 as the successor of Forbes. Tait entered at Peterhouse in 1848, Maxwell in 1850, but afterwards migrated to Trinity, and both, like Thomson (afterwards Lord Kelvin) before them, had William Hopkins as their private tutor. Each had his own strong personality, but the influence of that great teacher seems to have been of the best possible kind for the minds of all. Tait was Senior Wrangler and First Smith's Prizeman in 1852, and his first act when the Tripos result was declared was to telegraph home and ask that the news should be told to Gloag, his old mathematical master at the academy.

While professor of pure mathematics in Queen's College, Belfast, and working in the laboratory of Dr. Andrews, he was introduced by Andrews to Rowan Hamilton, at that time in the full tide of his quaternion work, and busy with the preparation of the "Elements" for publication. Then began an interchange of letters on quaternions, of which Dr. Knott, *con amore* as himself an ardent and accomplished quaternionist, has given a most interesting account. Apparently Tait's first letters, which were chiefly on difficulties raised by his perusal of the "Lectures on Quaternions," attracted Hamilton's attention to the writer as one likely to cultivate the new calculus and extend it to fields of physical research. Hamilton's own applications were mainly geometrical; Tait saw in quaternions a powerful instrument for the dynamical study of various branches of physics, which, in fact, placed at once in a new light all that analysis, applicable to so many different problems, in which Green's analytical theorem plays a prominent part. The result was his paper on Green's theorem, and, later, many of those physical investigations which form the latter part of his "Treatise on Quaternions."

Hamilton was a willing and voluminous correspondent, and his letters (the first was forty-five pages long, divided into thirty-two paragraphs), here printed, so far as they are quoted, with all the italics, small capitals, &c., which he used, even in his books, to mark different degrees of emphasis, abound in acute and suggestive remarks, which were no doubt due to the inspiration of the moment. The humour which he displays here and there, as in his "mortal leap from Chaucer to Moigno," and his description of the Abbé, is of a truly Irish flavour, and has the merit of unexpectedness.

The absence of quaternions from Thomson and Tait's "Natural Philosophy" has been the subject of some remark. It is now well known that the senior author could not be convinced that the quaternion calculus, or indeed any form of vector analysis, was of advantage in physical work. To this conservative view he adhered to the end of his life, and in a private letter of his later years, written, as he described it, politely and mildly as to a stranger, he states his adverse opinion with remarkable vigour. And there is the letter to Chrystal, quoted by Dr. Knott on p. 185, on the thirty-eight year war over quaternions.

It is somewhat remarkable that vectors should have led to so much correspondence of an animated sort. The respective merits of quaternions and the systems of Grassmann and others seem not merely to have kindled the intellects, but to have stirred the emotions of the various advocates to a surprising extent. The playful paraphrase by a physicist of the famous saying of Tertullian into "Behold, how these vector-analysts love one another!" suggests with a touch of irony that after all the differences may not be so fundamental as they appear, that perhaps each sees the truth, and may safely be left to fight its battle in his own way. Let each go on using the armour and weapons he has proved; no man can tell to whom the victory may be; perhaps after all to someone whose equipment seems lamentably inadequate. But nobody can help admiring the steadfast fidelity of Tait to the notation of the master, and his chivalrous defence of quaternions against all comers. He had a right to speak with authority: no man with the exception of Hamilton himself did more for quaternions or with them. And if the linear vector function ever yields its whole secret to the student of vector analysis, it will be because Tait has made the disclosure possible. Often light suddenly comes to a man who has turned a subject over in his mind for weeks or months or years. It is surely also possible that one explorer may enter into the labours of another, and quickly behold the promised land which the instinct and faith of the first pioneers told them lay beyond the mountains.

Cambridge had no more systematic student than Tait, and no university had a more faithful and duty-doing professor. The work to hand, the daily task, the common round of teaching, it was his joy to perform. In the opinion of some it is waste to keep such a man lecturing to elementary students; but Tait inspired his students, and that was surely a very great thing. As a lecturer on experimental physics he was well-nigh unapproachable; and he was well aided by his mechanical assistants, who understood his methods and knew that he could be depended on to take everything in the carefully thought-out and prearranged order. Without such order and close adherence to it, no man, however eminent, however great his genius even, can teach a university class effectively.

In his introductory and other occasional addresses, Tait often dealt with more or less controversial subjects. The tract which he wrote on "Thermodynamics" contains a sketch of the theory of energy, in which questions of priority of complete logical proof, for example, Joule's establishment of the equivalence of heat and work, are discussed with great force and cogency of argument, albeit with a dash of patriotism. Such things he also discussed in his popular lectures and lighter papers. His book on "Recent Advances in Physical Science," was a course of such lectures, taken down by a shorthand writer, and carefully revised. Its title is out of date now, but as a clear statement of the true foundations of the science of heat, and of the work done by Joule, Kelvin, Balfour Stewart, and others in that field, it cannot be excelled.

In thermodynamics he insisted always on the importance of Kelvin's idea of absolute temperature. Kelvin was undoubtedly behind Clausius in accepting the consequences of the equivalence of heat and work; but when his first scruples had been overcome, and Carnot's function had disappeared in the idea of absolute temperature, the scheme of relations of heat and work stood forth in a logical clearness, which no other mode of treatment has ever approached. The imperfectly specified thing called a "perfect gas," by means of which temperature is defined in many continental treatises, he cordially disliked, and he lost no opportunity of denouncing the treatment founded upon it. In the cause of accuracy Tait was zealous almost to slaying. No one who heard his lecture on "Force," to the British Association at Glasgow in 1876, will ever forget his dramatic denunciation of slipshod popular science and its professors.

Tait's association with Kelvin in the composition of the "Natural Philosophy" has been referred to. Not the least interesting chapter in Dr. Knott's book is the account of this collaboration. The two men had much in common, they were both pupils of Hopkins, their great mathematical power and sure physical instinct well fitted them to work together, but in other respects the combination was not so successful. Tait was orderly and methodical—that can be seen in his neat penmanship and clear and precise composition, which was fit, with scarcely an erasure or substituted word, to be sent to the printer. On the other hand, the perusal of matter in clear print on a proof-sheet, showed Kelvin so many opportunities of extension and amendment, that he immediately overflowed in new sections on the margins, to the dismay of the printers, and the augmentation of the bill of costs. Then Kelvin had so many irons in the fire; his thoughts were being carried away continually from the "Natural Philosophy," and that, of course, stood still, for there come times when one partner in such an enterprise cannot advance without the other. No wonder the book stopped at the end of the first volume.

For many years Tait was the general secretary of the Royal Society of Edinburgh, and of the 365 papers, the titles of which are enumerated in Dr. Knott's bibliography, by far the greater number were communications to the society's Proceedings or Transactions. Unlike most secretaries of learned societies, he was himself the most prolific contributor.

He never joined the Royal Society of London, though he was a royal medallist in 1886, and was often asked to allow his name to be submitted. Indeed, his heart was in Edinburgh and his work there. For the last twenty-five years of his life he never crossed the Tweed; the only occasions on which he left the city were his visits to St. Andrews, ten days in spring and six weeks in autumn, with one exception, when he went to Glasgow to deliver a lecture on thunderstorms.

Though not himself a great golfer, he was the recognised authority on the physics of the game. His explanations of the "carry" of a golf ball, of the action of toeing, heeling and slicing, all examples of his theory of the effect of spin, stood the severe test of his own experiments, and are beyond cavil. His papers on this subject—in NATURE and elsewhere—would form an interesting book on the dynamics of a spherical projectile in air, if they were collected.

Failing health, and the death of his son, Lieut. F. G. Tait, the great amateur golfer, at Koodoosberg in 1900, brought the toil of his strenuous life to a close. But at the last, only two days before his death, he was busy with his beloved quaternions, and wrote a sheet of notes of investigations on the linear vector function.

This notice is already too long, and yet nothing has been said of Tait's work on thermoelectricity, on mirage, or of "The Unseen Universe," and the "Paradoxical Philosophy." The two last-mentioned works, written in conjunction with Balfour Stewart, are interesting as an attempt to apply the principle of continuity to infer, and to some extent explain, the existence of an unseen system of things to which in some sort we stand in physical relation. Incidentally they show the strong yet unobtrusive religious faith of their authors.

A. G.

AUSTRALIAN PLANTS.

Australian Plants Suitable for Gardens, Parks, Timber Reserves, &c. By W. R. Guilfoyle. Pp. 478. (Melbourne and London: Whitcombe and Tombs, Ltd., n.d.) Price 15*s.* net.

THIS work, prepared, as we learn, at the request of a special committee, embodies the practical experience of its author during the past thirty-six years. Except for some five-and-twenty pages of preliminary matter, the book is not one that admits of being read. But this fact in no way detracts from its merits as a work of reference, or lessens the debt to Mr. Guilfoyle of Australians who care either for gardening or for Australian plants. The feeling, its author explains, which has inspired its publication, is a desire to arouse increased enthusiasm in regard to the native species. The introduction should at any rate have the effect of directing the attention of his compatriots to the fact that Australia is richly endowed with what is wonderful and beautiful in the vegetable kingdom. If it does have this effect, it will have well served its purpose, since all that can be needed to evoke the enthusiasm which is desired is some intelligent attention to the plants themselves.

Granted the existence of such enthusiasm the work before us must prove invaluable in guiding and controlling it. That some control will be needed an examination of Mr. Guilfoyle's lists abundantly shows. The value of the lists for this purpose is enhanced by the self-restraint which has enabled the author to confine to a couple of lines references to individual plants which those who are not themselves Australians would gladly have seen expanded to as many pages.

It is scarcely strange that the inhabitants of an autonomous State like the Australian Commonwealth should be less enthusiastic over their native plants than the inhabitants of Britain. The wattles and gums, the myrtles and honeysuckle trees, the Boronias, Brachycomes, and Epacrids of Australia do not yet arouse feelings and memories so keen as those aroused by the oak and thorn and gorse, the primrose or the daisy or the heather of Britain. There is, however, more than the mere absence of literary allusion or historical association to account for the fact. In Australia the number of forms capable of awakening interest or provoking admiration is so immeasurably greater than in Britain that the observer's attention is distracted. Even where, in spite of greater or less botanical differences, the plant-forms of the two countries are sufficiently alike to be comparable from an æsthetic point of view, as, for example, in the case of the Epacrids or Australian heaths and our familiar ling, the manifest superiority of the Australian plants scarcely suffices to produce the expected effect. Perhaps the fact that the enthusiasm of the Australian has to be extended to a dozen different forms, while we can concentrate ours on one or two, may be some explanation. Should Mr. Guilfoyle's own enthusiasm enable his fellow-countrymen to overcome this difficulty, he may truly be said to have deserved well of the Commonwealth.

The attempt made in a special list to bring some order out of the chaos which prevails in respect of the common names applied to Australian Eucalypts in different parts of the country, deserves especial attention. How great the prevailing confusion is will be readily appreciated if the Eucalyptus names recorded in Mr. Gerth van Wijks's "Dictionary" be examined. Mr. Guilfoyle's courage in endeavouring to deal with this troublesome question compels our admiration. It is perhaps too much to expect that everyone all over Australia will be willing to abandon the use of names to which they personally have become accustomed, and to be guided by what, after all, must at best be a somewhat eclectic set of substitutes. But if in this particular matter it can scarcely be hoped that Mr. Guilfoyle's action will receive the universal approval of his own generation, there is no doubt that some such action, if only on grounds of public convenience, is necessary, and it is more than probable that Australians of another generation will be grateful for the prescription of a stereotyped list of names.

THE CHEMISTRY OF CALCAREOUS CEMENTS.

The Chemistry of Testing of Cement. By Dr. C. H. Desch. Pp. xi+267. (London: E. Arnold, 1911.) Price 10s. 6d. net.

THE "cement" treated of in this volume is the group of calcareous cements—that is, the plastic materials employed to produce adhesion between stones and bricks in the construction of buildings and engineering works. The book deals, shortly but clearly, with the manufacture of the various kinds of calcareous cements, with their components, constitution, and properties, and with the mechanical and chemical methods of testing them.

Owing to the extending employment of concrete the production of cement is becoming more and more important, and the demands upon its qualities increasingly stringent. These more exacting requirements have so far been met with a remarkable degree of success, partly by improvements in mechanical processes, but also to no small extent through the cooperation of the chemist. For two reasons the services of the latter are likely to become of yet greater value in the industry. On one hand a still higher standard of quality may be demanded in the finished product, and, on the other, a larger variety of raw materials may be found to be utilisable in the production.

The complex character of the substances entering into the composition of calcareous cements, and the obstacles in the way of ready experiment with the products, have in the past greatly limited our knowledge of the chemical reactions which occur in the making and "setting" of these bodies. In modern practice, however, two things are helping to shed light upon the dark places. One is the introduction of "etching" methods, similar to those employed in metallography, for studying the structure of cements in their various phases; the other is the conception of cements as, essentially, colloids. Both these matters are fully explained and their importance emphasised in the volume before us.

The view adopted by the author as to what takes place during the setting of Portland cement is substantially that of Dr. Michaëlis. Assuming for the purpose of discussion that the cement materials consist of lime, alumina, and silica only, then the essential hydraulic constituent, alite, is formed from these by the action of heat during the process of manufacture. It is regarded as a solid solution of calcium silicates and aluminates. When water is added to the cement, it partly decomposes the alite, hydrolysing the aluminates in the first instance. The solution thus produced is a supersaturated one, and it presently deposits tricalcium aluminate. According to the quantity of water in the mixture, the deposit is either mainly colloidal or mainly crystalline; if the proportion of water is small it favours the production of a colloidal "gel." The excess of lime above that required for tricalcium aluminate remains in solution, or a part may be deposited as crystals of calcium hydroxide. This process is regarded as probably corresponding with the "initial set" of the cement.

As regards the subsequent gradual hardening, the argument is that water acts much more slowly on the calcium silicate contained in alite than on the aluminates, but when hydrolysis does occur the calcium silicate separates out in the colloidal form. The gel thus produced forms a coating round the cement particles, protecting them from further direct action of the water. But as the latter slowly diffuses through the colloidal coating, more and more of the alite is slowly hydrolysed, and the lime set free is absorbed by the gel, which thereby increases gradually in density and hardness, and loses its plastic qualities. To this gradual desiccation of the gel, which takes place even when the cement is immersed in water, is due the eventual hardening of the mass.

Evidence for the actual existence of colloid products in hardened cements is found in the fact that some of the components can be stained with eosin. Etching with acids shows the structure of the unchanged cement in the interior of the particles, around and between which lies the dyed colloidal gel.

The volume embodies the chief results of modern inquiries into what is admittedly a difficult subject. It is written in a true scientific spirit, and would be an excellent book to place in the hands of a chemist with progressive ideas, who wishes to study carefully the chemistry of calcareous cements. C. S.

GEOPHYSICS.

Physik der Erde. By Prof. M. P. Rudzki. Pp. viii+584. (Leipzig: Chr. Herm. Tauchnitz, 1911.) Price 14 marks.

THE course of lectures at the University of Cracow published by Dr. Rudzki in the book under review covers a wide range. The subject-matter lies on the border-line of astronomy, mathematics, geography, and geology, and the lectures have coordinated these different sciences very successfully. By readers in this country, where specialised studies so largely cramp workers into one narrow domain, the book should be greatly appreciated. It is much to be desired that more opportunity could be found for similar work in British educational methods; for those who agree with this view Dr. Rudzki's work will prove a useful stimulus.

In saying that the lectures have successfully coordinated the different subjects represented, the reviewer does not wish to suggest that the treatment is necessarily the happiest from the point of view of a student in this country. For instance, while the mathematical reader will find much to interest him and very little that he cannot follow in the subjects outside his own domain, he will find the mathematical part of the work occasionally incomplete or sketchy. At the same time the reader who is not a professed mathematician must frequently find the mathematics beyond his reach. Rather more or rather less mathemathics would probably suit a larger class of students. A second weakness of the book, and one which robs it of some value as a systematic treatise, lies in the somewhat arbitrary way in which certain branches of geophysics have been neglected, while others have been accorded very full treatment.

In general, however, the ground has been very thoroughly covered. Many valuable references are given throughout, and save for the last few years they seem very fairly complete. In his preface the author refers with regret to several interesting investigations which have appeared too late to be made use of in the text of the book. The reviewer has found few instances of work overlooked. Taking the work of this country alone—work which has in general received a full and generous treatment—the only important omissions that he has noted have been some of the investigations on wave problems of Prof. Lamb and the scientific results of Sir Ernest Shackleton's last Antarctic voyage. But all students reading the book must find many references which will be new to them, and the book has been made more serviceable by a useful index of authors and subjects.

Throughout the whole range of subjects considered—and there are included geodesy (practical and theoretical), seismology, isostasy, and the theories of tides, ocean currents, waves, seiches, rivers and glaciers—the treatment is fresh and full. As a type of the questions discussed in a most interesting manner the winding form of a river-bed may be selected for mention, also the problem of glacial epochs and the differing views as to the nature of the earth's interior. The general answer which Dr. Rudzki gives to the solutions so far offered for most of the problems he discusses is "Not proven," and no fault can be found with him for adopting so cautious a position. The book is replete with suggestions of unsolved problems, and would supply fruitful reading to many a student on the look out for a piece of research off the ordinary lines.

F. STRATTON.

THE EVOLUTION OF MAN.

(1) *Anthropogenie oder Entwickelungsgeschichte des Menschen, Keimes- und Stammesgeschichte.* By Prof. E. Haeckel. Sechste Auflage. Erster Teil, Keimesgeschichte des Menschen. Pp. xxviii+432+xvi plates. Zweiter Teil, Stammesgeschichte des Menschen. Pp. x+(433–992)+(xvii–xxx) plates. (Leipzig: W. Engelmann, 1910.)

(2) *Der Mensch: sein Ursprung und seine Entwicklung.* By Prof. W. Leche. (Nach der zweiten schwedischen Auflage.) Pp. viii+375. (Jena: Gustav Fischer, 1911.) Price 7.50 marks.

(1) BOTH these books are popular treatises discussing "man's place in nature" (to use the title of their English prototype), his origin, and development. They cover practically the same ground, and both aim at presenting the results of highly technical biological investigations in a form that will be intelligible to the educated layman. Nevertheless there is a marked contrast between them, one that in a measure reflects the influence of the difference in the attitude of the educated public towards the problems of evolution and the descent of man thirty-seven years ago and now. One of them is a weapon, forged in times of struggle, for the purpose of carrying offensive operations into the camp of those who were using every influence that casuistry and sentimentality could arouse to discredit Darwin and all his works. The other was written in more peaceful circumstances, long after such foolish animosities were buried, as one of the innumerable series of tributes which every country and class united in paying to Darwin's memory, on the occasion of the fiftieth anniversary of the publication of "The Origin of Species," two years ago.

This is the sixth edition of Haeckel's famous book. It first saw the light in 1874, in the days when the mere suggestion of the idea of evolution, in reference to man, was still regarded as "insulting" by many people. Its author was the most ardent and combative upholder of evolutionary ideas on the Continent, and he made no attempt to soothe the susceptibilities of his readers, preferring rather to set forth unpalatable views in the frankest and certainly not the least distasteful way. The book was originally flung as a challenge to the opponents of Darwinism, who replied by describing it as "a fleck of shame on the escutcheon of Germany."

Since then a vast change has taken place in the attitude of educated men towards the problem of evolution; but Haeckel has made surprisingly few changes in his book. From time to time, in the various successive editions, he has added liberally to the supply of illustrations, and tacked on a variety of tit-bits of new information, such as references to Pithecanthropus, the recent work on "the demonstration of the blood-relationship" of apes and man, and the results of investigations on the fate of the tail in man; but these are mere scraps of corroborative detail—embellishments to the edifice built in 1874, without altering the plan of the building or enlarging its dimensions. The great modern movements of biological thought in reference to heredity and evolution, and the results of recent morphological research, have made little or no impression upon Haeckel's book; its scope has not been enlarged to include the new learning; in spite of its veneer of modernity it is still a typical product of thirty years ago. But it is a wonderful tribute to its excellence that a book which does not claim to represent the present state of knowledge should maintain its position in competition with more recent works; it has, in fact, now attained the venerable rank of a classic.

The present edition is little more than a reprint of the fifth edition, which has appeared in an English translation. Slight additions have been made to the accounts of Amphioxus and the embryology of the chick, and a few more illustrations have been inserted; but these are mostly taken from old sources.

The author does not even provide a new preface; but in his introduction to the previous edition (1903) he frankly admitted that the literature relating to the problems discussed in his treatise had become so extensive and intensive that he made no pretence of keeping pace with it.

(2) Prof. Leche's book made its first appearance in Swedish at the time of the Darwin celebrations in 1909, and when the time came for the preparation of a second edition he made his interesting work available to a wider circle of readers by issuing this German edition.

The book is a simple and lucid description of the growth of evolutionary ideas, with an account of the men to whom we are indebted for this new learning.

Unlike Haeckel's treatise, which takes the form of lectures addressed to students of biology, but in virtue of its lucidity has become, nevertheless, a popular treatise, Leche's book is obviously written for the educated public in general, and therefore omits certain topics discussed by Haeckel, which are properly included in a treatise on biology, but not in works for wider circulation.

It is somewhat disappointing to the biologist familiar with the author's important contributions to comparative anatomy that Prof. Leche should have chosen to cast his book in so popular a mould. It would have been instructive to have had more information concerning the higher primates from one who is so great an authority on the other end of the mammalian phylum. But Prof. Leche has chosen the *rôle* of expositor, mainly of other people's work, and we are duly grateful for his clear statement of generally accepted views regarding man's origin and developmental history.

The book opens with an exposition of the growth of the theory of evolution, with an account of the work of Charles Darwin, his predecessors, co-workers, and followers, and it discusses the modern conflict between the teaching of Weismann and "Neo-Lamarkismus," expressing the opinion, for which he claims the support of Darwin himself, that the origin of species can be explained only by admitting the potency of the essential factors emphasised by both schools.

The second chapter is a simple exposition of man's place in the vertebrate series, explained by reference to the facts of comparative anatomy and embryology. Chapter iii. gives an account of the nature of the palæontological record, and deals at some length with the histories of the various vertebrate groups that have been recovered by this means, most of the space devoted to mammals being filled by the familiar story of the horse. The next three chapters deal respectively with man's structure as illuminated by comparison with that of other vertebrates; the light thrown on man's development by comparative embryology; and the nature and significance of rudimentary organs in the human body, the pineal body, the third eyelid, the palatal ridges, the coccyx, superfluous hair and teeth, and the vermiform appendix being the vestigial structures selected for discussion. There is a brief chapter on the brain, which can scarcely be considered adequate when it is remembered that it is the organ which has played the chief part in making man what he is.

The closing chapters are perhaps most useful to the zoological reader. They deal with man's nearest relatives, the primates, fossil-man and Pithecanthropus.

It is gratifying to find that Prof. Leche lends the weight of his support to the view, first set forth in NATURE in the year 1907, that Tarsius is the slightly specialised living representative of a very primitive group of primates, from which the lemurs and the apes were derived by specialisation along divergent lines; that in this sense Tarsius is the connecting link between these two suborders, because it is the least modified descendant of the common parents of all three suborders of primates.

There is a very useful summary of the circumstances of the discovery of the remains of Palæolithic man and Pithecanthropus, with an unbiassed account of the nature and significance of these much-discussed relics of fossil-man. In the chapters dealing with this subject he follows Schwalbe in most matters, and describes the recent trend of opinion on the Continent in reference to Palæolithic man, without committing himself, however, to any of the extreme views that are so much in evidence at the present time.

The volume closes with a brief statement in reference to certain points in the anatomy of modern man that have some wider significance of racial or sociological importance.

Prof. Leche's book can be heartily recommended as a calm and dispassionate summary of the present state of our knowledge of the structure of man, as it is interpreted by comparative anatomy. G. E. S.

GEOLOGY AND BUILDING STONES.

(1) *The Geology of Building Stones.* By J. Allen Howe. Pp. viii+455. (London: E. Arnold, 1910.) Price 7*s*. 6*d*. net.

(2) *British and Foreign Building Stones: a Descriptive Catalogue of the Specimens in the Sedgwick Museum, Cambridge.* By John Watson. Pp. viii+484. (Cambridge: University Press, 1911.) Price 3*s*. net.

(1) THERE has long been a demand for a book such as that now produced by Mr. Howe. It would be well for all architects, and also engineers, to go through some short course of geological training, leading up to the understanding of a geological map. Mr. Howe has to meet those cases where no preliminary work has been possible, and he describes in a clear manner the essential characters of rock-forming minerals. Quaintly, but properly enough, he includes ice, the mineral most utilised by the Eskimo. Knowing as he does the utility of the microscope, he introduces extinction angles in the table of the felspars on p. 20, but these are left unexplained, and the variation in the angle between the cleavages would surely be more interesting to the beginner. Thin sections of typical rocks are well illustrated in the later pages. The work of Dr. Flett, Mr. Lovegrove, and the author, has probably introduced the microscope to many "practical" men with good effect.

The classification of rocks employed is commendably simple. Trachyte seems to have slipped out of the table on p. 43, as a parallel with rhyolite and andesite, though it is described on p. 103. Mr. Howe does very well in avoiding local and specialised rock-names, though we suppose "kentallenite" (p. 89), the incorrect but accepted use of "granophyre" (p. 92), and "keratophyre" could scarcely be kept out. A large part of the book is naturally devoted to sedimentary rocks, and no reader will fail to appreciate their structure, and the interesting way in which structure records their modes of origin. The treatment of slate is an excellent example; we note that chemical composition is here so dominated by the compactness and by the fissile structure of the rock as to have no effect on relative durability (p. 287). Limestones are also adequately dealt with, the important oolitic stones of England being described in considerable detail. Among sandstones, we may direct attention to the interesting account of the Surrey "firestone" on p. 166. There is much in this book which will enable the professional geologist to give a "practical" touch to his teaching, and thus in turn to attract the technical student towards the broader aspects of geology. One of the chief rewards of the instructor in a modern college is to note the pleasure aroused when some familiar feature is explained. The "practical man" may know a good deal already about a stone, but he now sees it taking its place in the history of a world of stones.

Mr. Howe's chapter on the decay of building stone is especially to the point. He uses chemical symbols at times in his text in place of words, which is scarcely literary; but he shows well how sodium chloride and other salts increase the attack of rain-water on a stone, and how the acids liberated in towns also play their destructive part. A special section is devoted to the decay of limestones. The deleterious formation of gypsum in parts of buildings sheltered from the rain, or even beneath rain-washed surfaces, is impressively pointed out. Crystalline dolomites (p. 353) decay in the country through the more rapid solution of any calcite granules that are present, while in towns a worse evil befalls them, from the fact that magnesium sulphate is even more soluble than gypsum. The sulphuric acid in towns, of course, arises from the iron pyrites contained in coal. Mr. Howe's remarks as to our love for limestone (p. 9) should be taken to heart by architects.

There is a useful chapter on the testing of stones; but we question if the appendices which follow, containing lists of quarries, were worth compiling in view of the far more complete lists issued by the Home Office, and referred to on p. 435. A liberal description, however, not merely an enumeration, is given of the sandstones of Ireland (the heading accidentally calls them limestones). The reason for this treatment is not apparent, since a reference to the source of information, Kinahan's "Economic Geology of Ireland," would show that a similarly detailed essay might be written on any class of Irish stone.

It is one of the curses of curators that manuscript labels lead to cumulative errors in the names of places. Mr. Howe has succeeded far better than any copyist would have done. We do not know if his variations from Kinahan are accidents or corrections, for Kinahan was indifferent to proof-reading; but such words as Dundale, Geradmer, Blekinje, Thuringewald, Böhm-Brod, and Maenturog require emendation. Why write "the Tyrol," and also "Steiermark" and "Mähren"? But at such a book—the metaphor is obvious—we would not willingly cast a stone. We are additionally grateful for an index of twenty pages.

(2) Mr. John Watson's work represents an immense amount of patient application, behind which lies real enthusiasm. He has brought together a collection of building stones for the Sedgwick Museum in Cambridge, in which he aims at representing the whole world. He has presented a large number of the specimens, and furnishes a catalogue of rocks used in construction, leaving those used for decoration, road-making, and roofing for future work. On p. 8 he approves "a suggestion" that the University of Cambridge might be a fit place for "a national bureau, where building stone could be examined, tested, and reported on." The existence of the Geological Survey of Great Britain, as a public body of the first standing, would no doubt occur to our legislators, and the difference of outlook adopted in an economic and in a university museum is at once seen by Mr. Watson's choice of a classification. His stratified building stones are arranged according to their geological age, and are then grouped under their countries of origin. It is a question if this appeals even to the university student of petrology, and it certainly conveys no useful information to the seeker after building stones. The admirable index of fifty pages, surpassing that of the diligent Mr. Howe, does not set matters straight. There are thus twenty-six references to oolites, even though the Caen stone of p. 184 is omitted; but the seeker after sandstone will have to turn the pages of the volume. Granites, however, are copiously indexed as a group. The universities, having adopted law and medicine, have proceeded to engineering, mining, and distilling. It may now be too late to leave building construction and building stones to great technical colleges, of the type of the Royal School of Mines. Mr. Watson's book, issued at so very moderate a price, is a treasury of information for the inquirer. It is not the author's fault if it seems to emphasise that overlapping of functions which threatens to impoverish British centres of education.

SUPERNORMAL PSYCHOLOGY.

(1) *New Evidences in Psychical Research. A Record of Investigations, with Selected Examples of Recent S.P.R. Results.* By J. Arthur Hill. With an introduction by Sir Oliver Lodge, F.R.S. Pp. xii+218. (London: Wm. Rider and Son, Ltd., 1911.) Price 3*s*. 6*d*. net.

(2) *Personality and Telepathy.* By F. C. Constable. Pp. xv+330. (London: Kegan Paul and Co., Ltd., 1911.) Price 7*s*. 6*d*. net.

IT was in the early 'seventies of last century that men of scientific training began to take an interest in certain mental and physical phenomena which appeared to transcend the ordinary laws of psychology and biology. It has taken a generation to acclimatise some of these phenomena in the realm of serious and orthodox scientific pursuit, and the two present volumes represent further attempts, along two different lines, to win recognition for apparently supernormal facts, and to frame theories capable of bringing them into line with general knowledge.

Mr. Hill's book (1) is an eminently temperate and dispassionate statement and analysis of selected cases of clairvoyance and automatism, the former including the sayings of a professional clairvoyant, and the latter dealing with the "cross-correspondences," now fairly well known, between the automatic writings of Mesdames Thompson, Forbes, Holland, Verrall, and Piper. It is not difficult to perceive that the author inclines to the agency of disembodied human intelligences as the simplest explanation of many of the phenomena dealt with. When, in circumstances which exclude collusion as a reasonable hypothesis, phrases and allusions are simultaneously written out automatically by two or more persons in different continents, different phrases which only become intelligible on being pieced together, the case for assuming the operation of some intelligence different from that of the writers becomes strong. When, in addition, these phrases are characteristic of a Gurney, Myers, Sidgwick, or Hodgson, the temptation to attribute them to those deceased personalities is obvious. On the other hand, if telepathy and clairvoyance are real faculties, the proof of identity is faced with apparently insurmountable difficulties. Nevertheless, Mr. Hill's book is a valuable contribution to our knowledge of this difficult subject, and it is rendered particularly acceptable by the author's "careful and responsible truthfulness" and "unemotional habit of mind," to which Sir Oliver Lodge testifies in his introduction.

(2) Mr. Constable's book is an ambitious attempt to colligate the same range of facts by a new theory of personality. Experimental telepathy is assumed to be fully established, and is accounted for by the existence of an "intuitive self," which is in "timeless and spaceless" communion with all other intuitive selves. A large part of the book is taken up with a criticism of Kant and his transcendental dialectic, and the new departure claimed is the proof of the existence of the intuitive self from facts of ordinary human experience, chiefly relating to telepathy, or the reception of impressions otherwise than through the normal organs of sense.

The book as it stands can scarcely be said to succeed even in its main object, for even if telepathy were fully established, the possibility of some form of physical vehicle is becoming, if anything, increasingly obvious in these days of wireless transmission; and the whole conception of the "intuitive self" tends to remove these matters from all scientific procedure. An author who confesses his inability "to distinguish between time and space" (p. 34) is scarcely likely to convert physiologists or even psychologists to his views on crystal-gazing, or "psychometry," or communion with the disembodied. Any theory of survival likely to appeal to the scientific mind must be based upon physiological rather than metaphysical reasoning, and must, above all, remain in touch with the facts of racial and individual development. A physical scheme of immortality cannot be ruled out as an *a priori* impossibility while so many unknown forms of matter and energy remain to be discovered. Meanwhile, a transcendental self, independent of space and time, makes too great a demand on our powers of conception to be of any living scientific interest.

E. E. F.

OUR BOOK SHELF.

A Star Atlas and Telescopic Handbook (*Epoch* 1920). *For Students and Amateurs.* By Arthur P. Norton. Pp. 19+16 star and 2 index maps. (London and Edinburgh: Gall and Inglis, 1910.) Price 5*s.* net.

For the general use of amateur astronomers this is the best atlas and handbook we have yet seen. The sixteen maps are printed exceptionally clearly, and, while not overcrowded, show more than 7,000 objects. Each map is about 10 in. by 8 in., and is part of a lune, covering, exclusive of overlap, four hours of R.A., and 60° N. or S. of declination. The atlas opens out flat, and shows two maps joined together at the equator, so that about one-fifth of the whole sky is seen at once. Meridians and parallels mark every hour of R.A., and every tenth degree of declination, while marginal divisions enable a position to be fixed to the nearest 5m. or 1°. The polar regions are shown on two pairs of maps.

In addition to these excellent maps there are a large number of tables and a quantity of letterpress giving practically all the information the amateur is likely to require for ordinary work. The list of star catalogues, astronomical abbreviations and symbols, and the notes on astronomical terms are to be confidently recommended for their lucidity and trustworthiness. Then there is a number of notes on the planets, comets, meteors, eclipses, &c., which are very interesting, concise, and informative. The sun and moon are awarded rather fuller treatment, and a useful sketch-map of the latter forms the frontispiece.

All this is good, but what will probably appeal more strongly to the average amateur possessing a telescope is the section devoted to hints. These are eminently practical, and the observer is told how to take care of and to use his instrument, how to get to know its constants and capabilities. Should he wish to determine the focal length of his objective or mirror, or of his eyepiece, or the diameter of the field, or should he wish to clean the different delicate parts or undertake special work, he is advised tersely how to do it.

Then preceding each pair of regions there are a few notes directing attention to any special telescopic objects found therein; double stars, variables, nebulæ, and star clusters are located, and their special characteristics briefly described.

The whole work suggests that the author undertook a congenial task; the result shows he did it well.

W. E. Rolston.

Triumphs and Wonders of Modern Chemistry. A Popular Treatise on Modern Chemistry and its Marvels, Written in Non-Technical Language for General Readers and Students. By Dr. G. Martin. Pp. xx+358. (London: Sampson Low, Marston, and Co., Ltd., 1911.) Price 7*s.* 6*d.* net.

The author of this book has sought to make chemistry attractive to readers untrained in the methods of science, by offering them an account of some of the most surprising achievements of modern practical chemistry, and of the most startling deductions from recent chemical and physical speculations. These two subjects alternate throughout the book, but their treatment is of unequal value. Such practical matters as the liquefaction of air, the preparation of oxygen, and the artificial production of nitrogen compounds, are described in an interesting manner, and in an easy and popular style. The wisdom of the plan adopted in dealing with theoretical points is more questionable. The reader is presented, almost on every other page, with numbers intended to impress by their vastness. Such statements as that "in such an inconceivably short interval of time as the millionth part of the millionth part of a second there occur no less than 2,800,000,000,000,000,000 collisions between the little atomic worlds which make up a [candle] flame!" abound in every chapter, and the latest hypotheses concerning electrons and the æther are utilised freely to supply similar data. The exclamatory style of these portions, and the excessive attention given to the sensational and the marvellous, render much of the book fatiguing to the reader, and injure its value as a means of instruction, especially as no clear distinction is made between those wonders which are facts of experience and the most hazardous guesses as to the structure of the universe.

Some of the most interesting sections deal with natural marvels, such as the caverns of limestone districts, the diamond mines of Kimberley, and the sulphur deposits of Sicily and Japan, and the author's reading has enabled him to bring together a mass of curious information in which most readers will find something new or unfamiliar.

In spite of the defects on the scientific side, to which attention has been directed, it is evident that the author has a real enthusiasm for his subject, much poetic feeling, and considerable facility of expression, and that his book represents a genuine effort to communicate his enthusiasm to others.

Plant-Life on Land, considered in Some of its Biological Aspects. By Prof. F. O. Bower, F.R.S. Pp. ii+172. (Cambridge: University Press, 1911.) 1*s.* net.

THE first part of this book deals with the problem which the author has expounded more fully in his large work on the origin of a land flora. The life-histories of Ulothrix and Pteris, the flower of Cycadeoidea, and the motile sperms of Zamia are the central points in the earlier chapters. Then after discussing the limitations imposed upon plants by fixity of position, the author turns towards the golf links, noting by the way the incidents connected with plant increase and the biological features of sand-dunes. The golf links are introduced to serve as an object-lesson in plant colonisation. Finally, it is explained in the concluding chapter how the various themes treated as separate essays converge upon the all-important problem of descent. The facts and opinions set forth can scarcely fail to interest the general reader, who desires to become acquainted with modern views regarding the origin and development of the plant world, but he is likely to find the information somewhat disjointed and sketchy; thus he would certainly desire to learn more, if only hypothetical, of the transition from the fern to the flowering plant, and also of the evolution of the flower. Botanists are, of course, familiar with the subjects discussed, but to some the tale of the Culbin sands may be new, and all will appreciate Prof. Bower's "dicta" on golf links.

Butterflies and How to identify them. By the Rev. S. N. Sedgwick. Pp. 63. (London: Charles H. Kelly, n.d.). Price 1*s.* net.

THIS is an excellent little book for the beginner, and contains a quantity of useful information, for which we might often seek in vain in more pretentious works. There is a coloured frontispiece, representing three butterflies and two moths, and thirty-five photographic illustrations (some of them including a whole page of figures), representing scales, eggs, larvæ, and pupæ, besides perfect insects. Some of these are natural size, and others reduced or (occasionally) enlarged, and those of perfect insects are generally good, but the figures in some of the plates representing the butterflies of each month are rather too small, and have scarcely come out very recognisably.

The first chapter deals with metamorphoses, collecting, &c., and the second includes a complete list of British butterflies, with Latin and English names, and a sketch of the contents of the five families. In chapter iii. we find a table giving the month of appearance, food-plant, name, and locality, &c., of each butterfly, then a series of plates, to which we have already referred, showing the butterflies of each month from April to September, then notes on typical larvæ and pupæ, of which a representative series is figured, and, lastly, another table, giving name, brief descriptions of image, larvæ and pupæ, food plants, and locality; and a few pages of ruled paper for notes.

A few doubtful species are included, such as *Argynnis dia* and *Erebin ligea,* but if this is an error, it is an error on the right side. Altogether the book should be specially useful to schoolboy entomologists.

The Open Book of Nature: an Introduction to Nature-Study. By the Rev. Chas. A. Hall. Pp. xi+268. (London: A. and C. Black, 1911.) Price 3*s.* 6*d.* net.

VARIOUS allusions and the general tenor of the book indicate that the author's early proclivities towards natural history were developed at a time when there were few inducements, either in the shape of popular books or general appreciation, to take up the study of the natural sciences. Having derived so much pleasure from his studies he desires to arouse in others the spirit of observation and a similar enthusiasm for a knowledge of nature.

The earlier geological chapters are devoted mainly to dissertations on rocks and fossils; identification of flowers is the chief botanical feature, and zoology is introduced with botany in the description of a ramble which occupies a third part of the book. The final chapter containing practical hints is by no means the least useful, although the manipulation of microscope and camera are better postponed to a more advanced stage. The purpose of the author is best served in those passages where he describes his own observations and experiences. There is overmuch introduction of information which, referring to natural objects not easily obtained, cannot be practically confirmed, and it is certainly inexpedient to give a string of morphological definitions (as on pp. 120 to 130), some of which are admittedly incorrect; it would be wiser in every respect to refer the student to a text-book for such details. Undoubtedly the author would be a delightful companion in the field, but conversations that are instructive on a ramble appear fragmentary when offered as a set piece.

The Oxford Geographies. Edited by A. J. Herbertson. Junior Geography. Questions. Pp. 28. By F. M. Kirk. Statistical Appendix. Pp. 36. By E. G. R. Taylor. (Oxford: Clarendon Press, 1911.) Price 1*s.*

IF these questions and summaries—prepared to accompany Prof. Herbertson's "Junior Geography"—lead teachers to make boys and girls themselves take an active part in their geography lessons, and not merely listen to what the teacher has to say, they will serve a very useful purpose. The resourceful master should find no difficulty in basing practical work upon the material here provided.

LETTERS TO THE EDITOR.

The Deformation of Rocks under Tidal Load.

THAT a shore-line should be depressed by the weight of a high tide and rise again when the tide retreats is an idea that has occurred to many. Sir George Darwin has on certain assumptions calculated the form and amount of deformation to be expected under given tidal conditions. In the British Association Report for 1910, p. 49, I showed what had actually been recorded by Mr. W. E. Plummer at the Bidston Observatory, which lies two miles inland from high-water mark. At that place a 10-foot tide resulted in an angular deflection of approximately 0·2″. Had the instrument been nearer to the sea a greater change in inclination might have been expected.

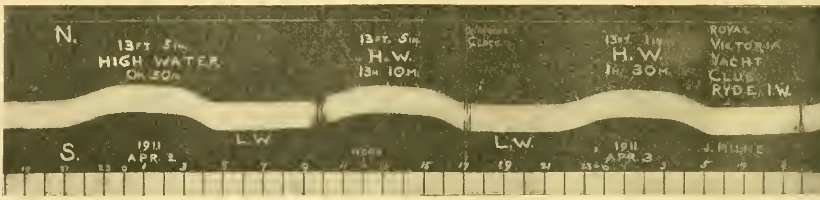

FIG. 1.—Record of Deformation of Ground by Tidal Load.

This year, between March 4 and May 24, an instrument similar to that at Bidston was, by the kind permission of the committee of the Royal Victoria Yacht Club, installed in the base of their premises at Ryde. The distance between this installation and high-water mark was 138 feet. The displacements due to a 10-foot tide were approximately 0·9″. This is more than I should expect to find at Bidston if that observatory were near to the high-water mark. If it would be really greater, then the soft Tertiaries beneath the Solent yield more than the hard sandstones which run seawards from Bidston. This may perhaps be a point of interest to geologists. The astronomer with his observatory near a seashore will realise the extent to which he is handicapped, due to tidal tilting, in relation to the man who makes similar observations twenty miles inland.

Considering the magnitude of the deflections due to tidal load, the geophysicists may wonder whether we could or could not in a country like Britain obtain satisfactory measurements of a terrain tide due to lunar influences. The definite measurements of the amount of bending which a tide produces on a floor of a shallow dish-like sea bed puts the hydrographer in a position to calculate the difference between what he observes in the rise and fall of the tide and what it would be if the bed had been absolutely rigid.

Lastly, as to the seismologist who has tried to find the relationship between earthquake frequency and tidal load. So far as I know, this has not yet been shown. The reason for this is perhaps because we have not confined our attention to earthquake regions where the effect of tidal load was marked.

The diagram (Fig. 1) is a half-sized reproduction of a "graph" at Ryde. The flat crests and sinuses of the waves indicate that the tide lingers for a considerable time at "high" and "low." The reason for this is apparently connected with the fact that Ryde is approached by tides from two directions. One enters the Solent from the east and the other from the west, but at somewhat different times.

Shide, Isle of Wight, July 5. JOHN MILNE.

Electrical Discharge—Possible Cause of Flare Spots in Photographs.

DURING a recent yachting cruise on the north-east coast, I sailed from Holy Island to St. Abbs, arriving off the harbour before the fishing fleet came out, and therefore dropped anchor off the entrance. About 5.30 p.m. some of the Scotch herring boats sailed out, and I photographed one shortly after leaving the entrance, and another when she was well outside. On having the two negatives developed and printed, I was disappointed to notice that both pictures were considerably marred by a white flare extending from the mast and yard of the sail skywards. At first I put down the flare spot to light leaking into the camera, or some sort of optical halation. On considering the matter more carefully, I was struck with the coincidence of both photographs showing the defect starting from the yard and the mast, and not at all visible on the lower dark sail. I talked the matter over with several friends, and eventually Mr. C. Faraday Proctor jokingly suggested it was evidently caused by electrical discharge. We both took the idea in a sarcastic spirit; but very soon we realised that the suggestion was not so ridiculous, and was well worthy of serious consideration, particularly as I remembered that the weather conditions had been thundery during the two previous days whilst sailing up from Blyth

Photograph of Flare Streak, possibly due to Electric Discharge.

to Holy Island. I then carefully examined other photographs taken on the following day of boats in the harbour, and several of these showed evidence of the same effect.

I enclose herewith three photographs.

No. 1 (here reproduced) shows the keel boat just sailing out of the harbour, taken Tuesday, June 20, 5.30 p.m., looking south.

No. 2 shows boat taken a few minutes later looking east.

No. 3 shows boats in the harbour looking north, taken about 1 p.m. on Wednesday, June 21. In the sky above all the masts are distinctly visible, pronounced white flares extending skywards. The photographs were taken on a Kodak film, exposure about one twenty-fifth of a second.

On the Tuesday the wind was blowing fresh from the north-west, and on the Wednesday the wind was still fresher from the south-west.

This note and photographs are being sent with the object of directing attention to the phenomenon, and with the hope of learning whether it has been noticed by others.

ARNOLD SPILLER.

Northumberland Yacht Club, Blyth, July 5.

Anhydrous Volcanoes.

THE cumulative evidence in Dr. Albert Brun's "Recherches sur l'exhalaison volcanique" leaves very little doubt but that the explosive action in volcanoes is due to decomposition of compounds of C, N, Cl, F, &c., held dissolved in the glass of the lava. All the theories about volcanic activity must be revised, as pointed out by that author; but along with the disappearance of the theory attributing the explosive action to water, there must be a disappearance also of the theory of a hot interior of the globe, as a corollary following on Dr. Brun's researches, if on no other grounds. For if a magma containing carbides, nitrides, &c., will explode with great violence if heated, then, supposing the earth's centre were hot, a single volcanic vent would allow the whole of the volcanic magma contained in the earth to swell and boil over on to the surface of the earth.

Accepting, then, Dr. Brun's conclusions, the volcanic magma below the crust must be cold, and only when heat is applied to it, through movements in the earth's crust, will the expansion take place and the volcano be formed. The gases given off from volcanoes, or expelled by heating obsidians to their melting points, are strongly reducing, and were, therefore, forced into the magma at a stage in the earth's growth (on the planetismal hypothesis) when the surface was incandescent from the infalling of meteorites, and when the atmosphere consisted of gases carried to the earth in these meteorites, principally CO, CO_2, H, N, and CH_4. The rock-silicates absorbing these gases gradually cooled down and were buried, and thus a supply of material was laid by from which the volcanoes of future ages could be formed. The absorption is more than mere occlusion, for an obsidian can be thoroughly weathered and absorb water throughout its mass, yet, when dried and then raised to fusion point, free chlorine can be given off, showing that the water cannot have had access to the storage chamber of the chlorine. Again, a granite powder may be sprayed with paraffin and heated to 1100° C. The excess of paraffin burns instantly, but a certain portion is fixed by the silicates and remains as paraffin within the rock-magma up to the explosion point, when it is expelled with explosive violence. Actual paraffin can be distilled from the pitchstone of Arran. If paraffin can be retained in a magma heated to above 1000° C., it means that it has practically entered into chemical composition with the silicates.

An obsidian retains some of the gases originally held in the magma, because it has cooled quickly; a certain time is necessary, even at fusion point, for the gases to be expelled; hence a lava will continue to give off gases as it flows down the side of the volcano, although a large proportion has escaped in the chimney, and will still be found to contain gas when it has cooled completely. The solidified lava, if left long enough, will slowly give off gases, N, Cl, CO, CO_2, CH_4, &c., but the life of a lava, before it becomes what Brun calls a "dead rock," is probably thousands of years.

There is certainly an analogy, if nothing more, between these results of Dr. Brun's researches, and the properties of radio-active substances. Helium must have existed in the earth's atmosphere when the surface was incandescent, for the same reason that it exists in the sun's atmosphere to-day, and it is possible that certain substances had the power of causing it to enter into a sort of chemical combination with them, like the paraffin in the rock silicates. Existing in the lower layers of the earth's crust near the centre, which I have given reasons to suppose is very little, if at all, above the temperature of outer space, these substances would retain the helium frozen in them, as the chlorine, paraffin, &c., are frozen in the rock silicates, and they could retain the helium for indefinite periods. When some of these substances, however, are brought by the ordinary processes of ore-formation into the warmer regions of the outer crust, they would give off their helium. The difference between the way in which the helium is held in radio-active substances, and that in which the gases are held in rock-silicates, is shown by the fact that the rate of expulsion of helium is unaffected by temperatures available in the laboratory, whereas the gases can be all driven off from a rock-silicate at one time. There may be nothing in this, but it may reassure some who are alarmed at the rate of decay of radium and see no possible sources of replenishment.

ERNEST H. L. SCHWARZ.

Rhodes University College, Grahamstown, June 12.

The End of the *Beagle*.

WITH reference to the letter in NATURE of June 1, the following particulars of what I know upon the subject may be of interest.

In the year 1863, at Hong Kong, a friend of mine purchased from the Government the dispatch gun vessel *Beagle*, which was at that time laid up, after being some years on the China Station. We had her thoroughly overhauled and repaired, and renamed her *The Stork* (a sacred bird of the Japanese). I then took her over to Japan, to the ports of Nagasaki and Yokohama, for sale. She was visited and examined by the Japanese; but no sale was effected at the time, and I took her back to Shanghai. However, she was eventually purchased by the Japanese Government, and after that I have no further knowledge of her movements.

The other *Beagle* mentioned in NATURE was an old 10-gun sailing brig, and I think there can be no doubt that she was the vessel in which Darwin made his scientific explorations. I see in the "Encyclopædia Britannica" that Darwin made his voyage in the *Beagle* in the years 1832 to 1836, several years before the *Beagle* that I commanded was built, so I presume that settles the matter.

H. C. SHOOSMITH.

54 Billing Road, Northampton, June 23.

[THE second line of the "Voyage of a Naturalist" describes the *Beagle* as a 10-gun brig. The vessel was barque-rigged, and is believed to have been about 280 tons.—ED. NATURE.]

The Osmotic Pressure of Colloidal Salts.

IN reference to the interesting letter of Dr. Hardy, published in NATURE of June 29, I should like to state that work on similar lines has been proceeding in this laboratory during the last year and a half. We have been investigating the general subject of "membrane-equilibria" and "membrane-potentials" in the case of non-dialysing electrolytes. An informal note on the principles involved in these investigations was read by me before the Physiological Society in December, 1910. Some time ago a paper dealing with the theory of these equilibria and potential-differences was sent to the *Zeitschrift für Elektrochemie*. In this paper, which is already in type, Dr. Hardy will find that I have arrived at equations expressing the membrane-potentials which are practically identical with the equation given in his letter. We propose, therefore, to continue our investigations on the subject.

Muspratt Laboratory of Physical and Electro-Chemistry, University of Liverpool, July 1.

The Date of the Discovery of the Capillaries.

DR. FRASER HARRIS is quite correct in stating that Malpighi (working with Charles Fracassati) demonstrated the existence of blood capillaries with the microscope in the year 1660. The two letters to Joh. Alph. Borelli announcing the discovery were published in folio at Bononia (Bologna) in 1661. This is now a rare tract, and not usually quoted. It is, however, doubtful whether

Malpighi first saw capillaries in the frog's lung or in the frog's bladder—probably it was the latter. Although, of course, he was not the first to practise injection methods, we may note that Malpighi traced the course of the vessels by (*a*) inflating them; (*b*) injecting mercury; (*c*) injecting coloured fluids. Both Sir Michael Foster and your correspondent appear to have overlooked the fact that the expression "Magnum certum opus oculis video" is not Malpighi's, but a translation from Homer, and is intended, I imagine, to be translated after the Malpighian manner as: "I see with my eyes a truly great work."

F. J. Cole.

University College, Reading, July 4.

Arising out of the letter on the above subject in Nature of June 29, by Dr. D. Fraser Harris, is the true date of the momentous discovery of what is the oxygen carrier of the blood. This discovery is put down to Sir G. G. Stokes, and the date some years later than 1862.

I wish to direct attention to a fact hitherto overlooked, namely, that Dr. John Roberts, of Plas Eryr, Clwtybont, Carnarvonshire, was the first to say (and to publish it) that the colouring matter of the blood (hæmoglobin) was the oxygen carrier. This can be verified by perusal of his thesis (for M.D. Edin., published in 1860, and now lying in the archives of Edinburgh University) on "Pigment."

Dr. Roberts is still alive and well.

R. Cadwaladr Roberts.

Heathfield, Cardigan.

THE FUR-SEAL QUESTION.

For some time past a conference has been sitting in Washington, in which representatives from Great Britain, or rather Canada, Russia, Japan, and the United States, have taken part, for the purpose of drawing up new regulations for the conduct of the Bering Sea seal fishery, and for the protection and restoration of the herd. *The Times* of June 28 contained an account of the findings of the conference, and in the issue of July 8 its correspondent at Washington reports that the new convention was signed on July 7. The full text of the agreement has not yet come to hand, but its main provisions, which are of great international importance, and of great interest to all naturalists, are said to be as follows. Pelagic sealing will be totally prohibited to all subjects of the participating countries for fifteen years, and measures will be taken to induce other countries to prevent its being carried on under cover of their flag; the United States and Russia, which own practically all that remain of the seal herds of the North Pacific, will pledge 30 per cent. of their catches for the purpose of paying a specified yearly dole to Canada and Japan to compensate them for abstention from the fishery, and the United States (it is said) will advance 40,000*l*. to each of the latter countries for the immediate compensation of persons engaged in the industry; the contracting Powers will admit no skins to their ports the origin of which is not properly certified; and, lastly, regulations are laid down as to the method of killing seals on land, and as to the establishment of guards upon the rookeries. These resolutions are, we suppose, still subject to ratification by the several Governments, but nevertheless we have good reason to believe, and every reason to hope, that the wise and liberal proposals thus stated may soon be adopted and carried into effect. The Washington correspondent of *The Times* reports that, so far as can be gathered, the convention will be accepted by the Senate. It will come into force on December 15.

The Bering Sea Arbitration of 1893 was an affair of such international magnitude that it is far from being forgotten. It is unnecessary and impossible to enter here into a review of that great debate, of all the causes that led to it, or of the minor questions that arose for a few years after its close. We may simply remind our readers that its chief result was the delimitation of a zone of sixty miles around the Pribylov Islands, within which zone pelagic sealing was prohibited during the season when the herd were living and breeding upon the islands, while at the same time the use of firearms was entirely prohibited to the pelagic sealers. A few years later pelagic sealing was entirely prohibited, both by America and Russia, in the case of their own subjects. But while it is impossible to enter here into either diplomatic or commercial history, a few words upon the general aspect of the case, and especially upon the natural history of the fur seals, may be of interest at the present moment.

The true fur seals, forming the old genus Otaria (now broken up into subgenera), belong to the more extensive family of the Otariidæ, or eared seals, the various members of which differ considerably in their habits. For example, Steller's sea-lion (Eumetopias), a large, ungainly animal, is sparsely distributed on a multitude of coasts and islands around the North Pacific; while, on the other hand, it is characteristic of the fur seals, throughout the whole area of their distribution in the Pacific and Southern Oceans, to resort to but few local breeding-places, where, in prosperous times, they congregate in great multitudes. Naturalists are not quite agreed as to the number of species of these fur seals, but the best-known breeding-places are, or have been (besides those in the Bering Sea), Robben Island at the Cape of Good Hope, the Auckland Islands, the Falklands, South Georgia and many other islands in the Southern Ocean, Lobos Island, at the mouth of the River Plate, Guadalupe, off southern California, and the Galapagos. In the Northern Pacific by far the greatest of the rookeries are those of the Pribylov Islands, St. Paul and St. George; next in order come those of the Russian Commander Islands, Bering and Copper Islands; while in the Sea of Okhotsk there is still a small rookery on Robben Island (now ceded to Japan), and on the Kuriles a number of rookeries were formerly known but are now either extinct or very nearly so. Dr. Jordan and his American colleagues ascribe specific differences even to the seals of these comparatively neighbouring breeding-grounds, and it is highly probable, if not certain, that the Pribylov seals from the eastern part of the Bering Sea, and the Commander Island seals from its western part, form absolutely separate communities, the long southward migrations of which in winter time follow different routes, the one towards the shores of British Columbia and the other towards those of northern Japan. For an unknown period, but probably for centuries, they have been exposed to attack by expert native fishermen, spearing them at sea in the course of these winter wanderings.

During the greater part of last century the history of the seal herds, of all species and in all their various haunts, is a long record of pillage and extermination; and nowadays the extent to which they have been reduced may be measured by the simple fact that a sealskin coat is a thing we very seldom see. In a comparatively few cases, especially on the American and Russian Islands and the Uruguayan Lobos Island, the herds have long been placed under proper control while on their breeding-grounds; and, so far as we are aware, the Lobos rookery, though small (for the island is less than a mile long), and though right in the track of commerce and close to a considerable town, is still maintained in comparative prosperity. But though on the Pribylov and Commander Islands the remains of the once immense herds are still considerable, yet they represent but a small fraction of the numbers that were massed there during living and even recent memory.

The life-history of the fur seals is, very briefly, as follows. The males grow to a great age and size, wholly disproportionate to that of the small and slender females; and this difference is, as usual, accompanied by the habit of polygamy. The old males arrive upon the breeding-grounds in May, some weeks earlier than the females, and take up their quarters on the rough beaches, generally on some prominent slab of rock; here they doze and sleep until the arrival of the females, who, heavy with young, slip quietly into their places in the harems. The birth of the young follows almost immediately, and soon afterwards the comparative quiet of the rookery is exchanged for a babel of noise and incessant quarrelling. The old bulls in possession of neighbouring harems contend with one another for the females, and the younger bulls, as yet wifeless, strive continually to carry off a straying cow, or dash into a harem when its owner has wandered a few yards away. Moreover, the old bulls are now in perpetual activity, rounding up their harems, hastening after errant cows, quarrelling with their neighbours, or engaging in fierce combat with the "idle" and predatory bulls. So all day long the noise of battle rolls along the *beaches* by the wintry sea, and the growling and the snarling, the confusion and the din, are for some weeks together indescribable.

The harems vary very much in numbers, fifty cows being not uncommon, while a hundred, or even more, have been occasionally recorded; but their numbers depend upon the prosperity of the herd, and fifteen years ago the average number seemed to be rather under twenty. The young males, or bachelors, from one to three or four years old, arrive about the same time as the females, but herd apart on grounds remote from those occupied by the breeding herd. The females and these young males go down to the sea to feed, but the old males starve rather than leave their posts; they come fat and vigorous in springtime, and are gaunt, emaciated, and scarred with the scars of many battles before they leave again in autumn. This family life, and the type of rocky coast resorted to by the herds, seems to vary little in the different species, and a photograph of the herd upon Lobos Island, for instance, is scarcely, if at all, distinguishable from one taken on the Pribylovs. At Guadalupe, however, by reason of the tropical heat, the seals resort to the dark volcanic caves that surround its coast-line, and to the same cause perhaps is due the thinner and very inferior quality of the fur, as compared with that of the northern species.

The old bulls display surprising agility, in spite of their bulk and clumsy form, climbing over the rough rocks and boulders in a wonderful way; and, in general, as is well known, these eared seals can waddle on their long, flapping flippers with greater activity and over much longer distances than might be expected. It was formerly the custom on the Commander Islands to drive the bachelor seals from the "hauling grounds" to the place of slaughter a distance of at least three miles up and down a rough mountain path. But Dr. L. Stejneger was once witness of a more remarkable case. Climbing to the top of a rocky mountain on Copper Island, certainly not less, if I recollect rightly, than 2000 feet high, he heard, as he reached up to the last rocky summit, an angry growl, and there, to his amazement, was a great old bull seal, and the beast was blind!

On the polygamous habits of the species, on the segregation of the young males, and on the superfluity of the latter (for both sexes being born in approximately equal numbers, a very large proportion of the males are destined to perish in the struggle for existence)—on these characters are based the practical methods for the conservation of the herd. The Government lessees kill the young bachelors only, by preference those of three years old, leaving what they consider a reasonable proportion to replenish the stock. It is generally agreed that on the American Islands this operation has always been conducted with reasonable care and moderation, and with no more cruelty than is implied in the rapid and skilful slaughter of a large number of defenceless creatures. But the other dangers to which the herds are exposed are neither selective nor in any way conservative. The pelagic sealer when at work around the islands kills not only the young males, but in still greater numbers the females of all ages, and it is certain that many

A Rookery Courtship on the Pribylovs. (From Nature, by Bristow Adams, in the American Commission's Report, 1896–7.)

pups on shore must in consequence perish of starvation; while the raider who lands upon the rookeries kills all and sundry, young and old, in one spell of merciless destruction. Nor is the seal altogether immune from natural causes of mortality, apart from old age and from the attacks of man; but though the grampus, for instance, now and then devours him at sea, there is only one known cause of mortality that is apparently serious. In warm countries a very considerable number of puppies die owing to the attacks of a species of Ankylostoma, a tiny nematode worm, the eggs of which lie among the earth and sand, and in one way or another are swallowed by the pup; and a species of the same dangerous parasite is found abundantly in the bodies of the many dead seal-pups that towards the end of the season are found lying upon the rookeries, and apparently in greater numbers on the more sandy and less rocky of these.

But whatever part this parasite or other accidents may play as causes of mortality, it is certain that they are not such as to prevent the permanent and healthy upkeep of the herds when under proper management and control, nor even to prevent the rapid recuperation of their numbers during periods of release from persecution. On the Galapagos every seal that could be found had been killed by 1887, and the fur trade was surprised when ten years later a vessel came into San Francisco with somewhat above 200 seals from that abandoned rookery. In like manner, the seals on Robben Island were practically exterminated about the time of the Crimean war, when for a year or two 15,000 or 20,000 skins were taken in single voyages, after which the catches dwindled to trifling amounts, and, finally, the place was abandoned, and its existence as a hunting ground all but forgotten; but after fourteen or fifteen years of quiet, the rock was again covered with seals, just as it had been in the old days when first discovered.

Of the present state of the Pribylov herds we have no precise information at hand, but it is at least known that the seals are greatly diminished since the time, some fourteen or fifteen years ago, when they were last visited by British agents; while even then, some years after the arbitration, they were, of course, immensely less than in the palmy days of the fishery. We hope all the more, accordingly, that the agreement which is now said to have been arrived at will in due course be ratified, in the hope and confident belief that in a few years' time this great source of wealth, and this wonderful spectacle of crowded, teeming animal life, will be again as it was in former times. But it remains to be mentioned that the decrease of the Bering Sea herds in recent years is not to be laid at the door of the Canadian sealers, or at least not to nearly so great an extent as of their opposite neighbours, the Japanese. The once large fleet of Canadian sealing schooners has dwindled, we believe, to some four or five, while ever since the Japanese war the Japanese have taken more and more to this pelagic industry. It is said that they were first led so to do when the Russian guards were removed from the Commander Islands during the war, and when accordingly the rookeries lay at the mercy of the first comer. In recent years they have been charged with actually raiding the American rookeries, and, in any case, as Japan was no party to the Bering Sea Treaty, the Japanese captains have up to the present been free to use firearms, and to pursue their trade up to the three-mile limit of the territorial waters. In 1908, the Japanese had a fleet of thirty schooners, some with as many as sixteen boats, which formed a cordon round the Pribylov Islands. There can be no doubt at all that this has told very heavily upon the herds. Lastly, it is right to say that the terms of the new agreement, and the compensation which it is proposed to pay to Canada and Japan for the loss of their pelagic interests, appear to be both liberal and enlightened, and indicate a sincere desire on the part of the United States and of Russia to do all that lies in their power for the attainment of a great national and general benefit, and for the preservation of one of the great phenomena of the living world.

D. W. T.

THE EDUCATION AND TRAINING OF ENGINEERS.

THE Conference on the Education and Training of Engineers, held at the Institution of Civil Engineers, at the end of June, of which a report appeared in our issue of last week, marks a further advance in the development of a scheme which has engaged the attention of the council during the last fifteen years, and cannot fail to have considerable influence on the future of the engineering profession. The first step was taken under the presidency of Sir John Wolfe Barry, when a system of qualifying examinations was established. Candidates who were desirous of entering the institution as students had to give proof of a sound general education developed upon lines suited to subsequent scientific study. Every candidate for associate membership was required to give proof of a competent knowledge of those branches of science which form the basis of engineering, and to have received an adequate practical training under actual engineering conditions. The council found it necessary, from the first, to organise special examinations; these are still continued, and largely availed of by candidates for admission in both the classes mentioned. On the other hand, the council was desirous of minimising the number of examinations to which candidates were subjected, and was prepared to recognise degrees or diplomas granted by universities, university colleges, and engineering colleges, but only on condition that the standard of attainment represented by these degrees and diplomas was not inferior to that imposed by the council's own examinations.

Subsequent experience has shown that the advantages which were anticipated at the outset have been more than fulfilled. The imposition of more stringent conditions put a temporary check upon the numbers of those who entered the institution, particularly in the student class, but this check was only of short duration, and the rate of admission speedily began to grow. It may now be confidently asserted that every associate member admitted to the institution has satisfied the council that he does possess a competent knowledge of both the science and practice of his profession. In fact, British civil engineering, through the action described, has fully established its claim to rank as a learned profession, while the stringency and standard of the conditions which must be fulfilled by all successful candidates are certainly in no respect inferior to those imposed by the medical and legal professions. Another important advantage resulting from the action of the council has been the establishment, throughout the British Empire, of a practically uniform standard of attainment for engineering graduates of universities and university colleges. This excellent result has come about chiefly because the authorities of these institutions have appreciated fully the advantages attaching to the recognition of their degrees by the council of the Institution of Civil Engineers as a substitute for success in examinations held by the institution itself; and, as before stated, the policy of the council has always been to minimise examinations so far as may be possible.

On the side of practical training the council has never delegated, and probably never will delegate, to any other body the duty of deciding whether or not the training of individual candidates is satisfactory. Not merely does the council insist on the production by candidates of articles, indentures, or certificates given by trustworthy persons who have personal knowledge of the training which each candidate has undergone, but it has instituted special and stringent forms in which the details of that practical training must be recorded, and these statements have to be supplemented and verified by the testimony of members of the institution who have personal knowledge of each candidate's career and work. In other words, while recognising the value of scientific education for engineers, the claims of practical training are in no way subordinated thereto; both are essential.

In 1903 the council decided to invite the cooperation of the leading engineering institutions in the United Kingdom in setting up a special committee which should consider and report to the council on the broad principles of engineering education and training likely to yield the best results. Sir William White, who was then president of the institution, was appointed chairman of the committee; its membership embraced a considerable number of men occupying eminent positions in the practice of all branches of engineering. The inquiries of the committee included general preparatory education, as well as the scientific and practical training of those who were proposing to enter the engineering profession. The work to be done, therefore, was very extensive in its range, and occupied the committee more than two years. The report was unanimous, and was approved by the council of the Institution of Civil Engineers and by the councils of the other engineering institutions which had been represented on the committee. That report has exercised great influence since its appearance, and as the council of the institution arranged for its publication at a low price (by Messrs. Clowes and Sons) it has obtained a wide circulation, both at home and abroad. One of the most valuable features in this report was an appendix containing the analysis of replies made by a large number of eminent practising civil engineers to a series of questions framed and circulated by the committee. From this analysis it became evident that the suggestions made in the report not merely represented the views of the members of the committee, but that the recommendations of the committee were endorsed by the great majority of engineers consulted. In the main the report undoubtedly represented, and still represents, the views of the leading men in the civil engineering profession. Five years have passed since the report was issued, and the council of the institution this year reached the conclusion that many questions of detail and of method which were involved in the realisation of the principles laid down in the report might with advantage receive further consideration. It was mainly for the purpose of affording an opportunity of discussing important questions of that kind that the recent conference was held.

The broad conclusions of the members of the conference in regard to preparatory education of boys who may be intended to become engineers were confirmatory of opinions expressed in the education committee's report of 1906: a good general education, including modern languages, was considered to be essential, and early specialisation was deprecated. The advantages obtained by engineering students who are attached to a university were generally admitted, but one most interesting feature of the discussions was an outspoken declaration by professors of engineering in favour of the practical workshop training being chiefly obtained in manufacturing establishments rather than in college workshops. As to practical training, anyone who has studied the subject cannot fail to have been impressed with the enormous importance attaching to friendly relations between engineering employers and college students.

The question of the period at which practical training should be undertaken by those who intended to receive a college training has been much discussed. The report of the education committee of 1906 recommended that boys after leaving a secondary school (say, at the age of seventeen or eighteen) should serve for about a year in mechanical engineering workshops, so as to gain some knowledge of practical conditions and work. It was also recommended that at the age of about nineteen they should proceed to college and complete their scientific training, taking courses of three or four years, and availing themselves of any opportunities for practical training during the vacations. After graduation, their practical training in such branches of engineering as they might desire to follow would be completed. This clear statement of the committee's report was not grasped by some of the speakers at the recent conference, some of whom argued that the whole of the practical training should be taken between the secondary school and the college, while others maintained that all the practical training should be taken after the college course was completed, in order that there should be no break between the secondary school and the college. The balance of opinion, however, was much in favour of the committee's suggestion, and that also represents the established practice in Germany. Formerly all practical training in that country was put after the technical university or high-school education; but experience led the Germans to adopt the system which the education committee recommended. After twelve years' trial of the new arrangement, the German authorities are more than ever in favour of its beneficial effects.

No doubt whatever was expressed as to the absolute necessity of thorough scientific training for all engineers. There was equally universal acceptance of the view that no man can be considered fit to take part in the design, as well as in the control and direction, of engineering works, unless there is added to a competent scientific knowledge a thorough practical training under actual engineering conditions.

In announcing their decision to summon the conference, the council expressed the hope that it would be widely supported by those interested in solving the difficulties and uncertainties which are experienced by aspirants to membership of the engineering profession. The result of the conference has shown that this hope was well founded. No one who took part in the conference will entertain the least doubt as to the value and interest of its proceedings or of the certain and considerable benefits which will result therefrom to the engineering profession.

W. H. W.

THE PROBLEM OF PITHECANTHROPUS.[1]

NEARLY twenty years have gone since Eugene Dubois, then a young surgeon attached to the Dutch forces in Java, and now professor of geology in the University of Amsterdam, discovered that remarkable individual to which he gave the name of *Pithecanthropus erectus*. The actual discovery, it will be remembered, consisted of the roof of a skull, a thigh bone, and two teeth; they were found in a fossil-bearing stratum on the left bank of the Solo or Bengawan, a stream which, after flowing through the province of Mediun—"the hell of Java"—in the centre of the island, turns in a north-easterly direction to reach the sea. Experts agree that the bones found were parts of the same individual or at least of individuals of the same race or species. As to the nature of the individual, there has been a wide divergence of opinion; the discoverer regarded it as more anthropoid than human, hence the name, while others, looking on it as altogether human, simply name it the "fossil man of Java."

The position of Pithecanthropus amongst the higher primates is still debated; while one school of experts places it in the direct line of human evolution, another regards it as part of a side stem which ended in extinction. The age of the formation in which it was found is also still under discussion; Dubois assigned the fossil-bearing layer to late in the Pliocene period;

[1] "Die Pithecanthropus-Schichten auf Java." Geologische und Paläontologische Ergebnisse der Trinil Expedition (1907-1908). Herausgegeben von M. Lenore Selenka und Prof. Max Blanckenhorn. Pp. xlii+268+32 (Leipzig: W. Engelmann, 1911.) Price 50 marks.

the evidence and expert opinion to be found in the well-illustrated and excellent scientific memoir now under review indicate a more recent age for Pithecanthropus. It belongs, not to the Pliocene, but at the utmost to an early Pleistocene formation.

The late Prof. Emil Selenka, who did more than any man of his time to advance our knowledge of the higher primates, saw very clearly that the right way to solve the Pithecanthropoid problems was not discussion, but exploration. After his death in 1902, his widow took up the aim he had in view, and the manner in which she has carried it out commands our unstinted praise. Only those who have organised a scientific expedition know the care, labour, and expense entailed. Financial assistance was obtained from learned institutions in Berlin and Munich, but the major part of the expenditure had to be met from Fräu Selenka's private purse. Scientific investigators and overseers had to be selected and sent out; coolies had to be engaged—as many as seventy-five were employed at one time—and barracks built for them; Fräu Selenka accompanied the expedition into this remote and unhealthy part of Java. Extensive mining and digging operations were necessary for the fossil-bearing layer lies under 35 feet of a sedimentary deposit of volcanic origin. In the seasons 1907-8 10,000 cubic metres of material were removed, and forty-three large boxes filled with the fossil remains found. The contents of these boxes were sent to Europe and distributed amongst seventeen specialists. Their reports, with an introduction by Fräu Selenka and a summary of results by Prof. Max Blanckenhorn, make up the present memoir.

So far as Pithecanthropus itself is concerned, the expedition was a failure; the stone which Dubois erected to mark the spot of his discovery was found, but no further trace was seen of the much-discussed fossil primate. In the dry bed of a tributary of the Bengawan—about two miles from the scene of Dubois's discovery—the crown of a human tooth was picked up; it is a human lower molar of rather remarkable dimensions, but otherwise showing no special feature beyond its state of preservation. Dr. Walkhoff found that the dentine within the enamel cap was replaced by a fossilised organic matrix. From its condition he infers that it may be older in point of time than the remains found of Pithecanthropus, and is inclined to regard it as the earliest known trace of man.

Dr. E. Carthaus has prepared even a greater surprise for the readers of this memoir. In the same stratum as contained Pithecanthropus he has found traces of man's existence. These traces are:—(1) Certain splinters of bones and tusks; (2) hearth foundations and wood charcoal. He is quite aware of the fact that jungle fires by ignition from volcanic outbursts still occur in Java, but believes the appearances he has seen cannot be explained by any accidental conflagration.

On the slender evidence thus brought forward by Drs. Walkhoff and Carthaus, Fräu Selenka supports the theory that man was a contemporary of Pithecanthropus, and that therefore the latter is an aberrant form, taking no place in the line of human evolution. The evidence, in our opinion, is rather of the nature of suspicion than of fact; the Selenka expedition leaves the problem of Pithecanthropus so far as concerns its structure and position, unchanged, but it may be otherwise as concerns its geological age. Dr. E. Carthaus regards the Pithecanthropus stratum as belonging to a comparatively recent Pleistocene formation; Fräu H. Martin-Icke finds that 87 per cent. of the gasteropods found in it are modern forms, and concludes that the formation must be well within the Pleistocene period; the evidence and opinion of the botanist, Dr. J. Schuster, tend to the same conclusion.

The problems relating to the estimation of the age of a fauna of a tropical and distant country are many and difficult; most palæontologists will follow the example of Dubois and look to the mammalian fauna as the means of fixing, if not the age, at least the degree of evolutionary change undergone by higher vertebrates in this part of the earth since the period of Pithecanthropus. It is the mammalian fauna which is best known; Dubois found remains of nineteen genera and twenty-seven species; Dr. H. Stremme and Dr. W. Janensch, who describe the mammalian remains of the Selenka expedition, found fourteen genera and seventeen species, many of which are new. The whole of the mammalian fauna contemporaneous with Pithecanthropus has been extinguished or modified, and hence those authorities lean towards Dubois's estimate that Pithecanthropus belongs to the Pliocene period. It is at least not on a point of geological age that Pithecanthropus can be excluded from the genealogy of modern human races.

Prof. Blanckenhorn's general summary of the results of the expedition constitutes one of the best chapters of this memoir. He recognises the difficulty of drawing a line between Pliocene and Pleistocene in the formations of Europe and the even greater complexity in correlating the geological data of Europe and Java. As a tentative hypothesis he places the age of Pithecanthropus in the first interglacial period, corresponding to the formation of the Norfolk beds; the Heidelberg man—whose lower jaw only is known from the Mauer strata—he places in the second interglacial period, while the Neanderthal race he assigns to the third period. From an anatomist's point of view this provisional dating will answer very well, for these three forms are certainly progressive steps towards the modern human type. A. KEITH.

DR. G. JOHNSTONE STONEY, F.R.S.

DR. JOHNSTONE STONEY has passed away, one of the last of those who, during the latter half of the nineteenth century, contributed to the development of the modern ideas of the constitution of the atoms, which have borne such a rich harvest during the last two decades.

It is often difficult to get back to the point of view from which to estimate correctly the pioneer work of those who took the first steps; often the new ideas introduced by them have become the commonplace, so to speak, of science, but it is just these first steps breaking away from the older positions which mark the far-seeing intellect.

So early as 1871 we find Stoney endeavouring to formulate a relation for spectral lines depending upon possible simple harmonic modes of vibration in the atom, and he succeeded in finding a numerical relationship of a simple character in the case of the hydrogen spectrum, which has proved to be the forerunner of much subsequent work. Twenty years later he returned to the subject in a paper in which he considered the question more systematically, viewing the internal movements of the atom as those of a planetary system. Much work had been done by others in the meantime in following up the clue which Stoney had found in the numerical relationships of the spectral lines of hydrogen, and he was able himself to show further that double and triple lines would be produced by perturbations of elliptic orbits described under controlling forces in the atom, double lines being attributed to apsidal motions, triple lines to precessional motions. These conceptions of the constitution of the atom afterwards found satisfactory support in Preston's observations on the Zeeman effect.

He took a keen interest in the development of the kinetic theory of gases, to which he made notable contributions. In 1867 he arrived at his estimate of the size of molecular dimensions, which is substantially that made by Kelvin a year or so later, and by Loschmidt two years previously.

By utilising his value of the mass of the atom Stoney was able to give, at the Belfast meeting of the British Association in 1874, the first calculation of the atomic charge in electrolysis. To this quantity he gave the name *electron*, which is now very generally adopted, and has proved a most suitable term. It was to the orbital movements of the electrons in the atoms, to which, as we have seen, Stoney attributed in 1891 the spectral lines and their various singularities.

Stoney invariably invented a nomenclature for the quantities he was dealing with, where none already existed. Such new terms are continually to be met with in his writings. Many of them have been found by others to be most convenient, and have consequently taken root in science, as, for example, his term *wavelet*, employed advantageously in his papers on microscopic vision, in connection with his method of resolution into plane wave fronts. This facility in suggesting suitable terms proved most useful when serving on the now famous committee of the British Association which devised our present system of electrical units, and of which he was one of the early members.

Stoney was the first to see that the movements in Crooke's radiometer were not due to radiation directly, but arose from unsymmetrical gaseous impacts resulting from unequal heating of the surfaces of the rotating vanes. His original explanation, however, required modification, afterwards supplied by Maxwell and Osborne Reynolds.

He introduced into cosmical physics considerations of a limit to each planet's power of retaining a gaseous envelope, which are of the highest interest in connection with the moon and with Martian questions. He showed that helium, as well as hydrogen, must eventually escape from the earth's atmosphere, a fact with important bearings on the past history of the radio-activity of the materials of the earth's crust.

Stoney's ideas were sometimes rather ahead of the recognised requirements of the day, and consequently paid the penalty of neglect which unfortunately sometimes happens in such cases; indeed, one of his papers on a periodic scheme of the elements, predicting, among other points, the atomic weights of the "inert" group, remained unpublished on the mistaken advice of one of the greatest of his contemporaries. This very scheme is now thought by many to be the most satisfactory of any yet devised.

He was essentially of a philosophic turn of mind, and wrote several papers on ontology and kindred subjects, but at the same time he took delight in all new developments of both industry and science, rejoicing that his span of life had coincided with what he considered would probably prove in the world's history to have been the period of most rapid advance, flowing from the first systematic application of scientific method on an extended scale to industrial progress. He would describe how as a child he had witnessed the first use of illuminating gas in the streets of Paris, and would with evident pleasure recount the many achievements of man in his time.

Stoney was born in King's Co., Ireland, in 1826. His mother was a Blood of County Clare. His ancestry belongs to the Protestant settlers in Ireland of the sixteenth and seventeenth centuries, a class from which has sprung so many of our great men of science, including Hamilton, Stokes, and Kelvin, but which, through economic and political causes, is now fast disappearing. He came from strong stocks on both sides, which have provided an unusually large number who have made their mark, including four Fellows of the Royal Society.

He was educated at Trinity College, Dublin, taking high place in his examinations. He was anxious to devote his life to collegiate work, and sat for the fellowship examination, the entrance in Trinity College to this, but, as in many other cases, his brilliant intellect was lost to his university through the unfortunate working of an examination system, now happily to be abolished.

For many years he held the post of secretary to the Queen's University of Ireland, a position affording him small leisure for pursuing his scientific researches. To his official duties he gave a wholehearted service. This involved much organisation of the scattered colleges which constituted that university, and it was with unfeigned regret he saw the work of these years abandoned on its dissolution.

All who came in contact with Johnstone Stoney were impressed with his sincerity and devotion to all which makes for truth and righteousness. He was veritably a prophet as of olden time. Younger scientific men who have had the privilege of knowing him will not easily forget his kindliness and encouragement.

He died on July 1, after a prolonged illness, in his eighty-sixth year, at his residence at Notting Hill Gate, where he had lived for some years.

F. T. T.

NOTES.

A new attempt is being made to work the alluvial goldfield in Helmsdale, in eastern Sutherland. The existence of gold there has long been known, and some of the gold of the ancient ornaments found in north-eastern Scotland may have come from that district. The first modern attempt to work the field was in 1869, when gold was obtained in the Kildonan and Suisgill Burns, two tributaries of the Ullie, the main stream of Helmsdale. Royalty was paid on about 3000*l.* of gold, but the amount obtained is said to have been considerably higher. The largest nugget was found in the Kildonan Burn, and weighed two ounces. The richest alluvial deposits were in the Suisgill Burn, a higher tributary of the Ullie. This burn flows over mica schists belonging to the Moine system, which have been invaded by granite dykes. The existence of gold in this granite was recorded by Bryce in 1870. The workings were stopped at the end of 1869 owing to damage done to the fishing and the farmers. A serious effort to reopen the field is now being made by the Duke of Sutherland. Gold is being obtained, but whether it occurs in paying quantities has still to be proved.

Dr. H. N. Dickson, president of the Royal Meteorological Society, in a letter to *The Times* of Thursday, July 6, raises the question of increasing the utility of the daily forecasts of weather issued by the Meteorological Office by more effective distribution. His letter suggests the general restoration of the afternoon service of weather forecasts, which is now only operative in the summer months. "Presumably these could be issued all the year round, and they could easily reach the general public before the arrangements for the next day's work were finally completed, provided proper facilities for distribution were given." The history of the public announcement of weather forecasts in this country includes some interesting chapters, and the last of them carries the story to the present day from the re-establishment of the issue of forecasts in 1879 by the Meteorological Council, which at that time was composed of Prof. Henry Smith, Warren de la Rue, Captain Evans, Francis Galton, Prof. G. G. Stokes, and Sir R. Strachey. After the experience of thirty-two years, it is time that a new chapter was begun in which the question of the distribution of forecasts should receive its share of attention.

WITH an extraordinary regularity, all the aviators in the European Circuit—with the exception of Valentine, who came to earth at Brooklands—recrossed the Channel in the last stage but one from Hendon to Calais on July 6. The following day Paris was reached by six of the competitors, the remaining three, Tabuteau, Védrines, and Barra, coming in at intervals during July 8, owing to various minor mishaps *en route*. The winner was Naval-Lieutenant André Conneau (who flew under the pseudonym of "Beaumont"), who completed the circuit in 58h. 36m. on a Blériot monoplane fitted with a 50 horse-power "Gnome" motor and a "Normale" propeller. His time works out at an average of more than 17 miles an hour. Those who obtained the next six places were Garros (Blériot), 62h. 18m.; Vidart (Déperdussin), 73h. 32m.; Védrines (Morane), 86h. 34m.; Gibert (R.E.P.), 89h. 42m.; Kimmerling (Sommer), 93h. 10m.; and Renaux (Farman biplane), 110h. 44m. Barra (M. Farman biplane) and Tabuteau (Bristol biplane) also finished. Renaux deserves a special word of praise, as he carried a passenger, M. Senoncques, throughout the race.

A SPELL of ideal summer weather has occurred recently over England, where in places the thermometer in the shade has risen to between 85° and 90°. For the country generally it is unfortunate that the high temperature was preceded by dry weather, and rains are now greatly needed. At Greenwich the thermometer in the shade exceeded 80° on the four days from July 5 to July 8, and on July 6, 7, and 8 it exceeded 86°, the highest temperature being 88°, on July 8. In the sun's rays the thermometer was 144° both on July 7 and 9. The shade temperature has not risen so high at Greenwich since the summer of 1906, when, it will be remembered, a reading of 94·3° was recorded on August 31, and on the three following days the readings were respectively 91·9°, 93·5°, and 91·0°, the last three observations being a record for September. The temperatures recently experienced are not excessive for July; in 1900, on July 16, the reading was 94·0° at Greenwich; in 1896, on July 14, 91·1°; in 1887, on July 4, 92·2°; in 1885, on July 26, 90·2°; and in 1881, on July 15, 97·1°, the latter being the highest temperature recorded at Greenwich since 1841. In the recent hot spell the thermometer registered 90° in London at Camden Square, at Epsom, and at Cullompton. A decided change of temperature set in during the evening of July 8, and the weather became much cooler, although the conditions continued dry. On July 11 the shade reading again touched 80° in parts of London, and a return of the hot weather seemed probable. The temperature experienced in England falls considerably short of that in the United States, where in many parts the sheltered thermometer has exceeded 100°. The official records of the U.S. Weather Bureau, which are not available in this country yet for a later date than July 2, show a temperature of 104° on that day at Marquette, Mich.; 104° at Valentine and North Platte, Nebr., on June 29; and 108° at Tuma, Ariz., on June 28 and 26. The hot spell in England can in no way be associated with the excessive heat in the United States. It is not conceivable that the heated air could traverse the whole extent of the North Atlantic. The atmospheric conditions were at the time similar in England and America, the type of weather being in both cases anticyclonic and the movement of the air very sluggish.

SIR HENRY MORRIS, Bt., has been elected president of the Royal Society of Medicine for the session 1911–12.

PROF. A. E. METTAM, principal of the Royal Veterinary College, Dublin, has been elected president of the Royal College of Veterinary Surgeons for the ensuing year.

Science announces that Dr. Leonhard Stejneger has been appointed head curator of the department of biology in the U.S. National Museum to succeed Dr. F. W. True.

THE council of the Royal Society of Arts has elected Lord Sanderson, G.C.B., chairman for the year 1911–12. Lord Sanderson has been a member of the society for more than thirty years.

DR. W. J. S. LOCKYER, whose recent articles upon the British solar eclipse expedition have interested many readers of NATURE, has just returned home by the *Mauretania*, quite recovered from the attack of fever which he had in Fiji.

THE death is reported, in his fifty-third year, of Dr. Julian W. Baird, since 1886 professor of analytic and organic chemistry at the Massachusetts College of Pharmacy, and dean of that institution since 1895. He had previously been on the scientific staff of the University of Michigan and Lehigh University successively.

MR. R. H. CHANDLER, of Kearsbrook, Belvedere, Kent, desires to direct attention to an exceptionally good section of the plateau drift of the chalk downs, exposed in a pit which has been recently opened by Mr. Benjamin Harrison, of Ightham. The section is in a field behind Two Chimney House, about half a mile from Terry's Lodge, near Wrotham, and is described as showing between 2 and 3 feet of plateau flints in a sandy clay, resting in pockets in the clay-with-flints.

THE Paris correspondent of *The Morning Post* states that the inauguration of the Aërotechnic Institute, near Versailles, founded by M. Deutsch de la Meurthe, who has endowed it with a capital of 20,000*l*. and a yearly income of 600*l*., took place on July 6. The institute has been provided with all the apparatus necessary for experiments in aëronautics and aviation. Speeches were made by M. Steeg, the Minister of Public Instruction, M. Liard, Vice-Rector of the Paris Academy, and Prof. Appel, Dean of the Faculty of Sciences in the University of Paris.

WE are informed by the Royal Society that the Mackinnon studentships for the ensuing year have been awarded to Mr. T. F. Winmill, of Magdalen College, Oxford, for research in structural chemistry, and to Mr. T. Goodey, of Rothamsted Experimental Station, for research on protozoa in relation to the fertility of soil. The Joule studentship for the ensuing period of two years has been awarded to Mr. Albert Eagle, Imperial College of Science, for research on the thermal relations of spectra of gases and on cognate subjects.

AT the meeting of the Royal Society of Edinburgh on Monday, July 3, the Makdougall-Brisbane prize for the biennial period 1908–9, 1909–10, was awarded to Mr. E. M. Wedderburn for his series of papers bearing upon the temperature distribution in fresh-water lochs, and upon seiche phenomena which occur at the interface of two layers of different density, whether that difference be due to difference of temperature or difference of salinity, published in the Proceedings of the society within the prescribed period, and also in the Transactions and Proceedings before and after that period.

A STRONG earthquake was felt at San Francisco and throughout a large part of central California and Nevada on the afternoon of July 2, and was evidently the most severe of all the successors of the great shock of 1906. The total damage was comparatively slight, but many buildings were cracked, part of the cornice of the Bank of California fell, and the coping of the Hall of Justice was cracked. The latter was one of the few buildings which escaped uninjured in 1906.

ON July 9, at 2h. 2·5m. a.m., a strong earthquake occurred in Hungary, the epicentre being at or close to Kecskemet, which lies about fifty miles south-east of Budapest. In this town, of some 50,000 inhabitants, nearly every house was damaged, some so seriously that they collapsed. In the neighbourhood of Kecskemet ten persons were killed by the fall of a house, and two others at Nagy Körös, twelve miles to the north-east. The shock was felt over a large part of Hungary, and was evidently of unusual strength when compared with previous movements in the same seismic centre. In his catalogue of Hungarian earthquakes for 1865–84, Fuchs records only seven slight shocks at Kecskemet or in the surrounding district.

ARRANGEMENTS have been made to hold the autumn meeting of the Iron and Steel Institute at Turin on October 2 and 3 next. On October 2 the members of the institute will be welcomed by the civic authorities of Turin, the Chamber of Commerce, and the reception committee of the Associazione fra gli Industriali Metallurgici Italiani. After the reception, the Carnegie gold medal for research for 1910 will be presented to M. Félix Robin, of Paris, and papers will be read and discussed. At the conclusion of the meeting, beginning on October 4, a tour in Italy has been arranged to visit Genoa, Pisa, Rome, Naples, Florence, Milan, and other places. Members desirous of attending the meeting must signify their intention on reply forms, to be obtained from the secretary of the institute, not later than August 22.

FROM a circular just received from South Africa we find that the ninth annual meeting of the South African Association for the Advancement of Science was to be held last week at Bulawayo under the presidency of Prof. P. D. Hahn. The four sections, with the name of the president in each case, are as follows:—Section A, astronomy, mathematics, physics, meteorology, geodesy, surveying, engineering, architecture, and irrigation; president, the Rev. E. Goetz. Section B, chemistry, geology, metallurgy, mineralogy, and geography; president, Mr. A. J. C. Molyneux. Section C, bacteriology, botany, zoology, agriculture, forestry, physiology, hygiene, and sanitary science; president, Dr. E. A. Nobbs. Section D, anthropology, ethnology, education, history, mental science, philology, political economy, sociology, and statistics; president, Mr. G. Duthie. The South African medal and fund for 1910 has been awarded to Dr. L. Peringuey, director of the museum, Cape Town.

THE United States Weather Bureau is forming in its library, at Washington, a collection of meteorological photographs, and will welcome additions thereto from all parts of the world. The following classes of pictures are among those desired:—(1) views of meteorological offices, observatories, and stations; (2) pictures of meteorological apparatus; (3) portraits of meteorologists—views of their homes and birthplaces; (4) views showing the effects of storms, inundations, freezes, heavy snowfall, &c.; (5) cloud photographs; (6) photographs of optical phenomena (rainbows, halos, Brocken specter, mirage, &c.); (7) photographs of lightning and its effects; (8) photographs of meteorologically interesting pictures in old books, or of early prints and paintings (*e.g.* contemporary pictures of the damage wrought by the great storm of 1703 in England). Persons who are willing to present such pictures to the Weather Bureau, or will furnish them in exchange for Weather Bureau publications, are requested to address: Chief U.S. Weather Bureau (Library), Washington, D.C.

DR. W. T. SHEPHERD has contributed to the Psychological Monographs, issued in connection with *The Psychological Review*, a paper entitled "Some Mental Processes of the Rhesus Monkey." His experiments lead him to conclude that this monkey is able to discriminate colours with speed and precision when it is presented with foods (rice) variously coloured red, pink, yellow, and green; that it can be trained to discriminate between double-octave differences in pitch of musical tones; that, alike in the formation and in the inhibition of habits, it is superior to the raccoon and far superior to various other mammals that have been examined. Dr. Shepherd believes that monkeys learn only to a limited extent by imitation, and that, although they may acquire a generalised mode of action when confronted with a series of similar problems, there is no evidence that they form true general notions or can truly reason.

The Japan Magazine for last April contains an interesting article, by Mr. Mikimoto, on the culture pearl industry, describing the methods employed in the Bay of Ago. Every year during the months of July and August small pieces of stone are deposited in those parts of the sea where the pearl oyster is abundant. In the third year of the oyster's life it is removed from the sea, and into the shells are introduced small pearls or pieces of nacre to serve as nuclei for the pearls. These are allowed to develop for at least four years, when they are taken up and the pearls recovered. The success of the industry is much restricted by the great mortality among the oysters due to what is called "red currant," an accumulation of microscopic organisms in the water, and a seaweed known to the Japanese as Mirumo (*codium*), which by its growth smothers the young oysters. These artificially grown pearls are said to resemble those of natural growth in colour, lustre, and symmetry. It is interesting to note that most of the work in this industry is done by women, who are believed by the Japanese to be able to remain longer under water and to perform more and better work than men.

THE report of the Lancashire Sea-fisheries Laboratory and Fish Hatchery for 1910 contains a number of interesting papers dealing both with economic and with more purely scientific subjects. Mr. James Johnstone's memoir on internal parasites and diseased conditions of fishes contains a detailed description of a new genus and species of trematode (*Paracotyle caniculae*), and Mr. W. J. Dakin provides a note on a new sporozoan from the whelk, which he also regards as belonging to a new genus and species (*Merocystis kathae*). Prof. Herdman, in conjunction with Mr. A. Scott, contributes part iv., dealing with the year 1910, of his report on the intensive study of the marine plankton around the south end of the Isle of Man, and in conjunction with Mr. W. Riddell gives an account of some plankton observations made on the west coast of Scotland, and compares them with those made in the Irish Sea. There is, indeed, much truth in the remark of these authors that, "for a complete understanding of the plankton changes throughout the year in the Irish Sea, it is essential that we should have full information, not merely as to the larger organisms of the zoo-plankton, but as to the planktonic conditions in general in both surface and deeper water along the north coast of Ireland and off the west of Scotland."

A PAPER on the educational treatment of stammering children, by Dr. J. T. McHattie, with discussion thereon, has been issued by the Medical Officers of Schools Association, and contains much information on the causation and remedial treatment of this distressing condition.

MESSRS. GOETSCH, CUSHING, AND JACOBSON publish an important experimental and clinical study on the functions of the hypophysis cerebri, a small organ situated at the base of the brain. If either experimentally or in certain cases of brain disease an increased discharge of the secretion of the posterior lobe take place, an increased amount of sugar appears in the blood, apparently indirectly through the action of the secretion in causing an increased discharge of the glycogen stored in the tissues. Later an increased tolerance for sugars is established, often with a tendency towards general obesity (Johns Hopkins Hosp. Bull., xxii., No. 243).

WE published recently (June 29) a short article on the progress of radiography in medical diagnosis, and alluded in particular to the work of the staff at Guy's Hospital in their investigation of pathological conditions of the intestine. In this connection we note the appearance of a new paper, a reprint of which has reached us, by Dr. A. C. Jordan, medical radiographer to Guy's Hospital (*Brit. Med. Journ.*, May 20), in which he shows that it is often possible to detect duodenal obstruction by the X-ray method after giving the patient a bismuth meal. Diseases of the duodenum are often extremely obscure, and this new method of diagnosing the condition will be welcomed both by the medical profession and the sufferers from such complaints.

To the Entomological Research Committee (Africa) the Natural History Museum owes a beautiful enlarged model of the tropical rat-flea (*Xenospylla cheopis*), which appears to be the main vehicle in the conveyance of bubonic plague to the human subject. The species is believed to have been a native of North Africa, but is now practically cosmopolitan. The model is about 12 inches in length.

WE have been favoured with a copy of part xxvi. of the elaborate work in course of publication by Messrs. Friedlander, of Berlin, under the auspices of the Royal Prussian Academy of Sciences, entitled "Das Tierreich," of which Prof. F. E. Schulze is editor. The first part was issued in 1896, and from the commencement the editor has been greatly assisted by Prof. Fritz Edler von Maehrenthal, of the aforesaid academy, whose death at Berlin on August 28, 1910, is deplored in a special leaflet, with portrait, accompanying the present issue. Dr. von Maehrenthal was born at Olmütz, Moravia, on January 2, 1857, and, after spending his youth at Gratz, eventually became chief official of the Prussian Academy. In the present issue of the "Tierreich" Prof. L. G. Neumann treats of the acarines of the family Ixodidæ in the detailed manner characteristic of the work as a whole. We are likewise indebted to Messrs. Friedlander for a sale catalogue of works and papers on recent and fossil mammals.

THE June number of *The Quarterly Journal of Microscopical Science* (vol. lvi., part iv.) contains a full description, by Mr. R. Kirkpatrick, of the remarkable sponge *Merlia normani*, which the author has now obtained in quantity from a depth of 60 fathoms near Porto Santo, Madeira. The nature of this enigmatical organism seems likely to give rise to as much controversy as did that of Haliphysema or Astrosclera. Mr. Kirkpatrick has at length settled down to the view that it is a siliceous sponge of the monaxonellid family Haplosclerldæ, which, in addition to the typical skeleton of siliceous spicules, secretes a basal skeleton of calcite. This basal skeleton takes the form of a horizontal perforated lamina, and the perforations are filled with what is believed to be sponge tissue. The evidence brought forward for this view, if not quite conclusive, is certainly very strong. The upper part of the organism, which rests upon the basal lamina, is an undoubted haplosclerid sponge, characterised by a new type of microsclere, to which the name "clavidisc" is applied, a name to which exception might perhaps be taken on the ground that the spicule is characterised, not by anything resembling a key, but by something resembling a keyhole. The author considers that the canal system of the sponge belongs to a new type, to which he gives the name "hymenopylus," characterised by the fact that the very wide openings of the flagellate chambers are guarded by a delicate sphincter membrane. It is probable that the flagellate chambers of most sponges are "hymenopylous," and the condition is very well known in the Calcarea, but, of course, such a structure can only be made out in exceptionally well-preserved material. The arrangement of the prosopyles, consisting "simply of spaces between the fused rays of the stellate bases of the collar-cells," which the author is led to believe may possibly occur among other tetraxonid sponges, has, of course, been known for many years in the common British *Halichondria panicea*. In short, the canal system appears to be of the normal eurypylous type so common amongst the Monaxonellidæ, and it was hardly necessary to coin a new term for the special benefit of this sponge. The paper is admirably illustrated, and will be read with great interest by all spongologists.

EXPERIMENTS described by Dr. R. Seeger in the *Sitzungsberichte der Kaiserlichen Akademie der Wissenschaften*, Vienna (vol. cxix., part 9), indicate that hemiparasites of the tribe Rhinantheæ transpire much more freely than autotrophic plants. Thus *Euphrasia Rostkoviana* and *Odontites verna* gave off 19 milligrams of water in 10 minutes, as compared with 6 milligrams transpired by *Veronica chamaedrys*, 1·8 by *Hydrangea hortensis*, and 0·48 by *Rhododendron hybridum*.

A FULL description of the forestry court at the United Provinces Exhibition held at Allahabad in December last year appears in *The Indian Forester* (March and April). The exhibition comprised timber specimens and products, trophies of sport, and other forest products which occupied the three main buildings. In addition there were installed a turpentine distillery, a wood-pulp laboratory, wood-working machinery, a lac factory, various artisan demonstrations such as the Hoshiarpur wood carvers, and an exposition of katha extraction. The success of the section may be largely accredited to the energetic president, Mr. P. H. Clutterbuck.

A SHORT note on comparative trials with calcium cyanamide, ammonium sulphate, nitrate of lime, and nitrate of soda as artificial fertilisers, is contributed by Mr. F. J. Chittenden to the Journal of the Royal Horticultural Society (vol. xxxvi., part 3). Calcium cyanamide or nitrolim and nitrate of lime are both products manufactured at a high electrical pressure and compete individually with the other two fertilisers tested. The results obtained with turnip crops indicate that the first two are of about equal value, but are slower in their influence than the last two. Nitrate of lime suffers from hygroscopic defects, and provides weight for weight rather less nitrogen than nitrate of soda. Calcium cyanamide also presents physical difficulties which have been obviated by the production of a hydrated form.

THE account communicated by Mr. T. G. B. Osborn in *The Annals of Botany* (vol. xxv., No. 98) of the organism, *Spongospora subterranea*, producing "corky" or "powdery scab" of potatoes, is interesting not only for its economic aspect, but also for the cytological results recorded. In the earliest stage, the organism was observed as a uninucleate amœba in the meristematic potato cells. The amœbæ divide to provide units for the invasion of new cells, as also to form several individuals in each potato cell. Eventually the various amœbæ in a cell unite to form a plasmodium. Later on nuclei become very apparent in the plasmodia before fusion occurs in pairs (karyogamy); two karyokinetic divisions ensue, after which the protoplasm round each nucleus rounds off into a uninucleate spore. The author concludes that Spongospora is a member of the Plasmodiophoraceæ, which group has many points of relationship to the Mycetozoa, differing chiefly in the parasitic habit, the method of division of the vegetative nuclei, and by the less constant presence of a flagellum on spore germination.

MR. R. CORLESS contributes to *Symons's Meteorological Magazine* for June a useful article on the distribution of rain in a barometric depression. It is known that the heaviest rain usually falls on the left side of the path of the centre of a depression, irrespectively of the direction of its motion. The reason for this is shown by a diagram and a simple formula. For the sake of argument, the author considers a depression in which the wind at some altitude is blowing tangentially to the isobars, and for the immediate purpose all that is required is that when the path of the air is straight the relation vd = constant holds good between v, the wind velocity, and d, the distance between the consecutive isobars. When the path is curved cyclonically, the value of v as determined from this equation is theoretically too large; the error increases with increasing curvature, and the maximum curvature is shown to be on the left side of the path of the centre. The air has no alternative but to rise, and an ascending current of air is admittedly a cause of rain; it is in this region (the left front quadrant of the depression) that heavy falls of rain actually occur. Of course, rain falls in other parts, but its origin may be quite different from that here suggested.

UNDER the title "La Temperatura in Italia," the Italian Central Meteorological Office has published, as part i. of vol. xxxi. of its *Annales*, a very complete summary of the mean temperature of Italy. The main part of the volume is devoted to tables giving the mean temperature for decades, wherever possible, for each year of the period 1866–1906. The mean temperature is computed from observations taken at 9h. and 21h., and from daily readings of maximum and minimum thermometers, by the formula $\frac{1}{4}(9+21+\text{max.}+\text{min.})$. Data are given for about 120 stations, though only a small number of these can supply information for the whole period. The later chapters contain summaries of the information given in the main tables. We find in them values of averages and extremes for months, seasons, and years. Numerous plates showing the geographical distribution add greatly to the value of the work. The preparation of the data has been in the hands of Dr. Filippo Eredia, whose name is a guarantee for the excellent arrangement of the results.

IN 1908 a number of experiments carried out by Mr. H. E. Watson, of Trinity College, Cambridge, added about 200 new lines to the spectrum of neon, bringing the total number of lines to 321. Further research, the results of which are published in the June number of *The Astrophysical Journal* (vol. xxxiii., No. 5, p. 399), has shown that certain regularities, suggesting subdivision into "series," occur in the oscillation frequencies of these lines. The lines appear to be divided naturally into three groups, one of 252 lines extending from the extreme red to λ 4071, a second of 29 lines extending from λ 3754 to λ 3370, and a third consisting of 40 lines between λ 3167 and λ 2736. On investigating the oscillation frequencies, Mr. Watson finds that there are distinct indications of regular differences which suggest the existence of a principal and two subordinate series, in which the lines are grouped in triplets and quadruplets with constant frequency differences, the whole arrangement resembling the blue section of the red spectrum of argon investigated by Rydberg. The investigation of these brighter lines and of the numerous weak lines is being continued, and it is hoped that, by methods not purely mathematical, a further elucidation of this remarkable spectrum will result.

IN the abstract of Prof. Silvanus P. Thompson's paper on harmonic analysis, printed in NATURE of June 29 (p. 607), it was stated that the process described to find the coefficient of any term in the harmonic series set down was subject to a limitation. This limitation was expressed in the abstract issued by the Physical Society, but was omitted in the abridgment published in NATURE in order to bring the report of the society within reasonable limits of space.

OUR ASTRONOMICAL COLUMN.

A NEW COMET, 1911*b*.—A telegram from the Kiel Centralstelle announces the discovery of a new comet by Mr. Kiess at the Lick Observatory on July 6. At 15h. 23·7m. (Lick M.T.) the position was

R.A. = 4h. 51m. 51·8s., dec. = 35° 15′ 2″ N.

A later telegram gives the position on July 7, at 14h. 39·7m. (Lick M.T.), as

R.A. = 4h. 52m. 54s., dec. = 34° 52′ 17″ N.

The comet is fairly bright, magnitude 9·0, and has a tail, but its position, about $1\frac{1}{2}$° north of ι Aurigæ, makes it a difficult object to observe in these latitudes. At 1 a.m. the altitude of ι Aurigæ is about 8°, and its direction is north-east.

NOVA LACERTÆ.—No. 5, vol. xxxiii., of *The Astrophysical Journal* contains a note by Prof. Frost discussing the observations of Nova Lacertæ and its spectrum, made at the Yerkes Observatory between December 31, 1910, and May 6.

A suspected nebulosity around the star, shown on the earlier photographs, was not confirmed by later observations with the telescope readjusted. Despite its distinctly red colour, the light from the nova was found to be strongly actinic, a phenomenon accounted for by the considerable extension of the spectrum into the ultra-violet. With the 40-inch telescope, Prof. Barnard found that a sharp crimson image of the nova, due probably to Hα, was formed 9 mm. further from the object-glass than the usual image, which conformed with the ordinary stars.

Two series of spectrograms were secured, one with the Bruce spectrograph, the other with an objective-prism camera having a U.V. 15° prism; the scale of the latter is such that the distance on the plate from $H\beta$ to $H\theta$ is 3 mm. The outstanding features of the spectra are broad bright hydrogen lines, and a very strong bright band which Prof. Frost designates λ 4640. On the Bruce spectrogram (scale, 1 mm. = 26·0 A.U.) dark shadings and bright maxima are suspected within these bright lines, and dark lines are seen on the more refrangible edges, especially in the cases of $H\beta$ and $H\gamma$. The displacements of the lines, if interpreted by line-of-sight motions, would indicate velocities varying from −1300 to +760 km. per second. Spectrograms taken on May 4 and 6 indicate a strengthening of the chief nebular line at λ 500, thereby suggesting that the change to the nebular state, apparently common to all novæ, had set in.

A number of observations of position, magnitude, and colour of the nova are recorded by various observers in No. 4509 of the *Astronomische Nachrichten.*

THE TAIL OF HALLEY'S COMET.—As an extract from No. 3 of *Ciel et Terre* we have received a paper in which Prof. Eginitis summarises the discussion concerning the appearance of the tail of Halley's comet on the night of May 20, 1910. Having demonstrated that an error of observation, at Athens, is out of the question, he explains the apparent digression between his observation and some others by the suggestion that at that time the earth was situated on, or very near to, the axis of the main tail. Thus only the nucleus bounded by nebulosity would be seen, and the form observed would be one that would change rapidly as the angle under which it was seen changed. The differences are thus reduced to a question of perspective, and it is argued that this would change quickly at that critical period.

THE GREAT RED SPOT ON JUPITER.—Mr. Stanley Williams, writing to the *Astronomische Nachrichten* (No. 4507), confirms the abnormal change of longitude of the Red Spot, which was observed by the Rev. T. E. R. Phillips and others. In addition, he remarks upon the great change in the visibility of the spot itself which has recently taken place. For several years the spot has been indistinct and not of its earlier characteristic red colour, but lately it has been, to Mr. Williams, not only a comparatively conspicuous object, but also strongly coloured. It would seem that the spot is now free from the overlying material which has for some time masked its characteristic clearness and colour. Mr. Williams's transit times, taken on May 10 and 17 and June 1 and 8, confirm the change of longitude, and show that the length of the spot has not changed; the difference of longitude, −7·7°, between June 1 and 8, if real, is remarkable.

DEFINITION OF THE TERM "DOUBLE STAR."—Having for some years been desirous of establishing a definite scope for the term "double star," Prof. R. G. Aitken recently prepared a scheme for this purpose and submitted it to the chief double-star observers of the world. The majority agreed that some restriction to the use of the term is necessary, while others believe that the difficulties in establishing a rigorous system would outweigh the advantages accruing from its adoption. Prof. Aitken publishes his scheme, and the correspondence respecting it, in No. 4505 of the *Astronomische Nachrichten.* His definition of a double star includes any two stars which come within the following limits of distance:—

1″	if combined mag. of components	is fainter than	11·0
3″	,, ,,	,,	9·0 B.D.
5″	,, ,,	lies between	6·0 and 9·0 B.D.
10″	,, ,,	,,	4·0 ,, 6·0 ,,
20″	,, ,,	,,	2·0 ,, 4·0 ,,
40″	,, ,,	is brighter than	2·0 B.D.

JUBILEE MEETINGS OF THE INSTITUTION OF NAVAL ARCHITECTS.

THE jubilee meeting of the Institution of Naval Architects opened on Monday evening, July 3, with a reception by the president, the Marquis of Bristol, which was attended by members and delegates from all parts of the world. H.R.H. the Duke of Connaught took the chair at the meeting on the morning of July 4 as honorary president of the congress, and the president's address was delivered at this meeting. Reference was made to the death of the late president, Lord Cawdor, whose personality and zeal marked him out as a leader whom men would be proud to follow. The present congress had a twofold purpose—to commemorate the jubilee of the institution and to bring together from all parts of the world the great leaders in this sphere of industrial activity. The council desired to do honour to their guests from abroad, and had determined to invite the following to accept honorary membership of the institution, the highest honour in their power to confer:—H.M. the King of Norway, H.M. the King of Spain, H.M. the King of Sweden, H.I.H. Prince Henry of Prussia, H.I.H. Archduke Ferdinand, H.R.H. the Duke of Connaught, H.R.H. the Duke of Genoa, Prince Roland Bonaparte, Lord Rayleigh, Admiral Dewey, Admiral Togo, and Admiral Ijuin.

Sir William H. White gave an interesting account of the history of the Institution of Naval Architects, in which he referred to Sir Nathaniel Barnaby, the only survivor of the little group of men whose meeting on January 16, 1860, practically secured the establishment of the institution. Looking back upon work which has been done by the institution, it may be claimed that the intentions of its promoters, on the whole, have been well fulfilled; in some respects they have been surpassed. The meetings of the institution have afforded exceptional opportunities for the discussion of questions affecting the science and practice of naval architecture and marine engineering, the construction of warships and of merchant ships, the shipbuilding policy of Great Britain, the safety of life and property at sea, the introduction of new materials of construction and structural arrangements, the development of experimental methods of research, the introduction of new methods of ship calculations and design, and the discussion of new inventions of various kinds. Before the institution was founded, naval science had no home in England; its treasures lay scattered far and wide in the form of memoirs and papers contained in the Proceedings of the Royal Society or in other publications. Everything worthy of publication now naturally finds its way to the Transactions, and through them to naval architects, marine engineers, and others interested in these subjects throughout the world. Every great movement may be said to have been chronicled for fifty years.

Fifty years' architectural expression of tactical ideas formed the subject of a paper by Admiral Sir Cyprian Bridge. In the year 1860 what may be called the seventeenth-century type of man-of-war was still represented in the British Navy. The gun, as the weapon without a rival, conspicuously dominated tactics. The great change introduced in 1871, the virtual abolition of the broadside system of arming ships, occurred at a time when the contest between the gun and armour was in full progress. Tactical considerations receded into the background. In 1871 we adopted as a weapon of war the Whitehead locomotive torpedo. It is a remarkable fact that the adoption of this weapon and the limitation of a ship's gun-armament to a small number of the heaviest guns that she could carry occurred almost simultaneously. We made no tactical provision for dealing with torpedo attacks; reliance was placed on passive defence arrangements exclusively. The French were the first to break away from the position above indicated. They had a vivid perception of the great tactical principle that concentration of the effect of weapons should be the end aimed at, and that concentration of the weapons themselves is merely the means. They armed their ships in accordance with this principle, and other nations had to follow their example. The ships launched or designed for our own navy during the last dozen years of the nineteenth century and the first two or three years of the twentieth supply monumental evidence of the reviving, but far from dominant, influence of tactics.

Fifty years' changes in British warship machinery were dealt with by Engineer-Vice-Admiral Sir Henry J. Oram. In 1860 the Navy List included a total of 499 ships, having a collective indicated horse-power of 540,000. In 1910 the number of warships was 585, of approximately 5,000,000 indicated horse-power. The founding of the institution coincided with the abandonment of the paddle-wheel in favour of the screw-propeller. The warship fitted with the most powerful machinery in 1860 was the *Warrior*, which had engines of 5469 indicated horse-power. The introduction of surface condensers was referred to, as also triple-expansion engines, the evaporator, and the steam turbine. The author also dealt with the troubles experienced in finding suitable boilers.

Mr. C. E. Ellis described the advances made in the manufacture of armour for ships during the last fifty years. To resist the attacks of guns of ever-increasing power, the thickness of side armour was increased from 5½ inches in the case of the *Agincourt* (1868) to 24 inches in the *Inflexible* (1881). The introduction of compound armour effected a revolution in ship protection. Its partial adoption for the turret protection of the *Inflexible* effected a saving of 600 tons in weight. Since then the efforts of Krupp, Captain Tresidder, and Harvey have led to great reduction in the weight of armour required. In evidence of this, a 12-inch plate, tested in 1897, was attacked by three armour-piercing projectiles of high quality. In each case the projectile was completely broken up, and no cracks appeared in the plate.

Dr. S. J. P. Thearle traced the developments in mercantile ship construction. Fifty years ago some of the ships of the mercantile marine were being built of iron, some of wood, and a small proportion were of composite construction. In 1860 the length of an average cargo steamer was less than 200 feet; now it has reached to 350 and 400 feet. Much of the development has been owing to the introduction of mild steel for iron. Finality has not yet been reached, nor is it likely to be in the near future.

It is of interest to note from the Hon. C. A. Parsons' paper, on the marine steam turbine, that there are now a total of 281 war vessels, 87 mercantile vessels, and 10 yachts fitted with his well-known turbines. The total horse-power of these amounts to 5,841,000.

An account of the progress of naval construction in Japan was given by Rear-Admiral Motoki Kondo. At present there are four navy yards in Japan, and two large private shipbuilding yards, capable of turning out the heaviest warships complete with their machinery. Armour plates of trustworthy quality are now being produced in the Kure Navy Yard. The author understands that the process is a special one invented by Japanese engineers, and that the results are fully up to the best armour plate of the day. The progress of naval engineering in Japan was described by Engineer-Rear-Admiral Terugoro Fujii, and the development of merchant shipbuilding in the same country by Dr. S. Terano and Mr. M. Yukawa. These acknowledged the debt which Japan owes to engineers in this country for advice and help.

A paper on the design and service performance of the Transpacific liners *Tenyo Maru* and *Chiago Maru* was presented by Prof. S. Terano and Prof. Baron C. Shiba. These vessels were built in Japan; they are the largest vessels yet produced in the East, and are the first turbine steamers in Pacific waters. During the last year, and owing to the uncertainty of oil-fuel supply in Japan and China, the owners decided to burn coal. Six of the boilers were converted to use coal, and the remaining seven still burn oil. It is found that the consumption of coal is 20 to 22 tons as against 14 tons of fuel oil.

Among the many other papers presented is one by Prof. A. C. E. Rateau, on the rational application of turbines to the propulsion of warships. Owing to the low efficiency at ordinary speeds, turbine machinery reduces by one half the radius of action. This does not have much importance to Great Britain, as she has naval bases in all the seas of the world; but other nations are not in the same position as regards turbines; indeed, one of the most powerful of these is about to replace turbines by reciprocating engines for her new battleships. The author describes a combination of reciprocating engines and turbines, introduced into the French Navy in 1906, which appears to meet the case. The destroyer *Voltigeur*, fitted with this system, shows consumptions, at speeds below 20 knots, slightly above those obtained in destroyers fitted with reciprocating engines. Above 20 knots the consumptions remain fewer than those of all other destroyers, even with turbines only.

On Wednesday, July 5, a large company proceeded to the National Physical Laboratory for the opening of the experimental tank. An account of the opening is given in another article in this issue.

THE OPENING OF THE NATIONAL EXPERIMENTAL TANK AT THE NATIONAL PHYSICAL LABORATORY.

THE National Experimental Tank for experiments on models of ships, recently completed at Teddington, was formally opened on Wednesday, July 5, and the great public interest taken in the work was evidenced by the number of distinguished guests who travelled to Teddington to be present at the ceremony. The chair was taken by Sir Archibald Geikie, who, as president of the Royal Society, is chairman of the general board of the laboratory, and he was supported by Lord Rayleigh, the chairman of the executive committee, with Lady Rayleigh, the Marquis of Bristol, president of the Institution of Naval Architects, and Lady Bristol; while among those occupying seats on the platform were Mr. A. F. Yarrow, Dr. Glazebrook, the director of the laboratory, and Mrs. Glazebrook, Sir Wm. and Lady White, Mr. G. S. Baker, the superintendent of the tank, and Mrs. Baker, H. E. Senor Edwards, Sir Wm. Crookes, Mr. R. W. Dana, Rear Admiral Capps, Herr Hüllmann, M. Bertin, Sir Norman Lockyer, Mr. Alex. Siemens, Sir J. W. Swan, Rear Admiral Moore, Mr. A. B. Kempe, Sir J. Rose Bradford, Sir J. Larmor, Sir Chas. Parsons, Prof. Unwin, Sir J. Wolfe Barry, Sir David Gill, and Mr. F. W. Black.

Sir Archibald Geikie, in opening the proceedings, referred to the efforts which had been made since 1901 by the Institution of Naval Architects to secure the funds necessary for the construction at the National Physical Laboratory of a tank for ship-model experiments of a national character, where facilities could be provided for experimental work necessary to shipbuilders to enable them to improve and perfect the principal features in the design of their vessels. The project has now been realised owing to the generosity and enthusiasm of Mr. A. F. Yarrow, who has provided the sum of 20,000*l.* for the construction and equipment of the tank, while the Institution of Naval Architects has secured guarantees amounting to 1340*l.* per annum towards the sum of 2000*l.* per annum for ten years considered necessary to ensure the successful working of the tank.

Lord Rayleigh, to whom fell the task of declaring the tank open, spoke of the pioneer work accomplished by the late Mr. William Froude, who in 1871 started a tank at Torquay, and by his investigations established the fundamental principles to be followed in the application of this method of research to the science of shipbuilding. The Torquay tank was followed by the Admiralty tank at Haslar, where the work so well begun by the father is now ably continued by his son, Mr. R. E. Froude. Other tanks are now in existence in shipbuilding yards in this country, as well as on the Continent and in the United States of America. At the request of the Institution of Naval Architects, Dr. Glazebrook has visited a number of these tanks, and every assistance has been cordially rendered him, in particular by M. Bertin in Paris and by Prof. Busley and Herr Gebers in Germany, in the effort to ensure that the new national tank, for which the laboratory and the nation are indebted to Mr. Yarrow, shall be thoroughly well equipped for its work. To the realisation of the scheme the architect, Mr. Mott, and the contractors, Messrs. Dick Kerr and Co., have also largely contributed, while the superintendent of the tank, Mr. Baker, and his assistants have worked hard to ensure that the details of the equipment should be in every way satisfactory.

In his further remarks Lord Rayleigh made reference to some of the more important of the principles established by Mr. Froude, and especially to the principle of dynamical similarity, which laid down the conditions and relations governing the application of "model" methods to problems of naval architecture, as well as to similar problems in aëronautics and other subjects. In illustration of this principle, instances were adduced of its application in the domain of general physics, among which may be mentioned Lord Kelvin's proof of the "gravitational rigidity" of the earth.

In response to an invitation from Lord Rayleigh and a general demand from the assembled guests, Mr. A. F. Yarrow spoke of the needs, national and individual, which it is hoped the tank will help to fill. He was glad to have the opportunity of thanking those who have cooperated in furthering the scheme for the construction of a national tank, and especially the Institution of Naval Architects and Sir Wm. White. As in other branches of engineering practice, scientifically organised experiment is necessary to enable the shipbuilder to take advantage of every possible improvement in design. In the stress of competition with other nations it is imperative that no means of advance should be neglected. Shipbuilders must cooperate in furthering the development of their profession, on which the safety of the nation largely depends. The Admiralty has in the past led the way to progress, and it is important that in the future it should continue to encourage firms who show keenness to initiate improvements.

Lady Bristol was then invited to start the carriage by which the models are towed along the tank, and an experimental run was made and a record obtained of the resistance of a model specially prepared for the experiment. This record, in the opinion of the experts who examined it later, was of an extremely satisfactory character.

In replying on behalf of the Institution of Naval Architects, Lord Bristol spoke of the assistance given by the institution in the work of establishing the tank, and of the important practical results which it is hoped may be the outcome of the work to be undertaken.

At the conclusion of the proceedings connected with the opening ceremony, the visitors were entertained at tea in the grounds of Bushy House, and had the opportunity of visiting other departments of the laboratory.

A description of the tank and its equipment were given in NATURE in the number for June 15 of the current year.

ASSOCIATION OF TECHNICAL INSTITUTIONS.

SUMMER MEETING AT CAMBRIDGE.

THE Association of Technical Institutions holds two public meetings every year, the annual meeting in London in the winter, at which the important business of the year is discussed, and the summer meeting, held in different places throughout the country, which the members regard as much a friendly gathering for the informal interchange of information as a serious conference to listen to learned papers. Nevertheless, at the summer meeting, which was held at Cambridge on Thursday and Friday last, very important questions formed the subject of the papers.

Training of Technical Teachers.

On the first day the association discussed the qualifications and the training of teachers of technological and commercial subjects, papers being submitted by Mr. C. T. Millis, principal of the Borough Polytechnic, S.E., Mr. A. Nixon, principal of the Municipal Evening School of Commerce, Manchester, and Dr. T. Percy Nunn. In view of the extension of the provision in both day and evening schools of instruction in technological and commercial subjects, and of the still further extension which could be brought about by the raising of the school-leaving age, the council of the association felt that a discussion of the qualifications and the training of teachers would serve a useful purpose, and it must be said that if nothing very definite was produced by the papers, or by the subsequent discussion, the subject is a very thorny and difficult one, and any light thrown upon it is helpful. Mr. Millis and Mr. Dixon dwelt most strongly on the need for practical or workshop experience in the teacher, while Dr. Nunn represented more the pedagogic aspect of the case, and insisted on his qualities as a teacher rather than as a skilled workman. All three papers, of course, regarded the combination of the two qualities as ideal.

Mr. Millis summed up the essential and requisite qualifications in the training of a good technical teacher as follows:—(1) a fairly good education; (2) a liking for teaching others; (3) a sound practical knowledge of the trade or industry which he has to teach—this must be gained from actual experience; (4) a knowledge of the growing trade literature and of the improvements and changes in the methods and processes of manufacture; (5) attendance at classes in the trade subject he has to teach; (6) a sound knowledge of the science or art subjects cognate to the trade or industry; (7) ability to teach both theoretical and practical work; and (8) ability to teach with energy and enthusiasm.

Dr. Nunn admitted at the outset that on one hand the belief was held that all teachers would be the better for training, but that on the other some people regarded the idea of training the highest class of technological teachers as almost an absurdity. The latter view, he contended, was not based upon their universal efficiency. "Some of these teachers have been and are among the most brilliant masters of the craft of exposition. Others have been so amazingly bad that, like ancient heroes, they have become centres of legend. Their reputation for boring and bewildering their students has grown into the cherished mythology of the institution which their genius as investigators illuminated." Yet it was the training of the teachers at the other end of the technological hierarchy —the teachers of workshop arithmetic, science, &c., preparatory to technical instruction proper—which carried us to the heart of one of the most thorny educational problems. School teaching, especially on the scientific and mathematical side, Dr. Nunn remarked, should aim at illuminating the practical value of knowledge in relation to adult activities in which the boy can imaginatively enter. The following quotation from Dr. Nunn's paper sums up his view of the training of the preparatory teacher:—

"If there is to be no break between 'general' and technical education; if the technical ideal is to rule throughout, then there must also be continuity in the training of the teachers. There should be no teachers of mathematics and science who have not come into real touch with the technical spirit in its new and liberal form, and have not added to their academic equipment the practical outlook and sympathy which it generally lacks so woefully. Side by side with them, for the greater part of their training, should be the teachers whose stronger technical bias marks them out for charge of the preparatory technical work of the central elementary and continuation schools. Some actual workshop experience should be an essential constituent of their course of preparation. Finally, we should have the technical teacher proper, the man who comes to his class daily from the workshop or the mill. The ideal would be reached where there was the closest association in training between the man who has real technical knowledge, but is ultimately drawn to teaching, and the man who, having received some training as a teacher, spends the greater part of his life in the actual practice of the trade which he teaches in the technical institute."

The general opinion of the members who took part in the discussion is well represented by Dr. Walmsley, of the Northampton Polytechnic, who declared that the training of the technical teacher was to be sought, not in the classroom, but in the workshop.

The School Attendance Bill.

On Friday morning the members listened to a most able exposition of the Government's Education (School and Continuation Class Attendance) Bill by Mr. P. Sharp, secretary to the St. Helen's Education Committee. Sir H. F. Hibbert, president of the association, occupied the chair, and pointed out that the carrying of the Bill into practice would mean large additions to elementary day schools, large additions to the staff, and considerable increases in the number of evening continuation schools. The Bill would involve the abolition of half-time, and its consideration would therefore bristle with difficult points so far as Lancashire and Yorkshire were concerned. The views of the association are represented in a resolution, passed at the suggestion of Mr. Hewitt (Liverpool), seconded by Principal Reynolds (Manchester), to the effect that, "while cordially approving of the general principles of the Bill in the effort to secure continuous education of all scholars under suitable conditions to sixteen years of age, this association is of opinion that the provisions of the Bill as introduced require considerable amendment, especially in the direction of fixing more definitely the age of fourteen as the normal age for leaving the day school and in the incidence of compulsion upon employers to afford facilities for the attendance of young people at continuation schools by the reasonable limitation of their hours of labour."

At the close of the business of the meeting the president presented, on behalf of the association, a handsome silver rose bowl and four candlesticks to Dr. R. S. Clay, principal of the Northern Polytechnic Institute, Holloway, "in recognition of his valuable services as honorary secretary from 1907 to 1911."

The master of Caius presided at a dinner on Thursday night at Caius College, and the president of Queen's College received the members on Friday night.

Ralph S. Hyams.

THE OPENING OF THE NEW BUILDINGS OF THE ROYAL COLLEGE OF SCIENCE FOR IRELAND.

THE scientific work of the Department of Agriculture and Technical Instruction for Ireland received welcome recognition through the opening of the new buildings of the Royal College of Science for Ireland by the King, accompanied by the Queen, as the first act of the royal visit to Dublin on Saturday last, July 8. The ceremony was under the control of the Commissioners of the Board of Public Works, and a picturesque temporary hall had been constructed in the Great Quadrangle, through the open side of which the front of the new college was visible. The vice-president of the Department of Agriculture and Technical Instruction (the Rt. Hon. T. W. Russell, P.C.), the higher officials of the Department, and the professors of the college, had the honour of being presented to their Majesties. The King was pleased to announce that he had conferred a knighthood on Prof. W. Noel Hartley, F.R.S., dean of faculty of the college, whose absence through temporary illness was greatly regretted. The architects, Sir Aston Webb, R.A., and Mr. T. Manley Deane, and the builder, Mr. W. H. McLaughlin, were presented to his Majesty, who knighted Mr. Deane upon the spot. A pleasing feature was the introduction to their Majesties of a deputation of the foremen engaged upon the works.

The Minister in Attendance (the Rt. Hon. Augustine Birrell, P.C.) then asked the King to open the college, and their Majesties, conducted by the officers of the Board of Works, visited the building. Though the ceremony had little of an academic character, the large number of visitors honoured with an invitation must have realised the place taken by science in the educational system now being built up in Ireland, and the honour conferred on Prof. Hartley will be warmly appreciated. When the classes begin work in October in the handsome building now provided, it is hoped that a scheme of correlation may be introduced by which the Irish universities will take advantage of the courses of instruction in applied science in the college. It is important to remember that the maintenance of such courses, from the days of the Science and Art Department onward, has been recognised as a part of the system of public education, and that the new building of the Royal College of Science for Ireland represents visibly the stimulus given to scientific observation and research by Sir Horace Plunkett and his colleagues when they reorganised the agricultural and technical instruction of the country.

THE EUGENICS EDUCATION SOCIETY.

THE annual report of the Eugenics Education Society shows how much progress has been made by the society during the three years of its existence. Besides quick growth of the parent stem, branches have spread from Liverpool to New Zealand; indeed, in New Zealand eugenic ideas seem to be making their way into legislation.

The main feature of the report, however, is the address of the new president, Major Leonard Darwin. Major Darwin emphasises the view that the study of heredity and its application to sociology is the main function of eugenics. He says:—

"Although the science of heredity is now young, yet certain not hitherto widely recognised conclusions can already be preached with absolute confidence:

"(1) That men are very differently endowed by nature in inherent mental and bodily qualities. . . .

"(2) That in normal conditions, although [individual] children differ widely from their parents, yet each generation closely resembles its predecessors in average inherent qualities; a truth which applies to every nation, and every separable section of a nation.

"(3) That it follows from these premises that, if one nation is more highly endowed than another in inherent qualities, that superiority will remain with it generation after generaton in the absence of disturbing causes. . . .

"(4) That if the least naturally gifted sections of a nation are reproducing their kind more rapidly than are those more highly endowed in mental and physical qualities, then the higher are being swamped by the lower, and the nation is decadent. . . .

"(5) Lastly, that whilst every effort to improve the environment of the nation should be made, modern science indicates that the beneficial results on the race of possible changes in external conditions are, in nearly all cases, likely to be far less than was formerly believed to be the case, the advantages being, moreover, probably dependent on the maintenance of the reforms in question; whereas no assignable limit can be placed to the amount of the improvement in the condition of the nation which might in time result from reforms affecting its inherent qualities, the results thus attainable being also of a vastly more permanent character."

In the necessary application of these principles in practice, Major Darwin places in the forefront the need of legislative power to segregate the feeble-minded. He says:—"Here the difficulties encountered ought not to be great, since public opinion is already largely on our side." Doubtless, instructed public opinion is almost or quite unanimous. But, unfortunately, instructed public opinion has little voting power in present political conditions, and the long delay in carrying out the recommendation of the Royal Commission on Mental Defect is impressing on us the unwelcome fact that the Government and Legislature will take no action, even in a case which is urgent and patent to every thinking man, unless there are votes behind it. All the more need exists, therefore, for the efforts of such associations as the Eugenics Education Society to awake the nation to the evils of further inaction.

On the other side, Major Darwin rightly points out that much might be done by the adjustment of taxation to give really effective economic relief to households consisting of large families of sound stock. He also revives the suggestion that the Government as an employer should pay salaries to include an allowance for every living child. As Government employees are usually picked men, this proposal has definite eugenic value.

Major Darwin concludes with a striking passage on the moral question. He says:—

"With regard to the moral aspects of eugenics, what is it which has hitherto been the chief aim of the moral teacher? Has it not been to enforce the necessity of self-sacrifice for the sake of our fellow creatures? The eugenic reformer now demands an enlargement of this code in the light of facts unknown to our ancestors, and pleads for the self-sacrifice of this generation for the sake of the moral and physical welfare of the countless millions of the unborn of the future. May not this be the greatest moral question of all?"

W. C. D. W.

PERUVIAN ANTHROPOLOGY.

UP to the present, the dearth of knowledge regarding the people of Peru has been due to the almost complete lack of anthropological examination of the living subject and to the nature of the material available, consisting largely of skulls accidentally or artificially deformed, normal specimens from this region being rare in our existing collections. We knew in a general way that Peru, shortly before the conquest, was peopled by at least three or four Indian races: the Aymara and Quichua in the central and southern highlands; the Huancas in the north; the Yungas or Chinchas along the coast, besides several still unclassified tribes in the north-eastern and northern territories. From recent accessions of material collected by the American museum, we are now able to differentiate the Aymara, representing a dolicocephalic type, from the middle coast people, who are brachycephalic. Further information has now been collected by Dr. Ales Hrdlicka, curator of physical anthropology in the United States National Museum, who has recently made a hasty tour through the coastal region and a more careful examination of two important sites, Pachacamac and Chan-chan or Gran Chimu. The results of his investigations are published in vol. lvi., No. 16, of the Smithsonian Miscellaneous Collections.

It now appears to be certain that the whole, or the greater part, of the Peruvian coast was originally peopled by a race of a single type, brachycephalic Indians of moderate stature. The remains of the earliest people are found in the huacas and some cemeteries associated with pottery of simple but interesting forms. Metal is scarce, and when found is gold. These people were followed by others of the same fundamental type, but of different habits, as is shown by the fact that their skulls have been subjected to occipital flattening and fronto-occipital deformations. In their graves are found copper and brass, with a little gold and some simple pottery. Upon this brachycephalic people a dolichocephalic race, probably from the north, intruded, and were the makers of the more highly ornamented pottery, some specimens of which are illustrated in this memoir.

The material collected by Dr. Hrdlicka contributes some other interesting facts. No case of rachitis was observed, and in only one vertebra was there indications of tuberculosis; but the evidence is not quite conclusive, and the age of the grave is uncertain. The specimens indicating syphilis were recent. Fractures were rare, the setting defective, and there were no indications of surgical skill. The evidence for trephining is confined to a single case. Finally, it is clear that the ordinary collections of Peruvian pottery possess no scientific value, as it is usually a heterogeneous mixture of specimens of different races and epochs. The work of exploration must begin *de novo*, and the new race of archæologists must adapt those methods of scientific excavation of which the work of Dr. Arthur Evans in Crete and Prof. Flinders Petrie in Egypt are such excellent examples.

AËRONAUTIC INVESTIGATIONS.[1]

THE Advisory Committee for Aëronautics was appointed in April, 1909. The first report of the committee was prepared in April, 1910, and presented to Parliament in July of that year. At the date of the preparation of that report no very large amount of experimental work had been completed: the first year's work was necessarily largely devoted to an examination of the ground to be covered, with a view to the determination of the questions upon which experimental information was most urgently required, and to the design and construction of the necessary apparatus.

The aim of the present report is to give a general account of the work of the committee during the year 1910–11. The technical papers giving the detailed results of the various investigations which have been carried out by the experimental department, with other reports and memoranda of general interest which have been laid before the committee, are no longer included with this report, but will be collected together in a volume to be issued separately. This will be referred to as the Technical Report of the Committee for the year 1910–11.

During the past year the committee has had under consideration a large number of questions which have arisen in connection with the constructional work in progress at Farnborough and at Barrow. At the National Physical Laboratory, also, a considerable proportion of the experimental work has been directed towards the solution of specific problems of airship design and the determination of the necessary experimental data. In addition, research of a somewhat more general character has been carried out, and some results of fundamental importance with reference to the future work to be undertaken have been arrived at.

Equipment for Experimental Work.—The principal apparatus which has been installed at the National Physical Laboratory for the purpose of the researches in aëronautics now in progress was described in the report of the committee for 1909–10. The most interesting and novel addition to the equipment during the past year is a circular rotating water channel, to be used for determining the forces acting on plates and small models in a circular stream of water. It is hoped that, with the aid of this, certain data of fundamental importance in connection with the motion of an airship may be determined, and, in general, that the forces acting on aircraft when executing turning movements in the air may be investigated. In addition, a special water tank has been provided for the study, by visual and photographic methods, of the eddying motion in the rear of plane and curved surfaces, balloon bodies, &c.

Air and Water Channels.—The laboratory has now at its disposal for resistance experiments two air channels—the larger air channel of 4 foot square section, specially constructed for the aëronautical work, and the circular channel of 2 foot diameter, previously employed by Dr. Stanton in his researches on the resistance of models in a current of air—and a water channel which continues to be of much value for obtaining results from which the corresponding data for air can be immediately deduced.

With these various means a large amount of experimental work has been carried out throughout the year. This work has included the determination of the resistance of a number of airship bodies of different forms, and the measurement for these forms of the "lift" and "drift" at various angles to the wind; the investigation of the relative stability of different airship models, and of the stabilising action of fins of different area and in different positions; the determination of the efficiency of various types of rudders and lifting surfaces, plane and curved; the air resistance of wires, stationary and vibrating, of stays and ropes, of model gondolas, model radiators, &c.; the investigation of the forces due to the wind acting on models of dirigible sheds of different forms; and of the forces acting under various conditions on a model of a girder of the type employed in the new Paulhan aëroplane.

Resistance and Directional Stability of Airship Models.—Perhaps the most interesting investigation among those enumerated above is that on airship models. The investigation has comprised a large series of observations on models of different forms, carried out at intervals throughout the year. The work has been directed to the determination of the head resistance for motion parallel to the axis, the "lift" and "drift" for motion oblique to the axis, the magnitude of the moment tending to increase the obliquity—called hereafter the negative righting moment—when the ship is at different angles to the relative wind, and the amount of fin area necessary to give a positive, in place of a negative, righting moment.

The work has been carried out in cooperation with the superintendent of the Army Aircraft Factory, who provided the models for the tests, the head and tail curves for which were systematically varied according to a plan devised by him. The object of the tests for head resistance was to determine the amount of change in resistance due to specific alterations of the curvature in head or tail, and ultimately to determine the forms of minimum resistance for a given gross lifting power and for a given net lift. The experiments led to the adoption of certain curves for head and tail, with a ratio of total length to maximum diameter of about 6 : 1.

The experiments on models inclined to the current determined the amount of dynamic lift obtainable owing to the inclination of the airship to the horizontal, as distinct from that directly due to the elevating planes, and at the same time the increase in head resistance owing to the obliquity.

The complete investigation of the conditions affecting the stability of path of an airship will no doubt take a

[1] From the Report of the Advisory Committee for Aëronautics for the Year 1910–11. [Cd. 5706.] (London: Wyman and Sons, Ltd., 1911.) Price 1½d.

considerable time to complete, but results of practical importance have been obtained in the determination of the negative or positive righting moments acting on models of airships of different forms. If an elongated model of the customary fish-shaped form be supported in a current so that it can turn about an axis through its centre of gravity, it tends to set itself at right angles to the current; when it is oblique to the current a moment acts on it tending to increase the obliquity. The amount of this moment has been investigated for different angles of obliquity in the case of several models; combined with the measurements of "lift" and "drift," this enables the magnitude and line of action of the resultant force on the model at any obliquity to be determined.

The next step was to find the amount of fin area necessary, and the best position for the fins, to give a positive in place of a negative righting moment. Experiments for this purpose have been carried out, and have led to interesting results. It was found, even with a considerably elongated tail, that if the fin were placed towards the rear of the tail and close to the body, the portion of the fin nearest the body was comparatively inactive, owing to the slow movement of the stream in this region. This slow motion of the stream near the tail was confirmed by photographs taken to investigate the nature of the flow past fish-shaped models.

These experiments have enabled the amount of fin area necessary to give a positive righting moment to be determined. Other questions which have to be investigated in connection with the general problem of stability are the effect of the instability of the wake, which does not leave the tail symmetrically when an airship body is moving parallel to its axis, and the "damping" action of the air as regards any motion which involves rotation, as when oscillations are set up, or in turning. Apparatus has been constructed with the aid of which it is hoped that the damping coefficient may be determined, and the effect of wake instability examined.

Air Resistance of Wires and Ropes.—The experiments which have been carried out on wires and ropes have also furnished results which will probably be of general interest. The tests were made on a large number of wires and ropes, including smooth wires of diameters ranging from 0·04 to 0·25 inch, with wire ropes of five or six strands and hemp ropes of three strands of diameters ranging from 0·1 to 0·6 inch.

The air resistance of the stranded ropes, per unit of the sectional area exposed to the wind, is found to be of approximately the same amount as that for small square plates. No great difference was found between wire ropes and hemp ropes at the same velocity. In the case of smooth wires, the resistance per unit of sectional area is appreciably less, the difference being of the order of 20 per cent.

Experiments were also made on the air resistance of vibrating wires; no appreciable effect on the air resistance was found at the vibration velocities reached, whether the wires were made to vibrate in a plane parallel to the direction of motion or perpendicular to it. It may be inferred, therefore, that in practice the air resistance of wires can be calculated on the basis of the values given for stationary wires in the table printed in the account of these experiments given in the technical report.

It is of interest to note that the values found at the National Physical Laboratory are in close agreement with the results obtained, also during the past year, for the resistance of stationary wires and ropes at the well-known aërodynamical laboratory at Göttingen under the direction of Prof. Prandtl. The work on airship models, and the results for the resistance of inclined plates, are also in general accordance with the observations of a similar character which have been made at Göttingen.

Wind Resistance of a Radiator of Honeycomb Type.—Experiments have also been made on the wind resistance of the honeycomb form of radiator. For the purpose of these tests, a scale model was made and its resistance compared in the wind channel with that of a solid block of the same external dimensions. The conclusion was that the wind resistance of such a radiator, in which the net area is about 25 per cent. of the total area, is approximately one half that of a flat board of the same dimensions.

It was considered of some interest to determine also the velocity of the air flow through the tubes of the honeycomb, and its variation with the length of the tube. In these experiments the tubes of the actual radiator were employed, and with a tube length of about 4 inches the wind velocity in the tube was found to be about three-fourths of the mean wind velocity outside. Reducing the length of the tube by one half produced an increase of only about 15 per cent. in the air velocity through the tube.

The general conclusion was that the honeycomb form of radiator is fairly efficient, and it does not appear that any considerable increase in efficiency can be obtained by diminishing the length of the tubes or by increasing the ratio of diameter to length beyond the value, viz. 1 : 12, which obtained in the type tested.

Other Tests in the Air Channel.—Among the other investigations which have been made in the air channel may be mentioned a series of tests on models of dirigible sheds of different design to determine the resultant force on each due to the wind; tests to determine the wind resistance of a model gondola; and a number of experiments on a model of the girder designed by Fabre and used in the new type of Paulhan aëroplane. The experiments on this girder were directed to the determination of its head resistance at various angles to the relative wind and also of the lift obtained from it when inclined about an axis parallel to its length. It was found that the efficiency of the girder, regarded as a small biplane, was about 50 per cent.

Small Water Channel for Visual and Photographic Work.—A small water channel has been constructed with a view to the investigation of the nature of the flow round an obstacle in a fluid medium. In this a steady stream of water is kept in motion, into which small models of plates, aërofoils, airship bodies, &c., can be introduced, and the nature of the flow can be studied with the aid of colouring matter added locally to the water.

With this apparatus interesting photographs have been obtained of the flow past plates and balloon models. These have shown that even for an elongated fish-shaped airship model the relative velocity of flow near the tail is considerably less than in the main stream, thus explaining the relative inefficiency, as regards the production of a righting moment, of the portion of a stabilising plane close to the body in this region.

Some valuable information has also been obtained with this apparatus as to the eddy formation in the rear of plane and curved plates, and the experiments on these will be continued.

Wind Pressure on Square Plates.—In connection with questions arising out of the model tests and the determination of the correction factor, if any, to be applied in passing from the results obtained in small model experiments to the corresponding full-scale values, an examination has been made by Messrs. Bairstow and Booth, of the National Physical Laboratory, into the experimental results obtained by different observers for the air pressure on square plates. Both Eiffel and Stanton in their experiments on square plates have found that the wind resistance per square foot of a small plate is less than that of a large plate, the difference, according to Stanton, as between plates 2 inches square tested in the wind channel and plates 10 feet square exposed in the open being about 20 per cent.

In the report of the committee for the year 1909–10 (p. 38) Lord Rayleigh pointed out the general form which, according to dimensional theory, the law of variation of resistance with dimensions must assume, and showed that such a variation as found by Stanton for square plates involved also a departure from the law according to which the resistance of a plate in a current of air is taken to be proportional to the square of the velocity. Messrs. Bairstow and Booth have shown that a formula can be found, falling under the general type indicated by Lord Rayleigh, which accurately represents the results both of Eiffel and Stanton over the whole range to which their experiments extended when both the dimensions of the plate used and the air velocity at which the results were obtained are taken into account.

The question is one which is at present mainly of theoretical interest, and the importance of which lies in the light it may throw on the comparison of water and air resistances. Lord Rayleigh in a second note, also printed in the technical report, has discussed the matter further, and has pointed out some difficulties in reconciling the general formula with certain conclusions from experiment. Some evidence is furnished by results recently obtained by Dr. Stanton in experiments on the flow of air in pipes and by the study, by visual methods, of the flow past obstacles in a water channel, but the matter demands further investigation before a final conclusion can be arrived at.

Friction of Air in Pipes.—Among the reports included in the technical report is a preliminary communication by Dr. Stanton of some results obtained for air friction by means of experiments on the flow in pipes, in which the effect of changes in the dimensions and roughness of the pipes is discussed. Some of the pipes tested were artificially roughened by cutting right- and left-handed screws along the inner surface of the pipes of pitch and depth proportional to the diameters. It is interesting to note that the dimensional relation for these artificially roughened pipes is precisely similar to that found by Messrs. Bairstow and Booth in their examination of the experiments on the normal resistance of flat plates of different sizes, referred to above.

Whirling Table and Propeller Tests.—A description of the whirling table and of the design of the dynamometer was given in the report of the committee for the year 1909–10. A number of tests on propellers of different types have been carried out with the apparatus there described, and particulars of some of these tests are given below. Recently, with a view to obtain increased propeller speeds, up to 3500 revolutions per minute, and a greater range and sensitiveness in the measurements, a motor of greater horsepower has been provided to drive the propeller, and a new dynamometer has been designed and constructed. A brake has also been added, since at high propeller speeds the propeller alone in some cases drives the whirling arm faster than is desired.

With the view of reaching as high an accuracy as possible in the future tests, especially at the higher speeds of translation, a careful study has been made of the motion set up in the air of the whirling table shed by the rotation of the whirling arm. As a result of the experiments, it was found that when the end of the arm was travelling at a speed of 35 miles per hour the mean velocity of the air in the shed at the boundary of the circle described by the arm was about 2 miles per hour, while the velocity of the air into which the arm was entering was 1·6 miles per hour. The air velocity was also found to be approximately proportional to the arm speed. The second figure gives the air swirl correction to the arm speed at 35 miles per hour required for the purpose of the propeller tests. In all future tests a direct determination of the swirl velocity will be made and the necessary correction applied.

Effect of Blade Area on Propeller Efficiency.—At the request of Captain Sueter, a series of tests was made to determine the effect on propeller efficiency of varying the width of blade. The tests were made on model propellers designed and supplied by Messrs. Vickers, Ltd., whose representative visited the National Physical Laboratory for a few days in order to take part in the work. Messrs. Vickers were also good enough to furnish the results of tests made at Barrow on a full-sized propeller, in order that these might be compared with the results of the small model experiments made at the laboratory.

For comparison with the full scale results, a test was first made on the corresponding model propeller at a speed of translation having a ratio to the test speed of the full-sized propeller equal to the ratio of the square roots of their linear dimensions. It was found that, for the same slip, the thrust and efficiency given by the model experiments differed only by a small amount from the values they should have as deduced by calculation from the full scale tests. The experiment is important from the point of view of the prediction of full scale results from small model tests, but the work so far done is not sufficient to justify any general conclusion as to the validity of the "model" law, which proved in this instance to be correct. It is hoped that further comparisons may be carried out shortly.

The further tests on the series of models were made at the speed of translation suggested by this preliminary work, and by reducing the width of blade from that used in the above experiment an increased efficiency was obtained. It was found that the maximum efficiency was reached at a disc area ratio of approximately 0·19.

Other Propeller Tests.—A series of tests has been made for the superintendent of the Army Aircraft Factory on some Ratmanoff propellers, to the design of M. Drzewiecki, who also paid a visit to the laboratory. These tests are not yet entirely completed, the intention being to carry them up to speeds of the propeller tip in the model equal to those occurring in practice with the full-sized propeller. For this work the new apparatus recently installed is required.

The particulars given in the detailed account of the propeller tests of the work so far done will, however, be found of interest. As is well known, the aim in the design of this propeller is that each element of the blade should strike the air at the same angle of maximum efficiency, the propeller being run at a definite ratio of translational speed to speed of rotation. The maximum efficiency reached with any of the propellers tested, at the propeller speeds attainable at the time when the tests were made, was 67 per cent., at a speed of translation of about 30 miles per hour.

In addition to the above, other experimental tests have been made, and some propellers have been tested for private firms or individuals.

Balloon and Aëroplane Fabrics.—A considerable amount of work has now been carried out at the National Physical Laboratory in connection with the testing of fabrics. The materials tested have included rubbered fabrics by various makers, oilskin, varnished silk, and other fabrics with special proofing, goldbeaters' skin, &c.

Strength Tests.—The apparatus employed for tensile tests has been supplemented by a testing machine by Messrs. Avery. This has been modified to enable wide variations in the rate of loading to be obtained. The dimensions of the test specimen now regularly employed are 20 cm. between the jaws of the testing machine by 5 cm. wide, and the usual rate of loading is such as to fracture the specimen in not less than two minutes.

Experiments to determine the effect of varying the rate of loading have been made, and it was found, for a particular fabric, that the ultimate strength found by rapid loading was about 14 per cent. higher than that found by slow loading. The rate indicated above as that now employed is practically equivalent to a dead-slow rate.

The existence of the speed effect just mentioned suggested the probability of a fatigue effect, and this question was also investigated. Some difficulty was experienced in devising a satisfactory method of test, as owing to the large and unavoidable variations between one sample and another, the usual methods of making fatigue tests are not applicable. With the method finally employed it was found that the strength of the particular fabric tested to withstand repeated applications of stress was about 11 per cent. lower than the strength taken on a single specimen loaded to rupture.

Bursting Tests.—Difficulties were originally found in making bursting tests owing to the fact that most of the earlier cylinders tested broke at the join. Finally, a cylinder of diagonally doubled material was obtained which did not burst at the join, and which broke at very high stresses. Damage done in this test led to the redesigning of the apparatus, and in the new apparatus arrangements have been made to enable the cylinder to be subjected to longitudinal tension in addition to internal pressure.

An account is given in the technical report of an interesting series of tests carried out with this apparatus. In these tests the ratio of the circumferential to the longitudinal stress varied from 2 : 1, corresponding to pure bursting test, to 0 : 1, corresponding to a pure tension. The tests appeared to indicate that the strength in warp or weft is approximately independent of stress applied in the direction at right angles. The behaviour of fabrics under various ratios of compound stress is being further examined by a graduated series of tests on a number of bags of a specially selected fabric.

In the above tests it was found that bags of parallel doubled material and of the same material diagonally doubled appear to be of nearly the same strength for a 1 : 1 ratio of stresses, while the tensile strength of the latter determined in the usual way is only half that of the former.

An account is also given by Mr. O'Gorman in the technical report of a large number of bursting tests carried out at the Army Aircraft Factory on a variety of fabrics. The object of these tests was to obtain a comparison with the ordinary tensile tests. The results showed that, on the average, the bursting tests on parallel doubled rubbered cotton gave results a little higher than the tension test, while for diagonally doubled fabrics the mean of the bursting tests was about 1½ times as great as the tension test. For single oilskin the bursting test gave a slightly lower figure than the tensile.

Tearing Tests.—Some tests have been made to determine the effect of a small wound in the fabric on its strength, with the view of indicating, if possible, the factor of safety necessary to ensure that such a wound or tear shall not immediately spread. The disturbance of stress distribution caused by such a wound is accommodated within a large but finite area of the fabric, which may be called the "danger rectangle." It was expected that the applied stress causing rupture of a specimen containing a relatively small cut of fixed magnitude would be independent of the dimensions of the specimen provided it were at least as large as the "danger rectangle," and the results obtained were in agreement with this theory. The necessary factor of safety for wounds of different sizes was given, for the particular fabric tested, as the result of these experiments. The work was limited to wounds of small size, which would, however, include ordinary bullet holes; apparatus is under construction to enable the work to be extended to wounds of larger dimensions.

Permeability Tests.—A large number of rubbered and other fabrics have now been tested for permeability by hydrogen. The apparatus employed continues to give satisfactory results, which can be relied upon to a high degree of accuracy. The practical conclusions to be drawn from these tests, especially when considered in conjunction with the weathering tests, would appear to be of considerable importance.

In the case of rubbered fabrics, the permeability is found to be more or less directly dependent on the quantity of rubber employed; the lighter rubbered materials show a higher permeability, a number of samples tested exceeding the maximum of 10 litres per square metre per twenty-four hours usually allowed in French specifications. This is especially the case with the parallel doubled cloths examined, and the work done points to the superiority of diagonal doubling from this point of view. The permeability of rubbered fabrics increases rapidly with rise of temperature, the increase being as much as 9 per cent. per degree centigrade in the samples tested.

Samples of oilskin, varnished silk, and of other fabrics proofed in various ways have also been tested for permeability. The exact nature of the proofing is not in all cases known. Some of these have shown excellent qualities as regards their hydrogen-holding capacity, the permeability in many of the samples being less than 1 litre per square metre per twenty-four hours, and in some instances not exceeding a quarter of this amount, with a less weight than that of the lighter rubbered fabrics above referred to. In some of these fabrics the hydrogen-holding capacity appeared to improve with rise of temperature.

Tests have also been made on a number of samples with joins. In the rubbered fabrics tested, and in some of the others, the permeability of the join was no higher than that of the rest of the fabric, but with proofing other than rubber the join has sometimes been found to have a much higher permeability. This is a point, therefore, to which attention must be paid. The joins have also sometimes shown a deficiency in tensile strength.

Weathering Tests.—The weathering tests of fabrics have been directed to the determination of the rate of loss of tensile strength and the rate of increase of permeability due to exposure in the open. The rate of diminution in tensile strength does not show any very important difference between the rubbered fabrics tested and those proofed in other ways. It is of interest, however, to note that the rate of deterioration was usually found to be most marked during the second month of exposure. Thus for one fabric the losses in strength in the first three months of exposure were approximately 9, 28, and 10 per cent., and similar figures have been obtained for other fabrics.

As regards the effect of exposure on permeability, the difference between the rubbered fabrics tested and some of the fabrics proofed in other ways has been very marked. In unprotected rubbered fabrics the deterioration in hydrogen-containing capacity has usually been comparatively rapid. The effect of the usual yellow protective colouring is, however, considerable. In several uncoloured samples, after fifty days' exposure in the open, the hydrogen leakage has been found to exceed 100 litres per square metre per twenty-four hours. A number of yellow fabrics, however, which have been exposed for some five or six months, are still moderately gas-tight, and, further, as regards tensile strength, are only a little weaker than the unexposed samples. From the more recent tests it appears that sunlight is the most important factor in producing deterioration.

On the other hand, the oilskins, varnished silk, &c., tested have not, in general, shown any appreciable increase in permeability with exposure. If taken down for test on a warm day, their hydrogen-holding capacity has often been found to have improved. In some cases where a sample has shown deterioration, it has again improved after further exposure, the temporary increase in permeability being probably due to crumpling when cold.

A very complete scheme of tests on rubbered and other fabrics is now in progress to examine more closely the rate of deterioration with exposure, and to distinguish between the relative effects of sun and moisture. Tests of various proofing materials are also being carried out at the laboratory, and some satisfactory results have been obtained.

Light Alloys.—A considerable amount of experimental work has been carried out on light alloys intended for structural work on airships and aëroplanes. Samples of the alloy known as "duralumin" have been supplied by Messrs. Vickers, Ltd., and the mechanical tests made on these were in general agreement with the results found at Barrow. Samples of channel bar tested at the National Physical Laboratory gave a tensile strength of 25·7 tons per square inch, and samples of wire 30 tons. Further investigation of this alloy will be undertaken, including ageing, fatigue, and corrosion tests, special attention being paid to the question of the permanence of the material. Tests of this kind are being made by the metallurgy department in conjunction with similar work on light alloys prepared in the laboratory. Some of these, at present being studied in connection with the work for the Alloys Research Committee of the Institution of Mechanical Engineers, are showing very promising results, tensile strengths up to 34 tons per square inch having been obtained, together with reasonable ductility and without recourse to special thermal treatment. When these new alloys have been more fully studied it is hoped that some of them will prove of service for aëronautical construction.

Meteorological Work.—The preliminary programme of experimental work adopted by the committee upon their appointment included the following items:—

(32) General information relating to the variation of wind velocity and phenomena connected with gusts of wind.

(33) Relative variation in speed and direction of the wind at different heights above the earth's surface.

(34) Vertical movements in the air.

(35) Rotary movements in the air.

(36) Electrical phenomena.

(37) Formation of clouds, snow, hail, &c.

The items numbered (32) to (35) were dealt with provisionally in a memorandum on details of wind structure, &c., by Dr. Shaw, presented with the report of the committee for last year. This has been followed up by further experimental work on vertical motion and rotary motion in the atmosphere at Pyrton Hill, by Mr. J. S. Dines, under the direction of the Meteorological Office. The results of the investigation are presented by three memoranda included in the technical report.

Electrical phenomena in connection with ballooning have been the subject of various communications to the committee.

Vertical Motion in the Air.—With reference to the first of the three memoranda above mentioned, the method which has up to the present been employed for the study of vertical motion in the air consists in observing, by means of self-recording theodolites, the variations in azimuth and altitude of a pilot balloon. With two such theodolites the path of the balloon can be determined both as regards its horizontal and its vertical motion, and the changes in vertical velocity due to air currents can be identified.

For the purpose of this work special self-recording gear was designed for attachment to an existing theodolite; two theodolites fitted with this self-recording gear, and specially constructed for the work, are now being provided. The apparatus is one which may be useful for many purposes besides that which has immediately led to its construction. The azimuth and altitude at any instant can be read off from the record with an accuracy of about one-tenth of a degree; this is sufficient for the purpose. The process of observing is thus simplified; with the self-recording instrument a balloon can be followed continuously without moving the eye from the instrument, and, further, the record can be taken by one observer only, whereas two are necessary in working with the eye-observing instrument.

A considerable number of records with this apparatus have already been obtained, and the results are in every way satisfactory. The records furnish definite evidence of the existence of vertical currents, but it is not yet possible to give any general discussion as to the conditions affecting vertical motion in the air as deduced from these observations.

Rotary Motion in the Air.—For the study of rotary motion in the atmosphere a special anemometer head has been designed to indicate both velocity and direction, with an apparatus to record automatically vector diagrams of the wind, from which the velocity and direction at any instant can be read. Full details of the construction are given in Mr. Dines's description.

In the earlier observations the head was mounted at a height of 36 feet above the ground; more recently a steel windmill tower has been erected for the purpose of these observations, and the head is now mounted on this at a height of 98 feet above the ground. There is no noticeable difference in the character of the diagrams taken at the two levels. The observations do not support the idea that eddy motion is the cause of the gustiness of the wind.

Some interesting particulars are given in Mr. Dines's report of comparisons between simultaneous records of velocity obtained from this anemometer and from a standard anemometer mounted on a house at a distance of 150 yards. As was anticipated from the work of previous experimenters, the individual gusts were not, as a rule, in agreement on the two records, but it is surprising to find that in certain cases squalls of five minutes' duration recorded by the anemometer on the house did not appear at all on the 98-foot record. A possible explanation of these differences is that an increase of wind velocity of as long as five minutes' duration may be confined to quite a narrow belt.

Gustiness of the Wind.—To aid in the study of gustiness, apparatus has been designed to register simultaneously the pull of a kite wire and the length of wire paid out. The tension record shows the fluctuations due to gusts, while, from the length of wire, with a knowledge of the vertical angle, the height of the kite can be approximately determined. A number of records have been obtained with this apparatus, and the discussion of these records by Mr. Dines will, it is thought, be found of great interest.

The mean gustiness found at altitudes from 500 to 1000 feet was 60 per cent. of the gustiness from 0 to 500 feet. Above 1000 feet no certain rule can be deduced from the observations. Easterly winds gave uniformly high gustiness factors; the anemometer at Pyrton Hill, where these records were obtained, is situated at the foot of the western slope of the Chiltern Hills, so that the gustiness of this easterly group of winds may be due to the previous passage of the air over the range. The decrease of gustiness with height does not appear to be dependent upon direction to any noticeable extent.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—At the Degree Congregation held on July 8 the honorary degree of Doctor of Laws was conferred on the Rt. Hon. Sir Joseph Ward, Bart., K.C.B., Premier of New Zealand. The following were admitted to the degree of D.Sc.:—William Ernest Fisher, David Frazer Harris, and Frederick Steward.

The Worcestershire County Education Committee has made a grant of 300*l.* to the University.

Mr. R. R. Cormack, lecturer in economic mineralogy, has resigned.

Mr. F. Lawrence Talbot has been appointed external examiner in the biology and chemistry of fermentation.

The following gentlemen have been appointed honorary assistant curators of the pathological museum for three years:—Dr. Stanley Barnes (medicine), Mr. A. W. Nuthall (surgery), Mr. J. T. Hewetson (diseases of women), and Mr. L. S. Sedgwick (comparative pathology).

Mr. J. Furneaux Jordan has been appointed Ingleby lecturer for 1912.

Prof. R. Beazley is to represent the University at the laying of the foundation-stone of the National Library of Wales, at Aberystwyth, by the King on July 15.

The tenure of the Walter Myers travelling studentship by Dr. John Dale has been extended for a further period of six months.

PRINCETON UNIVERSITY, it is announced in *Science*, has received gifts amounting to more than 20,000*l.*, of which 8000*l.* is for a lectureship in public affairs.

MISS STANCOMBE WILLS, an adopted daughter of the late Lord Winterstoke, has presented 10,000*l.* to Bristol Grammar School in memory of Lord Winterstoke.

DR. R. A. HARPER, since 1898 professor of botany in the University of Wisconsin, has accepted the offer of the Torrey chair of the same subject at Columbia University. Prof. Harper has had a somewhat unusual record, having begun his academic career as professor of the Greek and Latin languages at Gates College. From 1891 to 1898 he was professor of botany and geology at Lake Forest University.

THE Toronto correspondent of *The Times* states that Sir William Macdonald has completed a large purchase of land on the slope of the mountain adjoining Mountroyal Park, and will give the property to McGill University for a new campus and residential buildings. The purchase price was more than 200,000*l.* Including the cost of Macdonald College and its endowment, this brings Sir William Macdonald's total gifts to McGill University to about 2,000,000*l.*

IT was announced at the prize distribution at University College, London, last week, that Mr. R. C. Forster has made a further gift of 30,000*l.* to the fund for providing new chemical laboratories at University College. As Prince Arthur of Connaught, president of the appeal committee, wrote in acknowledging Mr. Forster's generous gift, this method "of commemorating Coronation year by promoting scientific study and research is a most happy one," and it may well be hoped that other wealthy men may adopt it so that the remainder of the sum required for the new laboratories may be subscribed at an early date. Early in the year, as was announced in NATURE (vol. lxxxv., p. 448), Mr. Forster gave 4500*l.* to complete the purchase of the site for the new laboratories. We trust that his generosity may inspire others to contribute, as further sums are still needed to complete the fund to supply a pressing need at University College.

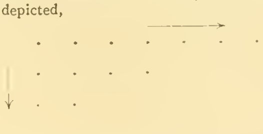
A RURAL SCHOOLS' EXHIBITION was one of the features of the Royal Agricultural Society's Show held recently at Norwich, and in connection with it the County Councils Association arranged on July 1 a conference on rural education. After a paper by Mr. Cloudesley Brereton on education in relation to agriculture, Sir George White, M.P., gave an address, in which he referred to the further education of school children. A leaving age of even fifteen years, he said, may be of little real value unless the great object of the teacher is to make the child think. "People," he remarked, "see a number of boys working in a manual class, say a carpenter's shop, and the first question they ask is, Are you going to make them all carpenters? They do not see that it is not the wood or the tools that are of consequence, but the play of intelligent thought that brings them together to produce a certain object which has been already formed in the brain. Those who assist in production should know something of the processes—such as a knowledge of mechanics—the principles upon which an industry depends, and the nature and property of the material they are using; then the work becomes more interesting, and the proficiency of the worker a matter of concern to himself as well as to his employer, and it is this conviction which has produced our technical schools. The time has surely come when manual training should be available and free to every scholar in our schools, and domestic economy in all its branches to every girl."

THE will of the late Dr. Harry Bolus, of Kenilworth, near Cape Town, contains a munificent provision for scientific and educational objects. Dr. Bolus's herbarium and library, the collection of which had been one of the principal works of his life, are left to the South African College, Cape Town, an institution in which he had previously shown his interest by a large contribution to the foundation of the chair of botany, which is called by his name. He leaves a sum of 20,000*l.*, invested in Government Stock at 4 per cent., on trust for the upkeep and extension of the herbarium and library. This amount will later be increased by an additional sum of 7000*l.* A further amount of 21,000*l.* is also left to the same college for the foundation of scholarships. It is directed that in the selection of scholars to benefit under this fund regard shall be paid to necessitous circumstances and proof of industry, and not exclusively to ability. Eventually Dr. Bolus's landed property, on which is situated the house in which he lived and in which he did the greater part of his botanical work, becomes the property of the college, the proceeds to be applied to the purposes previously indicated. This is the largest bequest ever made to an educational institution in South Africa.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, June 29.—Sir Archibald Geikie, K.C.B., president, in the chair.—Francis **Darwin** and Miss D. F. M. **Pertz**: A new method of estimating the aperture of stomata. The apparatus here described under the name of *porometer* is similar in principle to that devised in 1873 by N. J. C. Müller, but differs from it completely in construction. By a simple arrangement a current of air is drawn through the stomata of a living leaf, its velocity being measured by the fall of a water-column. At a constant pressure the rate of air-flow is necessarily dependent on the size of the stomatal pores, and it is accordingly found that agencies such as darkness or loss of water supply, which are known to diminish stomatal aperture, cause a striking drop in the rate of air-flow as recorded by the porometer. In studying the effect of severing the leaf stalk, and thus cutting off the water supply, it has been proved that the first effect of withering is a wide opening of the stomatal pore, confirming F. Darwin in Phil. Trans., B, vol. cxc., 1898, p. 548. The porometer has been found of value in attacking the question of the causal relation between stomatal aperture and transpiration. This subject, on which a large number of observations have been made, will be fully treated elsewhere. In the present paper a single experiment is given illustrating the parallelism between the transpiration rate and the condition of the stomata as revealed by the porometer.—S. **Chapman**: The kinetic theory of a gas constituted of spherically symmetrical molecules. This paper may be regarded as a sequel to Maxwell's kinetic theory of a gas the molecules of which repel one another according to the famous fifth-power law (Phil. Trans., 1867). Maxwell's deductions from his hypothesis were found not to agree with fact, but the theory was valuable, because it was the only mathematically rigorous kinetic theory in existence. When he wrote a later paper on the same subject (Phil. Trans., 1879) he was aware of the defects of his assumption, but was prevented by certain analytical difficulties from generalising his theory by adopting a wider hypothesis. In this paper these difficulties have been very largely overcome. With the same rigour as in Maxwell's theory, formulæ are deduced for the coefficients of viscosity, diffusion, and thermal conductivity in a simple or compound gas. The molecules are assumed to be spherically symmetrical, but no particular kind of interaction is postulated. The latter, however, is involved in the formulæ by the occurrence, as factors, of two definite integrals. Certain relations may be deduced without the evaluation of these factors. The most interesting of these is $\delta = \frac{5}{2}\mu C_v$, where δ is the thermal conductivity, μ the viscosity, and C_v the specific heat at constant volume. This formula, which was also obtained by Maxwell, has always been regarded as a special consequence of his hypothesis, whereas it only depends on the spherical symmetry of the molecules, and is true for rigid-elastic spheres, among other cases. In general, the formulæ can be completed only by the evaluation of the before-mentioned factors. In the paper this is done for the case of rigid-elastic spherical molecules, for centres of force repelling according to the inverse *n*th power law of distance, and for the case of rigid-elastic spheres surrounded by fields of attractive force. The last case furnishes a rigorous proof of Sutherland's formula for viscosity, and some important corrections to his theory are made. Finally, the formulæ obtained are compared with experimental results to test the accuracy of the various laws considered, and to obtain improved data concerning the molecules and other physical constants of gases.—Major P. A. **MacMahon**: Memoir on the theory of the partitions of numbers. Part vi.—Partitions in space of two dimensions, to which is added an adumbration of the theory of partitions in space of three dimensions. In this part the author considers the partitions of a number, the parts being placed at the nodes of an incomplete lattice in two dimensions. Thus, the lattice being of the nature depicted,



the parts are in descending order of magnitude in each row and in each column. The enumerating generating function is required. It is found that for a lattice of given specification and a given restriction upon the part magnitude the generating function satisfies a functional equation. From this the functional equation satisfied by the corresponding inner-lattice function, as is defined in part v., is deduced. This investigation then turns upon the determination of the fundamental solutions of this equation and the expression of the generating function by means of them. The complete solution of the problems in hand is thence obtained, and the inner-lattice function is shown to be expressible in an elegant determinant form. At the end of the paper the subject of three-dimensional partitions is broached. It is shown that the method of lattice functions is again available, and the particular case of partition at the summits of a cube is worked out in detail from this point of view. The further investigation of this interesting question is reserved for a future communication.—W. T. **David**: Radiation in explosions of coal gas and air.—Dr. T. E. **Stanton**: The mechanical viscosity of fluids. The paper deals with the experimental determination of the ratio of the shearing stress to the rate of change of distortion in fluids which are in sinuous or eddying motion. Thus in a fluid in eddying motion flowing through a parallel pipe of circular cross-section, if F is the mean shearing stress on any cylindrical surface of radius r concentric with the pipe, and v the average velocity in the axial direction of the fluid in this surface, then writing $F = \mu' \frac{dv}{dr}$ the object of the experiments was the determination of μ' as a function of the dimensions of the pipe and the velocity of flow. This ratio has been called by Osborne Reynolds "mechanical viscosity," to distinguish it from the corresponding ratio when the field is in steady or laminar motion, which is the ordinary coefficient of viscosity. The fluid chosen for the purpose of the experiments was air flowing at speeds up to 2200 cm. per second through pipes 5·08 and 7·35 cm. diameter. A small Pitot tube of width 0·25 mm., connected to a very sensitive gauge reading to 0·005 mm. of water, has been used for measuring the distribution of velocity, and a second sensitive gauge has been used for measuring the shearing forces. The results of the experiments are as follows:—(1) In pipes artificially roughened so that air friction varied as square of velocity of flow, the value of μ' was found to be proportional to the product of speed of flow v_c, and linear dimension of pipe l, *i.e.* $F=kv_c l \frac{dv}{dr}$ where k is a constant depending on the roughness. (2) In ordinary smooth pipes the corresponding relation was given by $F=Cv_c l f\left(\frac{V}{v_c l}\right)\frac{dv}{dr}$ where C is a constant and $f\left(\frac{V}{v_c l}\right)$ a function of the kinematical coefficient of viscosity V and the above product $v_c l$. (3) In ordinary smooth pipes of different diameters, owing to the existence of a region of viscous flow at the boundaries, exact similarity between the distributions of axial velocity from centre to walls only obtains when the two viscosities (μ and μ') are the same for each pipe.—Dr. G. W. C. **Kaye**: A silica standard of length. The general properties of fused silica, and in particular its remarkably low coefficient of expansion, render this substance specially suitable for the construction of permanent length-standards of the highest class. The coefficient of expansion of platinum-iridium, which has hitherto been the material almost exclusively employed in the best work, is about 9×10^{-6} per degree C., while that of silica over the ordinary range is about $0{\cdot}4 \times 10^{-6}$, *i.e.* one-twentieth of this amount. It is true that the best qualities of invar—M. Guillaume's nickel-steel containing 36 per cent. Ni—have expansion coefficients comparable with that of silica, but experience has shown that while invar is eminently useful for working standards, it is quite unsuitable for primary standards, owing to its large thermal hysteresis. Fused silica, on the contrary, has been found to be practically entirely free from this defect; it enjoys, in the matter of cost, an enormous advantage over platinum-iridium; furthermore, in view of the fact that primary standards are always handled by trained and skilled observers, its comparative fragility is of small consequence. Modern methods of manufacturing and working silica have rendered it possible to construct a silica line-standard metre. The present model, the first of its kind, consists of a silica tube into which are fused at its ends optically worked plane parallel slabs of silica. These carry the graduations, and their undersides are platinised. The graduations, defining the metre length, are made by cutting through the platinum film with a ruling diamond. The platinum deposit permits the ruling of very beautiful clean-edged lines. The bar is supported at the Airy points so that the slabs are horizontal. The lines are viewed from above through the slabs, and are thus seen to advantage. The apparent length of the standard is independent of any change of tilt of the cover-slips which are used to protect the platinum films. The thickness and position of the end slabs are so arranged that the image of each reference line lies in the "neutral plane" when the bar is immersed in water. The silica metre was annealed at about 450° C., and shrunk a little more than half a micron in the process. It is anticipated that its future secular variation will be negligible so far as practice is concerned.—Ridsdale **Ellis**: The properties of oil emulsions. Part i.—Electrical charge. The electrical charge on the globules and the contact potential at the oil-water interface were obtained from measurements of the migration velocity in an electric field. The apparatus used by Whitney and Blake and by Burton for determining velocity of migration were found not to be accurate, since they did not take into consideration the electrical circulation which takes place, and other factors. To avoid these errors a microscopic method was employed, and corrections for electrical circulation and other effects were introduced into the method of calculating migration velocity. For determining contact potential in presence of electrolytes it was found necessary to modify the apparatus in order to enable the evolution of gas at the electrodes to be avoided, which would otherwise prevent readings being taken. It was found that the magnitude of the contact potential at the oil-water interface is of the same order of magnitude for oils of various kinds, whether very pure or containing large amounts of impurities. Further, the contact potential at the oil-water interface is of the same order of magnitude as that at the glass-water interface and at the interface between the suspended particles of colloidal metals, lycopodium, quartz, and other substances. From these and other considerations it would appear that the contact potential in neutral solution depends almost wholly on the dielectric constants of the suspended particle and of the medium in which it is suspended. The contact potential at the oil-water and glass-water interface is a maximum in neutral or slightly alkaline solutions. Thus the addition of caustic soda at first increases the contact potential at the oil-water interface, but when the concentration exceeds 0·001 N the contact potential is diminished, rapidly at first, and then slowly. In the glass-water interface the maximum potential appears to be in neutral solution. If hydrochloric acid is added the contact potential is reduced very rapidly for small concentrations, but only slowly for comparatively high concentrations.—Dr. W. H. **Young**: A class of parametric integrals and their application in the theory of Fourier series. In this paper the following theorem, *inter alia*, is proved:—If $f(x)$ and $g(x)$ are two functions the $(1+p)^{th}$ power and $\left(1+\frac{1}{p}\right)^{th}$ power of which respectively are summable, and if (a_n, b_n), (α_n, β_n), be their Fourier constants, then the series the general term of which is $(a_n\alpha_n+b_n\beta_n)\cos n\theta$ is the Fourier series of a continuous function, a simple expression for which is given. From this theorem follows as a corollary that if the series

$$\frac{1}{2}a_0\,\alpha_0+\Sigma_{n-1}\,(a_n\,\alpha_n+b_n\,\beta_n)$$

converges it has $\frac{1}{\pi}\int_{-\pi}^{\pi} f(x)g(x)dn$ for its sum, and more generally it always has this expression for sum when the summation is performed in the Cesaro manner. The method employed is shown also to lead to results of analogous nature, previously known. It involves the study of certain parametric integrals, and of a theorem in the theory of sets of points stated and proved in the paper, to the effect that if a set of points of positive content be shifted bodily a sufficiently small distance along the straight line on which it is situated, it necessarily coincides with its original position as to a sub-set of points the content of which may be made as near as we please to the content of the set.—Dr. W. H. **Young**: A mode of generating Fourier series.—H. R. A. **Mallock**: Pendulum clocks and their errors. The errors to which pendulum clocks are liable may be divided into three classes, viz.:—(1) those which may affect free pendulums oscillating *in vacuo*; (2) errors depending on the action of the air or gas in which the oscillation takes place; (3) errors due to the escapement and maintaining mechanism. In good clocks unexplained variations of rate are not uncommon, and may be as large as half a second a day, or even more. At any rate, a clock the rate of which continues constant within 1/200,000 for a year or more is exceptional, and anything which succeeds in securing a constancy of rate better than five parts in a million may be considered an improvement. In discussing the various sources of change of rate, all matters (so far as the author knows) which can alter the period by as much as 10^{-8} are taken into account. It appears that most of the anomalous changes of rate are due to variation of friction in the escapement and maintaining mechanism, which acts chiefly, but not exclusively, by altering the arc of vibration. A graphic method is given for determining in detail the action of escapements on the period.—Prof. Sydney J. **Hickson**: Ceratopora, the type of a new family of

Alcyonaria. A specimen of a compound tubular coral was obtained by the naturalists of the *Blake* off Cuba in 100 fathoms of water. This specimen was figured by Agassiz in his account of the expedition, and referred to as "a supposed Favosites is probably a bryozoan genus allied to Heteropora." A more detailed examination of the dried corallum shows the presence of long tuberculate spicules, in addition to the crystalline calcareous tubular skeleton, which is formed in a horny matrix. There are no tubulæ, and the tubular walls are not perforated. The evidence suggests that this coral is an alcyonarian belonging to the order Cænothecalia, and it is proposed to give it the name *Ceratopora nicholsonii*.—Dr. W. **Watson**: Note on the sensibility of the eye to variations of wave-length. The author has compared the width of Edridge-Green's monochromatic patch with the minimum change in wave-length perceptible as a change in hue in the yellow under exactly similar conditions, and finds there is a marked difference. It is also shown that an admixture of white light would not account for the increased sensitiveness when two monochromatic patches are compared.—E. N. de C. **Andrade**: The distribution of slide in a right six-face subject to pure shear.—Major C. L. **Williams**: The viability of human carcinoma in animals.—Prof. W. B. **Bottomley**: The structure and physiological significance of the root-nodules of *Myrica gale*.—H. W. **Harvey** and W. B. **Hardy**: Note on the surface electric charges of living cells.—Prof. C. S. **Sherrington** and Miss S. C. M. **Sowton**: Reflex inhibition of the knee flexor.—Prof. H. E. **Armstrong** and Dr. E. F. **Armstrong**: The origin of osmotic effects. IV.—Note on the differential septa in plants with reference to the translocation of nutritive materials.

Zoological Society, June 27.—Mr. Frederick Gillett, vice-president, in the chair.—Dr. R. **Broom**: Some new South African Permian reptiles.—F. E. **Beddard**: Two new genera of cestodes from mammals.—Miss Ruth **Harrison**: Some madreporaria from the Persian Gulf; with a note on the memoir and some further notes on *Pyrophyllia inflata* by Prof. S. J. **Hickson.** This memoir dealt with a collection of corals made by Mr. F. W. Townsend, the most interesting species obtained being *P. inflata* and *Tremototrochus zelandiae*, the latter of which was identical with the specimens from Cook's Straits, New Zealand, described as *Conocyathus zelandiae* by Prof. Martin Duncan. A new species of Heterocyathus was described, and Prof. Hickson appended a note on the affinities of Pyrophyllia.—C. L. **Boulenger**: Variation in the medusa of *Moerisia lyonsi*. This paper was based on an examination of 400 specimens. Nearly 14 per cent. of these were found to be abnormal, and to fall naturally into two well-marked groups containing completely distinct phenomena. The author discussed these separately and in detail, and stated that he knew of no form in which such a variety of abnormalities occurred as in Mœrisia.—Cyril **Crossland**: (1) The marginal processes of lamellibranch shells; (2) warning coloration in a nudibranch mollusc and in a chameleon. As a pendent to the second of these papers, Sir Charles **Eliot** contributed a paper on chromodorids from the Red Sea collected and figured by Mr. Crossland, containing an account of three species of Chromodoris, which were noteworthy as being varieties of known species or forms hitherto imperfectly described.

Royal Microscopical Society, June 28.—Mr. H. L. Plimmer, F.R.S., president, in the chair.—Mr. **Strachan**: The structure of scales from *Thermobia domestica* (Packard). The author showed that the longitudinal striæ which appeared to project at the free margin of the scale were in reality the walls of a set of longitudinal tubes, and when pressure was applied to the scales the tubes might be made to collapse and disappear, and in some instances, when heat was applied, both fluid and air bubbles were observed to traverse the tubes. These tubes were on the convex side of the scales. Radial striæ also crossed the longitudinal striæ at various angles, and the author illustrated his paper by an ingenious model composed of two sets of parallel thin glass tubes in close contact, almost filled with fluid and sealed at the ends, one set containing oil of turpentine, the other ethyl alcohol. One set of tubes was fixed, the other set, placed in contact with them, could be rotated over a considerable angle. By illuminating this model obliquely and varying the angle at which the tubes crossed, all the appearances of beaded, exclamation, and cuneate markings observed in the natural scales could be reproduced exactly.—Mr. **Murray**: Further report on the rotifera collected by the Shackleton Antarctic Expedition of 1909. *Rotifera of New Zealand.* There were collected forty-one species of Bdelloids, and twenty-six species of other orders. Three new species were described—*Callidina microcornis, Rotifer curtipes*, and *R. montanus.* A species of Pedalion (not identified) occurred as a plankton animal in a great lake (Wakatipu). These Bdelloid fauna of New Zealand appeared to be poor, considering the variety of conditions found in different regions. *Rotifera of S. Africa.* During a short stay at Cape Town nine Bdelloids were collected on the lower part of Table Mountain. There was one new species, *Dissotrocha pectinata*, related to *D. spinosa.* This small collection was noticeable for the absence of any of the species characteristic of tropical and subtropical Africa, many of which occurred in other parts of Cape Colony.—Conrad **Beck**: Use of an interferometer for measuring small distances.

EDINBURGH.

Royal Society, June 5.—Dr. James Burgess, vice-president, in the chair.—The absorption of light by inorganic salts. No. 1, Dr. R. A. **Houstoun**: Aqueous solutions of cobalt salts in the infra-red. No. 2, Dr. R. A. **Houstoun** and Alex. R. **Brown**: Aqueous solutions of cobalt salts in the visible spectrum. No. 3, Dr. R. A. **Houstoun**: Aqueous solutions of nickel salts in the visible spectrum and the infra-red. No. 4, Dr. R. A. **Houstoun** and John S. **Anderson**: Aqueous solutions of cobalt and nickel salts in the ultra-violet. The four papers describe the first of a series of researches in which it is proposed to determine the absorbing power for light of aqueous solutions of inorganic salts under different conditions of concentration and temperature throughout the ultra-violet and infra-red, as well as in the visible spectrum. The absorbing power of a solution is specified by A, the molecular extinction coefficient, which fulfils the equation $I = I_0 10^{-Acd}$, I and I_0 being the intensity of the light before and after passing through the solution, *c* the concentration of the solution in gm. mols./litre, and *d* the thickness in cm. of the layer traversed. A varies with the wave-length, but is independent of *c* except for wide ranges and at particular points in some spectra. The salts investigated were the fluorides, chlorides, bromides, iodides, nitrates, and sulphates of cobalt and nickel. The apparatus used in the visible spectrum was a spectrophotometer, in the infra-red a linear thermopile with highly sensitive galvanometer, and in the ultra-violet a quartz spectrograph in combination with a photographic photometer of an entirely new type. A was fully determined for the twelve salts from $\lambda = 0{\cdot}22\ \mu$ to $\lambda = 1{\cdot}27\ \mu$, and the results were shown in the form of curves of a highly striking nature, A being approximately for these salts an additive property of the acid and base even at high concentrations. Cobalt has bands at 0·510 μ and 1·3 μ, nickel at 0·405 μ, 0·690 μ, and 1·21 μ. The sulphate radical exercises no absorption whatever; in the nitrates there is a band at 0·302 μ. The fluorides and chlorides have evidently a band just below 0·22 μ. The bromides have a band at 0·285 μ, and the iodides have two very intense bands in the ultra-violet which agree with those shown by an aqueous solution of iodine itself. Quantitative measurements were also obtained on the colour changes produced by concentration and heating. It was discovered that there are changes in nickel chloride and bromide in the violet analogous to but not so great as in the case of the cobalt salts, and so similar that any explanation of the cobalt colour changes must take account of them also.—Profs. Alex. **Smith** and A. W. C. **Menzies**: The vapour pressure of dry calomel. In a previous paper the authors showed that calomel vapour contained no measurable amount of Hg_2Cl_2 or of $HgCl$, and consisted wholly of the dissociation products mercury and mercuric chloride. According to chemical theory, therefore, when, by removal of all moisture, dissociation is prevented, the vapour pressure of the dry substance should be negligibly small. Brereton Baker obtained results which indicated that dry calomel had a vapour pressure of about one atmosphere. Experiments were made to test this point directly. The final result was in accord with the theory, but only after a prolonged drying for five and a half months in an oven at 115° C.

PARIS.

Academy of Sciences, July 3.—M. Armand Gautier in the chair.—H. **Deslandres**: Ionisation of the gases of the sun. Relations between the radiation and rotation of the heavenly bodies.—J. **Boussinesq**: Calculation of the absorption, in translucent crystals, of a pencil of parallel rays.—A. **Haller** and Edouard **Bauer**: Some ketones of the type of benzyl-dimethyl-acetophenone. Trialkyl-acetic acids and the alcohols related to them. Ortho-, meta-, and para-xylene-dimethyl-acetophenones were prepared by the action of the corresponding bromo-xylenes on the sodium derivative of isopropyl-phenyl ketone. These ketones were converted into the xylyl-dimethyl-acetamides, and these latter into the xylyl-dimethyl-acetic acids. The amides were reduced to the corresponding alcohols by sodium and absolute alcohol. The analogous para-methoxybenzyl compounds were also made.—L. **Mangin**: The existence of right- and left-handed specimens of certain Peridinia.—Ch. **Deperét**: The discovery of a large anthropoid ape of the genus Dryopithecus in the Miocene of La Grive-Saint-Alban (Isère).—A. **Perot**: Solar spectroscopy.—Alphonse **Berget**: A new apparatus for taking soundings:—J. **Clairin**: Bäcklund's transformations of the first kind.—E. **Delassus**: The linear integrals of the equations of Lagrange.—Marcel **Brillouin**: Surfaces of slip. Generalisation of the theory of Helmholtz.—D. **Montesano**: The linear congruences of conics.—J. **Pionchon**: Effect produced by the relative displacement of a metal and electrolyte in contact. The E.M.F. between two electrodes alters if one of them be moved or set in vibration. For example, if two zinc plates are placed in a solution of zinc sulphate, the E.M.F. between them is zero, whereas if one of them is shaken it becomes positive to the other. Analogous effects are produced with other electrodes and electrolytes. The E.M.F. of a Daniell's cell was 1·0944 volt. When the copper was shaken it became 1·0990, and when the zinc was shaken the value changed to 1·0754 volt.—Gustave **Le Bon**: The variations in transparence of quartz for ultra-violet light, and on the dissociation of matter.—A. **Leduc**: The expansion of vapours and the variation, with temperature and pressure, of γ, the ratio of their specific heats.—A. **Blondel** and J. **Rey**: The perception of light signals of short duration at the limit of their reach.—H. **Malosse**: Specific rotatory power of camphor dissolved in acetone. Tables showing the specific rotatory power of camphor in acetone solution at various concentrations, and at different temperatures.—J. H. **Russenberger**: Extension of the laws of capillarity to the case in which the elements of the capillary system are movable in regard to one another.—Marcel **Delépine**: Some supposed chlorides of iridium; condensed chlorides. The hexahydrate of chloroiridic acid, H_2IrCl_6, analogous to chloroplatinic acid, may be obtained by drying the product of the action of chlorine on chloroiridate of ammonium with sulphuric acid of not more than 70 per cent. strength. This crystalline substance, on being heated at temperatures between 100° and 250° C. in a current of air, slowly loses water, chlorine, and hydrochloric acid, leaving black amorphous residues, of which the compositions are not expressible by simple formulæ. The supposed lower hydrated chloride, $IrCl_3,4H_2O$, could not be obtained, nor could the author prepare the anhydrous chloride, $IrCl_4$, of Claus, by the action of sulphuric acid on chloroiridites.—Œschner **de Coninck** and M. **Raynaud**: The dihydrate of uranium trioxide. The substance $UO_3,2H_2O$, when gently heated, produces the monohydrate; the second molecule of water is only lost at a higher temperature with a slight loss of oxygen. The molecular weight of UO_2 was found to be 270·46 (mean of five determinations) by heating the dihydrate in hydrogen.—M. **Portevin**: Chromium steels.—Ed. **Chauvenet**: The carbonates of thorium. Hydrated thorium dioxide, $Th(OH)_4$, absorbs carbon dioxide at the ordinary pressure until it has the composition $CO_2,2ThO_2,4H_2O$. If the pressure be increased to 30 or 40 ats., the substance $CO_2,ThO_2,2H_2O$ is formed. The anhydrous oxide, ThO_2, if prepared by strong ignition, will not combine directly with carbon dioxide, but if it has not been heated above 430° C., the substance $CO_2,7ThO_2$ is produced. In the wet way, by the action of an alkaline carbonate upon a salt of thorium, $CO_2,ThO_2,8H_2O$ is precipitated; this easily loses water, producing the above-mentioned hydrated carbonate, $CO_2,ThO_2,2H_2O$.—G. **Vavon**: The hydrogenation of carvone. Carvone, in presence of platinum black, takes up two, four, or six atoms of hydrogen to form carvotanacetone, tetrahydrocarvone, and carvomenthol respectively.—E. E. **Blaise**: The keto-glutaric acids and the aldehyde acids of the succinic series.—Maurice **Lanfry**: The oxythiophenes.—H. **Colin** and A. **Senechal**: Catalytic oxidation of phenols in presence of iron salts.—Jules **Amar**: The law of output after work. Correction of a former note.—Louis **Roule**: Some peculiarities of the Antarctic fauna, from the collection of fish recently obtained by the expedition in the *Pourquoi-Pas?*—C. **Delezenne** and Mlle. **Ledebt**: Formation of hæmolytic and toxic substances by the action of cobra venom on yolk of eggs.

THURSDAY, JULY 20, 1911.

A DETECTIVE'S VADE MECUM.

Science and the Criminal. By C. Ainsworth Mitchell. Pp. xiv+240. (London: Sir Isaac Pitman and Sons, Ltd., 1911.) Price 6*s.* net.

IN the introduction to this fascinating book is suggested a special State department of criminal investigation. Police routine work, walking beats, directing traffic, quelling drunken street rows, is not, the author thinks, an effective school of deductive reasoning or scientific investigation. He would allow his investigators to enter the State service by another door; he would train them in applied science, and he would enable them to meet the clever criminal, as Sherlock Holmes loved to do, on the same intellectual plane. It would be unreasonable, however, to expect even from investigators so trained the same unerring instincts that surprise and delight us in the popular detective of fiction. The detective story is, we must remember, written backwards, and the author, having carefully laid his clues along the track of the crime, it is an easy matter for the detective, who is in the secret, to pick them up as he goes along.

Yet it is not impossible that the same faculty which enables one to devise ingenious detective stories would help in the actual detection of crime. Edgar Allan Poe, the first and greatest of detective story-writers, could not merely devise but detect. The wonderful inductive reasoning in the story of the murder of Marie Roger, in which, as in the popular puzzle game, each clue, even to the most tiny, is fitted into its place to complete the picture, was founded on the facts of a real murder, which was perplexing the police at the time, and the storyteller succeeded in unravelling the mystery when the detectives had failed. In Sir A. Conan Doyle the new department of criminal investigation might find a distinguished first president; than Mr. Mitchell's volume there could be no better handbook for its schools.

The book admirably indicates how, with ever-increasing advantage and success, the weapons forged by scientific research and discovery can be availed of in society's interminable war against the criminal. Of those agencies, electricity is one of the most effective, if not for detecting, for capturing the criminal. The man in the street is not quick at grasping the possibilities of a novel invention. At first it is popularly regarded as a new toy, a matter of amazement and amusement, but of no moment in the practical affairs of men; so it was in our own day with the telephone, the phonograph, and the biograph, with the miracles of the X-rays, radium, and wireless telegraphy. A great invention must prove itself and so live. Still, we find it hard to believe that the utility of the telegraph was less in doubt, and that it was as a criminal catcher it first established its reputation with the public.

"It is strange to reflect," writes Mr. Mitchell, "that it was not until it had been employed in the capture of a criminal that it was recognised in how many directions the electric telegraph might be of service to mankind."

Prior to that time the invention had been little better than a failure, from a commercial point of view, for though the railway companies had some time before this realised the advantages of the new system the Government had refused to have anything to say to it. It was thus little short of a revelation to the public when in 1845 the news was made known that a suspected murderer had been arrested through the agency of the telegraph.

But the telegraph has learned a lot about detective work since that time. It has even dabbled in photography, and is now able not merely to describe but to depict the fugitive criminal. The last word (so far at any rate) on this subject appears to be the telectograph invented by Mr. Thorne Baker, which, we learn from Mr. Mitchell, "may also be used with wireless installations for the transmission of simple pictures or diagrams, and by whose means it would be easy for a ship at sea to send or receive portraits." A picture of King Edward VII., transmitted in this fashion, and reproduced from the *Daily Mirror,* is one of the most striking of the many illustrations of the book.

In every department of crime science seems to have lent a hand to make easy the work of the detective and to harass the criminal, who, with his own finger-tips, is now compelled to print off an infallible means of identification. The book is full of fairy tales of science, more startling than the wonders of the "Arabian Nights." The retort and microscope of the analyst are the special bugbears of adepts in the higher and more scientific walks of crime.

In the old days the murderer caught red-handed could safely deny the bloodstain was human, and the microscope was unable to contradict him. It is not so now. By a method recently discovered the analyst examining the minutest stain of blood, dry, and scarcely discernible to the naked eye on the garment of a suspect, can tell to a certainty the species of animal in the veins of which it originally flowed. There is but one exception to the rule; the blood of the anthropoid ape gives the same reaction as human blood. One might fancy the spirit of Darwin rejoicing in this singular confirmation of his theories.

Mr. Mitchell possesses in a rare degree the gift of interpreting between the man of science and the public. The complicated process by which the blood of different animals is differentiated in the test-tube is described in clear and popular language easily understood even by the least scientific. The ultimate result is summed up in a few sentences, which make the matter plain to the humblest intelligence.

"A simple method of applying the serum test has recently been discovered. A small quantity of human serum is placed into a series of tubes, and into each of these is next introduced one drop of the fresh blood of different animals diluted with salt solution, or of the dried blood dissolved in that liquid. The tubes are now allowed to stand from thirty to forty-five minutes, and then examined. If, in the case of the blood of unknown origin there is a faint red precipitate (of coagulated blood), leaving the upper liquid clear, the blood is of human origin. On the other hand, the blood of other species of animals will have dissolved in the human serum, colouring it red. If the tubes are charged in the first place with the serum of the horse, ox, or other animal, the corresponding blood is coagulated, while that of any other animal dissolves."

Perhaps it is as well to explain to uninitiated readers that the "serum" is the liquid or watery substance of the blood.

The more cautious murderer, who resorts to the subtle agency of poison, has even more reason to dread the analyst, with his test-tube and microscope, than his brother in crime, who adopts the cruder methods of bone-breaking and blood-letting.

There has been a deal of romantic nonsense written about Cæsar Borgia and his more famous sister and their subtle and deadly poisons, "of which the secret is now fortunately lost to mankind." The modern poisoner has fluid, powder and perfume far more subtle and dangerous at his disposal, but amongst them are none that can elude the scrutiny of modern science. It is generally thought that arsenic was a constituent part of the mysterious Borgia poisons. Mr. Mitchell tells us, "with the more refined methods of analyses now available the tests are capable of detecting arsenic even in the minute proportion of one part in sixty million"—a minuteness which the imagination can scarcely conceive.

Under the pitiless eye of the microscope the most skilful and delicate handiwork of the forger is of no avail. We have in the book a hundred interesting illustrations of how his efforts are brought to nought. Does he trace the forgery over pencil writing, the microscope shows the pencil marks along the edges. Does he erase and write over, the most delicate lines are broad smudges, under the microscope the most skilful erasures are rough as unplaned wood. When the writer begins and leaves off, every joining, every doubt, every hesitation is plainly revealed, as if the eye at the microscope was watching the penman.

But it is not in scientific explanation and demonstration alone that this book excels; it is not to the scientific student alone that it appeals. By that vast and miscellaneous public vaguely classified under the head of "the general reader," it will be thankfully received and eagerly devoured. Mr. Mitchell illustrates his scientific disquisitions by vivid illustrations and judicious extracts from the most famous and exciting trials of ancient and modern times. We have many quaint pictures of the peculiar administration of justice in the good old days, when Lord Chief Justice Hale exerted himself to secure the conviction of Anne Turner, because he was afraid "lest by an acquittal countenance should be given to a disbelief in witchcraft, which he considered tantamount to a disbelief in Christianity."

We read, too, that in the trial of Anne Turner for the murder of Thomas Overbury (1615) evidence was given that she was in possession of parchments, some of which contained the names of the Blessed Trinity, others, on which were written +B+C+D+E, and another with a figure in which was inscribed the word Corpus, and to which was fastened a little piece of the skin of a man. In some of these parchments were the names of devils, who were conjured to torment the Lord Somerset and Sir A. Mainwaring if their loves should not continue, the one to the countess and the other to Mrs. Turner.

On evidence like this poor Mrs. Turner was convicted and sentenced to death. The form of the sentence was perhaps the strangest thing of all. The learned Lord Chief Justice Hale gravely informed the trembling woman that

"she had been guilty of the seven deadly sins, and that as she was the inventor of that horrid garb, the yellow tiffany ruffs and cuffs, he hoped she would be the last by whom they would be worn. To this end he ordered that she should be hanged in that garb. This was duly done, while, as a further condemnation of the fashion to which the judge had taken exception, the hangman wore yellow bands and cuffs."

We are not surprised to learn that the fashion died with its author, but we can scarcely imagine a Lord Chief Justice of our own day solemnly deciding that a lady should be hanged in a hobble or a harem skirt by a hangman similarly attired.

We have new trials as well as old in the book. The exciting question of the guilt or innocence of Mrs. Maybrick, on which Lord Chief Justice Russell entertained such strong convictions, is elaborately and intelligently discussed. We have a brief but very vivid *résumé* of the trial of Robert Wood, whose careless and callous behaviour in the dock excited such a strange fervour of sympathy and admiration, and of whom Mr. Hall Caine wrote after watching the case throughout, "Robert Wood, innocent of the murder of Emily Dimmock, is yet the most remarkable man alive." There is no space to enumerate the hundred and odd other trials not less interesting or remarkable which are summarised in the book.

There is a singular fascination in the detective story in fiction or real life. Any editor can tell how a sensational trial inflates the circulation of his newspaper. The magazines and the publishers and the public alike are clamouring for detective stories. Of all the characters in modern fiction, Sherlock Holmes is the best-known and most admired. A man who writes one passable detective story must write nothing else, for the public will accept nothing else from his pen.

In the book under review there is the material for a hundred detective stories. Every half a dozen pages contains the suggestion of a plot which needs only a little imagination and elaboration for its completion.

It is impossible within the limits of a review to do justice to the wealth of material in the book or to the attractive form in which it is presented to the public. Hypnotism, handwriting, dog training, food adulteration and its detection, and a score of other interesting topics are elaborately discussed, and illustrated by extracts from appropriate trials. The author exhausts his subject without in the least degree exhausting the interest and delight of his reader. His book possesses the two essential qualities of a good book: it is readable and it is worth reading. It serves up scientific facts and theories in a most palatable form, and we have high authority for the dictum, "Omne tulit punctum qui miscuit utile dulci." The illustrations, of which there is a vast variety, are scarcely less interesting than the letterpress. Once published the book becomes an essential *vade mecum* of the detective and the writer of detective stories. To the detective it supplies innumerable facts and suggestions which cannot fail to be useful in the practical work of his profession. To the writer it is a veritable mine of valuable material. The general public, who read mainly for amusement, but do not object to a little instruction unostentatiously slipped in as they go along, will find the book as fascinating as a new volume of Sherlock Holmes's adventures, and a great deal more instructive.

THE GENESIS OF CIVILISATION.

(1) *Marriage, Totemism, and Religion. An Answer to Critics.* By the Rt. Hon. Lord Avebury. Pp. xi+243. (London: Longmans, Green, and Co., 1911.) Price 4*s*. 6*d*. net.

(2) *The Golden Bough: a Study in Magic and Religion.* By Prof. J. G. Frazer. Third edition. Part ii., Taboo and the Perils of the Soul. Pp. xv+446. (London: Macmillan and Co., Ltd., 1911.) Price 10*s*. net.

(1) LORD AVEBURY opens his "answer to critics" with the following just remark:—

"In spite of the profound study which has been devoted by many learned and able philosophers to the origin and evolution of civilisation, there are still great differences of opinion on the subject."

His book, "The Origin of Civilisation and the Primitive Condition of Man," published forty-one years ago, was, as Mr. Lang rightly described it, "a pioneer work of great value and importance." But the best of theories would be expected to grow or change with the accumulation of new evidence and a closer analysis of the old, and both these conditions have been satisfied in the interval.

Among the author's original theories, that which showed most insight was the demonstration of the antagonism between idolatry and fetichism, in later terms, between religion and magic. Later research, however, has not so decidedly corroborated his views on the origins of marriage, exogamy, and totemism. A good deal of misconception that has existed, owing to the use of the same terms with different meanings, is now being removed, as in the case of "religion" itself. The one term for which there is no use is "superstition." But the modern distinction between "magic" and "religion," which Lord Avebury laid down long ago, while distinguishing between man's control of nature and "supernature's" control of man, between coercion and prayer, and so forth, rather ignores that vital component of both tendencies, which is known as animism, the belief in "spirit." The antagonism, on which Tylor has laid such stress, between animistic and non-animistic thinking, and the origin of animism itself, are certainly of profound importance in the evolution of culture.

In the case of marriage, however, there is as yet little agreement as to the meaning of the term in reference to origins. Lord Avebury himself, "for want of a better term," spoke of the "primitive" condition as "communal marriage," both words connoting legalism. "Promiscuity" erred in the opposite direction; its modern substitute is "group-marriage." Lord Avebury's view that exogamy and individual "marriage" arose from "marriage by capture" was largely based on customs which were cases not of capture but of elopement, a very different thing. He does not seem yet to have realised the difference; for instance, he brings forward the Kurnai custom, reported as capture by Fison and Howitt. But their actual words prove it to have been elopement. Speaking of "marriageability" between exogamous sections of a tribe, I once ventured to say that no "rights" were exercised in virtue of it. I meant rights as against the actual husband. In reply to this Lord Avebury (p. 20) quotes a case of "capture" where the captor has a right to the captive. He concludes, "Mr. Crawley is mistaken in questioning the right of the conqueror to his captive," a statement I did not make. But, further, the case he quotes is merely a case of elopement!

The defloration of the bride among the Central Australians by other men than the bridegroom was explained by Spencer and Gillen as a rudimentary (*sic*) right of marriage deriving from a previous promiscuity, by Lord Avebury as an "expiation" (to the tribe) for individual marriage, a vestigial right of communal marriage. Here, as in the analogous custom of "symbolic capture," the whole question is the psychological question of the nature of "survivals." Can, for instance, such a custom as that of a mock capture of the *bridegroom* (a not uncommon custom) be explained as a survival, in "play" or ceremony, from a previous real and serious practice of kidnapping? All cases of symbolic capture can be explained as quasi-magical or symbolic expressions of the idea of connubial possession. Similarly with the other custom. We may explain it as a quasi-magical or symbolic expression of the idea of consummation. Spencer and Gillen themselves note that the participators wear magical decorations. Similar acts of physical preparation with or without a magical irradiation are found everywhere; they are often performed by the parents of the bride. A case is just to hand (*Journal of the Royal Anthropological Institute*, xl (1910), 298) from the tribes near Lake Nyasa, where a man (it may be any man) is "called in to oblige." I have enlarged on this point because it is crucial in the question of marriage-origins, and largely made use of by the supporters of the hypothesis of primitive promiscuity. On the face of it the custom has nothing to do with group-marriage of to-day, and all analogy is against its being a survival from the "horde"-rights of the past. Lord Avebury approves the conclusion of Spencer and Gillen that "individual marriage does not exist either in name or in practice in the Urabunna tribe." But they themselves admit that every woman is the special *nupa* of one man, that those men who have the right of "access" (not the same thing as marriage) must obtain his consent, and that this is asked only in such circumstances as the "husband's" absence ("Native Tribes of Central Australia," p. 63).

No one denies that the earliest marital relations were in a fluid state, or that even with individual marriage the husband may have had to fight for the continued possession of the wife. Of the two extremes of animal analogies, the baboon and the gorilla type, Lord Avebury favours the former. In the evolution of social organisation it is quite probable that, given the latter type as the normal, the pendulum might at times swing to the former. In the ages before custom a tendency to individual marriage would have to struggle for existence, just as the tendency to individual property had to struggle. Customs like "avoidance" seem to be expressions of a fear of "trespass." The rise of the idea of fatherhood is closely connected with the property-instinct, and the evolution of marriage, generally, will receive its most probable demonstration when adequate account is taken of the psychological and historical relations between the ideas of ownership and marital possession.

The book suffers from the lack of an index. There are some misprints, *e.g.* M'Lennan for McLennan, Ling Roth for W. E. Roth, Reinack for Reinach.

(2) The second part of "The Golden Bough" is an enlargement of the original chapter on "Taboo and the Perils of the Soul." It fulfils the promise of the first part in the way of multiplication combined with continuity. In view of the fact that the two chief subjects of the volume bring us so very near to the origins of spiritual religion on one hand, and of the immense, complex, and changing body of human morality and law on the other, one regrets that neither subject is treated as a whole. Prof. Frazer points out that such a treatise would far exceed the limits he has prescribed for himself in "The Golden Bough." Nor can we fairly ask him for more than is necessary to place in the clearest light the central figure, the supreme subject, of the book, the idea of the god-man. When first propounded, twenty-one years ago, this idea, as a world-force, savoured of the improbable, but to-day we know it as an axiomatic principle of social evolution. The idea of a man who is "a pledge and guarantee of the continuance and orderly succession of those physical phenomena upon which mankind depends for subsistence" is, in its many forms, one of the most powerful factors in human history. It is a mistake to confine its operation to royal priests and divine kings; it is embodied in all who are vicars of nature, aristocrats of science and of commerce, no less than aristocrats of politics and religion. At one end we have the savage medicine-man, in his way a depositary of knowledge and a controller of supplies; at the other we have the inventor and the capitalist. But its most spectacular form is in religion, and of all great national religions, with few exceptions, it is the living nucleus. To have proved this so convincingly is the chief social service of "The Golden Bough."

Among new sidelights are the study of confession, showing the remarkable sensitiveness of the individual brain to the social judgment; the Eskimo theory of taboo (that brilliant discovery of Dr. F. Boas), a really fascinating chapter in human ethical thought, which we will not spoil by a *précis*.

In his preface and conclusion the author has some suggestive observations on the continuity of human nature and the fluidity of moral ideas.

"When all is said and done, our resemblances to the savage are still far more numerous than our differences from him; and what we have in common with him and deliberately retain as true and useful we owe to our savage forefathers, who slowly acquired by experience and transmitted to us by inheritance those seemingly fundamental ideas which we are apt to regard as original and intuitive."

"The old view that the principles of right and wrong are immutable and eternal is no longer tenable." The ethical theory and the moral practice of an enlightened future will owe much to the pages of "The Golden Bough," veritable leaves of a tree of knowledge. A. E. CRAWLEY.

CAMBRIDGESHIRE AND THE ISLE.

Highways and Byways in Cambridge and Ely. By the Rev. E. Conybeare. Illustrated. Pp. xviii+439. (London: Macmillan and Co., Ltd., 1910.) Price 6*s*.

THE Rev. Edward Conybeare has written a fascinating book about Cambridge and the Isle of Ely. He has taken as his theme a county and an isle the natural features of which to many seem dull, flat and unprofitable. Yet all England is beautiful and all England is interesting, and owing to the skill of his pen and to his wide knowledge, Mr. Conybeare has succeeded in telling us something interesting even of the meanest of Cambridge country villages. The fascination of the fens to those who like far-off horizons and gorgeous sunsets does not escape him.

To any member of the University of Cambridge Mr. Conybeare on his bicycle is as familiar a figure as the White Knight. It is on this bicycle that he has visited and inspected innumerable churches, remote villages, out of the way farmhouses, ruins, and antiquities. He has a most intimate acquaintance with the roads, lanes, and bypaths of this part of East Anglia, and his book adds a new joy to life to those inhabitants of these districts who are interested in the history of their forefathers.

Mr. Conybeare deals fully with the early history of the country, the Devil's Dyke, Fleam Dyke, tumuli and other prehistoric works, but he is equally at home with what, in comparison with these mounds, is modern history, and as this appeals rather more immediately to us, we venture to give as an example of his style two quotations, one of which is to the infamous Dowsing:—

"In 1863, Hardwick Church, which is so conspicuous an object from the roof of King's College Chapel, was purified by Dowsing, who notes with disgust that for dealing with 'ten superstitious pictures and a cross' he was here paid only 3*s*. 2*d*. instead of the 6*s*. 8*d*., which was his regular fee. The great iconoclast had the same grievance in the adjoining village of Toft, where he got 'only 6*s*. 8*d*.' for a specially heavy 'purification' of the church, involving the destruction of 'twenty-seven superstitious pictures in the windows, ten others in stone, three inscriptions, *Pray for the souls*, divers *Orate pro animabuses* (*sic*) in the windows, and a bell *Ora pro anima Sancta Katharina*.' The 'pictures in stone' were doubtless the alabaster images of the reredos, fragments of which are still preserved in the church, exquisite in modelling and colour."

Thus was the beauty of rural England destroyed by a fanatic and at a carefully calculated price.

The second quotation deals with national history and tells us that:—

"Near Hardwick is Childerley Hall, now a farm-house, and hither King Charles the First was brought by his captors, when carried off by Cornet Joyce from Holmby House, in Northamptonshire. He was not altogether an unwilling captive, for both he and the Army hoped to arrive at some mutual accommodation which would make both independent of that Parliamentary control of which both were heartily wearied. He was treated accordingly with the utmost respect, and during his stay at Childerley Hall (from Saturday, June 5, to Tuesday, June 8), the students of Cambridge 'flocked apace' to pay their homage to him. 'He is exceedingly cheerful,' writes a contemporary scribe, 'shows himself to all, and commands that no scholler be debarred from kissing his hand, for which honour they return humble thanks and *Vivat Rex*: and there the Sophs are in their gowns and caps as if no further than Barnwell.' Nay, even the great chiefs of the army, the men who at Marston and Naseby had faced and conquered him, Fairfax, Ireton, and Whalley, and Cromwell himself, came hither to join in this hand-kissing."

The book is by no means free from small, but to a resident stimulating, errors (like the minute gas-bubbles in soda-water), but in spite of these it will do much to popularise a countryside which has been too long neglected.

THE SUGAR CANE AND CANE SUGAR.

Cane Sugar: a Text-book on the Agriculture of the Sugar Cane, the Manufacture of Cane Sugar, and the Analysis of Sugar House Products; together with a Chapter on the Fermentation of Molasses. By Noël Deerr. Pp. xv+592. (Altrincham, Manchester: N. Rodger, 1911.) Price 20*s*. net.

IN this work the author has brought together very nearly all the information, both scientific and practical, which an enthusiastic planter, manager, or chemist would be likely to require in dealing with the production of cane sugar.

The first ten chapters—about one-third of the whole space—are devoted to description of the cane and its methods of culture. They include a section on the pests and diseases to which the plant is subject, with notes on the various devices which have been found most useful in combating them. In case anyone should question whether it was advisable for the author, a chemist, to devote a considerable amount of space to the botany, agriculture, and pathology of the sugar cane, as well as to its chemistry, an explanation is offered which enlists our sympathy at once. "I found it impossible," the author says, "to live on plantations without taking a keen interest in . . . all phases of the production of cane sugar."

We may hope that there are many others afflicted with the same kind of inquisitiveness. If so, Mr. Deerr's suggestion that his work may serve to fill a gap in English technical literature will no doubt be justified. On plants and insects he may not write with the authority of the professional botanist or entomologist; but that is not the whole story. To point out the road, one need not have helped to make it. A useful purpose is served in stimulating the reader's interest, and putting him in the way of getting further information when his curiosity is aroused. From this point of view the outlines given of the botany of the sugar cane, and especially the summary of the insect and fungoid pests that infest it, are by no means lost labour.

The factory operations connected with the production of sugar and molasses from the harvested cane are dealt with in the next ten chapters, and the remainder of the volume is chiefly concerned with the chemical control of the manufacture and with questions of sugar analysis. There is also a chapter on fermentation and distillation, with special reference to the requirements of the sugar house in respect of the production of rum.

Several years ago V. H. and L. Y. Veley ascribed the phenomenon of "faulty" rum to a micro-organism which they isolated and studied, but their conclusions were subsequently challenged by Scard and Harrison. The author has found in weak rum a fungus which, he says, is "similar" to that described by the Veleys. He does not, however, think it can be called the cause of faulty rum, inasmuch as it did not develop when placed in strong alcohol (75 per cent.). It was not killed, but no change could be traced in sound, clear rum when this was inoculated with a drop of the weak spirit containing the fungus. Apart from the question of micro-organisms as a cause, the turbidity shown by faulty rum on dilution is attributed to the presence of certain kinds of caramel, higher fatty acids, and terpenes.

The book represents a great amount of reading. It is not the author's first work on the subject, and his experience as chemist, manager, and sugar technologist is a guarantee that his own statements are likely to be practical and trustworthy, whilst for the views of authorities quoted copious references are given. Tested here and there on points within the present writer's knowledge, the information has proved to be accurate. The illustrations, which are numerous, include some excellent photographs and coloured plates.

C. S.

LABORATORY METHODS IN ZOOLOGY.

Zoologisches Praktikum. By Prof. A. Schuberg. Band i., Einführung in die Technik des zoologischen Laboratoriums. Pp. xii+478. (Leipzig: W. Engelmann, 1910.) Price 11 marks.

DR. SCHUBERG has set out to write a laboratory manual of methods for dealing with different groups of animals, but found that there was a good deal of general descriptive matter as to methods, apparatus, and reagents to be dealt with before the systematic treatment of the groups could be reached. It is this general part that occupies the whole of the present volume. A good deal of it resembles an instrument dealer's catalogue, and almost every piece of apparatus used for zoological technique is described and figured. Then the choice of instruments and their use and abuse are considered, with many experienced remarks. The routine of zoological procedure, fixing, staining, mounting, the use of the microscope, and so on, are dealt with. There are many useful references to books or papers that advocate special methods.

The volume is intended for "Hochschulen" and universities, but there are one or two points in which its usefulness might have been increased. There are, for example, no instructions as to how to collect and observe animals. A few remarks on nets and boxes do not constitute instruction, and general directions would be a most useful addition, if they were devoted to skinning and preserving; how to work different kinds of ground, sea, lake, moor, &c.; how to obtain material for observing life-histories. Another point omitted is the insertion of directions for collecting in other countries, especially in the tropics, where difficulties of unusual order have to be overcome. Again, the author does not appear to describe how any of the apparatus may be made. It is, of course, nearly always possible to buy what you require ready-made, but there are many advantages in knowing how to make the simpler pieces of apparatus, since not only the manipulation is learnt, but the physics of the working are mastered in a way that no ready-made machine permits. For physiological work particularly such training is simply invaluable.

The only other point that has occurred to us is the incomplete nature of the instruction on certain modes of procedure, a drawback common to so many "practical" text-books. Thus in reconstructing embryos or animals from sections, the author does not state exactly what to do or what precautions to take to ensure a satisfactory result. Perhaps, however, the subject will recur in his later volume. In fact, any judgment on this section of the work is premature until the second part has appeared, as we trust it soon will. We must say, however, that only the beginner will learn much from the present instalment. The methods are, so far as we have been able to test them, well known and ably advocated already. But to anyone who is fitting up a laboratory or starting out upon a course of practical study, the work may be heartily recommended.

CONSTRUCTION IN EARTHQUAKE COUNTRIES.

Le Case Nelle Regioni Sismiche e la Scienza delle Costruzioni. By A. Montel. Pp. iv+116. (Torino: S. Lattes and Co., 1910.)

THIS book, dealing with construction in earthquake-shaken countries, opens with a few words on the nature of earthquake motion, particularly acceleration. Then follows two scales of seismic intensity. After this a little is said about the nature of foundations, as, for example, whether they are upon soft or hard ground, on a slope, or on a plain. The materials used for construction are given considerable consideration, particularly the advantages that may be obtained by the use of ferro-concrete. The pictures, like those showing the framework of buildings, and various formulæ are old acquaintances, whilst the text which accompanies them in many places closely follows a translation from English into Italian. Its author, Mr. Montel, particularly refers to two books from which he has obtained his information; one is No. 4 of the publications of the Earthquake Investigation Committee of Japan, written almost entirely by Dr. F. Omori, and the other is "La Science Séismologique," by Comte de Montessus de Ballore. The other contributors to some eighty volumes issued by the Earthquake Investigation Committee have been omitted, and no reference made to the Transactions of the Seismological Society of Japan, in which we find accounts of almost everything that has been elaborated by Dr. Omori, and written about by Count Montessus and Mr. Montel.

Some thirty years ago, when Europeans were invited to Japan, their attention was naturally directed to earthquakes. These they measured, and earthquake motion was for the first time reduced to mechanical units. The result was that engineers and constructors learned for the first time something about the forces with which they had to contend. The visitors even went a little further, and tested their suggested formulæ by placing columns of masonry and other articles on a truck which could be moved back and forth at an increasing rate. The quickness or suddenness of motion required to produce the shattering or overturning of these objects was recorded, and theory brought into closer relationship with practice. For many years past new forms of buildings have been rising in Japan, and these are found to withstand earthquake movement better than their predecessors. The formula of C. D. West, formerly professor of engineering in the University of Tokyo, which is the foundation of all other formulæ, relating to the more important principles guiding constructors occupies a prominent position in Mr. Montel's work, but the name of C. D. West is not mentioned. About this we need not be surprised, because it is only found with difficulty in those works from which he quotes. But practical seismology has grown and it must not be supposed that the guests who visited Japan some thirty years ago did everything. Their work also had foundations.

So far as we know, Robt. Mallet was practically the first man who treated earthquake movement scientifically, and attempted to reduce it to practical units. Notwithstanding his work, engineers continued to regard an earthquake as something strong, and to resist its effects structures should be strong and heavy. Although M. Montel has not done all the justice he might have done by more extensive references, still he has produced a useful book, and if the principles it sets forth are adopted in the earthquake-shaken parts of Italy, they should do much to ameliorate the lot of inhabitants of those regions.

J. Milne.

OUR BOOK SHELF.

Notes on the Use of the Portable Reversible Transit Instrument and the Method of Calculation of the Observations. By Captain C. E. Monro. Pp. 60. (London: J. D. Potter, 1911.) Price 3s.

THIS excellent little handbook is written to serve as a practical guide for the use of beginners with the transit instrument. After a very slight amount of personal instruction, the learner will find a sufficient aid in this book, which gives ample directions for securing the best possible determinations of time. The notes are written in a thoroughly practical manner; the whole procedure to be adopted in setting up the instrument and in making and reducing the observations is explicitly set forth.

Captain Monro is well qualified by experience for compiling such a handbook, having taken the principal part in the important longitude determination Greenwich-Ascension-Cape in 1907; but beyond his own observations, he has drawn largely on the accumulated experience of Greenwich observers during the series of fundamental longitude determinations made by the Royal Observatory. These notes may, in fact, be regarded as embodying in the main the practice actually employed at Greenwich. In one respect, however, a deficiency is apparent, namely, with regard to the observations which depend on the use of the Right Ascension micrometer. This is presumably owing to the author having gained his experience near the equator, where slow-moving polar stars are almost unobservable; in consequence, he himself would have little occasion for using the micrometer screw. To this we attribute the fact that there is no explanation of how to determine the value of the screw, a very important instrumental constant in time determinations under ordinary conditions. Further, the example given of the reduction of a slow-moving polar involves an extravagant amount of arithmetic, and an excessive number of decimal places are employed. It may also be remarked that the wire intervals are better determined from special observations of two or three polar stars than by the laborious process of reducing some hundreds of equatorial transits.

Apart from this the book contains all that is necessary for the most refined work with the type of instrument described. The appendix, containing specimens of computing forms for the reduction of the observations, is a useful feature. Another appendix contains an elementary account of the theory of the corrections for azimuth and level. A. S. E.

Elements of Zoology; to accompany the Field and Laboratory Study of Animals. By Dr. Charles B. Davenport and Gertrude C. Davenport. Revised edition. Pp. x+508. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 5s. 6d. net.

THIS attractive work was issued ten years ago by Dr. and Mrs. Davenport, and it has now passed into a revised edition. In the interval the author has taken charge of the Carnegie Institute for Experimental Evolution and of the Brooklyn Institute Laboratory at Long Island, and he is consequently well qualified to introduce changes in the work that reflect to some extent the advance of zoological knowledge so far as it affects an elementary text-book. The chief feature of the work is the abundance and excellence of the illustrations. Scarcely less striking than the figures are the suggestive and interesting remarks on the habits and behaviour of the examples selected. There is little plan or sequence in the chapters. Each of them consists of an isolated study of some particular topic associated with a given form of animal life. By some curious oversight only one-half of the selected forms are figured, though illustrations of related forms occur in abundance, and there are, in addition, photographs of the localities in which the chosen animals may be found. The work is so attractive and will be so useful to teachers who wish to organise nature-study courses that we are loth to point out the few blemishes that we have noticed. Darwin, however, would object to be quoted as saying (p. 171), or rather writing "mold" for mould, and "plow" for plough. The Ranidæ occur over Africa, and are not limited, as suggested on p. 348, to the northern hemisphere and East Indies. The spotted salamander figured on p. 335 is called "A urode," a name which is certain to cause trouble and misunderstanding, as are many other curious vernacular names, such as "sow-bug" for Oniscus, "basket-fish" for branched Ophiuroids, "tumble-bugs" for the large dung-beetles, the "underwing" for Catocala, "spring azure" for blue Lycænas, and many others. Probably in the States these difficulties will not occur. We can heartily recommend this book.

Modern Industrial Chemistry, from the German of H. Blucher. Translated by J. P. Millington. Pp. xvi+779. (London: Gresham Publishing Co., 1911.) Price 30s. net.

THIS work is an attempt to survey the field of chemical technology and to bring the results within the compass of about 800 pages of well-leaded type. It is, lexicographically arranged, fairly well illustrated by "process" cuts, and plentifully interspersed with advertisements, or with references to the many advertisements between which the book itself is sandwiched. As might be anticipated from its origin, it deals mainly with German technology, and is especially rich in references to German patent literature. Another feature in which it differs from the ordinary run of such works is the prominence it gives to the nostrums and drugs with which modern chemical manufacturers, more especially in Germany, have flooded the markets of the world. Many of these are only of the most ephemeral interest, and certain of them are no longer in use, either because they have been found to be baneful, or because they have been superseded by others more convenient in use. As their names are to be found in modern pharmacological literature, and are presumably of interest to medical men, a catalogue of them, arranged alphabetically, may possibly be of some service. It must be admitted, however, that the information vouchsafed in the case of many of them is very meagre and not always authentic. Indeed, many of the titles in the book seem to be introduced for no other purpose than to direct attention to a trade advertisement.

The book may be of use in the counting-house of a manufacturer, but would be of very limited value to the specialist or the student of chemical technology.

Practical Plant Physiology. By Prof. F. Keeble, assisted by M. C. Rayner. Pp. xvi+250. (London: G. Bell and Sons, Ltd., 1911.) Price 3s. 6d.

BOTANICAL physiology is one of the most instructive branches of science, because it provides an excellent test of a student's capabilities and is particularly suitable for inculcating the spirit of original research. Both these objects are kept in view by the author of this practical text-book, where they supply the main undercurrent flowing below the more obvious stream of information conveyed in the text. The course outlined is also thorough and complete, as the student is led systematically by argument and experiment through the sequence of problems connected with plant nutrition.

Indeed, it will be speedily ascertained by those who start the course that the experiments indicated require considerably more time than is ordinarily devoted to this branch of botany; however, in this case there is no great objection to superfluity, as it is a simple matter to leave out those experiments considered to be less important. In the circumstances the author was well advised to touch only lightly upon the sensitivity of plants, which is discussed in the last chapter.

The general method of exposition is original, and a certain number of experiments, such as that devised by Dr. F. Blackman for illustrating the dependance of germination upon oxygen supply are additions to the courses generally followed in botanical laboratories. There is overmuch insistence on the correlation of guessing, reasoning, and trying, and perhaps a superabundance of chemical and physical tests. But these are minor matters of opinion, whereas there can be no question that the book is original, vigorous, and stimulating.

The Statesman's Year-Book. Statistical and Historical Annual of the States of the World for the Year 1911. Edited by Dr. J. Scott Keltie. Pp. lxxii+1412. (London: Macmillan and Co., Ltd., 1911.) Price 10*s*. 6*d*. net.

This is the forty-eighth annual issue of a work of reference which has become indispensable to administrators, statesmen, and students of economics and geography. The volume has been thoroughly revised and brought up to date—a preliminary section of additions and corrections including the results of the 1911 census of the United Kingdom. A series of new maps is provided, and these include maps of the new projected railway routes to India; railways, navigable waters, and steamship routes; the new Liberian Boundary, 1909; the northern territory of Australia; and of the Panama Canal from the latest reports of the Isthmian Canal Commission.

Several sections of the book have been greatly improved—those dealing with Turkey, Spain, and China may be mentioned. Altogether this issue of the "Year-Book" will preserve the high reputation the work has secured, and the editor may well be congratulated upon his efforts to maintain the accuracy and usefulness of the volume.

Catalogue of the Serial Publications in the Library of the Manchester Literary and Philosophical Society. Compiled, under the direction of the honorary librarian, C. L. Barnes, by A. P. Hunt. Pp. vi+177. (Manchester: Published by the Society, 1911.) Price 2*s*. 6*d*.

The object of this catalogue is to make known the wealth of periodical scientific literature in the library of the Manchester Literary and Philosophical Society. The total number of current publications at present received by the society is 810, and they come from all parts of the world and cover every branch of science. The catalogue is excellently arranged, and is provided with an exhaustive index. It should be of great service to members of the society and to others engaged in scientific research.

The Lore of the Honey-Bee. By Tickner Edwardes. Pp. xx+196. (London: Methuen and Co., Ltd., 1911.) Price 1*s*. net.

The first edition of Mr. Edwardes's book on the bee was reviewed in the issue of Nature for November 5, 1908 (vol. lxxix., p. 6). This fourth edition is a cheap re-issue of what has already proved a popular work; and, at its present price, such an interesting history of the folk-lore of the bee and account of its activities should become known to a wider circle of readers.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of Nature. *No notice is taken of anonymous communications.]*

The Deformation of Rocks under Tidal Load.

I have read with interest Prof. Milne's letter under the above title in Nature of July 13, and congratulate him on the promising character of the results. As he himself remarks, the subject theoretically is not a new one. Its geophysical interest lies largely in the possibility of deriving information from the observed phenomena as to the elastic character of the earth's crust. Several difficulties, however, stand in the way of this information. The earliest mathematical treatment of the problem, so far as I am aware, is that by Sir G. H. Darwin, to which Prof. Milne refers. The problem which he actually solved relates to the effect of load on the surface of an elastic solid material which is *homogeneous, isotropic,* and *incompressible.* In ignorance of this solution, I obtained another[1] in 1896—a simple deduction from the important solution by Prof. Boussinesq for material bounded by an infinite plane—which is somewhat more general, in so far as it does not assume incompressibility in the material, but otherwise is subject to the same limitations. In practice, the most important of these limitations are probably the assumptions of homogeneity and isotropy. Very possibly, an expert mathematician familiar with recent developments of the mathematical theory of elasticity might have no serious difficulty in removing these restrictions in part or in whole. For instance, if a solution were obtained for the case where there is a relatively thin superficial layer differing in elastic quality from the remainder, it would immediately throw light on what is to be expected from differences in the surface strata.

The solution derived from Boussinesq's for the homogeneous solid is simple, the formula for the vertical component w of the elastic displacement at a point in the plane of the loaded surface being[2]

$$w=\{(1-\eta)/2\pi n\}\iint (p/r)d\sigma,$$

where p is the normal pressure over the element $d\sigma$ of surface, situated at a distance r from the point where w is being measured, n denotes the rigidity, and η Poisson's ratio for the material, dw/dx gives the slope measured in the direction of the axis of x, supposed horizontal. We see at once that however complex the distribution of load may be, the slope varies directly as $1-\eta$, and inversely as n. For a given value of n it is 50 per cent. greater when Poisson's ratio is $\frac{1}{4}$—as it approximately is in steel—than when the material is incompressible.

There is, however, another aspect of the case that has to be taken into account. The influence of the tide does not consist solely of the pressure effect. At high-tide we have a large additional quantity of gravitating material, the attraction of which modifies the direction of gravity at the land station. If we compare the readings of a delicate spirit level at mid-tide and at high-water, there is an apparent change of level $\psi_1+\psi_2$, made up of ψ_1 due to the actual slope of the surface carrying the level, and ψ_2 due to the alteration in the direction of local gravity. Under the conditions postulated in my solution of the problem

$$\psi_1/\psi_2=2(1-\eta)g\rho a/3n,$$

where g is gravity, a the earth's radius, and ρ its mean density. The ratio varies enormously for values of η and n that exist in known materials. Thus we have, measuring n in grammes weight per sq. cm.,

$$\eta=0{\cdot}25,\quad n=80\times10^7,\quad \psi_1/\psi_2=2 \text{ approximately},$$
$$=0{\cdot}5,\quad n=11\times10^7,\quad =11 \quad ,,$$

The first thing to be considered is what does the instrument used actually record? Is it ψ_1 or $\psi_1+\psi_2$? In the latter event, unless ψ_2 is relatively negligible, we must

[1] See *Phil. Mag.*, March, 1897, p. 173.
[2] Proc. Physical Society, vol. xv., p. 36, and *Phil. Mag.*, *l.c.*, p. 177.

calculate it before we can arrive at the true bending effect. If the material is homogeneous and elastic, the vertical plane of steepest slope at any place contains the direction of the resultant gravitational force. But while the gravitational effect must be as instantaneous as gravity itself, the bending effect will show a lag unless the material is perfectly elastic, so far, at least, as tidal load is concerned. It is manifestly a case in which measurement of the apparent slope in two perpendicular planes is likely to add materially to knowledge. An estimate which I made in 1896 for the effect of tides in the Thames at Kew Observatory, assigning the low value of 11×10^7 grammes weight per sq. cm. to the rigidity, and assuming the material incompressible, made the difference of the slope between extreme high- and low-water only of the order $0''\cdot05$, and so too small to be measured satisfactorily by the Milne seismograph at the observatory. CHARLES CHREE.

July 15.

Hamilton and Tait.

IT may at first sight seem a little ungracious to take exception to a statement in the extremely gratifying review of the "Life and Scientific Work of P. G. Tait," which "A. G." contributed to NATURE of July 13. But the point is one which brings out in a remarkable degree the great modesty of Tait in regard to his own achievements. Your reviewer says that Tait "was introduced by Andrews to Rowan Hamilton, at that time in the full tide of his quaternion work, and busy with the preparation of the 'Elements' for publication."

Now it is, I think, clearly established in the "Life," by means of quotations from Hamilton himself, that when the correspondence with Tait began Hamilton had stopped working at quaternions, that the correspondence drew Hamilton back to the study of his calculus, and that, as I put it in the "Life," p. 132, it was Tait "who fired Hamilton with the ambition to write his second great 'Treatise on Quaternions.'" This is proved by Hamilton's own words, quoted on p. 131 of the "Life." Since possibly many readers may not be interested in the quaternion side of Tait's activities, I take the liberty of reproducing this quotation here. Writing on January 21, 1859, Hamilton remarked:—

"As to myself I cheerfully confess that I consider myself to have, in several respects, derived advantage, as well as pleasure, from the correspondence. It was useful to me, for example, to have had my attention *recalled* to the whole *subject* of the *quaternions*, which I had been almost trying to *forget*; partly under the impression that nobody cared, or would soon care, about them. The result seems likely to be that I shall *go on* to write some such 'Manual,' not necessarily a very *short* one—as that alluded to in a recent paragraph."

It seems clear that without the Tait correspondence, Hamilton would never have undertaken the second treatise. This was one of the discoveries which I was privileged to make when the correspondence was committed to my care. To me it was a very surprising discovery. I had often conversed with Tait about his relations with Hamilton—and he was critical as well as appreciative in these reminiscences—but I never heard him say anything as to the part he played in the first beginnings of the "Elements." In his own writings, such as the prefaces to the successive editions of his treatise, or the biographical notices he wrote of the great Dublin mathematician, Tait had ample opportunities of telling the story of his intimate connection with Hamilton's second treatise. But not the least hint was ever given. It may be that Tait felt his hands tied because of the absence of any reference in the "Elements" to the correspondence. But we must remember that Hamilton did not live to complete his work or to write more than the merest fragment of a preface. Now that we know the truth from Hamilton's own letters, the whole episode is a fine example of Tait's modesty, and even self-effacement, in regard to his influence in shaping scientific development. The story throws such a beautiful light upon the character of Tait that I am sure your reviewer will thank me pointing out the one slight inaccuracy in an otherwise perfect review. C. G. KNOTT.

The Fruiting of the Tamarisk.

THIS exceptional season is having strange effects on many of our native plants and animals, and naturalists would do well to note these before it is too late.

For many years I have tried without success to find *Tamarix anglica* in fruit in Britain. The absence of fruit, and the rarity of the tamarisk except where obviously planted, seemed to support the idea that it was of fairly modern introduction.

A few years ago, however, fragments of rope, found in Roman Pevensey and sent to Kew, were pronounced to be formed in part from the inner bark of tamarisk. This seemed to favour the inclusion of the tamarisk in the British flora, though rope found in a Roman seaport may quite well have been manufactured abroad.

This season the negative evidence yielded by the absence of seed has also broken down; and if a plant seeds once in its lifetime, it may hold its own and establish its right to a place in our flora—as the Cornish elm has done.

I planted last spring some young tamarisks on a steep bank of loose sand in my garden at Milford. During the long drought they received no water; they are now seeding freely, and the winged seeds are being dispersed by the wind. If the plant reproduces itself from these seeds, sown under natural conditions, the cycle will be complete; but the garden is a quarter of a mile from the sea, and the test may be too severe a one.

Tamarisk is essentially a desert and sea-coast plant, and it would be worth while to examine any tamarisks growing on sand-dunes, to see whether they also are seeding, and to see whether seedlings come up. Possibly the tamarisk may be a survivor from times when desert or "loess" conditions extended over western Europe. We have found the fossil remains of many of the desert animals, but plants decay in porous deposits of dust, and desert plants are seldom washed into ordinary alluvial deposits. CLEMENT REID.

Sunshine and Fleas.

ARISTOTLE (H.A. viii. 605*b*) makes the following curious and perplexing statement:—*πάντα δὲ τὰ ἔντομα ἀποθνήσκει ἐλαιούμενα· τάχιστα δ', ἄν τις τὴν κεφαλὴν ἀλείψας ἐν τῷ ἡλίῳ θῇ.* That is to say: "All insects die if they be smeared over with oil; and they die all the more rapidly if you smear their head with the oil and lay them out in the sun." So Pliny, Albertus Magnus, and recent commentators read and interpret the passage. But in the former half of the sentence, for *ἐλαιούμενα*, several MSS. read *ἡλιούμενα*: *i.e.* not "if they be smeared with oil," but simply "if they be exposed to the sun"; while in the latter half there is an obvious ambiguity, which inclines me to think that *τὰ ἔντομα* is used *sensu restricto,* and that *τὴν κεφαλὴν* refers, not to the insect's head, but to the experimenter's.

I take it, in short, that the heat of the sun was the main agent recommended for the destruction of the insects, and it is interesting to find this agency again coming into practical use for a very similar purpose. One of the latest of the Indian Medical Department's "Scientific Memoirs," by Capt. J. Cunningham, is entitled "On the Destruction of Fleas by Exposure to the Sun." The writer recommends the wholesale disinfection of clothing and baggage, for the special purpose of destroying plague-carrying fleas, by the simple process of laying out the garments or bedding on a sandy floor, exposed to the full rays of the sun. The author has made many careful and elaborate experiments, and has succeeded in showing that in less than an hour's time, under an Indian sun, the fleas are all dead.

D'ARCY W. THOMPSON.

The Oban Pennatulida Again.

MARINE biologists may be interested to hear that the bed, near Oban, of the largest British pennatulid *Funiculina quadrangularis*, and the smaller *Virgularia mirabilis* described by Mr. W. P. Marshall and the late Prof. Milnes Marshall in 1881 or 1882 (I have no books of reference with me) is still apparently in very flourishing condition. In a couple of hauls of the small Agassiz trawl, from this yacht yesterday, between the islands of Kerrera and Lismore, at depths of eighteen to twenty fathoms, I got about a dozen fine specimens of Funiculina, the largest of which measured nearly four feet in length. The bed must be of considerable extent, as the hauls were not on the same spot, and both brought up equally good specimens of these magnificent pennatulids. Most of the large specimens of Funiculina, by the way, were not caught in the trawl-net, but were balanced across the front of the frame, at each end, in such a precarious position as to make one wonder how many others had been lost in hauling in. The bottom deposit was evidently fine mud. W. A. Herdman.

On the Non-simultaneity of Suddenly Beginning Magnetic Storms.

In his paper "On the Supposed Propagation of 'Equatorial' Magnetic Disturbances with Velocities of the Order of a Hundred Miles per Second," read before the Physical Society of London, November 11, 1910, and published in the Proceedings of that society, vol. xxiii, pp. 49–57, Dr. Chree, in reviewing my paper published in the *Journal of Terrestrial Magnetism* (vol. 15, pp. 93–105), expressed some doubts as to my views on the subject of the non-simultaneity of suddenly beginning magnetic storms.

It seems to me that there should not be any doubt as to my position on this point when I stated in my above-mentioned paper (*loc. cit.* p. 103) that the evidence there presented confirmed what Dr. Bauer had stated, namely, that magnetic storms do not begin at the same instant all over the world, and added a little further on that a new view-point in the discussion and analysis of magnetic storms is thus introduced, meaning that a new view-point must now be had on account of this non-simultaneity of the occurrence of the beginning of the storms which, I believe, the data shows to exist.

I agree with Dr. Bauer in his conclusion that the abruptly beginning magnetic storms are not simultaneous all over the world, and this conclusion, it seems to me, is supported, not only by the data in my paper, but by that in his paper which appeared prior, and in that which has appeared subsequent, to mine. The Number of Possible Elements and Mendeléeff's "Cubic" Periodic System.

According to Rutherford's theory of "single scattering" ("On the Scattering of α and β Particles by Matter and the Structure of the Atom," *Phil. Mag.*, May, 1911), and to Barkla's "Note on the Energy of Scattered X-Radiation" (*ibid.*), the numbers of electrons per atom is half the atomic weight; thus, for U, about 120. Now, a reconstruction of Mendeléeff's "cubic" periodic system, as suggested in his famous paper "Die Beziehungen zwischen den Eigenschaften der Elemente und ihren Atomgewichten" (*Ostw. Klass.*, No. 68, pp. 32, 36, 37, and 74), gives a constant mean difference between consecutive atomic weights $=2$, and thus, from H to U, 120 as the number of possible elements (van den Broek, "Das Mendelejeff'sche 'Kubische' Periodische System der Elemente und die Einordnung der Radioelemente in dieses System," *Physik. Zeitschr.* 12, p. 490). Hence, if this cubic periodic system should prove to be correct, then the number of possible elements is equal to the number of possible permanent charges of each sign per atom, or to each possible permanent charge (of both signs) per atom belongs a possible element. A. van den Broek.

Noordwijk-Zee, June 23.

Phases of Evolution and Heredity.

I should like your reviewer of the above book in Nature for May 25 to consider the following points:—

1. In a tall-dwarf crossing where the results are read in plants, the ultimate ratios considered as due to a probability combination of the egg-cells and pollen grains the influence of which necessarily ends within a generation, explain why we do not get the ratio in the plants coming out in F^1.

2. To my query, "How is the recessive element expressed in F^1? It has not disappeared as it reappears in F^2 unaltered. It is not expressed in the 'soma' of the plant: where is it?" your reviewer answers "In the germ-cells."

If, however, the determinants of the recessives are expressed in the germ-cells, *i.e.*, in the propagative part of the plant, so must those for the impure dominant and dominant plants. These plants segregate in a 1 : 2 : 1 ratio, and therefore the determinants for the contrasted unit-characters must be in that ratio in the propagative part of the oospores. Does the reviewer not admit the accuracy of my view after all? D. Berry Hart.

5 Randolph Cliff, Edinburgh.

I find it very difficult to follow Dr. Berry Hart. If he means, by the question which concludes his letter, to ask whether I accept his theory as truly representing, once and for all, the causes which determine the Mendelian ratio 1 : 2 : 1, my answer is an unqualified negative; not because I think I know what the true theory is, but because I do not think the time is yet ripe to formulate it. Dr. Hart's theory is evidently different from the accepted Mendelian theory; and it may be nearer the truth. Whether it is or not, further experiment alone can show. The Reviewer.

Available Laboratory Attendants.

The London County Council has for some time been referring to us a certain number of boys who have been trained as laboratory attendants in their higher grade and secondary schools, and whose services they are unable to retain after they have attained seventeen years of age. We are anxious to find suitable vacancies either in chemical works or laboratories for these boys, who are of a distinctly superior type and some of whom have profited by their experience to pass the Board of Education examinations in inorganic chemistry.

Some of these boys who were placed by us, thanks to a letter published by you last year, are doing well and giving satisfaction to their respective employers.

Should any of your readers, now or at any future time, have a vacancy for such a lad, I should be glad to hear from him.

Mersenne's Numbers.

I desire to announce the discovery which I have made that $(2^{181}-1)$ is divisible by 43441. This leaves only 16 of the numbers (2_q-1) originally reported composite by Mersenne, still unverified. I have submitted my determination to Lt.-Col. Allan Cunningham, R.E., who has kindly verified it.

It is interesting to know that while $(2^{181}-1)$ is divisible by 43441, the quotient when divided by this number (43441) leaves a remainder 21839. This latter result has been verified by two divisions.

Market Place, Stockport, June 12.

The Fox and the Fleas.

Some readers of Nature may be interested in seeing the following passage from one of Liebig's letters to Wöhler, dated Giessen, June 24, 1849, as showing that the story has long been familiar, at least in Germany:—

"Das freiheitsmörderische Gesindel ist nun, wie beim Fuchs die Flöhe in dem Bündel Heu, in einer Schlinge gefangen . . .," &c. William A. Tilden.

The Oaks, Northwood, Middlesex, July 10.

Cabbage White Butterfly.

Would some entomologist state if he knows of any reference to the fact that the larvæ of the Large Cabbage White seek to arrange themselves in pairs—male and female—when they pupate?

Can the sexes be distinguished externally in the larval and in the pupal stages? E. W. Read.

Sutherland Technical School, Golspie.

NOTES ON THE HISTORY OF THE SCIENCE MUSEUM.[1]

II.

IN the former notes I referred to the early history of the Patent Museum.

By 1874, in consequence of the acts of the Commissioners of the 1851 Exhibition, land for the proper display, on the one hand, of objects chiefly illustrating art and its application to industry, and, on the other, of objects illustrating natural history, had been provided, and buildings for these purposes, as well as a School of Science, had been commenced. But for the Patent or Science Museum, no building had been erected on the five acres assigned to it by Lord Palmerston on the land bought in 1863.

In this year the question of museums was considered by the Duke of Devonshire's Commission, and the collections at South Kensington were inquired into. The question of the Patent Museum was specially considered, and it was pointed out that objects illustrating patents should find their true place among those dealing with the advance and applications of the physical and mechanical sciences.

As a result of this inquiry, the Duke of Devonshire's Commissioners recommended to the Government the establishment of what they were the first to call a Science Museum, in which was to be included not only patented objects, but those necessary to illustrate the advances of both pure and applied science. I give the following extract from their fourth Report :—

"81. While it is a matter of congratulation that the British Museum contains one of the finest and largest collections in existence illustrative of Biological Science, it is to be regretted that there is at present no National Collection of the Instruments used in the investigation of Mechanical, Chemical or Physical Laws, although such collections are of great importance to persons interested in the Experimental Sciences."

"82. We consider that the recent progress in these Sciences and the daily increasing demand for knowledge concerning them make it desirable that the National Collections should be extended in this direction, so as to meet a great scientific requirement which cannot be provided for in any other way."

"83. The defect in our collections to which we have referred is indeed already keenly felt by teachers of Science. If a teacher of any branch of Experimental Science wishes to inspect any physical instrument not in his possession, as a teacher of Literature would a book, or a teacher of Biology would a specimen, there is no place in the country where he can do it."

"93. We accordingly recommend the formation of a Collection of Physical and Mechanical Instruments; and we submit for consideration whether it may not be expedient that this Collection, the Collection of the Patent Museum, and that of the Scientific and Educational Department of the South Kensington Museum, should be united and placed under the authority of a Minister of State."

Here then we find the definition of a "Science Museum" as resulting from all the inquiries made by the Duke of Devonshire's Commission. Their statement regarding its organisation under a Minister of State was evidently inserted, because in another Report they pointed out the importance of the whole National Museum system being under a Minister of State, instead of being in two water-tight compartments, one of them controlled by a body of Trustees without Government responsibility.

This is too large a question to be entered upon in these notes, but it may be pointed out that if this recommendation had been acted upon the recent discussions would never have arisen.

A step was at once taken by the Government to facilitate the carrying out of these recommendations, and a loan collection of scientific apparatus was brought together in 1876, as an object-lesson of what such a Science Museum might be in relation to the "Patent Museum," arranged for by Lord Palmerston in 1863, which would form part of the new museum. Still no steps were taken to commence the building.

The building of the new Natural History Museum, however, was proceeding; it was finished in 1880. It has been shown that the land allotted for natural history purposes by Lord Palmerston was five acres. The completed museum building covered nearly four acres, and was erected in the centre of a space of about eleven and a half acres, fenced off from the remainder of the sixteen and a half acres purchased in 1863, in such a manner as to make it difficult to apply the eight acres not built over to any other service, or even to expand largely the museum itself without injury to its architectural features. As to how this state of things, so different from that to be gathered from Lord Palmerston's speech, came about I have no information.

The recommendations of the Duke of Devonshire's Commission touching a Science Museum had much influence in leading the Commissioners of the 1851 Exhibition to adopt proposals for the future appropriation of their estate.

Even while the loan collection of scientific apparatus in 1876 was indicating the national importance of such a museum as the Duke of Devonshire's Commission had suggested, the 1851 Commissioners began their proposals to bring it into being by offering to endow a Science Museum with money and land.

I quote from the sixth Report (p. 41) the action taken in 1876 :—

"Influenced by these considerations, and by the regrets expressed by the Royal Commission on Scientific Instruction, in their Report already quoted, we concluded that there could be no more appropriate employment of a portion of our resources than to expend them on a building on our own Estate, for the advancement of scientific study and research, and, in connection with the South Kensington Museum, to receive the important contributions of instruments which we understood would be made to the nation at the close of the Loan Exhibition already alluded to.

"We, therefore, proposed to Her Majesty's Government that 100,000*l.* of the amount we might realise, or might be enabled to raise on ground-rents, should be devoted to the furtherance of the recommendations of the Royal Commission on Scientific Instruction by erecting, on a site opposite the Government Science Schools, a building suitable for a Museum of Scientific Instruments, or for a Library of Scientific Works, and for laboratories of scientific research and instruction. And we made this offer on condition that the Government would undertake to maintain the building, when erected, in the manner proposed. The site referred to is partly our property and partly the property of the Government, and we suggested that, in exchange for a conveyance of the part belonging to us, the Government should return to us two small portions of the site of the Exhibition of 1862, which project into our main square."

The proposal then was very similar to the present one, utilising the land to the north of the Natural History Museum building.

Events, however, indicated that the Commission's land to the north of the plot first proposed would be a more convenient site for the Science Museum, and a second letter was addressed to the Govern-

[1] Continued from p. 16.

ment in 1878, in which the Commission again offered to convey land and to provide 100,000*l*. for a Science Museum to be built on a plan to be approved by the Government.

The view of the Commission is thus expressed in their sixth Report (p. 44):—

"*The proposed new building would complete the group of buildings already erected by the Commission, and these . . . would alone satisfactorily realise the first conception of the illustrious Prince who conceived the idea of purchasing the estate.* Should the Government eventually acquire also the ante-garden for the extension of the Science building now proposed, or for other public buildings, and thus connect our direct work with the Natural History and the South Kensington Museums, *the success of the plans of the Prince Consort would be complete.* The national collections of Mediæval and Recent Art would have their home on the portion of the Estate purchased with the funds derived from the Exhibition of 1851 which lies on the east of Exhibition Road; the Science collections on the portion of the Estate which lies on the west of that road."

This offer was declined by the Government in 1879 on the ground of the depression of trade, and that the establishment of such a museum was not sufficiently urgent!

After this the Commissioners took no further action with regard to the Government until 1888. In the meantime, however, they had granted land for the erection of the City and Guilds Institute and the Imperial Institute.

In a letter of 1888 the land to the south of the Imperial Institute Road, reaching to the land conveyed to the Government in 1864, was offered under the old conditions, namely, "that the land shall be permanently used for purposes connected with Science and the Arts." This plot consisted of 4½ acres, valued at 200,000*l*. It was offered to the Government for 70,000*l*., and the contained southern gallery (already leased to the Government) for 30,000*l*. This offer was accepted.

In the year 1907, in spite of the Commissioners' repeated efforts, we had no Science Museum, and the Commissioners had no more land to offer.

All that remained in 1906 was given to the governing body of the Imperial College of Science and Technology, the new institution which is to bring together all the colleges already built, and to be built, on land presented, or sold at reduced value, by the Commission for scientific purposes.

The existing buildings are the College of Science, the site of which was given gratis; the City Guilds' College, the site of which is rented at one shilling per annum; and the new Chemical and Physical Laboratories of the Imperial College, on a site sold by the Commission at less than half its value.

It may be said that, adding the value of these old plots to that of the three given in 1906, the Commission has really endowed the new institution to the extent of some 400,000*l*.

But if a Science Museum was desirable before such a bringing together and extension of science teaching and research as the new institution affords, it is vastly more important now, when advanced research in the applications of science to the national industries is to be fostered along new lines. The opinions of those most competent to judge of the national importance of a Science Museum thirty years ago can be gathered from an appendix to the Commissioners' sixth Report (p. 130), in which is printed the memorial addressed to the Lord President of the Council in 1876.

Such a museum is vastly more important now, but its location at South Kensington, in close contiguity to the Imperial College, has become imperative.

In 1907, mindful of what the Commission of the 1851 Exhibition had attempted to do during the whole time of its existence up to that time in furtherance of the completion of the National Museum organisation, I considered it my duty to call the attention of the Commissioners to the fact that practically the whole of the land belonging to them had been allocated, and that, so far, no proper provision had been made for a Museum doing for the Physical, Chemical, and Mechanical Sciences what the British Museum Library does for books, the Galleries for Antiquities, the National Gallery does for pictures, and the Natural History Museum does for the Biological Sciences.

In a memorandum to the Commissioners urging the early erection of such a museum I wrote:—

"How, then, can its early erection be brought about? I submit by holding out a special inducement to the Government to utilise in this direction some part of the land sold to the Government in 1888 still waste between the old and new buildings of the College of Science and adjacent thereto.

"The importance of the eastern part of this site for the purpose I have indicated has long been recognised. In 1891 it was ignorantly offered by the Government to Mr. Tate for an art gallery, but when the facts had been inquired into, the offer was withdrawn by the then Chancellor of the Exchequer, Mr. Goschen. Both in a memorial presented to Lord Salisbury and by a deputation to the Lord President of the Council and the Chancellor of the Exchequer it was pointed out that were the corner site in question not occupied by the science collections the teaching in the Royal College of Science would be cut in two when the new laboratories were erected (they have been erected since). On this ground the Government withdrew the offer to Mr. Tate, and reserved the site for future science buildings.[1]

"The frontage of this plot, which indeed is the last important and considerable *frontage* remaining, is in Exhibition Road, stretching from the Natural History Museum grounds to the Imperial Institute Road. It lies exactly between the old and new Royal College of Science buildings.

"I may add that the frontage available in Exhibition Road is over 360 feet; that is, 60 feet longer than the west frontage of the Victoria and Albert Museum, and only 17 feet shorter than the frontage of the new buildings of the British Museum. . . .

"Were this building erected, all the ground once possessed by the Commissioners along Cromwell Road and to the south end of Exhibition Road would have been utilised for the purposes of Science and Art, Art on the east side, and Science on the west side of Exhibition Road, as was originally planned.

"Were the southern galleries—the old Exhibition refreshment rooms—taken down, and the dangerous spirit museum removed to a safer site, such as the Natural History Museum Gardens, some distance west of the main building, there would be a space of more than four acres between the Natural History Museum and the Chemical and Physical Laboratories, and stretching from Exhibition Road to Queen's Gate, not only with the frontage to which I have referred, but another in Queen's Gate. Here, indeed, it would be possible, as a variant of the plan I have suggested, to erect a Science Museum similar to the one offered by the Commissioners to the Government in 1878, and indicated on their plan. Much of this land is not at present permanently occupied, and the Solar Physics Observatory is under notice to quit, a new site at Caterham having already been fixed upon.

"It seems desirable that this long-standing question of a Science Museum should be again discussed, and

[1] Accounts of what took place will be found in NATURE, February, 1891, and March, 1892, vols. xliii. and xlv.

without delay, because if any buildings are erected on the spaces referred to, any such Science Museum as the Commissioners have had in contemplation during the last thirty years, for which they have freely given their land and offered money, will be impossible of realisation, to say nothing of future extension.

"I have reason to think that if the Commissioners would again take up the question, remind the Government of their continuous action and appeal to the Government to consider the matter, such an appeal would be received sympathetically. If such an appeal could be accompanied by the renewal of the offer, already twice made, to provide a money contribution towards the building, the matter would, of course, become still more hopeful.

"The last Annual Report shows that the Commissioners have in hand funds available for such a purpose, and, speaking as a Commissioner, I can conceive no more worthy expenditure, as it will give full effect to the great purposes the Commissioners have had in view during the whole time they have been engaged in carrying out the late Prince Consort's wise advice as to the best use of their property in the nation's interest."

In 1910 the Commissioners took action in the matter. In the "Further Correspondence" already referred to [Cd. 5673] is given a letter (June 25, 1910) from the Secretary:—

"The Board of Management of the Royal Commission for the Exhibition of 1851 have recently had before them a proposal to establish at South Kensington a permanent building for the accommodation of the National Science Collections. . . .

"Believing that the application to such an object of a portion of their surplus funds would be consistent with the declared policy of the Commissioners, they have resolved to recommend to the Commissioners a repetition of their former offer of 100,000*l*. towards the expense of providing a Museum, subject to their being satisfied that his Majesty's Government are prepared to make provision, so as to secure the erection of an adequate building."

On August 25, 1910, the Treasury accepted this offer. While this correspondence was going on the Office of Works was writing to the Trustees of the British Museum with regard to the Northern Boundary, a subject dealt with in the previous notes.

We now learn from *The Times* report of Mr. Runciman's speech on the Education vote (July 13, 1911) that at last some compromise has been arrived at.

"Since the first announcement was made about the site of the Science Museum I have entered into negotiations with the Trustees of the British Museum, and we have now arrived at an agreement which will give us the land we require for the Science Museum and will not interfere with the development of the Natural History Museum, so that we shall have in South Kensington a group of museums which will be the envy of foreign nations." NORMAN LOCKYER.

THE ROYAL COMMISSION ON TUBERCULOSIS.

THE Reports of Royal Commissions are as a rule based almost entirely on summaries of oral evidence submitted by authorities, expert or otherwise, on the subjects with which these Commissioners have been called together to deal. Such Commissions can be expected to give little more than a *résumé* of what is already known.

In the Final Report of the Royal Commission on Tuberculosis (Cd. 5761; price 6*d*.) it is soon made manifest that here something more than personal opinions of even the most eminent authorities have been brought together. The very genesis of the Commission made this necessary. The greatest living authority on the subject of tuberculosis, Robert Koch, had for long taught that tuberculosis was a disease common to animals and man, a disease induced by a specific micro-organism, the tubercle bacillus. Of this micro-organism there might be varieties in which the virulence or disease-producing activity might be higher in one and lower in another, but they were still essentially and specifically the same wherever they were found in the tuberculous lesions, whether of man or of animals.

At the International Congress held in London in July, 1891, Koch had turned round (perhaps not suddenly, though the announcement of the *volte face* had come with startling suddenness) and had announced that the tuberculous disease of cattle was not the same thing as tuberculosis of the human subject, and that the tubercle bacillus found in the tuberculosis of cattle was non-virulent for man.

The experimental work on which this statement was based was considered by many of the scientific men who heard the pronouncement to be totally inadequate to bear the wide generalisations founded upon it.

Lord Lister, the late Prof. Nocard, Prof. Bang, Sir John McFadyean, Dr. Sims Woodhead, and others were in agreement that the statement, if true, would revolutionise our whole attitude to the tuberculosis problem, and that before it could be accepted independent and corroborative evidence must be obtained.

Sanitarians in the United States appreciated the importance of this to the full, and the morning after Koch's address was given a telegram was received in London from Washington stating that the tenor of the address had been noted, and that arrangements, financial and otherwise, had been made to carry out experiments to test the trustworthiness of Koch's thesis.

Although a resolution asking the British Government to appoint a Royal Commission had been carried at the meeting of the Executive Committee, the business of the closing meeting of the Congress had been practically concluded, and no resolution asking for this Commission had been brought forward, and none could be found. One or two members of the Executive Committee, however, had carried the terms of the Resolution in their memories, they were hurriedly committed to paper, and the matter was placed before the meeting. Lord (at that time Sir James) Blyth had made a most generous offer to place a farm or farms at the disposal of any Committee or Royal Commission appointed, and it was evident that any such Commission set to work to inquire into the question would be able to carry on its investigations under most satisfactory conditions.

In these circumstances the Right Honourable Walter Long, M.P., then President of the Local Government Board, advised her Majesty Queen Victoria to appoint a Royal Commission with instructions to inquire and report with reference to tuberculosis:—

1. Whether the disease in animals and man is one and the same.
2. Whether animals and man can be reciprocally infected with it.
3. Under what conditions, if at all, the transmission of the disease from animals to man takes place, and what are the circumstances favourable and unfavourable to such transmission.

The Commission appear to have laid down a very definite plan, from which there has been no deviation. It was asked to inquire and report on the above questions. No inquiry except an actual experimental investigation seemed to give promise of any trustworthy results, and the scheme of work did not include the taking of oral evidence.

The answers to the questions, though very guarded in many directions, are, where the Commissioners have made up their minds, clean cut and definite. No pretence is made to answer any questions but those contained in the reference, and anyone going to this Report for general information on the subject of tuberculosis generally will come away greatly disappointed, but on the questions the Commission was asked to answer the expert will find ample material for thought.

Is the disease in animals and man one and the same?

Before this question could be answered the Commissioners had apparently to satisfy themselves that the tubercle bacilli found in animals (especially bovine) and man (*a*) were the same, morphologically, culturally, and pathogenetically; or (*b*) they differed in one or other or all of these aspects, and, if they differed, whether any modification of these aspects ever occurred under either natural or artificially produced conditions.

The conclusion at which the Commissioners arrive is that it is practically impossible to differentiate the bacillus found in the bovine animal suffering from tuberculosis from that found in certain cases of tuberculosis in the human subject. The bacilli are alike in every respect—morphology, cultural characters, and virulence. In the human subject, however, especially in cases of pulmonary tuberculosis, a type of tubercle bacillus occurs which, though resembling morphologically that found in bovines suffering from tuberculosis, differs considerably in cultural characters—*e.g.*, rate of growth on artificial media and in virulence. Both types produce rapidly progressive tuberculosis in the human subject and certain other animals, but only one, the bovine type, is specially active when introduced into the bovine animal. It is obvious, then, that wherever a tubercle bacillus is found, it may set up tuberculosis in the human subject, whatever it may be able to do in the cow. Moreover, the disease, when set up in the human subject, always runs much the same course, whether the exciting agent in its production is the one form of the bacillus or the other.

The answer to the second term of reference—"Whether animals and man can be reciprocally infected with it"—follows as a kind of corollary. There is ample evidence put forward to prove that many cases of fatal tuberculosis in the human animal (usually in children) have been set up by the bacillus proved to have been the cause of the disease in bovines. On the other hand, the type found naturally only in the human subject appears to set up in the bovine merely a non-progressive tuberculosis. It was found, however, that adult human beings are sometimes infected by the tubercle bacillus of bovine type, even the lungs becoming involved, whilst it is evident from recorded experiments that cattle have not by any means complete insusceptibility to the attacks of the tubercle bacillus of human type. These facts are of primary importance when, as is evident from the work recorded, there are such gradations in all the differentiating characters in many of the strains of bacilli separated from ordinary cases of tuberculosis in the human subject—a gradation that becomes even more marked and important in the groups of bacilli isolated (*a*) from the lesions in cases of lupus and (*b*) from the tuberculous in the horse.

Granting that the foregoing may be accepted, it follows that the third term of reference concerning the conditions under which transmission of the disease from animals to man takes place can only be answered through a study of the susceptibility (*a*) of the animal and (*b*) of man. The susceptible individual, whether brute or human, will be most affected, and by the widest range of tubercle bacilli as regards gradations of virulence. Each individual affected will constitute a centre of infection, and the greater the number of these susceptible individuals exposed even to "weak infections," the greater the chance of further transmission of the disease. It would appear that residence of a tubercle bacillus in any animal or series of animals for a considerable length of time may increase the virulence of that bacillus for the special species in which it is "cultivated." This certainly occurs in connection with other micro-organisms—*e.g.*, the pyogenic streptococci and certain forms of micro-organisms giving rise to septicæmic processes—still no direct evidence is adduced by the Commissioners that this takes place in connection with the tubercle bacilli, though in the course of their work they came across an enormous variety of grades of virulence in the tubercle bacilli from various sources in man and the lower animals. The bovine type of bacillus occurs with such frequency in children, especially in sites connected with the alimentary canal, that it seems impossible to ignore the causal relationship between tubercle bacilli found so frequently in the milk given by tuberculous cows and the tubercle in the child; whilst, on the other hand, the tubercle bacilli usually associated with pulmonary tuberculosis in the adult human subject being of the human type, have probably passed through a number of men and women, one transmitting it to the other in direct succession.

During the few days that have elapsed since the appearance of the Report some criticism has been directed against it on the ground that all the moot questions concerning tuberculosis have not been answered. This is surely unreasonable, as it cannot be too clearly recognised that the reference to the Commissioners was exceedingly closely defined. They had no authority or power to go beyond this reference. Indeed, the time—ten years—required for the elucidation of the special questions referred to them gives a definite indication of the propriety of the limitations imposed upon and accepted by the Commission.

Many and most important questions bearing on the cause and cure of tuberculosis have still to be answered. This can be done only by well-trained men working on an organised plan, co-operating whole-heartedly for a considerable period, and well supplied with financial means, facilities, accommodation, and equipment. That some organised scheme of work will be devised can now scarcely be doubted, and it is to be hoped that it will be adequately supported by Government. Such legislation has long been under consideration, and it may be that it has been held back until the appearance of this Report. Now, *bis dat qui cito dat.*

Although the Commissioners make no direct recommendation as to legislation, anyone who reads their Report can have little doubt as to their opinion on this matter, and we feel satisfied that those in high places will realise that in bringing forward such legislation as may be necessary to ensure a pure milk supply, their hands are greatly strengthened by the findings here recorded.

The Commissioners were evidently splendidly served by the Secretary and by their staff of scientific assistants, as they insist very strongly on the value of the services rendered by these gentlemen in the carrying out of the scheme of work planned at the outset.

In conclusion, it may be pointed out that one name not hitherto mentioned in connection with the formation of this Commission is that of Sir Herbert Maxwell, who, during the Congress and until the completion of the arrangements for the Commission, planned carefully and worked indefatigably to get together a thoroughly representative Commission.

THE GYROSTATIC COMPASS.[1]

MESSRS. ELLIOT BROTHERS, the English makers of the Anschütz gyro compass, are to be congratulated on the publication of an admirable account of the principle, construction, and practical use of this, the newest and most marvellous of all applications of the gyrostatic principle to a useful purpose. This book is chiefly translated from the German publication by Anschütz and Co., but the more mathematical part, due originally to Herr M. Schuler, has been modified by Mr. Harold Crabtree and Mr. Alfred Lodge so as to be more in accord with English mathematical usage. Commander Chetwynd and Commander Marston have also assisted in making those parts which deal with practice as useful as possible. With such skilled collaboration and with so admirable an original to work upon, it is not surprising that the result is so charming and instructive.

A gyrostat may be supported so that it has three (angular) degrees of freedom, or so that it has only two, one angular motion being constrained. With three degrees of freedom and really perfect balance the axis of rotation would maintain itself indefinitely in space and so the axis of rotation, if it were set parallel to the earth's axis, for instance, at any time and place would, rotation being maintained, retain that parallelism indefinitely, and show both latitude and the ship's course. The trouble is partly the difficulty of obtaining sufficient gyrostatic stability, but chiefly the impossibility of obtaining a really perfect balance, and so, however small the turning couple due to want of balance may be, precession will be set up and a cumulative error will grow and make the indications useless. If, however, the axis of a gyrostat is subjected to an elastic constraint tending to keep it level, but allowing it to tilt in spite of the constraint, and if, further, the gyrostat is supported so that no couple acts upon it in azimuth as resulting from the support, then with sufficient gyrostatic capacity the whole combination cannot rest in any position except that in which the axis is pointing north and south very nearly, and the direction of rotation is in the same direction as that of the earth. For if the axis should be in any other direction the rotation of the earth will, through the elastic constraint, tend to elevate one end of the axis and depress the other, and under this constraint the axis will precess towards the north and south direction. When, however, this direction is reached, the axis will be neither exactly level nor at rest, and the motion would, like a pendulum, continue as far to the other side if some system of damping were not introduced.

In the Anschütz gyro compass the gyro wheel is supported by a hollow steel ring immersed in mercury and with the centre of flotation a little above the centre of gravity, thus giving the necessary elastic constraint to the axis. The whole floating system (Fig. 1) is located by the compound piece, S, T, the two parts of which serve as two electric poles communicating with a three-phase motor within the gyro wheel A in the casing B. The compass card, R, is carried by the casing B. The third electric pole is supplied by the mercury, Q, and floating hollow ring, S, of steel. The whole case for the mercury, K, is carried on gymbal rings, like an ordinary compass. The gyro wheel, A, is run at a speed of 333 turns a second, and is subject to a bursting stress of 10 tons per square inch. Its axle, like that of a de Laval turbine, is sufficiently flexible to enable the wheel to establish its own dynamical axis, and it is supported on ball bearings of the highest perfection.

Beautiful as the invention is, closely as the material and construction approach perfection, perhaps no detail affords such a pleasing surprise as the system by which the damping of the motion, to which reference has been made, is effected. Side holes are provided in the casing, A, for the admission of air, and at the bottom there is a tangential opening through which a blast of hot air escapes. As something like half a horsepower is being absorbed within the casing, this air circulation affords the necessary cooling. The orifice, a, b (Fig. 2), for the escape of air is partly covered by a shutter, u, carried by a pendulum, so that when the gyro axle is horizontal the escape of air is symmetrical on either side of the shutter, but when it is inclined the escape of air is greater on that side on which the axle is elevated. The reaction due to the increased escape of air on one side tends to turn the casing round opposing the precession, and so bringing the axle towards the horizontal position. It therefore comes about that each excursion of the axle is only about one-fifth of the previous one in the opposite direction, and in about three hours from starting with axle level and 45° east or west, it has settled down steadily to its position of rest almost exactly due north and south.

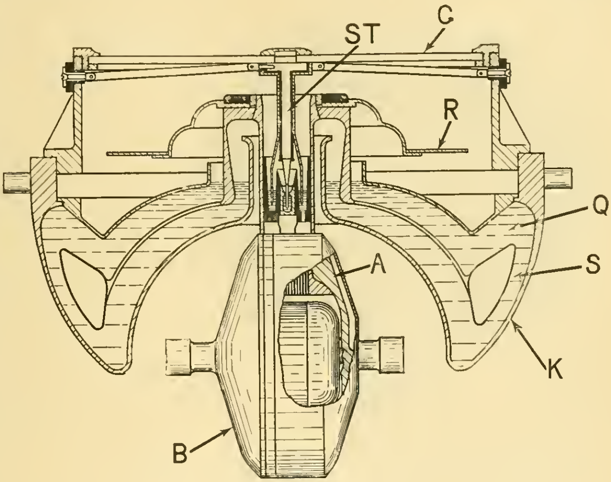

FIG. 1.—Vertical section through the centre of the gyro compass as constructed for use on board ship.

Almost exactly, but not exactly; not that there is any vagueness as to the point of rest, but because there are certain corrections, a latitude correction, with which the little weight, t, has to do, and which

[1] "The Anschütz Gyro Compass. History, Description, Theory. Practical Use." Pp. ii+109. (London: Elliott Brothers, 1910.)

can be made thereby zero for any particular latitude in one hemisphere only. There is a second correction due to the ship's motion in latitude, small and independent of the particular instrument, and there is a third correction, a ballistic correction due to change in the ship's motion in latitude. Space does not admit of these being followed out, but they are fully explained.

The directive force of the gyrostatic compass is about fifteen times as great as that of an ordinary magnetic compass undisturbed by surrounding iron. In addition, therefore, to its being undisturbed by the magnetism of the ship or the movements of heavy magnetic pieces, such as guns, a master gyrostatic compass may be set up in a protected and quiet spot low down in the ship, and there control a number of dials placed in convenient positions for steering or for taking azimuth observations. These local dials are provided with central dials geared up thirty-six times, so that a complete turn corresponds to ten degrees. With such a compass to steer by and steering

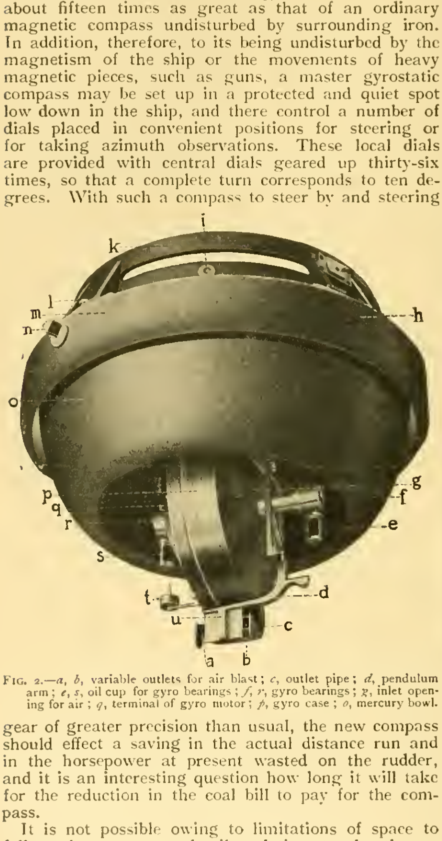

FIG. 2.—*a*, *b*, variable outlets for air blast; *c*, outlet pipe; *d*, pendulum arm; *e*, *s*, oil cup for gyro bearings; *f*, *r*, gyro bearings; *g*, inlet opening for air; *q*, terminal of gyro motor; *p*, gyro case; *o*, mercury bowl.

gear of greater precision than usual, the new compass should effect a saving in the actual distance run and in the horsepower at present wasted on the rudder, and it is an interesting question how long it will take for the reduction in the coal bill to pay for the compass.

It is not possible owing to limitations of space to follow the numerous details relating to the theory, construction, and use of this beautiful instrument, but anyone with a sense of fine mechanics will appreciate this excellent exposition, even though he may never have the chance of running the compass himself.

C. V. BOYS.

THE PRESERVATION OF ANCIENT MONUMENTS.

THE report of the Inspector of Ancient Monuments for the year ending March 31, 1911, is the first by the new inspector, Mr. C. R. Peers. There are 104 monuments under the care of the Commissioners of Works, forty-eight in England and Wales and fifty-seven in Scotland. During the last year fifteen monuments have been placed under the protection of the Ancient Monuments Acts, ten in England and Wales and five in Scotland. Eight of the newly-protected monuments are situate in Anglesey, all prehistoric monuments, three of which have recently been astronomically surveyed by Sir Norman Lockyer and others. Of the two prehistoric Orkney monuments now under protection, the Chambered Mound of Maeshowe has received the attention of the same authority.

Useful linear measures are given of the monuments noticed in the report, and in one case, as a sort of nest-egg, we have the information that the bearing of the dolmen at Trefigneth "comes within one degree of the line of the winter solstice." Never a word is found referring to the available astronomical surveys, while it may safely be asserted that the formal protection of the Anglesey and Maeshowe monuments is largely due to the local interest awakened in the astronomical inquiry. In connection with the statement that "no adequate record has up to the present time been kept of the treatment of each monument year by year," surely the annual reports issued by the Pembrokeshire archæologists should have been mentioned.

"Certain observations of a general character" are most timely and important. "The first Ancient Monuments Act has now been in operation for twenty-nine years. Of the fifty-one prehistoric monuments scheduled by it as worthy of preservation by the State, twenty-six have been placed under its provisions, by the consent of the owners, while the rest, for various reasons, have not been so placed. In regard to these latter, the position of the State is entirely unsatisfactory, and these monuments are in a worse case than if they had not been noticed in the Act." The second Act of 1900 has a wider scope, with the grand result that we have now three castles and three monastic buildings added to the State waifs and strays! This report, like others of its kind, reveals the deplorable ineffectiveness of high-sounding measures. It also shows that where a scientific survey of a monument is first made and the results duly published, owners of such properties are among the first to recognise the necessity for effective protection. Lord Boston, Lord Sheffield, and Major Fox-Pitt have nobly led the way in Anglesey. The first and foremost factor in the case is scientific inspection, and monuments are best preserved in accurate measures.

JOHN GRIFFITH.

THE PORTSMOUTH MEETING OF THE BRITISH ASSOCIATION.

IN about six weeks' time, on August 30, the citizens of Portsmouth will have the privilege of welcoming the members of the British Association for their annual meeting. In many respects this meeting will be a contrast to that at Sheffield last year. Portsmouth cannot offer the attractions of large engineering works or manufactories, but at the same time it holds a unique position as the first naval port of the United Kingdom, and one of the most ancient of its boroughs. The borough of Portsmouth fifty or sixty years ago included only a small portion of the island of Portsea, on which the town is situated. There were walls and gates (which were closed every day at sunset) and a military governor. The walls are gone, but some of the old parts of the town are still well worth a visit. Three years ago the borough boundary was enlarged, now including the whole of the Island of Portsea.

Opportunity will be offered to members of the British Association to inspect the old corporation plate dating from Queen Elizabeth onward, and the old charters of the town, covering the last 500 years, can also be seen in the Town Hall, and are of great interest. The population of the borough has increased during the last decade by upwards of 40,000, the number of inhabitants, as shown by the census just completed, being about 232,000.

Not being a university or large industrial centre, Portsmouth cannot perhaps boast of as many large halls as other cities in which the association has met, but the accommodation will be found quite adequate. The general reception room will be in the Connaught Drill Hall, which is the headquarters of the 3rd Hants Volunteers. Here will be obtained all the literature relating to the meeting, tickets for excursions, postal facilities, &c. Most of the sections will be housed in the Municipal Technical College, a fine building, erected about four years ago at a cost of more than 70,000*l*., and situated close to the Town Hall. This latter building itself will probably accommodate one or two of the sections, and is a magnificent edifice resembling the Town Hall, Leeds. As mentioned above, there are no large works, but several of the excursions will deal with objects of naval interest, such as visits to battleships, the dockyard, Whale Island (the gunnery school), or the *Vernon* (the torpedo and wireless telegraph instruction ship). Other excursions will include visits to Arundel Castle and various parts of the South Downs, and to the Isle of Wight. The Mayor proposes to give a garden-party to all members of the association, as well as a banquet to all the officers.

A good local guide-book is now well in hand, by the aid of which visitors will be able to find their way to the numerous objects of interest without difficulty, and also acquire much interesting information with regard to the borough and environs generally. If the number of visitors is large, the question of accommodation may present some difficulty. The best available accommodation in lodging-houses will probably soon be exhausted, as even at the end of August there are still a considerable number of visitors in the town. There are plenty of hotels, but in view of the above facts it will be well to apply early to the local secretaries for particulars of housing accommodation, as if the housing question is left until a few days before the meeting the choice may be very limited. There is no doubt, however, that the town and outlying districts will be able to accommodate as many as attend the meeting.

Portsmouth has during the last few weeks taken a prominent part in the Coronation Naval Review, and this has to a slight extent interfered with the meetings of the various committees which are dealing with the British Association gathering. Arrangements will, however, now go ahead fast under the guidance of the local secretaries, and in a few weeks we hope to publish further details respecting the meeting, which promises at present to be well up to the standard of any of its predecessors, both as regards work and pleasure.

It will be seen from the subjoined provisional programmes received from recorders of sections, that the scientific proceedings of the meeting promise to be of interest and importance.

Provisional Programmes of Sections.

Section A (Mathematical and Physical Science).—The presidential address, by Prof. H. H. Turner, will be delivered at 10 a.m. on Thursday, September 1. Three discussions have been arranged: one on the principle of relativity, to be opened by Mr. E. Cunningham; one on stellar distribution and movements, to be opened by Mr. A. S. Eddington; the third (in conjunction with Section G) on mechanical flight, with Mr. A. E. Berriman as opener. The following papers have been promised:—Prof. Pettersson, on great boundary waves; parallactic tide set up in the bottom layers of the sea by the moon; Prof. F. T. Trouton, on peculiarities in the adsorption of salts by silica; Major Hills, on the infra-red spectrum; Prof. F. R. Watson (of Illinois), on the effects of air currents on sound; Prof. L. Vegard (of Christiania), on the properties of the radiation producing aurora borealis; and by Prof. W. H. Bragg, on the corpuscular nature of rays.

Section B (Chemistry).—*Discussion on colloids:* The theory of colloids, Prof. Freundlich; (1) colloids in pharmacy, (2) the blue absorption compounds of iodine with starch and other substances, Dr. G. Barger; the colloid theory of cements, Dr. C. Desch; adsorption of bromine by graphite, Dr. E. Wechsler. *Discussion on indicators and colour:* The origin of general and of specific absorption, Dr. T. M. Lowry; absorption spectra of vapours, J. E. Purvis; absorption spectra and refractive power of metallic vapours, P. V. Bevan; the use of indicators in modern physico-chemical research, H. T. Tizard; the application of methyl orange for the determination of the affinity constants of weak acids and bases, Dr. V. H. Veley. Joint meeting with Agricultural Sub-Section (Monday). Discussion on the part played by enzymes in the economy of plants and animals, opened by Dr. E. Frankland Armstrong; some points in the treatment of wheaten flour, A. E. Humphries. *Papers:* Optically active systems containing no asymmetric carbon atom, Prof. W. H. Perkin and Prof. W. J. Pope; the diffusion of gases through water, Prof. C. Barus; the compressibility of mercury, Dr. W. C. Lewis. *Reports:* Electric steel furnaces, Prof. A. McWilliam, and those of the Research Committees.

Section G (Mechanical Science).—Joint discussion with Section A on aëronautics, opened by Mr. A. E. Berriman; over-type superheated steam engine, Captain H. Riall Sankey and Mr. W. J. Marshall; suction gas plants, Mr. Tookey; Diesel engines, Mr. Chas. Day; the vibragraph, Mr. Digby; experiments on wireless telegraphy, Prof. G. W. O. Howe; electrical steering, Mr. Haig; electrical drives for propellers, Mr. H. A. Mavor; smoke abatement, Dr. J. S. Owens; on the origin and production of corrugation on tramway rails, Mr. Worby Beaumont; crude oil marine engines, Mr. J. H. Rosenthal; portable wireless telegraphy equipment, Captain H. Riall Sankey; the gyro compass, G. K. B. Elphinston; the single-phase repulsion motor, T. F. Wall.

Section H (Anthropology).—The proceedings promise to be as interesting and as varied as usual. The chief feature will be a discussion on totemism, to be opened by Dr. Haddon, and to which papers are to be contributed by a number of distinguished foreign guests of the section, including Dr. Kohler, Prof. Graebner, M. A. Van Gennep, Prof. Hutton Webster, and Dr. Goldweiser; among the English anthropologists who hope to be able to contribute papers or to take part in the discussion are Prof. Frazer, Mr. Hartland, Dr. C. G. Seligmann, and Mr. R. R. Marett. Archæological papers will cover a wide field. Miss Adela C. Breton will exhibit paintings and frescoes from the Temple of the Tiger, Chichen Itza, and other ruins in Mexico and Yucatan, and will describe some recently discovered Costa Rican and Peruvian painted vases. She will also give an account of the present position of archæological study in Peru. European archæology will be covered by an important paper on the recent discovery of pleistocene man in Jersey by Mr. R. R. Marett, who has been in charge of the excavations of the caves in which the remains have been discovered; Dr. A. Keith, in a series of papers on palæolithic man will describe a second skull recently discovered in the same locality, and said to be from the same level as the well-known Galley Hill skull, a skull of Magnon type from Dartford, and remains of a pygmy race from Spain. Among papers dealing with the Mediterranean and Egyptian area may be mentioned Prof. G. Elliot Smith's paper on the foreign relations and influence of the Egyptians under the Ancient Empire, and Prof. Flinders Petrie's account of the Roman portraits discovered by him in Egypt during the last season's excavations. In ethnography and the study of religions, the papers to be contributed by Mr. W. Crooke on the cow and the milk, Major A. J. Tremearne's notes on Hausa folklore, M. Malinowski on the economic functions of magic, and Dr. C. G. Seligmann on the divine kings of the Shilluk, are of interest and importance. Mr. J. Gray will bring before the section the important question of the institution of an imperial bureau of anthropology, while a cognate matter will be discussed in a paper by Mr. H. Peake, in which the author urges the desirability of instituting an anthropometric survey of Great Britain.

SECTION I (PHYSIOLOGY).—Presidential address, Prof. J. S. Macdonald; discussion on ventilation in confined quarters, especially in relation to ships, Dr. L. Hill, Prof. N. Zuntz, Mr. L. Woolhard; discussion on inhibition, opened by Prof. C. S. Sherrington, followed by Mr. Keith Lucas, conduction between muscle and nerve, with special reference to inhibition, and Prof. J. S. Macdonald; frequency of colour-blindness in males, Dr. Edridge-Green; heat production and body temperature during rest and work, Prof. J. S. Macdonald and Dr. J. E. Chapman; rhythmical stimulation of cooled frog's nerve, Dr. J. Tait; electrical stimulation of the frog's heart, Dr. J. Tait; photochemical changes in yohimbine solutions, Dr. J. Tait and Dr. J. A. Hewitt; some considerations on the influence of hæmoglobin in the hæmolysis of red blood corpuscles, Dr. H. E. Roaf; the chemistry of heat coagulation of proteins, Dr. Harriette Chick and Dr. C. J. Martin; new researches on phagocytosis, Prof. H. J. Hamburger; a photometer for hetarochromatic photometry, Prof. C. S. Sherrington; model to illustrate Listing's law of the movements of the eyeball, Prof. C. S. Sherrington; comparison between the nervous taxis of the cat's knee and that of the anthropod claw, Miss S. C. M. Sowton and Prof. C. S. Sherrington.

SECTION K (BOTANY).—Presidential address, Prof. F. E. Weiss. Joint meeting with Sections C and E on the relation of the present plant population of the British Isles to the Glacial period, opened by Mr. Clement Reid. Discussion on the principles of constructing phyto-geographical maps. Semi-popular lecture, by Mr. Francis Darwin. *Papers:* Some petrified Jurassic plants from Scotland, Prof. A. C. Seward; recent work on the Jurassic plants of Yorkshire, H. H. Thomas; the structure of the oldest known synangium, and its bearing on the origin of the seed, Dr. M. Benson; on the mode of formation of the Pettycur material as gathered from internal evidence; a fifteen-year study of advancing sand-dunes, Prof. H. C. Cowles; new proposals in ecology, Prof. F. E. Clements; phytogeography as an experimental science, Prof. Massart; the vegetation of pebble beaches, Prof. F. W. Oliver; the brown seaweeds of a salt-marsh, Miss S. M. Baker; the Swiss National Park and its flora, Prof. C. Schröter; the water-content of acidic peats, W. B. Crump; the wilting of moorland plants, W. B. Crump; the presumptive hybrid *Anagallis carnea*, Prof. F. E. Weiss; the morphology of leguminous nodules, Prof. Bottomley; nuclear osmosis as a factor in mitosis, A. A. Lawson; nuclear division in Spongospora, A. S. Horne; the polyphyletic origin of the Cornaceæ, A. S. Horne; the transference of sugar from the host plant to a parasitic Cuscuta, S. Mangham.

SUBSECTION AGRICULTURE.—Presidential address, Prof. W. Bateson; cider sickness, B. T. P. Barker and Mr. Hillier; the effect of grass on apple trees, S. U. Pickering; the inheritance of strength in wheat, Prof. T. B. Wood; crystalline nitrogenous constituents of mangolds, Prof. T. B. Wood; suggestions relating to the existing system of imperial avoirdupois weights, J. Porter. Discussion on bacterial diseases of plants, opened by Prof. M. C. Potter; bacterial diseases of the celery and swede, J. H. Priestley; bacterial gum diseases, F. T. Brooks; bacterial diseases of the potato plant in Ireland, Dr. G. H. Pethybridge; experiments on the wart disease of potatoes, G. T. Malthouse; potato disease, A. S. Horne. *Discussion:* How best may the university agricultural departments come into contact with the farmer, Principal Ainsworth Davis; the American and Canadian systems, R. Hart-Synnot; the place of the agricultural instructor, J. H. Burton. Joint discussion with the Chemical Section. The part played by enzymes in the economy of plants and animals. Popular lecture by Mr. A. D. Hall, the soils and farming of the Southdowns; commercial ovariotomy in pigs, F. H. A. Marshall and K. J. J. Mackenzie; temperature variations during the œstrous cycle in cows, F. H. A. Marshall and K. J. J. Mackenzie; the effects of ventilation on the temperature and carbon dioxide of the air of byres, J. Hendrick; the effect of minute electrical currents on the growth and metabolism of bacteria, Prof. J. H. Priestley and Miss E. M. Lee; the effect of high tension electric discharges and current electricity on plant respiration, Prof. J. H. Priestley and Mr. R. C. Knight; the effect of pyrophosphates on animals, Dr. J. A. Gardner; application of genetics to horse-breeding, C. C. Hurst; the inheritance of milk yield in cattle, J. Wilson. The *chief features* of the programme are: Discussions on problems at present of great importance in agriculture: (1) Bacterial diseases of plants; (2) the University Agricultural Departments and the practical farmer; (3) the *rôle* of enzymes in the economy of plants and animals; (4) some important live stock questions; (5) semi-popular lecture: a scientific study of the local agriculture.

NOTES.

THE Brussels correspondent of *The Times* announces that Prof. W. Spring, professor of general chemistry in the University of Liège, died on July 17 after an operation on the throat.

THE Council of the Royal Society of Arts attended at Clarence House on Friday, July 14, when the Duke of Connaught, president of the society, presented its Albert Medal to the Hon. Sir C. A. Parsons, F.R.S., "for his experimental researches into the laws governing the efficient action of steam in engines of the turbine type and for his invention of the reaction type of steam turbine and its practical application to the generation of electricity and other purposes."

A MEETING of the Institution of Mechanical Engineers will be held on July 25 and 26, at Zürich. The meetings will be held in the Swiss Polytechnikum. Among the papers to be read may be mentioned:—Electric traction in Switzerland, by Mr. E. Huber-Stockar, of Zürich; results of experiments with Francis turbines and tangential (Pelton) turbines, by Prof. Franz Prášil, of Zürich; some new types of dynamometers, by Dr. Alfred Amslér, of Schaffhausen; rack-railway locomotives of the Swiss mountain railways, by Mr. T. Weber and Mr. S. Abt, of Winterthur; high-pressure water-power works, by Mr. L. Zodel, of Zürich.

THE annual general meeting of the Society of Chemical Industry was held last week in Sheffield, under the presidency of Mr. Walter F. Reid, a summary of whose address appears elsewhere in this issue. Dr. Rudolf Messel, of London, was elected president for the ensuing year. The applied science department of the University was visited, and in an address given to the visitors, Prof. Arnold said that for the future students of the Royal School of Mines, if they wish to obtain the School of Mines diploma for iron and steel metallurgy, must take their fourth year of study in the metallurgical department of the University of Sheffield, and must pass its examination. Numerous visits were made to factories in and near Sheffield, and the visitors were entertained at several receptions.

AN important Act has been adopted by the New York legislature dealing with the sale in New York State of wild American game. Owing to the efforts of Senator H. R. Bayne to secure the passing of the Bill, the new Act is often called the Bayne law. Stated briefly, the new law prohibits in New York State, at all seasons, the sale, or importation for sale, of any species of American wild game, save hares and rabbits. These rodents have been declared a pest to fruit-growers. No longer will it be possible for ruffed grouse, pinnated grouse, any American quail, woodcock, snipe, or any American shore-bird, wild goose, brant, or wild ducks of any species, to be sold in the State of New York, no matter where they may have been killed. The Bayne law provides, however, that certain species of game that can be reared successfully in captivity, and killed by hand, may be sold and consumed, under certain restrictions.

The twenty-sixth congress of the Royal Sanitary Institute is to be held in Belfast on July 24 to 29. Dr. Louis C. Parkes, deputy-chairman of the council of the institute, will deliver a lecture to the congress on "The Prevention of Tuberculosis: A National Task." Prof. H. R. Kenwood will deliver the popular lecture on "The Open Window." More than two hundred authorities, including foreign and colonial Governments, Government departments, county councils, county boroughs, and other sanitary authorities, have already appointed delegates to the congress; and as there are over four thousand members and associates in the institute, a large attendance is expected. A health exhibition of apparatus and appliances relating to health and domestic use will be held, as practical illustration of the appliances and carrying out of the principles and methods discussed at the meetings. There will be many exhibits relating to the planning of cities and towns arranged by the executive committee of the Town Planning Exhibition. The meetings of the congress have been arranged in two sections, one concerned with sanitary science and preventive medicine, the other with engineering and architecture. Conferences have been arranged during the meeting of municipal representatives, port sanitary authorities, medical officers of health, engineers and surveyors, veterinary inspectors, sanitary inspectors, women on hygiene, and on the hygiene of childhood. The local honorary secretaries are Messrs. W. H. Bailie, J. Munce, and J. G. Harris.

The fifteenth International Congress on Hygiene and Demography will be held in Washington, D.C., from September 23 to 28, 1912, under the honorary presidency of the President of the United States. Dr. H. P. Walcott, president of the State Board of Health of Massachusetts, will be the active president. Twenty-two Governments have accepted already an invitation to participate, and in addition each of the States of the Union has received an invitation which includes its contained cities. The committee on organisation includes Dr. Hermann Biggs, Dr. John S. Billings, Prof. R. H. Chittenden, Prof. Irving Fisher, Prof. Theobald Smith, and Prof. W. H. Welch. The secretary-general is Dr. John S. Fulton, Army Medical Museum, Washington, D.C. The official languages will be English, French, and German. The work of the congress will include an exhibition of recent progress and the present condition of the public health movement in the cooperating countries, and scientific meetings. For the latter the congress will be divided into nine sections. The sections, with the presidents, are:—(1) Hygienic Microbiography and Parasitology, Prof. Theobald Smith; (2) Dietetic Hygiene, Hygienic Physiology, Prof. R. H. Chittenden; (3) Hygiene of Infancy and Childhood and School Hygiene, Dr. A. Jacobi; (4) Industrial and Occupational Hygiene, Dr. G. M. Kober; (5) Control of Infectious Diseases, Dr. Hermann Biggs; (6) State and Municipal Hygiene, Dr. Frank F. Westbrook; (7) Hygiene of Traffic and Transportation, Dr. W. Wyman; (8) Military, Naval and Tropical Hygiene, Dr. H. G. Beyer; (9) Demography, Prof. Walter J. Willcox. Inquiries and applications for membership should be addressed to the secretary-general.

The account in the July issue of *Man*, by Miss A. C. Breton, of some of the museums of archæology and ethnology in America, will excite among British students of these sciences mingled feelings—admiration at the enterprise and liberality of the American people, and regret that the contrast between the institutions of America and those in England is so clearly to our disadvantage. The museums described in this paper are the New York Natural History Museum, the Brooklyn Institute, the Peabody Museum of Harvard College, the Yale University Museum, the Philadelphia Academy of Sciences, the National Museum at Washington, and the National Museum of San José, Costa Rica. Practically all these representative collections are provided with suitable buildings and adequate staffs; each has its library, to which access is readily permitted, and arrangements are made by which the officials usually spend part of each year in field work, and are thus in a position to supply to inquirers first-hand information.

The present uncertainty of some of the evidence on the ethnology of the Australian race is embarrassing to those who are engaged in the study of the aborigines of that continent. Prof. Frazer, for instance, in his recently published treatise on "Totemism and Exogamy," bases his conclusions regarding the customs of the Arunta tribe on the researches of Messrs. Spencer and Gillen, and dismisses the sources upon which the Rev. Mr. Strehlow has drawn in his description of another branch of the same tribe as "deeply tainted." Again, in the July issue of *Man* Mr. R. S. Mathews contradicts the statement of Dr. Howitt that descent among the Kaiabara tribe is patrilinear, and suggests that this error has led Mr. A. Lang into erroneous conclusions regarding them. Mr. Lang, again, in the June issue of *Man*, disputes Mr. Mathews' view that the phratries represent two ancient distinct races, one of the Papuasian type, with curly hair, the other fairer, with straight hair, akin to the Dravidians and Veddahs. It is much to be desired that the Federal Government, by the establishment of an ethnological bureau or by the appointment of a special commission, should undertake an official investigation into the ethnology of the aborigines before they finally disappear, and arrange for the preparation of a series of authoritative monographs on the native races, such as the valuable series which we owe to the enlightened Government of the United States on the American Indians.

In *The Entomologists' Monthly Magazine* for July, Mr. E. G. Bayford directs attention to the potency of electric light in attracting insects, and its consequent value to collectors, more especially those to whom beetles are the chief favourites.

To *Naturwissenschaftliche Wochenschrift* for July 2, Mr. P. J. du Toit, of Zürich, contributes an elaborate and well-illustrated summary of Dr. Broom's views with regard to the derivation of mammals from the theromorphous or (in the wider sense of the term) anomodont reptiles. After referring to the development of the idea of the existence of such a relationship, the author describes the mammalian features observable in the theromorphous limb-skeleton and limb-girdles, and then proceeds to discuss Seeley's views as to the reptilian nature of Tritylodon. While admitting the possibility of that genus being a mammal, Mr. du Toit points out that its resemblances to the theromorphs are so marked that there is considerable justification for including it in that group. As regards the mammalian features in the theromorph skeleton, the following are regarded as the most important:—The union of the pubis and ischium to form an innominate bone, which is unknown in any other reptiles except certain chelonians. An entepicondylar foramen to the humerus, found also in the tuatera. The fusion of the coracoid with the scapula—paralleled among certain salamanders. The differentiation of the teeth into series. The union of the quadrate with the adjacent elements of the skull. The relations and mode of articulation of the two-headed ribs. The resemblance of the tarsus (especially as regards the tibio-tarsal position of the line of flexure) and phalanges to those of the monotremes. These features become more and more pronounced in the specialised types until they culminate in a form like Tritylodon, which may be regarded as a reptile actually in process of conversion into a mammal. By an increase in the length and strength of its limbs, accompanied by increasing power of sustained locomotion, and likewise by a special development of its dentition and jaws, one of the primitive theriodonts acquired, in consequence of this greater activity, a better kind of blood-circulation, warm blood, and a mobile, hairy skin—in other words, became a mammal.

PROMINENT among the articles in *Tropical Life* (June) is an account of two plantations of Ceara rubber in German East Africa. In this colony the trees of *Manihot Glaziovii* mature so rapidly that tapping of a very light nature is permitted already, in the third year. At this stage the incision method of pricking necessitates careful manipulation, and is said to produce about ½ lb. of rubber per tree. In the first instance the trees were planted about 10 feet apart; but latterly a more open formation, in which they are set 13 feet apart, has been adopted. The chief pest is the white ant, which has to be combated by discovering and destroying its communities.

AN article on the Coniferæ, communicated by Dr. A. W. Gothan to *Naturwissenschaftliche Wochenschrift* (June 18), deals mainly with the distribution of the various subfamilies in past epochs as compared with their distribution at the present time, but the author takes the opportunity of referring to changes in family relationships that have been proposed as a result of paying more attention to vegetative characters; in this connection reference is made to the proposition enunciated by Dr. F. Vierhapper, that the Taxaceæ, Taxoideæ, and Cupressineæ should be united in one family, the Taxocupressaceæ, on account of similarity in wood and leaf structures. The author also directs attention to the interest attaching to the fossil genus Baiera as a constituent of the group of Gingkophyta.

THE sweet potato, *Ipomoea Batatas*, is one of those cultivated products of which the origin may be conjectured, but cannot be positively determined, and the varieties are so numerous and confused that identification and classification present unusual difficulties. These complexities are discussed in a bulletin issued as vol. iv., No. 1, of Contributions from the Botanical Laboratory of the University of Pennsylvania, where the author, Dr. B. H. A. Groth, describes a novel analytical method of scheduling that offers certain advantages, as in the incorporation of new forms. Representing each character by a letter, and the different variants of this character by numbers, each variety is scheduled under a series of arbitrary marks; thus the index of the variety Georgia begins A1B2C1D1 . . ., while A2B2C2D2 . . . is the beginning of the index of the variety Ticotea.

WE learn from *The Agricultural News*, No. 236, that the Botanic Gardens of St. Vincent contain the only known specimen of *Spachea perforata*, a large tree estimated to be at least 100 years old. The leaves are lance-shaped, while the flowers are borne in terminal racemes, each flower containing small rosy petals and stamens, which are all fertile; the fruits are small. It is further stated that the flowers are distinct and attractive, and produced in great profusion; they are largely visited by bees. The tree is not only of botanical interest, but is decorative as well.

FROM the report on the operations of the Department of Agriculture of the Madras Presidency, 1909–10, recently to hand, it is possible to obtain a fair general idea of the work a handful of Englishmen are doing among the natives in improving systems of agriculture that have for centuries remained unchanged. Much of the time of the staff is occupied in teaching; but the value of their work is being increasingly recognised, and numerous samples are now sent in to the laboratories for report. Each year the report shows that some fresh progress has been made and some new economy discovered; the value of drilling seeds, of saving on the seed rate, and other matters are dealt with here.

THE Bulletin of the Department of Agriculture, Jamaica, vol. i., No. 4, contains an excellent account, by Mr. Cousins, of the cultivation of the banana and the conditions under which success has been attained. Restricted as this plant was in the early days to virgin soils only, it was thought to be a crop that must soon cease to count in the islands. But the growers have learnt how to irrigate bananas, and also how to grow them on heavier types of soils, so that now there seems no obstacle to their cultivation wherever they would be thought useful. There are also some articles on local farm animals that will be of much interest to the technical reader, and, as usual in this publication, some excellent illustrations. Altogether the bulletin is an excellent number, on which its editor may be congratulated.

IT has long been recognised that a liberal supply of protein is necessary for dairy stock, and the earlier German investigations pointed to the conclusion that a cow in full milk should receive 2·5 lb. of digestible protein daily per 1000 lb. live weight, and that the albuminoid ratio, *i.e.* the ratio of digestible protein to non-nitrogenous foodstuffs should be 1 : 5·4. But practical men soon began to depart from these values, and investigations in America justified their action, showing that less protein was necessary. An investigation recently published by Messrs. Woll and Humphrey, and published as Research Bulletin No. 13 of the University of Wisconsin Agricultural Experiment Station, while emphasising the need of an ample protein allowance, brings out the fact that only large milk-yielders can economically receive a large protein diet.

COLORADO affords an interesting example of a country formerly devoted to ranching, and now becoming more closely settled, and consequently requiring a more general system of farming. An agricultural college and experiment station has for some time been engaged in studying the numerous problems involved in the transition, and the members of the staff issue frequent bulletins giving advice to settlers. No subject is too trivial for study; among a batch recently to hand is one on the care of farm machinery, and another showing how to build a wall or a house of adobe, a local soil that may be made to set like concrete. Exportable crops like fruit and potatoes naturally come in for considerable attention, and directions are also given for raising such crops as are needed for home consumption.

MR. E. C. ANDREWS, of the Mines Department of New South Wales, has issued in the Journal of the Royal Society of New South Wales (vol. xliv., 1911, pp. 420–480), an interesting paper on the structure of eastern Australia. He adopts the view that Australia has not been subjected to any recent folding, and that the main features of its present relief are due to vertical earth movements. Australia has been thus divided into a western "horst" and an area of Eastern Highlands separated by the Great Plains. The Eastern Highlands are a peneplane, which, according to the author, were in Miocene times but little above sea-level.

The whole of the eastern coast of Australia is a geographical unit, and is due to a series of step faults. Mr. Andrews accepts this coast as constructed on the Pacific type. He holds that Australia was uplifted at the end of the Tertiary, and the resultant plateau has since been deeply dissected by the formation of the canyons. For the period of the uplift he proposes the name of the Kosciusko Period after the highest part of the plateau. His paper includes a valuable list of the fault scarps and sunken areas in eastern Australia.

A RECENT number of *The Geographical Journal* (vol. xxxvi., pp. 537–553) includes a valuable paper by Messrs. A. E. Kitson and E. O. Thiele on the geography of the Upper Waitaki basin in New Zealand, illustrated by a series of beautiful photographs. The authors describe the structure of this country in some detail, and with especial reference to its glaciation. In opposition to Haast's view, that the country was a plateau dissected by glacial action, they claim that the great valleys were all formed in pre-glacial times. From the authors' summary of the recent literature on the glacial geology of this part of New Zealand, it appears to be now generally accepted that the glaciers have only modified valleys which were pre-glacial in origin. The authors conclude that the lakes, valleys, and fiords originated along radial fractures. Their work throws considerable doubt upon the existence of the ice sheet, which is supposed by some authors to have covered most of the South Island of New Zealand. The three great lakes of the Waitaki basin are shown to be moraine dammed.

THE Board of Education has issued the reports for the year 1910 (price 9*d*.) on the Geological Survey, the Geological Museum in Jermyn Street, the Science Museum at South Kensington, and the work of the Solar Physics Committee. The activity of all these bodies represents an important contribution by the State to scientific education. We note that, among many practical questions considered by the Survey, building stones are to be placed on the roof at Jermyn Street for comparative tests of the effect of the London atmosphere. We have also received three recent publications of the Geological Survey from the Board of Agriculture and Fisheries. Mr. Strahan describes the geological model of Ingleborough and district, now in the museum at Jermyn Street. This pamphlet (price 4*d*.) is beautifully illustrated by a geological map and a photograph of the model before colouring, and will appeal to teachers of geography. Dr. B. N. Peach provides another educational pamphlet in his "Description of Arthur's Seat Volcano" (price 6*d*.), which includes a geological map showing the relation of the mass to the city of Edinburgh. Messrs. Reid, Barrow, and Dewey have written the explanation of the colour-printed sheets 335 and 336 of the English map (price 1*s*. 6*d*. each), the memoir being on the country around Padstow and Camelford (price 2*s*. 3*d*.). The petrography is of interest, especially in connection with the pillow-lavas, and the district includes old workings for stream-tin, pits in china-clay, and the great quarry of Delabole in slate of Devonian age. A quarto palæontological memoir by Mr. T. Thomas deals with the British Carboniferous Orthothetinæ (price 2*s*.), and is accompanied by a fine plate by Mr. Brock.

THE officiating director-general of Indian observatories (Mr. J. H. Field) has issued a memorandum, dated June 8, on the conditions prevailing before the advance of the south-west monsoon of 1911. The monsoon rainfall in India is known to be affected by many external conditions, and among those believed to be the most important are the barometric pressure in South America and the Indian Ocean and the snowfall in North-west India, &c. After examining these conditions on the plan adopted by Dr. Walker, it is estimated that the total rainfall for the period June–September will not differ from the normal by more than about 5 per cent., a defect being more likely than an excess.

THE results of rain and river observations made in New South Wales during 1903–8 have been published by the Commonwealth Bureau of Meteorology. These include all available rainfall totals from 2298 stations, with monthly maps and notes for each of those years. In addition to the rain maps and tables for the above period, the records are given for all previous years. These values have been included in an average map for all stations for which means of not less than fifteen years were available; some of the results of this map were referred to in NATURE of September 22, 1910. The list of heavy daily rainfalls previously published by the late Government astronomer has also been brought up to date.

THE Akademische Verlagsgesellschaft of Leipzig has issued a small pamphlet on "Radiumnormalmasse und deren Vervendung bei radioaktiven Messungen," by Prof. Rutherford. It deals with the necessity of producing an international standard of radium, which has arisen owing to the differences recently discovered between the standards used in different countries. For the comparison of standards it suggests a compensation method, depending on the use of a constant source of radiation like uranium oxide and of the inverse square law. For small standards, such as are used in the determination of the radium content of rock specimens, solutions of radium salts containing one millionth of a milligram of radium per cubic centimetre are suggested. The conclusions as to the establishment of the radium standard arrived at by the Brussels conference last year are reproduced. They have already been given in these columns (October 6, 1910, vol. lxxxiv., p. 430).

THE *Revue General des Sciences* for June 30 contains the annual *revue* of astronomy for the year 1910 by M. P. Puiseux, of the Paris Observatory. It is divided into sections, which are devoted to planets and comets, the sun, the stars and nebulæ respectively. In the first section, the work of Cowell and Crommelin on Halley's comets, of Eddington on the theories of formation of the tails of comets, of Backlund on Encke's comet, and of Lowell, Campbell, and Albrecht on the markings of Mars, all receive attention. The section on the sun is devoted mainly to the work of Hale and of Deslandres on the constitution of sun spots; that on the stars to the spectroscopic work which has been done in order to determine the motions in the line of sight of a greater number of stars, and so provide means of testing more accurately the theories of Kapteyn and of Eddington that there exist two lines of main drift in their proper motions.

IT is difficult for anyone with normal colour-sense to appreciate the mental picture of a colour-blind person. An interesting experiment for illustrating what is seen by people with a defective red sensation—the commonest form of colour-blindness—has been devised by Mr. C. R. Gibson. The device consists of a pair of spectacles with plane signal-green glasses and a series of coloured wools. When the glasses are put on, of course, no red rays can enter the wearer's eyes, so he is in the position of a person who cannot distinguish red as a colour. He will thus match scarlet wool with black, yellow with green, pink with light blue, or crimson with dark blue, and will see any coloured object as the majority of colour-blind people see them. The experiment is instructive as well as amusing, and it provides a simple means of realising the effects of colour-blindness. The spectacles and wools are manufactured by Mr. J. Trotter, optician, Glasgow, and the price at which they are sold is 2*s*. 6*d*.

We have received from Messrs. Isenthal and Co. their latest publication on Moscicki condensers, and Giles valves as applied to the protection of electric power transmission lines against atmospheric disturbances and surges. High-tension condensers for radio-telegraphy in particular are also dealt with. The publication is exceedingly well produced, the theory of surges and the practice of line and station protection being dealt with in part i., while part ii. deals chiefly with condenser batteries and choking coils and radio-telegraphy. A summary of the contents of various standard books dealing with these subjects is briefly given and set out with remarkable clearness in the brief description given. A noteworthy chapter is that dealing with the selection and design of plant, including generators, motors, transformers, and switches, and some very useful tables are included, giving safety coefficients for cables. The pamphlet is well illustrated with photographs and diagrams of the apparatus described. The Moscicki condensers and Giles valves are once again very fully dealt with, together with a list of places where they have been installed.

Messrs. Watson's price list of apparatus for electro-therapy and diagnosis is too well-known to require detailed description. The novelties are principally found in the therapeutic section. The "Prana" carbon dioxide snow apparatus is described and illustrated. It is intended for the treatment of nævi and lupus, warts, and other superficial diseases. The apparatus is made in three different sizes. The carbon dioxide is contained in a cylinder, and is allowed to escape into a receptacle which permits of free evaporation with the production of carbon dioxide snow in the form of a crayon 5 inches long by 1 inch or ½ inch in diameter. A special high-frequency apparatus is constructed for diathermy or thermo-penetration. In this apparatus the heating effect of the high-frequency current is encouraged and used. Considerable benefit appears to have been obtained in various rheumatic conditions and neuralgia, sciatica, &c. These new high-frequency currents are at a voltage less than 3000 volts, but currents of 500 to 3000 milliamperes are used, and with the strongest doses the patient feels absolutely nothing except the increase in temperature. Thermometers introduced in animals prove that the increase is internal, and greatest in the path between the electrodes. Beyond the effects produced by the heat there are no other physiological or chemical effects. When the current is employed long enough, albumin coagulates; and tumours, &c., can be destroyed by these means: coagulated tissues behave like foreign bodies, and are gradually expelled. In the radio-active substances meso-thorium, of the same activity as pure radium bromide, is quoted for at the price of 12*l*. 10*s*. per milligram. Radio-thorium is listed at the price of 1*l*. per gramme. Several special radium applicators are illustrated.

Engineering for July 14 contains an illustrated description of a "Stock" oil-fired converter which is in operation at the works of the Darlington Forge Co., Ltd. All classes of steel can be manufactured in this converter, from soft-steel castings to special steels of the highest class. In form it resembles the ordinary Bessemer converter; it is lined with ordinary silica fire brick, and is used, not only for the conversion or blowing of iron, but also for melting the actual charge of iron and scrap by means of oil fuel, no separate cupola being required. The oil fuel—crude petroleum—is used for melting the charge, and when this has been effected the oil pipes are withdrawn and blowing commences. The air does not enter at the bottom and pass up through the molten metal as in a Bessemer converter, but is blown down on the top of the metal. For a three-ton converter, melting takes about 1½ hours and blowing from fifteen to twenty minutes, the total time, including charge, being about two hours. As an example of the punishment the steel will stand, the following may be mentioned: A steel wheel, about 4 feet 9 inches in diameter, was dropped edgewise on a steel ingot from the following heights—5 feet, 10 feet, 15 feet, and 20 feet, without showing signs of fracture. A drop of 40 feet on the rim broke one spoke. After this four more drops of 40 feet on edge caused no further fracture either to the rim or the spokes, and the wheel was finally broken up by a steel three-ton ball dropped ten times on the boss from a height of 40 feet. Some remarkably thin castings have been made.

OUR ASTRONOMICAL COLUMN.

Comet, 1911*b*.—Observations of the new comet discovered at the Lick Observatory on July 6 are recorded in No. 4511 of the *Astronomische Nachrichten*. Prof. Abetti, at Arcetri, on July 8, estimated the magnitude as 6·0, and Prof. Wolf found, the same day, that the photographic magnitude was 7·5; his photographs show a tail.

MM. Lagrula and Schaumasse observed the comet at Nice on July 8, and, in No. 2 of the *Comptes rendus* (July 10), they describe it as a bright object presenting a globular condensation surrounded by a nebulosity which is extended towards the S.S.W.; the whole appears to have a diameter of about 2·5′.

From observations made on July 6, 8, and 9, Prof. Kobold has determined the following elements, which are said to be similar to those of Comet 1790 I.

Elements.

$$T = 1911 \text{ June } 20{\cdot}6354 \text{ (M.T. Berlin)}$$

$$\left.\begin{array}{l}\omega = 99^\circ\ 31'{\cdot}99' \\ \Omega = 172^\circ\ 27'{\cdot}52 \\ i = 148^\circ\ 39'{\cdot}25'\end{array}\right\} 1911{\cdot}0$$

$$\log q = 9{\cdot}89936.$$

An ephemeris derived from these elements gives 4h. 26m. 27s., +32° 54·0′ as the position for July 20 (12h. Berlin M.T.), with a daily decrement of about 2m. in R.A. and 13′ in declination. The calculated magnitudes for July 12 and July 20 are 6·5 and 6·4 respectively. Given a clear horizon the object should be visible, with opera-glasses, from midnight to dawn; at about 10.30 it rises some 30° east of north, and at 2 a.m. is about 20° above the horizon. The present position is about one-third the distance between ι Aurigæ and ζ Persei from the former star along a straight line joining the two.

The Solar Eclipse of April 28, 1911.—Dr. L. A. Bauer sends us a detailed narrative of a journey to Tau Island of the Manua group, where observations were made of the total solar eclipse of April 28, 1911. The U.S. cruiser *Annapolis* took Dr. Bauer from Pago-pago harbour, Tutiula Island, to Tau. Dr. Bauer's prime object was to secure magnetic observations during the eclipse, and he arranged for simultaneous observations to be made at the five magnetic observatories of the U.S. Coast and Geodetic Survey, as well as at Apia, Christchurch, and Melbourne. His attention was, therefore, devoted to this subject, and the astronomical observations were made by officers of the ship.

Mr. Abbot, director of the Astrophysical Observatory of the Smithsonian Institution, provided Dr. Bauer, at short notice, with a hand-driven, equatorially mounted, double-lens camera of about 11½ feet focus, and suggested one exposure of 15s., and another as long as possible—about 1m. 10s. These exposures were made, and four negatives were obtained as the result. On account of a difficulty with the sighting telescope just before totality, a hastily-constructed finder had to be employed, and this did not prove wholly successful as a means of keeping the image central upon the plates. The photographs show, however, the inner corona and some details and extensions mainly on the north-eastern and south-western edges, reaching out in places to a distance of more than half the sun's apparent diameter. The size of the photographic image of the sun's disc upon the plates is nearly one and one-fifth inch. No member of the shore party, or of the party aboard the *Annapolis,* reported having seen these coronal extensions, or any stars, which fact is probably due to the comparative brightness during totality, writing being easily legible. The times of the four contacts were observed by the shore party, as well as aboard; the observed duration of totality was 2m. 1s.

The magnetic observations cannot be discussed until those made at other stations within and without the eclipse track are available for comparison.

THE LIGHT OF ALGOL'S COMPANION.—In a previous paper Mr. Joel Stebbins arrived at the conclusion, from his selenium photometer observations, that the companion of Algol is brighter on one side than the other, the difference being caused by reflection and by the heating effect of the primary on the one side, chiefly the latter. His argument for the untenability of the reflection theory having been questioned, he returns to the subject in No. 5, vol. xxxiii. of the *Astrophysical Journal,* and shows by a different method that only a small portion of the extra light can be due to reflection. Our knowledge of the radiations emitted by the satellite is insufficient to determine the question definitely, but it is evident that radiation, and not reflection, is the chief cause of the extra brightness of the one side.

OBSERVATIONS OF MIRA.—The maximum of Mira which took place in July, 1910, was observed at the Catania and Utrecht observatories, and the results appear in No. 4506 of the *Astronomische Nachrichten.*

Dr. Bemporad finds that the maximum, mag. 3·3, took place on July 21, 1910, and the neighbouring minima on March 25, 1910, and February 17, 1911, respectively; for the maximum, this was fourteen days earlier than predicted by Guthnick's ephemeris. The mean period would appear to be about 318 days, and the range of magnitude nearly 7.

Prof. Nijland's observations give a maximum, of mag. 3·2, on July 20, 1910, and a tabulated comparison of observed dates, with predicted dates for the last seven maxima, shows a period ranging from 342 to 310 days.

MICROMETER MEASURES OF JUPITER.—Dr. Lau continues his series of papers on Jupiter in No. 4509 of the *Astronomische Nachrichten,* where he records the micrometer measures, made during the opposition of 1910, of many different features. A number of minor changes from the previous oppositions were noted, the matt-white egg-shaped mass which was so marked a feature of the 1905 opposition being totally invisible. The geometrical network joining bands iii. and iv. was frequently seen and its points measured. Sketches of the Red Spot region show that while on April 10, 1910, the spot was of the usual pointed-egg shape, on May 4 its western extremity had become rectangular, and on May 10 dark masses of matter at the middle of both sides gave it an egg-boiler form.

PHOTOGRAPHS OF THE AURORA BOREALIS.—Prof. Carl Störmer, of Christiania, sends us abstracts from the *Comptes rendus,* in which he describes his method of taking simultaneous photographs of the aurora for the purpose of determining its altitude, and gives the results so far obtained. The photographs accompanying the paper of May 1 are very striking, and were taken in northern Norway during February and March, 1910, while from the diagrammatic summary of the results it is seen that the greatest proportion of auroræ measured were at altitudes ranging from 100–150 kms.

THE EPHEMERIS FOR HALLEY'S COMET.—Preliminary measures of plates showing Halley's comet, taken with the Crossley reflector during the period March 27 to May 27, are published by Dr. H. D. Curtis in No. 4506 of the *Astronomische Nachrichten.* A comparison with Dr. Ebell's ephemerides shows that the necessary corrections to the latter are of the order of only +12s. and $-0{\cdot}2'$ to $-0{\cdot}9'$.

THE DIFFERENTIAL QUALITY OF THE MOON'S REFLECTED LIGHT.—No. 4510 of the *Astronomische Nachrichten* is accompanied by a splendid two-colour photographic reproduction of the full moon, showing the different quality of the light reflected by different regions of the lunar surface. The reproduction is from negatives obtained by Dr. Miethe and Herr Seegert, whose work and results have already been described in these columns.

SUTTON DOUBLE STAR OBSERVATIONS.—Dr. Doberck continues his record of double star observations made at Sutton in No. 4507 of the *Astronomische Nachrichten.* These particular observations were made during 1910–11, and deal with more than 100 doubles, including α Geminorum and α Leonis.

THE CANYON DIABLO, OR COON BUTTE, METEORITES.—An interesting paper by Mr. C. R. Keyes, dealing with the multeity of meteorites in the Painted Desert, Arizona, appears in No. 9, vol. xix., of the Transactions of the Academy of Science of St. Louis. After discussing the volcanic nature and the general geology of the surrounding land, the author arrives at the conclusion that Coon Butte, a conspicuous mound, was not formed by any abnormal meteoric fall, as has been frequently suggested, but is probably of volcanic origin. That such immense numbers of meteoric stones ("heavy stones" or "green stones") have been secured in the immediate neighbourhood he explains by the extraordinary dryness of the atmosphere preventing weathering, and the assiduity with which the objects have been sought; in fact, he suggests that any desert district enjoying similar climatic conditions would probably prove as fruitful in these objects as has the Painted Desert.

UNIVERSITY DEVELOPMENT IN WALES.

OPENING OF NEW BUILDINGS BY THE KING AND QUEEN.

THE visit of the King and Queen to North Wales in connection with the historical ceremony of investiture of the Prince of Wales at Carnarvon has been happily associated with two events of international as well as national interest: the opening of the new buildings of the University College of North Wales at Bangor by the King, and the laying of two foundation stones of the National Library of Wales at Aberystwyth by King George and Queen Mary.

The development of the university movement in Wales will probably stand out as a unique feature in contemporary history, owing to the large extent to which its success depends on popular enthusiasm and support. It owes its inauguration to the foundation, in 1872, of the institution in Aberystwyth, which still bears the name, "University College of Wales." When the establishment of colleges for North and South Wales was decided on as a result of the deliberations of the Government Committee appointed in 1880, the appeal for funds met with an enthusiastic response, not only from the wealthier, but also from the poorest classes of the community, the miners and quarrymen at Bethesda contributing their shillings, and even the children in the board schools contributing their pence. The question of permanent buildings was, however, deferred until the movement had time to mature, with the result that the work of the University College at Bangor has up till this year been carried on entirely in the buildings of the old Penrhyn Arms Hotel, while until recently the college at Cardiff was wholly located in what had previously been an infirmary.

It was only four years ago that King Edward laid the foundation stone of the buildings which were opened by his son last Friday, and in the interval there has been raised in Upper Bangor a fine college, the architectural features of which will compare favourably with those of the more ancient foundations of Oxford and Cambridge. As will be seen from the illustrations, the college stands on a hill overlooking the old town of Bangor, in a park the slopes of which are in the spring covered with bluebells. It is quadrangular in form, the class-rooms being on the first and second floors facing the park, while the other sides of the quadrangle are occupied by administrative buildings, examination rooms, and studies, and the Prichard Jones hall. On the left of the tower are seen the museum and library, which, when the scheme is completed, will form the side of a great outer quadrangle, the remaining sides being allocated to the science departments. The work of these is, however, for the present, being continued in the old college. The new building, in which the arts departments are located, thus forms the first step in a larger scheme, for the completion of which further funds will have to be raised. It has been built at a cost of 130,000*l.*, and was opened by the King nearly, if not quite, free of debt.

The largest individual contribution has been the *Aula magna*, given by Sir John Prichard Jones, whose name it bears, built at a cost of 15,000*l.* The library, given by the Drapers' Company at a similar cost, is an excellently equipped building, which, though so new, reminds one of the college libraries at Cambridge. In addition to this gift, the Drapers' Company has further maintained for many years a department of electrical engineering in conjunction with the department of physics. But in passing between these buildings we notice a stained glass window bearing the inscription, "Presented by the Postmaster and Staff of the Bangor Post Office." As another example of the varied character of the contributors, we note the recent donation of 100*l.* to the building fund by a member of the teaching staff of the Girls' County School. The site of the college, valued at 15,000*l.*, was given by the "Mayor, Aldermen, and Citizens of Bangor," and this gift was followed by a further contribution of several thousands to the building fund from the same source.

A special feature of the new college is the open cloisters outside the lecture rooms, as shown in our second illustration, thus ensuring efficient ventilation.

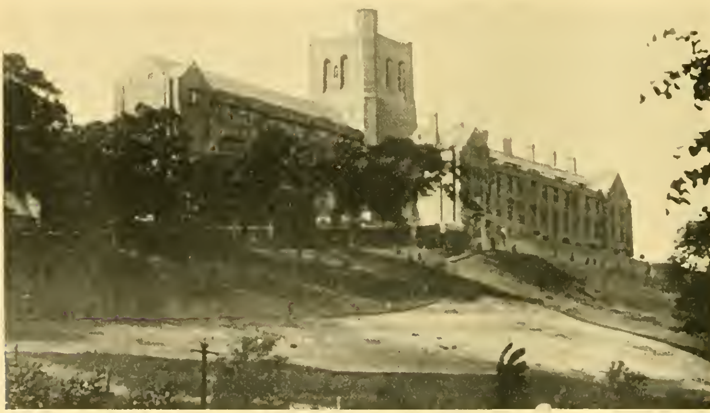

FIG. 1.—Front view of the new buildings of the University College of North Wales, Bangor. To the left of the tower are the museum (lower floor) and library (upper floor). Right of the tower are students' common rooms (ground floor), opening on terrace, lecture room (first and second floors) and Professors' rooms (in the attics).

The opening ceremony was performed in the presence of a large and representative gathering. We had Mr. Balfour and Mr. Lloyd George, not only sitting together on the same side of the house, but sharing a programme; Lord Hugh Cecil, the master of the Drapers' Company, and other distinguished guests. At the preliminary banquet, Mr. Balfour, in his speech, expressed the opinion that those who have planned and carried out this work have proceeded on right lines. They have not been modest in their ambitions, and they have been right. The building was planned on a scale that is not only adequate, but has the germs of development, which will render it adequate to future strains. Much of the advantage of a university education lies in the memories of those who have enjoyed it. When great architecture is linked with beautiful surroundings, subtle impressions are formed which move men until their dying day. It is well worth while to have great ideals as to the work. This breadth of view as to the ideals of education and culture is animating all those who preside over and control the courses of study, and Mr. Balfour advised them to be as magnificent in their ideas as the architect has been in the edifice. There are those who attach supreme value to the training of the youth and the utilisation of opportunities otherwise unused, of talents that would otherwise fall out. We should not narrow our ideals to training intelligent youths to pass difficult examinations. Apart from examinations, youths educate each other often most effectually, and each one who looks back on what he gained at the university finds that it does not always consist only in the advantage derived from lectures. There is another function that every university should aim at. In dealing with knowledge, art, and literature they should be the custodians of all that is highest, and not the less so because we are living in a democratic age. Wales and its colleges feel this ideal as much as any community. Wales has had its share of those divisions of opinion that are the effects and causes of national vigour, but in university education Wales is a land of brothers. All classes are animated by the same ideals, and make the same sacrifices in the great cause. But this brotherhood goes far beyond the limits of nationality. This place is not merely a Welsh seat of learning, for learning knows no limitations; it will take its place in the wider brotherhood which extends throughout the civilised world. There are many occasions on which national differences may arise, but the function of a university is to make the country a community of nations, one army conquering the same enemy, one band of workers united in a common cause.

The National Library of Wales, the foundation stones of which were laid at Aberystwyth the following day, owes its origin to the same movement. It was founded by Royal Charter in March, 1907, and its objects embrace "the collection, preservation, and maintenance of every form of literary and artistic production, whether printed or manuscript, relating to Wales and to the Celtic peoples and languages, as well as all literary works, whether connected or not with Welsh subjects, composed, written, or printed in whatsoever language, on whatsoever subject, and wheresoever published, which may help to attain the purposes for which the University of Wales, the university colleges, and other educational institutions were created and founded, *especially the furtherance of higher education and of literary and scientific research.*" The foundation of this library is largely the result of the efforts of Sir John Williams, Bart., who for more than thirty years has been purchasing books, which he has presented to the library. These have been temporarily housed in the Aberystwyth Assembly Rooms.

The site of the permanent buildings, situated on a hill overlooking the town, has been presented by Lord Rendle. The Exchequer grants which the library has received up to the present have been proportionally far below those made to similar institutions in Scotland and Ireland. The new library will, it is hoped, receive some of the privileges enjoyed by the libraries of Oxford and Cambridge with regard to the acquisition of copyright books. It is, however, clearly understood that a condition of such a concession is the maintenance of the international character of the library, and of the provision contemplated in the charter as a safeguard against its becoming a purely Welsh institution. In these circumstances we confidently hope that scientific literature of all nations will be adequately represented. At the same time, it is important for English workers to realise the scientific importance of much that comes under the more Welsh side of the library. At present numbers of manuscripts and documents, full of historic interest, are scattered about in remote districts, and the foundation of a central collection cannot fail to bring to light important new contributions to our knowledge of history and anthropology. A further step in the same direction is the National Museum at Cardiff, of which the foundation stone will be laid next year, and which will, it is hoped, serve to preserve records of the druidical and other remains which are gradually disappearing under the devastating influence of utilitarianism. The astronomical interest connected with these remains will be well known to readers of NATURE. A photographic survey of the antiquities of Wales might, one would think, be inaugurated with

FIG. 2.—Interior of the quadrangle, showing the open cloisters by which the lecture rooms are approached. On the left-hand side is the block containing the Assistant Lecturers' private rooms; on the right a corner of the tower.

advantage in connection with either the library or the museum, perhaps both.

The proceedings in Aberystwyth were attended by delegates from most of the universities of the United Kingdom, as well as the Royal Society and similar bodies, and these received hospitality at the Alexandra Hall (the residence of the women students), which thus became the scene of pleasant meetings between the brotherhood of university workers so well described by Mr. Balfour. The memories which we shall carry away of this gathering will be ranked in the same group with our pleasantest reminiscences of British Association meetings. We could have wished that royal honours had been conferred on some representative of science, as it is probable that such a distinction would have given an impetus to an aspect of the university movement which must always be kept prominently in the foreground.

G. H. BRYAN.

TECHNICAL TRAINING AND UNIVERSITY GRANTS.

IN the House of Commons on July 13, in Committee of Supply, the President of the Board of Education made his annual statement reviewing the work of the Board during the previous year.

Dealing with the museum work of the Board of Education, Mr. Runciman referred to the controversy over the question of a site for the Science Museum. He said:—"Since the first announcement was made about the site of the Science Museum I have entered into negotiations with the Trustees of the British Museum, and we have now arrived at an agreement which will give us the land we require for the Science Museum and will not interfere with the development of the Natural History Museum, so that we shall have in South Kensington a group of museums which will be the envy of foreign nations."

In the course of his further remarks, Mr. Runciman referred to technical training and university grants. Subjoined are a few extracts from *The Times* report of his speech.

HIGHER TECHNICAL TRAINING.

"I regret to say that from all I learn of the work done in the provinces and of the work done on the Continent, I have to confess that it is in the field of higher technological forces that we have most leeway to make up.

"It is true that in many directions large sums of money are being devoted to the endowment of technological chairs in almost every modern university. Great bequests have been made during the past year. The University of Liverpool has recently founded a professorship of naval architecture, largely owing to the generosity of Mr. Elder. They have also created a department for the study of the problems of town planning—a new and rather interesting department. There are at the present time at least two departments in modern universities for the study of aëronautics. A professorship has been founded at Leeds for the study of the gas, coal, and fuel industries. In the same university instruction is being provided in woolcombing and spinning, for which the Clothworkers' Company has given a sum of no less than 50,000*l.*, making, I believe, the school at Leeds one of the most valuable technical schools in Europe. In the north of England a sum of 35,000*l.* has been applied for the teaching of mechanical engineering, and in three universities sums of 30,000*l.*, 50,000*l.*, and 70,000*l.* respectively have been provided for the promotion of chemical science.

"In London 60,000*l.* has been set apart by the University Association for the training of women in the study of the science of the household. Great progress has been made, I am glad to think, in the departments of metallurgy and chemistry in the north. In the sciences at the Imperial College great improvements have been made in the last twelve months, and I believe now that the leaders of the great industries are well alive to the fact that in the development of higher technological work lies much of the hope for their future success. I need not mention agriculture except in passing. Two agricultural colleges have been linked up with modern universities.

"When one records all, there is still left the feeling that in England there is not full appreciation of higher technological work, and when we make comparison of the number of students at German and English universities it is all to the advantage of Germany and not to our credit. In the eleven modern universities of England at the present time full time students number 9600, and if you add 7000 at Oxford and Cambridge of under- and post-graduates, you have a total for England and Wales of 16,600 students. It sounds like a large number, but when you remember that Germany has 63,000 students in similar institutions we may well say we have a long journey before us."

UNIVERSITY GRANTS.

"The most important departure made in the administrative work of modern universities is to be found in the change in distribution of the Treasury grant. Over a long period the Treasury grants given in large sums were spent at the discretion of the modern universities under the advice of a committee set up by the Treasury. There is no other education work for the Treasury to do, and there was unfortunately a certain amount of overlapping, because technological work came under the Board of Education, and it was felt that for administration in these matters and, I think, also for the simplification of regulations under which modern universities work, it was of the first importance to avoid waste in administration and overlapping, and the universities themselves agreed. With that object the Government have decided to transfer the distribution of this annual grant to the Board of Education, and now the only Government department modern universities have to deal with is the Board of Education. I am glad to think this meets with the approval of modern universities, and in the many conferences I have had with their representatives they have shown the desire to do their best to work with us for the common end, the extension and efficiency of the work falling under their guidance and control.

"I cannot pretend to say that the Board of Education is at the present time sufficiently equipped to do the whole of the work undertaken by the advisory committee appointed by the Treasury. I have, therefore, set up a small advisory committee to deal with the distribution of these grants. I am glad to say I have secured the service of Sir William McCormick as chairman, who is well known for his services under the Carnegie bequest, and was one of the most active members of the Treasury committee. Associated with him are Sir J. A. Ewing, C.B., F.R.S., Sir William Osler, F.R.S., Miss Emily Penrose, Sir Walter Raleigh, Sir John Rhys, and Sir Arthur Rücker, F.R.S. They are a small and, I may add, a very distinguished committee, and they have already started their meetings, one of their first arrangements being to give Hartley College, Southampton, now struggling to exist as a university college, another year in which to accumulate funds for carrying on university college work."

APPLICATIONS OF SCIENCE TO INDUSTRY.

THE annual meeting of the Society of Chemical Industry was held at the Cutlers' Hall, Sheffield, on Wednesday, July 12, the president, Mr. Walter F. Reid, being in the chair. In his presidential address, Mr. Reid dwelt on the rapid developments of the application of science to industry, and said it was quite impossible for anyone to keep up to date in all branches of applied science. But, though the tendency of the present age was towards specialisation, too minute sub-division had its disadvantages, and there would always be a demand for trained men who had a good general knowledge of science and of the methods of applying it. Manufacturing chemists frequently receive advice from those engaged in other industries to employ more skilled assistants in the factories. Mr. Reid quoted some figures given by Mr. Barker North, in his recent presidential address to the Association of Teachers in Technical Institutions at Southport, showing that the chemical factories stood at the head of all our great industries as regards the proportion of skilled supervision employed. The value of the net annual output per head of those employed in the manufacture of chemicals, coal-tar products, drugs, and perfumery, was also considerably in excess of that in any other of the nine chief trades of the country, the amount being 185*l.* per year, while the next was iron and steel with 118*l.*

It was sometimes alleged that the nature of the training given to students in this country was not of a sufficiently practical character, and that some foreign nations were superior to us in this respect. He did not think it could at present be said that the facilities for acquiring knowledge were less in Great Britain than in any other country—in fact, in some of our institutions they were superior. The most important piece of evidence upon which a final judgment could be passed, however, was wanting. They had no information as to the careers of students after they left the colleges or universities. This alone was the final measure of success. Degrees or examinations were but milestones along the road, although they were sometimes quoted as if they were the main end to be attained. Each centre of tuition could, no doubt, give the names of some former students who had been successful in their careers, but what interested him most was the ultimate fate of the rank and file, who supplied the bulk of the assistants in factories. Frequently he had had to engage assistants for various industries, and in one respect they were all deficient. They did not realise that the object of the industrial chemist, like that of the alchemist, was to produce gold, and that every factory operation must yield a profit, failing which it must inevitably cease. In this direction their German colleagues were, perhaps, more advanced, for "Waarenkunde," or knowledge of merchandise, was a recognised subject of tuition, and current price lists were not unknown to students.

In another way, students met with difficulty at the beginning of their career; they were not taught what kind of apparatus and plant was likely to be available for them in practice. Teachers who had not worked in factories could not properly teach students practical work in industrial chemistry. The problem for the student was how to acquire practical knowledge at the commencement of his career. In this he thought employers might materially assist by giving their younger employees more leisure to attend meetings of societies such as the Society of Chemical Industry, and by procuring journals and other literature which the assistant was unable to purchase. A good factory library was of the greatest pecuniary benefit both to employer and employed, but in how many factories did they find one? The rapid march of progress necessitated continuous study. They must all remain students. Sometimes an apparently casual observation might lead to important results if it was followed up, but if the factory chemist was taught to consider himself merely as a kind of teaching machine, and original observation was discouraged, business could not progress.

Mr. Reid recalled how many great industries had arisen from very small beginnings. The fixation of atmospheric nitrogen as an industry was still in its infancy. In 1781 Cavendish found that, on passing an electric spark through a mixture of carbon dioxide and hydrogen, nitrous acid was produced. He communicated his observation to Priestley and Lavoisier, neither of whom could obtain the same result. Cavendish's observation was more accurate than his method, for he made his experiments in vessels containing only a partial vacuum, and the nitrogen and the residual air yielded nitrous acid. In 1784 R. Kirwan repeated the experiment with atmospheric air, and again found acid. Here we had the English origin of what was destined to become one of the great industries of the world, but which was being developed chiefly in foreign countries. When Tyndall made his classic researches on glaciers, he little imagined that factories would arise in the Alps with a glacier at one end of the system and nitric acid of 98 per cent. running into carboys at the other.

The history of the development of modern smokeless powder had never been told. Soon after graduating at Berlin, Mr. Reid was commissioned by the Argentine Government to report on the mineral resources of that country. In carrying out the work, he had to penetrate into a wild region where his gun was the chief source of the daily food. There were few opportunities for cleaning the gun when work was finished, and as a result the gun was ruined by rust. When he returned to England, he endeavoured to find some means whereby rust might be prevented. He heard of the work done by Von Lenk with gun-cotton, and he also heard from the officials of the Patent Safety Gun-cotton Co., Stowmarket, that the manufacture of powder for firearms had been abandoned because of the great irregularity of the explosions and the number of accidents that had happened. He made a long series of experiments, and finally found that by gelatinising nitrocellulose, either completely or partially, the explosion could be rendered quite uniform. Some of the first experiments were made with a paste forced through a perforated plate similar to those used in the gutta-percha industry. The threads thus produced were cut into short lengths, and gave good results. But in those days, when cartridge cases and gun or rifle chambers were adapted to black powder, which was twice the bulk of the new product, there was a great disinclination to make the necessary alterations. A partially-gelatinised, bulky powder had, therefore, to be made for the market. It was called "E.C." powder—the initials of the Explosives Co., Ltd., who were then owners of the Stowmarket Works. It was only recently that sporting guns and cartridge cases had been specially made to suit the fully gelatinised powder, which had now almost supplanted black powder for sporting purposes. The utility of the new powder for military purposes was evident to civilians from the beginning, but our military authorities, after testing it, said that it could not be adopted, because the trajectory was so much flatter than any powder then in use, and that the sights of all army rifles would require alteration. The British rifles being so short-sighted, he had no option but to turn to our neighbours of France. In November, 1881, he showed the powder and method of manufacture to the military attaché at the French Embassy, but it was some time afterwards before the French produced their powder "B," and this forced the hand of our military authorities at home. To-day, even the sights of our military rifles had been altered; in fact, he believed there was no part of either rifle or cartridge that had not been altered, and the art of war had been changed throughout the world.

Fifteen years after the process had been worked out, he learned that a German botanist, Hartig, had made experiments in the same direction in 1847. The pamphlet in which he described his experiments was extremely scarce. He knew of only one copy of it in Great Britain, and he had been unable to obtain it in Germany, so that his ignorance on the subject in 1881 might perhaps be excused.

The president next gave illustrations of the discovery of the method of silvering glass, a paper on which was written as long ago as 1867 by Justus von Liebig; of the discovery of Portland cement by Aspdin, the Leeds mason; and how both these discoveries led to important industrial results. He showed how fogged photographic plates led to the discovery of the Röntgen rays. Bolsover, in repairing the handle of a knife composed partly of silver and partly of copper noticed that these metals adhered to one another when fused. This laid the foundation for Sheffield plate. Dr. John Wright's invention of the use of cyanide of potassium in electro-plating was the outcome of research, and about the same time another inventor was busy on the same subject. One of the brothers Siemens found a method of electro-plating which he considered new, and brought it to England, where he offered it to Elkington. The latter was able to show him an almost identical process already at work. Mr. Reid next referred to the discovery of the vulcanising of india rubber by Hancock, which showed the necessity, not only of patient work, but also of perseverance and careful observation. Hancock had made a number of mixtures of india rubber with various substances, none of which appeared to have any particular advantage. The samples were put on one side for some months, when the whole of them were treated with oil. It was noticed that a portion of one sample was not acted upon by the oil, and on looking up his records of the samples Hancock found that this particular one had been heated to about 300° F., and that it contained sulphur. Incidents of this kind could be multiplied. He hoped he had shown the younger members of the society the advantages, first, of original work in connection with their industries; secondly, of careful observation and diligent inquiry into anything that might appear new to them; and thirdly, of perseverance until they had obtained some definite result.

TRIALS OF ROAD MATERIALS AND CONSTRUCTION.

THE use of motor vehicles has so completely altered the conditions of the wear and tear of the roads, that it has become necessary to find some new method of maintaining the surface and preventing the nuisance of the dust arising from the wear of the surface by the wheels of the motors. During the last few years various processes have been tried, chiefly directed to finding some more durable means of binding the surface material with which the roads are covered. The most successful so far have been by the use of tar asphalt or oil for binding the broken granite or other road material used for repair.

The new Road Board, with the view of securing a service test under uniform conditions, has made arrangements with the Kent County Council for carrying out a series of experiments on trial lengths of a main road, to be carried out under the direction of its advisory engineering committee. The site selected for these experimental trials is on the main road from London to Folkestone between Eltham and Sidcup. This road is thoroughly representative of the average condition of heavy road traffic. The average number of vehicles using this road in one day includes 322 motors of all kinds, and 454 horse-drawn vehicles, the traffic density amounting to 500 tons per yard of width.

The experiments are to be carried out under the direction and superintendence of Mr. Maybury, the county surveyor of Kent, who has paid special attention to this subject, and has so far succeeded in maintaining the surface of the main roads in Kent in excellent order. The special subjects to be taken into consideration are:—The first cost of the coating, and the future cost of maintenance and efficiency. Twenty-three different processes are to be given a trial, each extending over a length of a hundred yards. They include ordinary water-laid and rolled macadam; the same with a tared surface; tar macadam; and several patent processes.

Arrangements have been made for an inspection of the work while it is going on by those interested, and a pamphlet has been issued by the Road Board, giving full particulars and copies of the conditions and specifications under which the trials are to be carried out. This pamphlet is to be obtained at Messrs. Waterlow and Sons, London Wall, E.C.; price eighteenpence.

METEOROLOGICAL REPORTS.

PHILIPPINE *Weather Bureau* (1908).—The part of the annual report now received includes (1) the administrative report for the fiscal year ending June 30, 1908, and (2) hourly meteorological observations made at the Manila Central Observatory during the calendar year 1908. The activity and popularity of the department dealing with storm warnings may be gauged from the fact that during a typhoon 160 telephonic inquiries were received in a single day. Telegraphic observations were received twice daily from twenty-nine foreign stations, and include reports from Japan, China coast, Formosa, and Indo-China. Special attention is directed to the "immense service" to shipping and other interests which the Eastern Extension and Great Northern Telegraph Companies have for years rendered in allowing free transmission of meteorological messages. The mean temperature of the year 1908 was 79·2° (rather below the normal); the maximum, 97·2°, occurred in May, and the minimum, 61·7°, in February. The rainfall was 97·7 inches (about $21\frac{1}{2}$ inches above the normal); none fell in April (the average being 1·2 inches). Among the large number of seismic disturbances reported from different localities in the fiscal year only one violent shock occurred, viz. on November 24, 1907, in south-east Luzon.

Davos Meteorological Station (1910).—The annual summary, printed as a supplement to the monthly weather charts published by the Curverein, gives the mean maximum temperature in January and July, respectively, as 29·7° and 59·5° F.; mean minimum, 12·9° and 39·6°; absolute maximum, 77·5°, in July; minimum, −9·6°, in February. Rain (and melted snow) amounted to 45·6 inches (9·3 inches above the normal). Snow fell in every month except June and August. Sunshine was recorded during 1605·6 hours, which was much below the average (1790·7 hours for 1885–1905).

Bombay and Alibag Observatories (1910).—The mean temperature of the year was 79·1°, being 0·3° below the normal; the maximum hourly temperature was 92·7°, in June, and the minimum 61·5°, in January. The rainfall was 67·86 inches, being 7·3 inches below the normal (1873–96); June received a fall of 23·92 inches, being $3\frac{3}{4}$ inches above the average. Milne's seismograph registered fifty-seven earthquakes; those of November 9 and December 13 and 16 were great disturbances. The mean magnetic declination was 0° 57′ 43″ E.; inclination, 23° 35·7′; horizontal force, 0·36845 C.G.S. units. During the year there were 102 calm days, 236 days of small, 25 days of moderate, and 2 days of great disturbance. Part of the observatory is still infested by white ants, although the floor has been cemented; it is now proposed to use Minton tiles.

Falmouth Observatory (1910).—The report of this important station, maintained by the Royal Cornwall Polytechnic Society, and one of the normal meteorological observatories subsidised by the Meteorological Committee, is of more than usual interest. It contains meteorological means for the lustrum 1906–10, and for the forty years 1871–1910; also sea-temperature observations taken about one mile outside the harbour for the same lustrum, and means for thirty-one years, compiled with great care by the superintendent, Mr. E. Kitto. The monthly means of air temperature in 1910 were:—January, 44·2°; July, 58·2°; year, 51·1° (0·4° above the normal). Rainfall for year, 52·84 inches (7¾ inches above the normal, due partly to an unusually heavy fall, 9·22 inches, in December). The percentage of possible duration of sunshine was 38 (which was exactly normal). The mean temperature of the sea in 1910 was 52·1°; the only months in which the mean was below that of the air were May–August. In the valuable work of terrestrial magnetism the observatory received grants amounting altogether to 100*l.* from the Royal Society and British Association. The principal mean values for the year were:—declination, 17° 41·6′ W.; inclination, 66° 29·1′ N.; horizontal force, 0·18802 (C.G.S. units).

The Fernley Observatory, Southport (1910).—The principal station of this important observatory is situated in the Hesketh Public Park; the equipment is very complete and in duplicate. There are also branch stations at Marshside (for anemographs), Birkdale, and Barton Moss. The director, Mr. Joseph Baxendell, is an enthusiast in the work, and meteorologists are indebted to him for various improvements in self-recording instruments and for inquiries into many interesting details. Among several such matters in the present report we may mention (1) the alteration of a Richard hair hygrograph to enable daily instead of weekly traces to be obtained from the instrument, and some valuable results have already been obtained. (2) Careful experiments have shown how the readings of a thermometer were vitiated by the metallic fittings of an instrument in the enlarged Stevenson screen. The mean temperature of the year was 48·7° (0·5° above the average); maximum, 78·2°, in July; minimum, 16·0°, in January. The rainfall was 35·04 inches (2·14 inches above the average). Bright sunshine, 1568·4 hours (11·9 hours above the average). A rather surprising cold wave was felt by the deeper underground thermometers; its greatest effect was at 10 feet in February and at 20 feet in March. The very useful table of comparative statistics at other health resorts and large towns again appears in the report.

Mysore Meteorological Department (1909).—This seventeenth annual report, carefully compiled by Mr. N. V. Iyengar, chief observer in charge, contains detailed observations at the high-level stations Bangalore (3021 feet), Hassan (3149 feet), Mysore (2518 feet), and Chitaldrug (2405 feet), with means for the seventeen years 1893–1909. As in former years, the results have been worked out in great detail. Over the province as a whole the departure of the mean annual temperature from the normal was insignificant. The highest monthly mean maximum was 96·1°, in March and April at Chitaldrug, and the lowest mean minimum was 57·2°, in January at Hassan. Absolute maximum, 100·6°, in April at Chitaldrug; minimum, 52·2°, in January at Hassan. The mean rainfall was nearly 16 per cent. above the average. The rainfall statistics have been separately published (NATURE, February 16).

Deutsche überseeische meteorologische Beobachtungen (1909).—The nineteenth volume of this series of observations, published with the assistance of the Colonial Department, now extends to 116 quarto pages, and is divided into three sections:—(1) monthly and yearly means at certain hours at stations under the immediate control of the Deutsche Seewarte in various parts of the world; (2) observations at stations in German East Africa; and (3) observations in Togoland (West Africa). The monthly and yearly results for all stations in sections (2) and (3) will be eventually published in the *Mitteilungen* from German protectorates by Baron v. Danckelman. Full particulars about instruments and references to information about stations are given, and the extreme values are printed in thick type. These observations are of the greatest importance to meteorological science, and yearly increase in value.

Sonnblick Society (1910).—As a preliminary to the investigation of the influence of climate upon the variations of the Goldberg glacier it was decided, with the financial assistance of the Vienna Academy of Sciences, to have a survey made of the district. After removal of many difficulties, Baron v. Hübl proposed to make use of Dr. Pulfrich's stereoscopic method; the work was satisfactorily carried out by the Military Geographical Institute, and a coloured plan has been added to the present report. The following are some of the meteorological results for the Sonnblick Observatory (Rauris, Austria), altitude 10,187 feet:—mean temperature: January, 7·9° F.; July, 30·4°; year, 19·6°; absolute maximum, 47·7°, in July; minimum, −13·5°, in January. Melted snow and rain, 67·8 inches, on 258 days. Fog occurred on 281 days; each month had at least twenty days. Particulars relating to other mountain stations are given, as in previous reports.

BIRD-NOTES.

THE April number of *The Emu* contains an interesting account, by Mr. S. W. Jackson, of the nesting haunts of the rufous scrub-bird (*Atrichornis rufescens*), which, together with *A. clamosa* of Western and South-Western Australia, represents a peculiar family group. The expedition, which took place in September, 1910, was directed to the high Dorrigo scrubs at the head of the Bellinger River, New South Wales, where the first known nest and eggs were taken twelve years earlier. In addition to obtaining a second nest and eggs, it was the object of the expedition to procure a female, of which no example was then known. The nest finally discovered, of which photographs are given, was a large dome-shaped structure, with a tubular entrance, built amid thick bush in a tussock of dead carex grass. It was constructed of this grass and leaves, with a lining of a hard dry material made of wood-pulp, upon which the two eggs rested. The latter were removed by constructing a kind of extemporary ladle, but were eventually returned for a time to the nest as a lure to the female, who, however, eluded all attempts at her capture. A pair of lyre-birds had their nest and playground a short distance away.

To the May number of *British Birds* Mr. A. L. Thompson contributes a summary of the most recent records of stork-migration. It is now established that there is a south-easterly migration of storks across Europe in autumn, birds ringed in Denmark having been taken respectively at Brandenburg, near Frankfort-on-Oder, and in Austrian Silesia. This migration is remarkable in that its line cuts at right angles the route taken by the great majority of birds at the same season. As regards migration to and from Africa, Prussian storks have been taken in Syria, Palestine, and near Alexandria in some instances in the first, and in others in the second, year after marking. One Hungarian stork was also taken in Syria. On the other hand, three Prussian storks were severally taken during their first autumn near Lake Chad, on the Blue Nile, and on the Victoria Nyanza; a bird which left Pomerania at the end of August was taken in north-east Rhodesia early in December, while a Prussian stork was shot in the Kalahari during its first winter. Further, there are records of seven Prussian storks taken in the Transvaal, Natal, Basutoland, and the north of Cape Colony, and also of about a dozen Hungarian birds from the same area, while one was obtained so far west as German South-West Africa. With one exception, all these birds were taken during the northern winter; but the exception was captured in July. So far as the records admit of generalisation, it appears that storks generally return to their original summer haunts; but there is a notable exception in the case of a bird hatched near Brunswick in 1908, which made its appearance a couple of years later about 437 miles away, in eastern Prussia. This instance, together with the Lake Chad and German South-West African records, and the one noted below, indicate that further inquiry is necessary before our knowledge of the subject can be regarded as anything like complete. Very remarkable is the capture near Barcelona in September, 1910, of a bird hatched in the neighbourhood of Cassel, as this west German stork took a line of flight almost exactly the opposite of that followed by its fellows hatched in Denmark and north-east Germany.

Mr. J. H. Gurney in the course of his report on Norfolk birds for 1910 (*Zoologist* for May) alludes to the increasing scarcity of the corn-crake—which he attributes to the shooting of these birds in the south of France—and likewise to the recent visitation of crossbills. Most of the latter have departed, but when and where they went is another matter. A crane shot at Thornham in August was one of the rarities. In a note on the food of starlings, the author adduces evidence to prove that these birds are harmful to young wheat and oats, eating the sown grain as, or before, they sprout. On the other hand, they undoubtedly destroy large numbers of noxious insects.

Among several "Educational Leaflets" received from the American National Association of Audubon Societies, reference may be made to the so-called Virginian quail, or "Bob White" (*Colinus virginianus*), a bevy of which forms the subject of the illustration here reproduced. The

A Bevy of Californian Quail. From U.S. Educational Leaflet."

bird is a valuable asset to the United States, partly on account of the revenues derived from shooting rights and partly owing to the quantity of noxious insects and weeds it destroys. It is estimated that a family of a dozen quail would consume about 800,000 insects and 60,000,000 weed-seeds in the course of a year. When reposing, the members of a bevy arrange themselves in a circle with their heads directed outwards, and in such a position, except, of course, when snow lies on the ground, are stated to be almost invisible, even at a very short distance.

To the June number of *British Birds* Messrs. Ticehurst and Jourdain contribute an article, illustrated with maps, on the distribution of the nightingale in Great Britain, the subject being treated county by county. As regards the extreme south-western and northern limits of the range of the species, the authors endorse the view that neither in Devonshire nor Yorkshire has there been any extension within the period when, if it had occurred, it could be definitely traced. In Yorkshire, nightingales appear to have bred a century ago as far north as they normally do at the present day, occasional occurrences beyond the usual range having probably occurred in the past in much the same manner as is the case nowadays. It is noteworthy that the range of the bird in Yorkshire is strictly limited to the lowlands, only one instance of its breeding above the 250-feet contour being recorded. The alleged instances of the occurrence of nightingales northward of Yorkshire are regarded as not proven.

In an article in *The Irish Naturalist* for June Mr. R. M. Barrington attributes the great rush of birds observed in the south-east of Ireland during the night of March 29 to a combination of special circumstances affecting the ordinary spring migration. Owing to the prevalence of north-east winds over a great part of Europe, the birds had probably to halt in the south, where they collected in numbers. At Valentia, Pembroke, and the Scilly Islands the wind veered to the south on March 29, although north-east winds continued over the rest of the British Isles. The night was moonless, and after the birds had crossed the Channel they encountered a bank of fog off Ireland, which caused their hosts to become disorganised and attracted first by the lighthouses and then by the lights of the towns.

Exquisite photographs of birds and other animals illustrate a pamphlet on the "Ross Bird-stalker," written by Mr. C. Dixon, and published by Ross, Ltd., New Bond Street. The pamphlet advertises a stereo-prism binocular, stated to be well fitted for the purposes of the field-naturalist. R. L.

AMERICAN ETHNOLOGY.[1]

THE study of the Chippewa songs and music collected by Miss F. Densmore in Minnesota is of exceptional interest. Every phase of Chippewa life is expressed in music. Many of the songs are very old, and are found in several reservations; others are said to be the more recent compositions of certain men who composed them "during a dream" or "upon awaking from a dream." It is still customary for the Chippewa to celebrate an important event by a song. None are the exclusive property of families or clans; a young man does not inherit the right to sing his father's songs, but if he likes he may learn them by giving the customary gift of tobacco. As with the songs of the Murray Islanders of Torres Straits, the melody is considered more important than the words. It is permissible and customary to compose new words for old tunes, but they are always similar in general character to the words previously used, the idea being the important thing. Indian songs are not recorded in a definite system of notation, and a standard of absolute exactness is lacking; the melody-trend and the principal rhythm of the song, however, are constant. "Indian music seems to belong to a period in which habit takes the place of scale consciousness. Habit in the choice of musical intervals is formed by following a line of least resistance or by a definite act of the will, or may be the result of both, the voice at first singing the intervals which it finds easiest, and afterward repeating these intervals voluntarily. . . . The present study is not an analysis of fractional tones, but of melodic trend and general musical character; therefore the ordinary musical notation is used, with the addition of a few signs in special cases." A vibrato or wavering tone is especially pleasing to the singers; it is difficult for them to acquire, and is considered a sign of musical proficiency.

The songs fall into several classes, such as Dream songs, War songs, Love songs, Mocassin-game songs, Woman's-dance songs, and *Mide* songs. The *Mide* (Grand Medicine) is the native religion of the Chippewa. It teaches that long life is coincident with goodness, and that evil inevitably reacts on the offender. Its chief aim is to secure health and long life to its adherents, and music forms an essential part of every means used to that end. Both men and women are eligible for membership. There are eight degrees, persons being advanced from one degree to another on receiving certain instructions and bestowing valuable gifts. Meetings are held in the spring of each year, but it is permissible to hold initiation meetings in the autumn.

[1] Smithsonian Institution, Bureau of American Ethnology. Bulletin 45.—"Chippewa Music." By F. Densmore. Pp. xix+216. Bulletin 37.—"Antiquities of Central and South-Eastern Missouri." By G. Fowke. Pp. vii+116. (Washington: Government Printing Office, 1910).

All members are expected to attend one meeting each year for the renewal of their "spirit power." The life enjoined on the members is a life of rectitude. They are taught that membership does not exempt a man from the consequences of his sins. Lying, stealing, and the use of liquor are strictly forbidden. Various stages of initiation are described, and the appropriate songs with their music are given, each of which is accompanied by a reproduction of the mnemonic pictograph. All the songs are recorded in mnemonics on strips of birch bark, each record serving as a reminder of the essential idea of the song. The following examples illustrate these pictographs.

The Medicine song, illustrated by a figure, is: "Light—Around you—Chief—Woman." The picture was drawn by a woman, who stated that the horizontal line represents the edge of the wigwam, along which are arranged various articles of value indicated by the dots. At each end are torches, the light of which falls on the gathered wealth, causing many of the articles to glitter. These articles belong to a woman standing with upraised hands and wearing a pearl necklace with a locket. In singing this song the woman pointed to one portion of the picture after another, tapping the birch bark lightly as she sang.

The fourth song (p. 59), for initiation into the Sixth Degree of the *Midewiwin* (Grand Medicine Society), is: "Who is this—Sick unto death—Whom I restore to life?" The pictograph represents the body of the person to be initiated, on whom are seen lines representing the "strength" he is to receive through the *Mide*. "The words of the song refer to the person who is being initiated. Many sick persons are initiated in order that they may be restored to health. The *Mide* comprehends health of body, mind, and spirit in one general idea." It is somewhat unfortunate that this short memoir is simply entitled "Chippewa Music," for on reading the title a non-musical person might be led to overlook a piece of work which, as we have seen, covers a much wider ground.

As the result of two seasons' field work, Mr. Gerard Fowke has published a memoir on the mounds near the Missouri river, mainly between Gasonade River and Moniteau Creek. The mounds were erected on narrow ridges, with no regard to orientation; each contained a vault with sides sloping outwards, and composed of irregular stones. They contained one or more skeletons, either doubled up or disarticulated, the flesh having been first removed; in these cases the bones sometimes appear to have been thrown carelessly into the vault. The bones were in such a decayed and friable condition that very few could be preserved or measured. Dr. A. Hrdlička states that most of the crania are of the dolichocephalic Indian type, two or three being extreme forms in this respect, suggesting similar specimens recovered in New Jersey from the burials of the Delawares and also from the mounds of the Illinois River. A large number of the vaults are figured, as well as objects found within them. The author states that:—"As the Osage Indians never ascended the Missouri farther north than the Osage River, and as the stone vaults above that point show progressively more skill in their construction, we must attribute them either to the Kansa Indians or to some tribe whose name is now lost."

A. C. HADDON.

RADIANT MATTER.[1]

THE velocity with which helium is cast out by radio-active bodies at the moment of change varies considerably from one element to another. Thus the radiant atoms of radium C possess a far higher velocity than those of uranium or ionium. This fact is apparent in the greater distance to which the α rays of the former will penetrate in air or in any other substance. The distance traversed in air is known as the "range." The following table shows the ranges of α rays from the various known radio-active elements. Thus we see that whereas the helium from radium C is projected nearly 7 centimetres, that from uranium only reaches 2·7 centimetres. In the thorium series, one of the elements, thorium C, attains a range of 8·6 centimetres. This is the longest known.

Range in Air.

	cm.		cm.
Radium C	7·06	Thorium C	8·6
Radium A	4·83	Thorium X	5·7
Emanation	4·23	Thorium emanation	5·5
Radium F	3·86	Thorium B	5·0
Radium	3·54	Radiothorium	3·9
Ionium	2·8	Thorium	3·5
Uranium	2·7		

	cm.
Actinium X	6·55
Actinium emanation	5·8
Actinium B	5·5
Radioactinium	4·8

By a most ingenious series of observations, Bragg has revealed some unexpected and interesting features attending the ionisation effects of the α rays upon gases through which they are projected. By measuring the amount of ionisation effected at different points along the path of the ray, Bragg and Kleeman have shown that at first, when the velocity is greatest, the ionisation effected is least, and that the amount of ionisation—that is, the number of ions created greatly increases just before the atom comes to rest.

Let the ray be supposed to move along the line AB—this line representing the range. If at each point of its

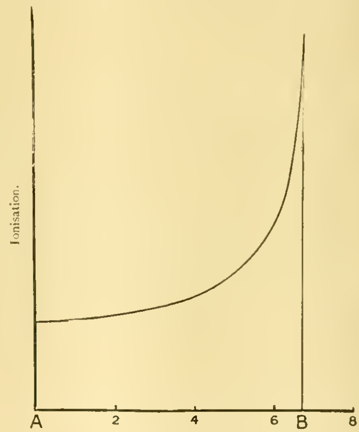

FIG. 1.—Range in cm. of air.

path we erect a perpendicular line proportional to the number of ions created by the flying helium atom, then, by joining up the ends of these lines, we obtain the curve shown. It will be noticed that a very well-defined maximum exists, after which the ionisation rapidly drops to nil. The curve reproduced is due to Geiger, who has added considerably to our knowledge of the subject.

Here is a small speck of the substance, pitchblende—the uranium ore from which radium is derived. All the elements of the uranium series are present. We are sure, then, that every α ray proper to this series, the ranges of which are given in the table, is being emitted by this particle of pitchblende. Let us form a mental picture of what is going on around it.[1]

Furthest out of all, the helium from radium C is projected. It attains a distance of 7 centimetres. The greater part by far of its ionisation is done near the end of its flight. Hence, remembering that these rays are darting radially in all directions from the piece of pitchblende, there is a shell of intense ionisation of spherical form existing around this pitchblende, and at a distance

[1] From a lecture delivered before the Royal Dublin Society on February 3, by Prof. J. Joly, F.R.S.

[1] This might, possibly, be realised by condensing water vapour upon the ions according to the method described by C. T. R. Wilson (Proc. R. S., June, 1911).

of between 6 and 7 centimetres from it. This is entirely due to radium C. Within this shell we have a spherical shell due to radium A. It is the next we meet as we go inwards. It has an extreme diameter of 4·8 cm. The next shell is created by emanation. Its radius is 4·2 cm. The shell due to radium F succeeds at 3·8 cm.; then comes that made by radium, and, lastly, a very intense one due to the nearly coincident effects of three rays, two due to uranium and one to ionium. The weight of this particle of pitchblende is about one-tenth of a gram. If all its rays escaped freely at its surface, some 9600 α rays would leave it per second, and the number of ions created in the air per second would be about 960 millions. The diagram (Fig. 2) shows the successive shells, as they could be formed in air, to half scale.

We shall now pursue the study of radiant matter within the confines of another branch of science—that which deals with the nature, origin, and structure of the rocks. We gain this much by the transfer, that the invisible effects we have just been endeavouring to picture to ourselves as taking place around a radio-active body in equilibrium may be studied at our leisure, visibly inscribed in the ancient rocks. We require the microscope, however, in order to carry on our observations.

If we extract a flake of brown mica from the granite near Dublin and look at it through the microscope, we

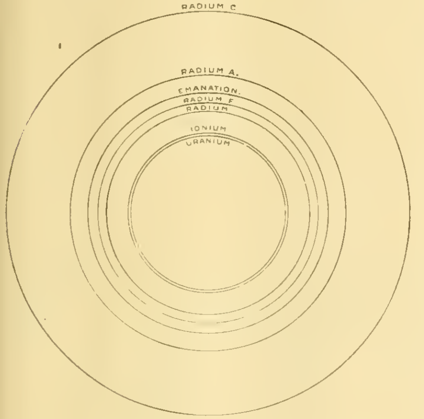

FIG. 2.

find here and there dark circular or disc-shaped marks. In the centre of each is a small crystal. This in most cases is the mineral zircon, which became enclosed in the mica at an early stage in the formation of that mineral. The dark area extends around the zircon like a darkened border, and, if the crystal is small enough, takes on the form of a perfectly true circle.

The remarkable occurrence of these dark circular spots, or "pleochroic haloes," as they are called, has been known to more than one generation of petrologists, and has always excited interest. Their origin has until lately been unexplained. Sollas, some years ago, prophetically stated his belief that they were to be ascribed to the presence of some rare earth in the zircon. When the minerals of the rocks were searched by Strutt for radio-active bodies, it was found that zircons were intensely radio-active—a concentration of uranium having in some manner taken place in these early formed bodies. The minerals apatite and allenite are also sometimes conspicuously radio-active, and around these, also, haloes often exist.

Let us then suppose that the halo is due to the radioactivity of the minute crystal around which it extends. We know that the radio-active elements in the zircon discharge helium atoms at high velocity into the surrounding mica. If these α rays have power to affect the mica by ionisation, just as they colour glass or affect a photographic plate, then there will be a certain region affected extending just so far as the rays can penetrate and no further. It will be a test of this explanation if the radius of the circular marks is found to be just the correct distance to which the rays could travel in mica.

Now Bragg and Kleeman have determined the principles upon which we may estimate from the observed ranges in air the range of α rays in any substance the chemical nature and density of which are known. Accordingly, we may calculate the ranges of several α rays in biotite. The table below gives the results.

Range in Biotite.

	mm.		mm.
Radium C	0·033	Thorium C	0·040
Radium A	0·023	Thorium X	0·026
Emanation	0·020	Thorium emanation	0·025
Radium F	0·018	Thorium B	0·023
Radium	0·017	Radiothorium ...	0·018
Ionium	0·013	Thorium	0·016
Uranium	0·013		

We see, as might have been expected, and as, indeed, was shown to you at the beginning of this lecture, that the mica is much more effective in stopping the rays than is the air. The extreme penetration of the rays from radium C is only thirty-three thousandths of a millimetre—a distance invisible to the unaided eye. This should be the limiting radius of a halo formed from the elements derived from uranium. If the thorium series was responsible, then we might expect haloes having a radius extending to the range of thorium C, that is, about forty thousandths of a millimetre. Now these are just the dimensions we find in the rocks when, by suitable appliances, we measure the sizes of haloes. Some have a radial dimension of 0·033 mm., and are then easily identified as due to the uranium series, and some scale 0·040 mm.; these are thorium haloes. Many scores of measurements confirm these results. Actinium haloes are not found; and this fact supports the inference already alluded to, that this element is derived from uranium as a very subordinate derivative, its effects being masked by the much greater vigour of the radiations from the radium series of elements. There is, then, no doubt, from the foregoing evidence alone, that haloes are the result of radiant matter.

It is of much interest to note that Rutherford has generated the equivalent of a halo in glass. In the course of experiments in which he had radium emanation contained in a capillary tube, the halo developed as a coloured border around the capillary, the radial dimensions being just such as corresponded with the penetration of α rays in glass. In the figure (Fig. 3), which I owe to the kindness of Prof. Rutherford, the central dark band is the capillary, the bordering narrow shaded area the halo.

It may also be mentioned that the experimental application of radium to biotite produces just such a darkening of the mica after some months as we see in the natural halo.

The circular or disc-like appearance of the halo is due to the fact that it is presented to us as the cross-section of a sphere. The true form is spherical. This is proved by the fact that when a crystal of mica is cut across the cleavage, the form is still circular (Fig. 5). This shows that the α rays are projected equal distances, or at least produce equal effects, along and across the cleavage—a fact not without considerable interest in itself, for it would hardly be expected on first consideration.

In the haloes which we have seen upon the screen there is no differentiation between the effects of the slower moving rays and those which move faster. The effects of the former must lie inside those due to the latter. The obliteration of the inner shells or spheres of ionisation is explained on the same principles as account for the loss of detail upon an over-exposed photographic plate. In the case of over-exposure the contrast is lost, because the effects of the lower lights have overtaken those of the higher lights, a uniform blackening ultimately resulting. If the radiant matter has been acting intensely on the mica for a very long time, the several shells of ionisation are merged in the accumulation of the feebler effects which are always progressing at all points along the path of the ray as shown in the Bragg curve.

We should expect, however, to meet cases where, either from the smallness of the quantity of radio-active material or from the recentness of the formation of the rock, there is a proper or correct exposure, so that the successive shells of ionisation, which we may picture to ourselves as surrounding a particle of pitchblende in air, would, as developed in the mica, be made visible to the eye. In this anticipation we assume that Bragg's laws apply to the ionisation of a solid.

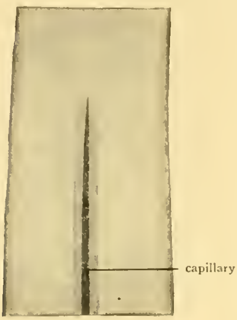

FIG. 3.

Now we do indeed find the several spheres of ionisation—or at least many of them—beautifully depicted in certain minerals, and thus we, at one and the same time, find additional, indeed overwhelming, evidence that the haloes are due to α rays, and also, what would be hard to establish experimentally, that Bragg's laws govern the effects in the solid medium.

Here is a group of well-exposed haloes in the biotite of co. Carlow. You see the outer ring due to radium C, and the gap of feebler ionisation between it and the shell due to radium A. We even find some which are actually "under-exposed." These often have got no further than the record made by the intense triple effect due to uranium and ionium. I show you this photograph again, but this time with an engraved scale of hundredths of a millimetre, which was photographed without disturbing the microscope; so that it is possible for you to verify the fact that the dimensions of the fully formed haloes are all over the plate alike, and just that which the radiant matter from the uranium series of elements would account for.

It is possible to trace the development of haloes by observation of those arising from a feebler and feebler central radiation. A succession of photographs taken to the same enlargement reveals that the innermost sphere is first formed. Then this widens under the rays from radium and emanation, and the outermost sphere, for some unexplained reason, often becomes conspicuous before radium A has produced much effect. The effects of the latter rays sometimes appear as a distinct ring.

We find a striking comment on the immense age of the haloes and of the containing rocks by a study of these objects, for it is easy to show that the growing haloes we have now been looking at are the accumulated effects of ionisation acting with extreme slowness. It is calculable directly that, even if we supposed the minute nuclei of some of these haloes to consist, not of zircon, but of the most radio-active ore known, pitchblende, the rate of expulsion of the α rays has, owing to the smallness of the quantities of radio-active substances involved, been fewer than eighty in a year. But this is not all. Some of the nuclei are identified with certainty as zircons. If we ascribe to these a radio-activity even greater than Strutt found in his highest measurements, one or more years would have elapsed between one expulsion of consecutive helium atoms and another. But geological time is long; and we may still recognise in the feeblest haloes the work of many millions of atoms of radiant matter, each exerting its own small effect, but these effects carefully preserved and accumulated. In short, we recognise the halo and detect its nature and origin on the same principles as we recognise by their light-effects accumulated upon the photographic plate the presence of stars invisible to the eye.

We find, then, in the rocks a record of the laws of radiant matter in the handwriting of the radiant matter itself—a record which took many millions of years to inscribe. Haloes are not found in the younger rocks. We must clearly recognise the halo as the result of the integration of effects of unimaginable feebleness; and as we see them in the Archæan granites, they probably date their beginnings from times long antecedent to the appearance of life upon the globe, not fewer than 100 million years ago.

They assure us, therefore, of the remote antiquity of the atomic instability which calls radiant matter into existence. But even more they tell us of the enduring stability of the ordinary elements. If the common and abundant elements which occur in and around the mica emitted radiant matter, even at the slowest rates, the clear transparency of the mica must long ago have vanished, and the whole become obscured under the effects accumulated during the ages which have elapsed since the formation of the rocks.

We seem entitled to conclude that the atomic stability and instability which we observe to-day have prevailed during geological time.

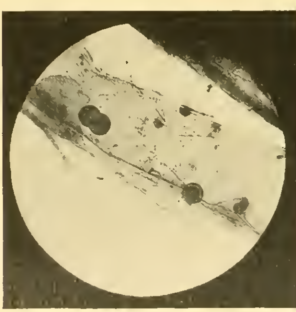

FIG. 4. Radium haloes in cleavage plate of biotite (co. Carlow); enlarged about 76 diameters. Two overlapping haloes are present, as well as a few under-exposed haloes.

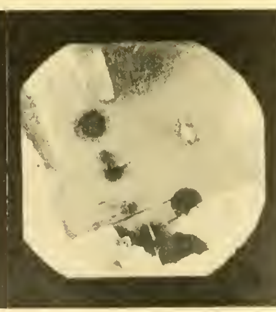

FIG. 5.—A radium halo (lower right-hand part of the field) and a thorium halo (upper left-hand part) in brown mica in a granite. The mica is cut across the cleavage. Enlargement about 114 diameters. The thorium halo shows an inner sphere due to the thorium X. The ratio of the diameters of inner and outer spheres will be found to be as 2·6 : 4·0.

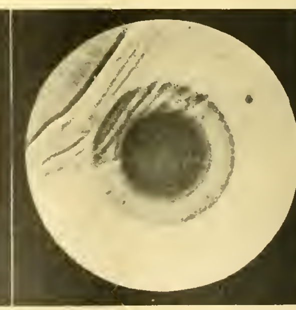

FIG. 6.—A single radium halo from the Carlow biotite. It is enlarged to about 500 diameters. The inner dark disc is due to emanation. The radium A sphere succeeds and appears to be less developed than that of radium C. Viewed on cleavage.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—A special degree congregation is to be held on July 27 in connection with the meeting of the British Medical Association, in Birmingham, at which it is proposed to confer the honorary degree of LL.D. on the following gentlemen:—The Rt. Hon. John Burns, President of the Local Government Board; Sir Francis Lovell, K.C.M.G.; Dr. R. H. Chittenden, professor of physiology in Yale University, U.S.A.; Prof. H. Oppenheim, Berlin; Prof. Paul Strassman, Berlin; Dr. Byrom Bramwell, president, Royal College of Physicians, Edinburgh; Dr. J. A. Macdonald; Dr. R. A. Reeve, professor of ophthalmology, Toronto; and Prof. Sims Woodhead.

IT is announced in *The Times* that the Chinese Minister has consented to become patron of the United Universities' scheme for a university for China. The Rev. W. E. Soothill has been appointed acting president of the university for five years. Mr. Soothill was formerly principal of the Imperial University, Shan-si, China, and is the author of standard works on the Chinese language.

THE French Physical Society, the International Society of Electricians, and other learned societies, are cooperating in the inauguration of a fund to honour the memory of the late M J. Joubert, of the Pasteur Institute. The object of the fund is to found a scholarship, with which the name of Joubert will be associated, tenable at one of the institutions with which he was connected as pupil or teacher. Subscriptions may be sent to M. Gauthier-Villars, 55 quai des Grands-Augustins, Paris.

THE issue of the *Johns Hopkins University Circular* for May takes the form of the "Johns Hopkins University Register, 1910–11." The historical statement with which the volume opens shows that the university was incorporated on August 24, 1867, and its original endowment amounted to about 600,000*l.* This fund has been supplemented by several gifts, including 200,000*l.* in 1902, until now the income-bearing funds amount to more than 900,000*l.*, the total assets being 1,300,000*l.* In June, 1909, the General Education Board offered to contribute to the university 50,000*l.* towards the endowment, provided the institution could secure, on or before December 31, 1910, a supplemental sum of 150,000*l.*, in cash or pledges. By the date mentioned the sum of 188,600*l.* was secured, more than sufficient to meet the condition imposed by the General Education Board. The Legislature of Maryland, too, has this year made a grant of 5000*l.*, which will be repeated next year.

THE fifteenth Oxford Summer Meeting will be held at Oxford from August 3 to 28. The general scheme of lectures is intended to illustrate the place and part of Germany in world history, and its contribution to literature, art, science, theology, and philosophy. The inaugural address will be given by Viscount Haldane. One section of the meeting will consist of lectures on the epoch-making names in German science. These discourses include: Humboldt, by Mr. H. J. MacKinder, M.P.; Helmholtz, by Sir Joseph Larmor, F.R.S.; Liebig and Bunsen, by Sir William Tilden, F.R.S.; Johannes Müller, by Prof. F. Gotch, F.R.S.; Von Bär—the founder of modern embryology, by Prof. G. C. Bourne, F.R.S.; the evolution of medicine in Germany, 1850–1900 (Virchow and Koch), by Sir W. Osler, F.R.S.; and Gauss and modern astronomy, by Mr. J. A. Hardcastle. There will also be a special class for instruction in field map-making under Mr. Mackenzie, and classes in educational psychology.

THE Royal Commissioners for the Exhibition of 1851 intend to put into operation at an early date a scheme of industrial bursaries. The scheme is as follows. The commissioners propose to establish a scheme of industrial bursaries for young men who, after a course of training in a university or approved technical college, desire to enter engineering, chemical, or other manufacturing works. The bursaries are intended to enable suitable applicants to tide over the period between their leaving college and obtaining remunerative employment in industry. The value of the bursary will depend on the circumstances of the candidate, but will, as a rule, not exceed 100*l.* a year. A bursar will be elected in the first instance for one year, but the tenure of his bursary will ordinarily be prolonged for a second year provided that the commissioners are satisfied with the work done by the bursar during his first year. In special circumstances a bursary may be renewed for a third year. The appointments to the bursaries will be made by the commissioners from among candidates recommended by the authorities of certain selected universities and technical schools. In dealing with these recommendations, great weight will be given to evidence that a candidate has the practical abilities likely to lead to his advancement in manufacturing work, academic success alone being an insufficient recommendation. The candidate must be a British subject under the age of twenty-five. The candidate must have been a *bona fide* student of science for a term of three years. The candidate must further satisfy the commissioners (*a*) that he has obtained, or can within one month of election obtain, a post in some engineering or other manufacturing works approved by them; (*b*) that he is in need of pecuniary assistance to enable him to accept such a post. A bursar may, if the commissioners approve, spend part of the tenure of his bursary in studying a special industrial process or processes in works either at home or abroad. No bursar shall enter a firm as a premium pupil without the special consent of the commissioners. A bursar must submit a report of his work to the commissioners on the expiration of each year of his bursary. Forms of application may be obtained from the secretary to the commissioners.

SOCIETIES AND ACADEMIES.

DUBLIN.

Royal Dublin Society, June 27.—Prof. T. Johnson in the chair.—Prof. G. H. **Carpenter**: Injurious insects and other animals observed in Ireland during the year 1910. The points of interest in this paper are the record of a second brood of the codling moth (*Carpocapsa pomonella*) in the south-west of Ireland, and the occurrence of the maggots of *Scaptomyza flaveola* and an unknown Cecidomyid on turnips in county Louth.—Prof. J. **Joly** and L. B. **Smyth**: The radium-emanation content of soil gases and its escape into the atmosphere. The emanation content of soil gas is measured by filling a suitably calibrated electroscope with gas drawn from certain depths in the soil. The rate of its escape at the surface of the soil is investigated by means of a collector, which covers a certain area of the soil, and beneath which a slow current of air circulates. The air current is finally led through a charcoal absorption tube. It is believed that natural conditions are best realised by this collector. It is found that the conditions favouring the maximum rate of exhalation are dryness and openness of the capillaries of the soil. These conditions also lead to a fall in the emanation-content beneath. In accordance with this, the daily readings of emanation-content and of exhalation at the surface when plotted show opposing curvatures. The amount escaping at the surface is very considerable. The rate of escape is often more than sufficient to account for the decay of the emanation in a radio-actively homogeneous atmosphere extending to a height of 5 kilometres, and possessing an emanation-content equal to the average found by Eve and others. Soil within the city of Dublin is found to contain less emanation and exhale less than soils in the suburbs. To the south of the city the soil is specially rich, the quantity of contained emanation near the surface per litre being such as would be in equilibrium with a quantity of radium of the order 10^{-9} gram, the quantity exhaled per square metre per hour being also of this order. The causes influencing the quantity of radium emanation in the soil are under investigation, as well as the influence of the emanation upon vegetable life.

PARIS.

Academy of Sciences, July 10.—M. Lippmann in the chair.—B. **Baillaud**: Remarks on a volume of the photographic catalogue of the sky, Paris zone.—M. **Renaut** was elected a correspondant for the section of anatomy and zoology, in the place of the late M. Armand Sabatier.—MM. **Lagrula** and **Schaumasse**: The Kiess comet, 1911*b*. Observations made at Nice. Three observations are given for July 8. The comet appears as a bright globular condensation surrounded by a nebulosity.—

M. **Javelle**: The Wolf comet. Observations made at Nice with the Gautier equatorial of 76 cm. aperture. Data given for July 5 and 7. The comet appears like a star below the 14th magnitude.—Silvanus P. **Thompson**: A new method of harmonic analysis by the algebraic summation of determined ordinates. The method described is specially adapted for the harmonic analysis of tides, of diurnal magnetic variations, and of the periodic motion of the mechanisms for the distribution of steam in steam engines.—G. **Sagnac**: Interferential strioscopy and striography analogous with the Foucault and Töpler optical method of striæ.—Ch. **Fabry** and H. **Buisson**: The radiation from mercury vapour lamps. The numerous applications of quartz mercury vapour lamps renders desirable precise measurements of the yield of radiation, visible and ultraviolet, under various conditions of employment. The proportion of ultraviolet rays emitted by a given lamp depends greatly on whether it is water-cooled or not, and also upon the age of the lamp.—L. **Benoist**: The application of the chemical harmonica to chronophotography. An acetylene flame, issuing from a fine jet, is placed in a glass chimney, and from the pure note thus obtained the time of vibration can be determined with considerable accuracy. A mirror is fixed to the rotating apparatus the velocity of which it required to measure. The high actinic power of the flame renders the application of photography very easy.—M. **Girousse**: A means of suppressing the troubles caused on telegraph lines by energy-carrying cables. A description of a simplification of the method proposed by Voisenat. The immunity obtained against an alternating current has been proved experimentally, and details are given.—R. **Boulouch**: The sine relation of Abbe is a condition of stigmatism. The condition of true aplanetism.—A. and L. **Lumière** and A. **Seyewetz**: The development of photographic images after fixing. If a very dilute solution of sodium thiosulphate is used for fixing, the Neuhauss method can be much simplified. The formulæ of the solutions taken are given, and also an alternative solution containing mercury salts instead of silver.—Marcel **Guichard**: The extraction of the gases from copper heated in a vacuum. The complete elimination of the gases from copper by heating is difficult to realise, and requires in all cases a very lengthy period of heating.—H. **Gault**: The lactonisation of the α-ketonic esters, α-ketoadipic ester, and in general, the esters of α-ketomonoacids and α-ketodiacids under the influence of condensing agents, forms lactones by the elimination of a molecule of alcohol between two molecules of the ester. Several examples are worked out in detail.—Ph. **Dumesnil**: The preparation of some unsymmetrical benzyl-dialkylacetic acids. Starting with ketones of the type $C_6H_5.CO.C(R_1R_2R_3)$, prepared by the method of Haller and Baur, the prolonged action of sodium amide in boiling xylene upon these ketones gives the amide $NH_2.CO.C(R_1R_2R_3)$, from which the corresponding acid is readily obtained by hydrolysis with sulphuric acid.—E. **Léger**: The constitution of some nitro derivatives obtained by the action of nitric acid upon the aloins.—A. H. **Richard**: A dimethylpentene obtained by the action of heat upon a dimethylcaoutchouc. Methyl-isoprene polymerises in exactly the same manner as isoprene. Under the influence of light and heat it gives a rubber-like mass: the dry distillation of the latter gives a homoterpene as the principal product.—M. **Gard**: Is the law of uniformity of hybrids of the first generation absolute? It has been found that for the genus Cistus the uniformity found by Naudin is not fixed.—J. E. **Abelous** and E. **Bardier**: The influence of oxidation on the toxicity of urohypotensine. The toxic power of urohypotensine is increased by oxidation.—H. **Bierry** and J. **Larguier des Bancels**: The action of the light emitted by the mercury lamp upon solutions of chlorophyll.—M. and Mme. **Lapicque**: The useful duration of the discharges of condensers: experiments on the snail.—A. **Imbert**: A graphical study of work done by a file. The curves obtained showed clearly the differences between an apprentice and a practised workman: pathological conditions in the latter are also clearly brought out, a fact of medico-legal importance.—J. **Bergonié**: The respiratory exchanges in chronic articular rheumatism and the modifications which they undergo by muscular exercise electrically stimulated. The respiratory exchanges, in subjects affected by chronic articular rheumatism, are very appreciably lowered, in one case to about 3/5 of the normal. The light bath appeared to be without any influence on these cases, but muscular exercise, electrically stimulated, caused these exchanges to approach the normal.—Jules **Courmont** and A. **Rochain**: Vaccination against the pyocyanic infection by the intestinal method.—A. **Sartory**: The value of Meyer's reagent in the examination of the blood. Meyer's reagent ought not to be considered as a specific test for blood in chemico-legal researches, and should only be used for corroborative purposes.—A. **Fernbach** and M. **Schœn**: Some observations on the mechanism of the mode of action of the proteolytic diastases.—Alexandre **Lebedeff**: The mechanism of alcoholic fermentation.—J. **Wolff** and E. **de Stœcklin**: The specificity of various combinations of iron from the point of view of their peroxidasic properties. A reply to some criticisms of H. Colin and A. Sénéchal, the authors giving the results of fresh experiments in support of their views.—Paul **Hallez**: The double function of the ovaries in some Polyclads.

THE ENCYCLOPÆDIA BRITANNICA.

The Encyclopaedia Britannica: a Dictionary of Arts, Sciences, Literature, and General Information. Eleventh edition. Vols. xv.–xxix. (Italy—Zymotic Diseases, and index volume.) (Cambridge: University Press, 1911.)

A GENERAL notice of fifteen volumes of the dimensions of "The Encyclopædia Britannica" can, at best, be based only on a process of "browsing" through them, and of turning to a subject here and there as it strikes the mind. In these volumes there is ample scientific material on which to examine two claims that have been put forward on behalf of the work on general grounds. The first is that its use as a work of reference purely, for the discovery of one isolated fact or another, is not its only use, not even its primary use, since for this purpose a reference book of less ample size probably fulfils any demand that the ordinary inquirer is likely to make. Not that "The Encyclopædia Britannica" fails in this object; the number of its article headings is well known to have been enormously increased in the present edition, every judicious addition of a heading adds to its value as a work of reference simply, while the existence of an index volume, though somewhat elaborating the mechanical process of discovering an isolated fact, eliminates the necessity of exercising imagination in finding information to which no article heading directly points. But beyond this, it is claimed that the work is usable by readers as a library in itself, and, secondly, that the desire to make it thus usable has justified the new editorial policy of making the articles under the broad scientific or other headings, not exhaustive treatises on the whole of each subject, but, wherever possible (it is not always so), comparatively brief notices confined strictly to main lines, and indicating to the reader the further headings to which he may turn if he desires to pursue the subject. Another most important aid in this pursuit has been given, as will presently be seen, as a new feature of the index volume.

A few of the articles under general scientific headings in the second half of the volumes may be taken as illustrating the above thesis. Dr. A. N. Whitehead's article on mathematics covers little more than four pages; it defines the science, briefly reviews its history, and indicates its scope and application, and in doing the last it indicates upwards of fifty other headings, under which any branch of the subject may be pursued. Dr. Max Verworn's notice on physiology is laid out on similar lines; anatomy, cytology, digestive organs, respiratory system, touch, smell, taste, vision, hearing, plants (physiology), are a few of the branch lines to which this concise summary shows the way. In the article on zoology, Sir E. Ray Lankester writes at greater length, it is true, than do either of the authors just named in their general treatises, but he does not go outside the history of the whole subject, with particular reference to the various important systems of classification which have been laid down, leading up to that adopted in "The Encyclopædia Britannica" itself. It may be added here that the editors have not feared the adjectival heading (a form open to much abuse in reference books, as such headings are not easy of preconception by the reader) when it appears appropriate, from the point of view of the specialist, to a clearly defined compartment of a general subject. Thus Zoological Distribution and Zoological Nomenclature are very properly made the headings of separate articles, instead of being made great sections under the general heading of zoology. The one is dealt with very clearly by Mr. Lydekker, who has contributed a great mass of zoological matter to the whole work; the other is by Dr. Chalmers Mitchell, who incidentally gives his high authority to the subject of zoological gardens.

The index has in a large degree followed the model of that provided in the tenth edition, but certain obvious improvements have been introduced. By the use of a distinctive type it is made clear when any index heading is also an article heading in the text. The reader is thus able to appreciate at once that any references which follow under such an index heading are merely supplemental to the article itself, and it would appear that a more judicious selection of such "casual" references has been made than was made in the index to the last edition. Indeed, some of the larger blocks of index references, as, for example, those dealing with the history of large countries, have obviously been made, not by simply collecting and editing the references gathered by independent indexers in the course of their work, but by means of a selection (by one hand) of the verbal references which a user of the index would naturally expect to find, and the subsequent attachment of the proper page and volume numbers to them. This must have involved a great deal of research, and as such work was dependent upon the completion of the whole of the text, it may be said that the index has been issued with laudable promptitude.

But the new feature of the index volume referred to above, as an aid to the pursuit of a given broad subject through the whole of the work, is perhaps more worthy of praise than the index itself. This is the classified list of articles, which the editors "believe to be the first attempt in any general work of reference at a systematic catalogue or analysis of the material contained in it." Under such broad divisions as art, biology, geography, history, medical science, physics, &c. (there are twenty-four of these divisions in all), and under appropriate departments within each, practically the whole of the article headings in the "Encyclopædia" are classified and subclassified, so that a reader who wishes for a bird's-eye view of all the article headings in the department (say) of pathology, therapeutics, and surgery, can turn up that group and see them at a glance. This is a most important addition to the use of the "Encyclopædia," not as a work of general reference, but as a special encyclopædia on any given subject. Incidentally it furnishes perhaps a more remarkable conception of the magnitude of the work than do even the textual volumes themselves; the department of pathology, therapeutics, and surgery alone is found to contain nearly 250 separate articles, exclusive of biographies (which are always classified together at the end of each main division or department). The editors of the list have evidently been faced with an exceedingly difficult problem in allocating some of the headings to their most appropriate department; any system of duplication which would have allowed every department to indicate every article which had any bearing upon it would have become hopelessly cumbrous, and those who use this list may sometimes have to turn from their own special subject to a kindred department. But the whole list is so clearly arranged that this process presents no difficulty.

It would be improper to attempt a detailed notice of any one branch of science in a general survey of a series of volumes which include such notable contributions as the article on Palæobotany by Dr. D. H. Scott, Prof. Seward, and Mr. Clement Reid; Prof. H. F. Osborn's Palæontology; Mr. Leonard Spencer's Mineralogy and Prof. J. F. Kemp's Mineral Deposits; Dr. Stockman's Pharmacology; Prof. Poynting's article on Sound; Magnetism, by Shelford Bidwell, and Terrestrial Magnetism, by Dr. Chree; Map by Dr. Ravenstein and Col. C. F. Close; Prof. Abbé's Meteorology; Ocean and Oceanography, by Dr. H. R. Mill and Prof. Krümmel, and a host of others. But it is possible to refer in general terms to the satisfactory character of the illustrations which classify so many of these important treatises, from the admirable textual sketches which serve to illustrate the main features of some of the remarkable ancient maps described by Dr. Ravenstein, to the coloured plates accompanying the articles on pathology and parasitic diseases. The coloured plates are for the most part exceedingly good; most of them (such as the beautiful Orders of Knighthood, in the preparation of which King Edward VII. took so great an interest) fall outside the scientific articles. Reference, however, may be permissible to the admirable illustration under "Process" of the four stages of the three-colour process, worth far more than its bulk in textual explanation. The half-tone reproductions can only be criticised on the score of occasionally showing evidence of printing at high pressure, while there are some faults of manufacture—in the volumes before us we have happened upon one plate bound in duplicate, while a certain plate-map which is indexed does not appear. But as a whole the half-tones are excellent, and some which call for high detail, such as those illustrating "Lace" or "Pathology," are beyond praise. Engineers will value the cosmopolitan series of plates and line diagrams in the articles on ship and shipbuilding, to which Sir Philip Watts and the Rev. Dr. Warre have contributed. The line drawings throughout the work have printed satisfactorily on the thin paper, and the fineness of some of the zoological drawings (for example), or those illustrating Mr. A. H. Smith's article on jewelry, is admirable.

It will be understood that the examples named are chosen at hazard out of hundreds, for the illustrations, if their treatment by the manufacturers is open to the criticisms already made, afford evidence of systematic editorial arrangement and of no sparing hand on the part of the publishers.

The statistician has found less material for his use in the present than in past editions of the "Encyclopædia." It is no doubt a misfortune that the publication of the whole work had to be timed a little in advance of a period at which there became available that most important series of statistics, the decennial census returns. But the editors have deliberately disregarded (save in exceptional cases) the often deceptive intercensal estimates of population. In other departments it would probably have passed the wit of man to devise mechanism for the insertion of the latest figure in every statistical statement in twenty-eight volumes published almost simultaneously, even if it had been thought desirable, which (as the "Encyclopædia" is not an annual publication) it was not. But whereas the notices on the divisions and towns of the United Kingdom and the United States have been relieved of a considerable mass of statistics, the two general articles under these titles have been made the receptacle of a large number of figures, brought down to the latest available dates, which, being set in tables or other comparative forms, will probably be of use to a greater number of readers than if they had been distributed through the lesser articles.

The principal conclusion of a general survey of the completed work is that the editors deserve to have it realised that they have made a library—not only a dictionary—not a year-book. The work may contain some errors of detail, whether the result of the march of events during its compilation, or simply of a compiler's human fallibility; it would be beyond human work if it did not. But it appears to be surprisingly free of editorial misjudgment in respect of the selection of article headings and the apportionment of space to every department of knowledge. The existence of the classified list shows that the editors are not afraid of exhibiting their selection, and the reader who finds an apparent gap in it will probably discover on reference to the index that the subject he seeks is really an indivisible part of a wider one. And by following this process he will probably be paying the makers of the "Encyclopædia" the compliment of using it as they intend it chiefly to be used.

COMPARATIVE ANATOMY.

Vorlesungen über vergleichende Anatomie. By Prof. O. Bütschli. 1 Lieferung, Einleitung; Vergleichende Anatomie der Protozoen; Integument und Skelet der Metazoen. Pp. viii+401. (Leipzig: W. Engelmann, 1910.) Price 12 marks.

THE method of studying comparative anatomy that will ever be associated with the honoured names of John Hunter and Gegenbaur appeals strongly to the student of medicine, and those who specialise in human anatomy, as being the most interesting and instructive way of learning the significance of the animal economy. The comparison of homologous structures in the whole range of the animal kingdom and the realisation of their varying development and differing arrangement throw light upon their functions, and in our day explains the process of evolution of complex from simple structures. John Hunter embodied this method in the arrangement of his museum; Gegenbaur developed it in his lectures and his books.

But many systematists, whose chief aim in life is to study the differences with which they hedge round their multitudes of species, view with suspicion a method of studying zoology which lays chief stress upon the resemblances that help us to link together the various members of the animal kingdom.

Thus Prof. Bütschli's text-book, continuing as it does the best traditions of the famous Heidelberg school, is sure of a warm welcome from the morphologist, whatever view the species-monger and the devotees of the type-system of teaching zoology may think of it.

It was with mixed feelings that those who had been "brought up" on Gegenbaur's great book and had come to revere the great master, read the new edition of the Comparative Anatomy which was issued twelve years ago, after he had passed three score and ten years. When a man has reached that age it becomes impossible to keep in touch with all the manifold ramifications of such a science as morphology, even when, as in the late Prof. Gegenbaur's case, he had grown up with it and taken a principal, if not the leading, part in making the new branch of learning.

It required a younger man to write the new and simplified book that was urgently wanted; and no one was more fitted to undertake this task than Gegenbaur's pupil, who took charge of the course of lectures in zoology at Heidelberg in 1884, when his teacher relinquished the task. It is these lectures which are embodied in the book under consideration. The English student who may have spent weary hours trying to puzzle out the meaning of some of Gegenbaur's cryptic German and involved sentences will appreciate the lucidity of Bütschli's style and the ease with which his meaning can be grasped.

This volume represents only the first part of the text-book, and consists of four sections:—(1) An introduction, explaining terminology, and the scope and general conceptions of comparative anatomy; (2) a very complete, yet concise, summary of the distinctive features of all the considerable groups of animals; (3) the comparative anatomy of protozoa; and, finally (4), more than three-fourths of the volume are devoted to the account of the tegumentary and skeletal systems.

The integument and its various specialisations, scales, hairs, feathers, and glands, receive very full treatment. This is all the more welcome and valuable, as this branch of anatomy suffers from neglect more often perhaps than any other. A great mass of information concerning both invertebrates and vertebrates is crowded into a comparatively small space without any sacrifice of clearness.

After a general discussion of the nature of skeletal structures and the forms they assume in invertebrates, the early forms of the notochord are described, and then a succinct account is given of the forms assumed by each bone of the skeleton in the vertebrata.

One of the great features of this book is the abundance and the excellent educational value of the illustrations. Although they consist of semi-diagrammatic line drawings or half-tone reproductions of simple drawings, they are so free from unnecessary and confusing detail, so clearly labelled and really illustrative of the text, that the reader experiences no difficulty in following and understanding the descriptions.

Prof. Bütschli can be congratulated on having produced the first part of an introduction to comparative anatomy which is both of exceptional scientific merit and singularly well adapted to the needs of elementary students.

G. E. S.

THE BENIN GROUP OF NEGROES.

Anthropological Report on the Edo-speaking Peoples of Nigeria. By N. W. Thomas. Part i., Law and Custom. Pp. 163. Part ii., Linguistics. Pp. ix+251. (London: Harrison and Sons, 1910.)

THE Niger Delta, from Yorubaland on the west to the Cross River on the east, is a field of African ethnology which is only very slightly made known to us at the present day, but promises to yield some very interesting and important additions to our knowledge of negro races, when fully worked. Owing to its physical conditions, the area covered by the delta of this river—some 260 miles by 100—is still unexplored in some portions; indeed, down to about fifteen years ago the land everywhere at a distance of one mile from the banks of the navigable creeks had scarcely been seen by a European. Though there are within the delta tracts of undulating, well-drained soil much of the district is excessively swampy or covered with very dense bush, scrub, mangrove thicket, or magnificent but impenetrable forest. Mosquitoes and large Tabanid flies swarm and the former serve to inoculate the blood of the European with the germs of malarial and black-water fever. Yet (I write from old personal experience) where there is no native population at hand to supply from its blood the malarial *bacilli*, the Niger Delta is not necessarily unhealthy to Europeans, and the stinking mud around the mangrove swamps, though it smells mephitically, is not, so far as we know, the cause of any disease.

In addition to the great difficulties of land-transport, which hitherto have limited the routes of the Delta explorers to the water-courses, the disposition of numerous tribes is still very hostile to the European. Consequently from one cause and another, a wholesome fear of savage cannibals and poisoned arrows, of enormous crocodiles, of thunderstorms, lightning, torrential rain and tornadoes of wind, of a sunshine which is sometimes sickeningly hot, of sparsity of food supplies, and dread of fevers and dysentery, we are still very deficient in our knowledge of the tribes of the Niger Delta. Rumours of late from well-informed sources point to the existence in the region between the Forcados and the Nun of a pygmy or dwarfish people said to be yellow-skinned and steatopygous, and speakers of a "clicking" language; from the Rivers Pennington and Middleton comes a singularly savage and prognathous type of negro, so wild and barbarous that it is still (I am informed) difficult to get speech of them.

In addition to these unclassified folk of the least-known part of the Delta (Forcados to the Nun), the negroes of the Niger mouths and their accessory streams are now arranged in the following ethnic groups. Beginning on the west, the Edo or Benin peoples, treated of in the book under review; the Jekri on the south or south-west of these; the Ijō, south-east of the Edo (Sobo), and especially in the eastern part of the main delta, between the Nun mouth and Opobo; the Ibo, north of the Ijō; the Arō ruling caste (almost semi-Caucasian in their physiognomy and skin-colour), between the Ibo and the Cross river; and the semi-Bantu Kwō and Akwa tribes between the Opobo and the Efik people of Calabar. Some of the Arō men and women resemble the Fula in their clear-cut, delicate profiles, their thin, well-formed lips, and lithe, finely-shaped bodies; and (as already remarked) there are savages from the western part of the delta, which, to the reviewer, seemed of an exceptionally low and brutal type.

The Edo-speaking people of the ancient kingdom or confederation of Benin are mainly the subject of Mr. Northcote Thomas's monograph, though allusions to and some comparisons are made with certain of the other tribes of the Delta and with the Yoruba of Lagos hinterland. Linguistically and racially the Edo group seems to be allied to the Yoruba and also to the E'we family (of Dahome). Their somewhat remarkable civilisation (like that of the Arō and Efik to the east and south, so strikingly superior to the barbarity of the Ijō and Kwō) has come to them from the north and north-east, and may perhaps be traced back to the Songhai culture of mediæval Nigeria.

Mr. Thomas has very little to say about the bronze-casting which has made the culture of Benin famous in ethnology. It seems to have died out almost entirely amongst the Edo people of to-day, who confine themselves to forging brass and iron ornaments and implements.

The work under review deals in part i. first with the affinities of the Edo people and the surrounding tribes, so far as there are any. Then comes a brief sketch of the Edo speech, followed by ethnological notes on this people, between pp. 11 and 123; an appendix on the pronunciation of the Edo speech, together with sample vocabularies for filling up by other inquirers. Also there is an interesting appendix on genealogies and terms and degrees of kinship; and another on suggestions, for other anthropologists, as to the best procedure in photographing African peoples. (Though not without interest these appendices on linguistics and on photography are disappointing to the already trained ethnologist, who expects Mr. Thomas's book to be entirely filled with the results of his own researches.) Part ii. contains (*a*) a number of interlineally translated texts to illustrate the Edo, Ishan, Kukuruku (and numerous dialects), and Sobo languages; (*b*) a grammar of the Edo (Bini, Benin) language; (*c*) a comparative dictionary of the Edo languages and dialects; and (*d*) an Edo-English dictionary.

The index comes near the end of the first part, and is singularly poor and inadequate. It is strange that this should be so in a work which is sufficiently good and important to merit very full indexing. For it may be said without more ado that Mr. Northcote Thomas's study of the Edo-speaking people will take a prominent place in ethnological works dealing with the negro. It is all first-rate, first-hand information, and errs only by omission and not by commission. Particularly valuable are the sections dealing with religion and magic; with marriage and birth customs; with native law and trial by ordeal; and the notes on the native calendar. The texts taken down from the many native informants not only exhibit the exact structure of the different languages, but illustrate very effectively the subject-matter of negro stories, the somewhat gross indecency of speech in regard to certain legends, and in general the outlook on the world around them of negroes that have hitherto been almost entirely uninfluenced by the modern European.

In arranging the English version in his comparative dictionary, Mr. Thomas should have invited the assistance of someone acquainted with African zoology. There are no "pheasants" or "crow pheasants" in Africa, and no "badgers." H. H. JOHNSTON.

COLOUR AND CONSTITUTION.

Die Beziehungen zwischen Farbe und Konstitution bei organischen Verbindungen. By Prof. H. Ley. Pp. viii+246+Taf. ii. (Leipzig: S. Hirzel, 1911.) Price 7 marks.

MANY chemists will welcome Prof. Ley's work on the relations existing between selective absorption and constitution in the case of organic compounds. The subject has attracted considerable attention of late years, and probably more definite conclusions would have already been reached had physicists rather more knowledge of organic chemistry and organic chemists a better acquaintance with physical conceptions.

The work is divided into two parts, 204 pages being devoted to the subject indicated in the title, whilst the remainder of the book deals with the methods of spectroscopic work. Prof. Ley insists at an early stage on the necessity of making no distinction in kind between selective absorption in the visible and ultra-violet regions of the spectrum, and proceeds to a consideration of Beer's law, "extinction-coefficient," and the influences, such as concentration, solvent, and temperature, which cause variation in absorption spectra.

In dealing with the different theories which have been proposed to account for the colour of organic compounds, Prof. Ley starts with the early efforts of Graebe and Liebermann and of Witt, and divides the chromophors into eight groups. One cannot fail to be struck with the universal existence of conjugated double linkages in compounds which show selective absorption, though in the ketenes chromophoric properties seem to be associated with adjacent double linkages. The triple linkage, on the other hand, seems to have little effect, and benzoylphenylacetylene is a colourless compound. The quinonoid constitution of many coloured compounds and H. Kauffmann's more recent development of the auxochrome theory are then discussed, whilst considerable attention is devoted to the influence of the solvent and the variation of the position of absorption bands which is likely to be produced by association of solvent with solute. Due recognition is given to the importance of the work now being carried out by Purvis on the selective absorption of substances in the state of vapour, in which case the influence of solvent is quite eliminated.

Considerable interest attaches to the attempted physical explanation of selective absorption, and use is made of the mass of experimental material accumulated by Hartley, Baly, and others. Baly's idea of "isorropesis" does not commend itself to the author, who is in favour of an electronic theory.

As may be expected in a book written in the Leipzig laboratory, much attention is given to the quinonoid rearrangement frequently assumed when a change in colour accompanies salt formation. One might gather from this portion of the work that "chinoide Umlagerung" was specially associated with Leipzig; *e.g.* on p. 169 one finds regarding phenolphthalein :—

"Der Beweis, dass den Salzen chinoide Konstitution zukommt, beruht auf der Existenz zweier verschiedener Äther. Neben dem farblosen laktoiden Dimethyläther existiert ein roter chinoider Äther, der zuerst von Green und King dargestellt und eingehend auch von K. H. Meyer und Hantzsch, untersucht wurde."

One would scarcely realise the great importance of Prof. Green's work on the phthaleins by reading this passage; and it may be pointed out (see pp. 176–7) that the hydroxy- and amino-azo-compounds have engaged the attention of several workers.

The colours of complex salts introduces some inorganic chemistry, whilst in the last few pages—devoted to method—spectroscopes, spectrographs, &c., are described, and an outline of the manner of working with these instruments is given. J. T. H.

THE NON-METALLIC MINERALS OF ECONOMIC VALUE.

Die wichtigsten Lagerstätten der Nicht-Erze. By Dr. O. Stutzer. Erster Teil, Graphit, Diamant, Schwefel, Phosphat. Pp. xv+474. (Berlin: Gebrüder Borntraeger, 1911.) Price 16 marks.

THIS work is designed to supplement the treatise of Prof. Beck on "Mineral Veins and their Contents," by giving an account of the deposits of those useful mineral substances which are not classed as "ores." The first volume, now published, is evidently the fruit of a vast amount of labour and bibliographical research, and deals only with four classes of materials, to each of which the amount of space devoted is as follows—graphite, 88 pages; diamonds, 94 pages; sulphur, 81 pages; and phosphates, 198 pages. In the case of each of these materials, the author, after preliminary notices of its mineralogical characters and modes of occurrence, proceeds to compile from the most varied sources descriptions of each of the districts in which it occurs. These descriptions are illustrated by page blocks (of which there are no fewer than 108 in the volume) giving sketch maps, sections, drawings, and photographs. Very miscellaneous information is supplied in these accounts of localities, including statistics of annual yield with prices and total values, and even, in some cases, examples of forms of agreement between sellers and buyers. In the case of the South African diamond fields, however, these statistics are, unfortunately, not brought down to later date than the year 1908.

As a rule, the references to authorities are ample and satisfactory, but we notice some marked exceptions. The author's acquaintance with British scientific literature would appear to be much more limited than his knowledge of German, American, and even Japanese sources of information. Thus a section of the Upware phosphatic beds is stated to be "after W. Keeping-Penrose," and the puzzled English reader is left to find out that the information about British deposits is obtained, at second hand, from a Bulletin of the United States Geological Survey, written by Mr. R. A. F. Penrose, jun., in 1888! We are reminded of the ingenuous remark of a compatriot of the author, who, when it was pointed out to him that a research he had published had been long before anticipated in this country, said, "Ah, that was buried in the catacombs of the Royal Society's Transactions!" In like manner, we find that Mr. Teall's interesting account of the phosphatised trachyte of Clipperton Atoll, published in the Quarterly Journal of the Geological Society in 1898, is ignored, while many less interesting deposits in the Pacific are fully described.

After the discussions of the distribution and statistics of the materials in the various districts, the author proceeds to consider such general questions as their origin, artificial formation, and metamorphoses. The treatment of these more purely scientific problems, however, is quite subordinate to that of economic and statistical questions, and little of novelty or special interest is to be found in these sections of the book.

An exception to this may, perhaps, be found in the useful abstract, on pp. 254 to 262, of the views that have been put forward concerning the origin of beds of sulphur, including the possible production of some of these deposits through the agency of bacteria, like Beggiatoa and Chromatium. On the whole, however, the work is to be commended for its technological rather than its scientific value.

ELECTRICITY AND MAGNETISM.

(1) *Beispiele und Uebungen aus Elektrizität und Magnetismus.* By Prof. R. Weber. Fünfte Auflage. Pp. viii+330. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 4.80 marks.

(2) *Experimentelle Elektrizitätslehre, verbunden mit einer Einführung in die Maxwellsche und die Elektronentheorie der Elektrizität und des Lichts.* By Prof. H. Starke. Zweite Auflage. Pp. xvi+662. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 12 marks.

(1) THIS is a collection of nearly nine hundred examples in electricity and magnetism. They are all numerical in character, and each is completely

worked out. Where required, the exercise is explained by means of a diagram. It is recognised that certain preliminaries are required to enable the student to understand electrical problems, and, to this end, the earlier questions relate purely to mechanics, hydrostatics, and heat. The examples are very varied in type, and include cases of interest, both theoretically and practically. There follows a short section in which the various mechanical, thermal, and electrical units are defined, and the book concludes with numerous tables, in which these units are collected, together with others giving the values of the various physical constants required in the working of the exercises.

It is somewhat doubtful whether the procedure of asking a question and at once giving the answer can be of much benefit to a student. It surely tends to discourage the use of the student's own initiative. A few illustrative worked examples should suffice, the rest being left for the learner to undertake.

The book is well printed, but it may be mentioned that some six of the introductory pages are missing from the copy submitted to the reviewer; it is to be hoped that this mistake does not extend to the whole edition.

(2) The second edition of this excellent treatise on electricity and magnetism, by Prof. Starke, has been brought thoroughly up to date by the addition of numerous paragraphs and chapters. Besides all the experimental and theoretical considerations usually found in text-books on this subject, many special electrical applications are deal with at length. Particular attention is given to the production and properties of electro-magnetic waves and to the practical uses of the latter in wireless telegraphy and telephony. As indicated in the title, the electro-magnetic theory of light is also dealt with, especially the explanations of the various optical phenomena upon the electron theory. In the thirteenth chapter this theory is extended to thermal and electrical conduction, and to the different thermo-electric effects. The section devoted to the conduction of electricity in gases has been largely added to, so that most of the latest work in this department of physics is considered. The new chapter on radio-activity gives a brief general outline of the rapidly progressing work which has been done in this direction, and includes a table giving the various radio-active substances at present known, their life-periods, types of rays, and physical properties. Finally, the author devotes an appendix of considerable length to the theory of moving electrons and the principle of relativity.

In every respect this book has claims to be regarded as a standard work on electro-magnetism. The alterations and additions in this edition have brought it, as far as possible in a general text-book, to the level of modern scientific research. To all those desirous of becoming acquainted with the present state of knowledge in this subject it can therefore be thoroughly recommended. It may also be mentioned that the type, diagrams, and paper are excellent.

CELLULOSE EPHEMERIDES.

Literatur der Zellstoff- und Papier-Chemie und der Papier-Technik im Jahre 1909. In Auszügen dargestellt. By Prof. C. G. Schwalbe and A. Lutz. Pp. 158+xix+94. (Berlin: Gebrüder Borntraeger, 1911.) Price 5 marks.

Zur Kenntnis der Cellulosearten. By Dr. W. Schulz. Nebst einem Vorwort, by Prof. C. G. Schwalbe. Pp. vi+100. (Berlin: Gebrüder Borntraeger, 1911.) Price 3.20 marks.

THESE publications are indicative of the extraordinary specialisation of cellulose chemistry, and at the same time of a tendency to intensive elaboration of detail in investigation, and more particularly of records, which, however interesting to the specialist, are drawn in too narrow a perspective to rank in the general literature of the science.

The former is a bibliographical record, sufficiently defined by its title. It is produced under the auspices of a youthful technical society, the "Verein der Zellstoff- und Papier-Chemiker," which is doing much useful work, and very fully justifying its foundation and existence. The matter of the volume is exhaustive, the records take the form of abstracts, which are duly concentrated and presented under a well-considered scheme of classification, with full indexes.

The second volume is a record of research towards establishing a method of diagnosing the more important industrial celluloses in terms of differentiating factors. This work is evidently inspired by Prof. C. G. Schwalbe, and in a short preface he claims for the author's results at least a definite promise of achievement, a claim which is somewhat at variance with the conclusions recorded *en résumé* on pp. 85–86, 99–100; these are rather of negative import.

The main scheme of investigation is a study of acid hydrolysis, taking as a measure of the degree of hydrolysis the reactions of the products with alkaline cupric oxide (Fehling's solution), and as a first stage (*a*) combination in the cold with cupric oxide (hydrate), and secondly (*b*) reduction to cupric oxide, on boiling.

The quantitative determinations are recorded under a special nomenclature, thus:—"Cellulosezahlen" (*a*) "Korrigierte Kupferzahlen" (*b*–*a*); and after the particular hydrolytic treatment "Hydrolysierzahl" (*b*′) and "Korrigierte Hydrolysierzahl" (*b*–*a*′).

The numbers recorded for a selection of ten typical marks of sulphite celluloses are, as the author admits (*loc. cit.*), unconvincing. An *a priori* consideration of the method would, we think, have enabled the author to predict the generally inconclusive result. It has been long established that the hydrolytic resolutions of cellulose can proceed very far under the action both of acids and alkalis without liberating CO groups. It is clear therefore that cupric reduction is only a partial measure of cellulose hydrolysis. And generally oxidations by alkaline cupric oxide are highly complex reactions, even the classical reactions with the sugars are by no means well defined, and remain therefore of essentially empirical order. Without detracting in any way from the author's results as quantitative observations, we suggest that they should have been recorded in simple terms, that is, without the adventitious aid of a special nomenclature, which merely obscures their significance.

A more important section is that devoted to a careful study of the supposed total hydrolysis of cellulose to hexose groups, and the implied problem of fundamental constitutional import. The author rightly recognises that the experimental verifications of the view that "cellulose is a polyhexose anhydride," are wholly defective; indeed, with progress in investigation the actual yields of sugars or their immediate derivatives obtained from (cotton) cellulose are extremely variable and generally much below the statements of the earlier observers, Braconnot, Béchamp, Flechsig.

The later investigations of Ost and Wilkening indicate that the hydrolysis is complicated by the formation of acids of low molecular weight, and their results with the author's present contribution undermine the plausible assumption that cellulose is a close analogue of starch.

In his study of the hydrolysis of the normal cellulose, the author has taken as his starting point the well-known intermediate products obtainable as colloidal hydrates, thus Guignet's "Cellulose Colloide," Flechsig's typical "Amyloid," "Parchmentised Cellulose," and Ekström's so-called "Acid Cellulose." These products, tested in relation to Fehling's solution, and the particular scheme of hydrolysis previously described, gave extremely variable numbers, thus for the "Korr: Hydrolysierzahl" 7·3, 26·7, 17·6, 30·4, for the products in the above-named order. Following the section devoted to a careful study of these proximate products, is the complementary section on "Die Abbauendproduckte der Baumwollecellulose und des Sulfitzellstoffs."

From the preface (Schwalbe) we abstract the important result of these laborious observations, which is that the author obtained from cotton cellulose only 40 to 50 per cent. of its weight of the hexose (dextrose), either as such, or calculated from the yield of ozazone, and from sulphite celluloses less than one-half this yield.

This work we commend to the careful study of those who take a special interest in cellulose chemistry. In this case also we can commend the author's minutely detailed record of experimental conditions, which are quite essential. The only criticism we offer is that the work would have been more fruitful if spread over a smaller range of the intermediate products.

The differentiation of these is relatively unimportant. The concentration of the investigation upon the endeavour to account in any one case for the 100 parts of cellulose taken into work, in terms of the final products of hydrolysis, would have furnished a much more valuable and positive contribution to *the* fundamental problem.

As a further suggestion, the resolution of the acetate or "Acetolysis" of cellulose appears to be more promising of attaining to ultimate hydrolysis, the elimination of OH groups keeping the breakdown of the complex on simpler lines of cleavage (comp. W. Schliemann, *Annalen*, 378, 366, 1911).

Much work is being done in this direction, and we may expect before long to integrate the contributions from the two directions of experimental study into comprehensive schematic constitutional formulæ for the typical celluloses. We may anticipate from this a new light on "organic" chemistry in the full sense of the term.

OUR BOOK SHELF.

The Law of Sex Determination and its Practical Application. By Laura A. Calhoun (Mrs. E. E. Calhoun). Pp. 254. (New York: The Eugenics Publishing Co., 1910.) Price 1.50 dollars net.

THE theory suggested in this book is that "the sex of the embryo in man and the higher animals is determined in the ovary from which the ovum in question is developed. In the normal female the ovary of the right side yields ova which on fertilisation develop as males, and the ovary of the left side yields ova which are potentially female." "The writer is not in a position to furnish absolute verification, through methods of anatomy or physiology, of her theory. She has no laboratories nor methods of precision by which her theory can be directly tested. But she is convinced of its truth from her own extensive experience in its practical application for a period of thirty years." She has instructed her friends, and "the results have always verified the law, which during thirty years of observation and testing have never failed."

We shall not give away the ingenuous author's practical recipe, but the general theory is that the right ovary is responsible for the males. This will be good news for those who believe that men are always in the right. "In normal mothers the right ovary always produces ova that, when fertilised, develop as boys. The left ovary always produces ova that, when fertilised, develop as girls. And the mother determines the sex of her child when she consciously or unconsciously directs the fertilising spermatozoa to her right or left ovary." The evidence in support of the theory consists of references to a relatively small number of cases where obedience to the author's practical suggestions was followed by the appearance of a girl or a boy as desired.

A theory similar to the above was brought forward in 1909 by Rumley Dawson, and in dealing with either of them we are met by the difficulty of applying precise experimental tests in the case of man. The experiments of Doncaster and Marshall, reported in the *Journal of Genetics*, November, 1910, show that "in the rat it is not true that ova determining one sex are produced from one ovary, and those determining the opposite sex from the other, for each rat, with one ovary completely removed, produced young of both sexes. This does not, of course, prove that the "right and left ovary hypothesis" is not true for man, but its definite disproof for another mammal detracts from its probability." It may also be recalled that birds have only one ovary.

The book before us is in great part made up of quotations, mostly from sound authorities, such as E. B. Wilson, W. E. Castle, L. Cuénot, and T. H. Morgan. It is a well-intentioned book, but it does not contribute much to the difficult problem discussed.

New Zealand Plants and their Story. By Dr. L. Cockayne. Pp. viii+190. (Wellington: John Mackay, 1910.)

FOR some years past it has been Dr. Cockayne's endeavour to arouse amongst the settlers in the Dominion a better knowledge and appreciation of their exceptionally interesting native flora, and with this object he has, in addition to his various official reports, contributed from time to time popular botanical articles to different local journals. The material for several of these articles has been worked up into the more homogeneous ecological account now published by the Government of New Zealand for the benefit of private individuals and for instruction in schools.

The wealth of botanical treasures is truly great. Thus the forests comprise mixed forests—in which the ancient kauri pine, *Agathis australis* and *Beilschmiedia tarairi*, are conspicuous—and pure forests of *Podocarpus dacrydioides* and Nothofagus. The mixed forests are the homes of abundant lianes—to mention only species of Metrosideros, the liliaceous *Rhizopogon scandens* and *Lygodium reticulatum*—many tree ferns and epiphytes. No less interesting are the shrubs, chief amongst which are the subalpine species of Olearia, Cassinia, and Veronica, while the manuka, *Leptospermum scoparium,* and allied species play an important part in the physiognomy of the native heaths. Then again the alpine meadows are rich in floral gems, notably species of Euphrasia, Ourisia, Celmisia, and Ranunculus. Amongst plant curiosities the vegetable sheep, *Raoulia eximia,* is the most unique.

In addition to the ecology, chapters are devoted to an account of the early explorers, naturalised plants, the stories of four common plants—New Zealand flax, manuka, Fuchsia, and *Cordyline australis*—and plant cultivation. The few examples noted above will serve to indicate how rich and unique is the New Zealand flora; Dr. Cockayne's treatment is fully equal to his subject, and one could only wish that he had much more space to enter into greater detail. The numerous illustrations, although imperfectly reproduced, contribute a better realisation of the plant scenery.

De la Méthode dans les Sciences. Deuxième Série. by B. Baillaud, L. Bertrand, L. Blaringhem, E. Borel, G. Lanson, L. March, A. Meillet, J. Perrin, S. Reinach, and R. Zeiller. Pp. iii+365. (Paris: Félix Alcan, 1911.) Price 3.50 francs.

THE first series of studies in the methods of science by distinguished French writers was reviewed in NATURE on September 23, 1909 (vol. lxxxi., p. 361). The present volume has the same general characteristics, though the point of view is more technical and less philosophical. The following branches of science, which were not dealt with in the former volume, receive attention—astronomy, physical chemistry, geology, botany and palæobotany, archæology, literary history, linguistics, and statistics. The essays should assist in providing the reader with a broad general view of scientific methods, and help to correct the narrowness which may result from a too exclusive absorption in a restricted field of scientific investigation.

Essays in Historical Chemistry. By Sir Edward Thorpe, C.B., F.R.S. Third edition. Pp. xii+601. (London: Macmillan and Co., Ltd., 1911.) Price 12s. net.

PREVIOUS editions of this valuable work have been reviewed in these columns at some length, the first in our issue for April 12, 1894 (vol. xlix., p. 551), and the second in that of August 14, 1902 (vol lxvi., p. 365). The present edition differs from the last in including the memorial lecture on Julius Thomsen delivered to the Fellows of the Chemical Society on February 17, 1910. We also notice an addendum to the life of Prof. Stanislao Cannizzaro, who died at Rome on May 10, 1910.

School Planning at Home and Abroad. By William H. Webb. Pp. 42. (London: The Sanitary Publishing Co., Ltd., 1911.) Price 1s. net.

AT the annual congress of the Royal Sanitary Institute, held in September last at Brighton, Mr. Webb read a paper on "Large Public Elementary Schools in Town Districts." The paper is here published in book form, and illustrated by plans and other diagrams. Mr. Webb's inquiries respecting the characteristics of school buildings in various parts of Europe and America enable him to provide those responsible for the design of new schools with many useful hints.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Rearing of Sea Urchins.

I ENCLOSE a photograph which may interest your readers. It is one of a water-colour painting of a sea-urchin, magnified 4 diameters, which has been reared in my laboratory by Dr. Cresswell Shearer. It is a hybrid, a cross between *Echinus milearis* (male) and *E. esculentus* (female), both obtained from the Plymouth Marine Laboratory. The cross was effected in the early part of March last. It was kept in thoroughly aërated seawater for

some time, but has for the last three months been living in a bell-jar with part of an old crock covered by worm tubes, without the water being aërated in any way. It generally shelters in the day time under the crock. When disturbed, it moves actively away from the light, and still appears thoroughly healthy. It shows what may be done in an inland laboratory with simple appliances.

J. STANLEY GARDINER.

Zoological Laboratory, Cambridge, July 10.

Absorption Markings in "K" Spectroheliograms.

MR. EVERSHED'S remarks in NATURE of May 11 cause me to think that possibly an essential difference in the method employed for reproducing original negatives for journalistic purposes might go far towards explaining the difference of definition and richness of detail in M. Deslandres' plates. Anyhow, we are now assured that the Kodaikánal negatives show in the main the same structures as those taken at Meudon. Yet if the former admittedly permit such a great amount of K_2 radiation to mingle with K_3, it seems to me risky to base certain reasonings on the appearance of the resulting spectroheliograms. Accepting Prof. Hale's interpretation, given now many years ago, that K_3 represents the highest level and K_2 an intermediate one, I submit that the Meudon plates are more likely to represent the true spectroheliographic aspect of the sun. It may be, as Mr. Evershed says, that the dark concentrations called flocculi are entirely due to variations in the intensity of the narrow absorption line (or, in my opinion, rather the other way about); but is not this variation due, if not entirely, at least to a great extent, to the presence or absence or degree of intensity of the K_2 radiations on either side of K_3? A study of M. Deslandres' spectroheliograms taken on the sectional principle leads one irresistibly to think so. From the preceding remarks anyone can gather why I considered, and still do, the assumption of alternating appearance and disappearance of the large flocculus covering the range of prominences during March and April, 1910, rather unlikely.

As regards the points raised by me about absorptively acting clouds seemingly cutting off the range of prominences sharply at one common level, I must adhere to my statements. They are the result of *repeated* direct observation, and the phenomenon was strikingly on view again only as recently as April 26, when a fine range of prominences on the north-east limb showed it fairly well. I have given in *The Observatory* recently a summary of my observational experiences up to date, and amongst other matters also refer to the often seen phenomenon of dark matter being interposed between solar prominences and the observer at levels attained by the luminous portions of the prominences themselves. Such observations have by no means remained unique, and I possess, through the kindness of Mr. Slocum, a pair of excellent photographs depicting it in a case of some fine prominences seen during October, 1910. As regards my several visual observations of apparently overlying flat and dark clouds (*darker* than the general dark tint of the surrounding sky) abruptly stopping the bright upwards flowing prominence vapours, I feel certain that if Mr. Evershed had been at my side at the time his practised eye would not have failed him to see what I saw, but whether he would have been able to record it on a photographic plate in monochromatic light (Hα) without an eclipse I hesitate to say. I hope, however, that the hypothetical overlying cloud will not be taken as of the nature of "smoke" over a fire. In my opinion it is more a case of the rather abrupt entry of rising hot vapours into a well-defined, more or less horizontal, stratum of considerably less temperature, and that at a comparatively abnormally low solar level. I readily admit that the cases are few where the circumstances necessary for the phenomenon favourably combine with the all too rare cases of the equally necessary perfect definition.

ALBERT ALFRED BUSS.

"Barrowdale," 22 Egerton Road, Chorlton-cum-Hardy, Manchester, May 13.

IF it is true, as Mr. Buss suggests, that variations in the intensity of the components of the emission line K_2 on either side of the absorption line K_3 are sufficient to account for the dark markings occasionally found in spectroheliograms, then the Kodaikánal plates should show them as conspicuously as those taken with a high dispersion instrument, which isolates the central line. Yet this, as Mr. Buss has himself pointed out, is not the case. In studying high dispersion spectrum photographs of the solar disc, one occasionally discovers places where the K_3 line is abnormally dark, and the same thing may also be well observed in the line Hα. When the spectroscope slit chances to cross one of these linear markings, an intensely black spot is seen on the absorption line, and this will usually remain visible or run along the line if the solar image is moved slightly. In the case of the lines H and K, the components of the emission lines H_2 and K_2 are, I think, always weak at the points of greatest darkness in the absorption lines, and for this reason they may possibly contribute somewhat to the final result in our plates.

The intermittent character of the absorption marking described by me in *The Astrophysical Journal* for January is, I think, demonstrable from a careful study of our spectroheliogram negatives, notwithstanding the fact that these plates are of a somewhat composite character, representing the sun in K_2 and K_3 radiations. The disappearance of the enormously extended marking between March 25 and 26, 1910, could be accounted for, it is true, on the supposition that in the interval between these days there was a development of velocity in the line of sight exceeding 15 kilometres per second; this would alter the wavelength sufficiently to throw the dark K_3 line entirely off the camera-slit. But such motion in a prominence usually, if not always, presages a complete dissolution.

Instances of the rapid disappearance of these curious absorption markings are not infrequently met with in Hα spectroheliograms, which show them so much more clearly than do the low dispersion calcium plates. Since completing the construction of the new auto-collimating spectroheliograph of this observatory, I have obtained a nearly continuous daily series of Hα plates during April and May of this year. These are taken with the camera-slit adjusted on the central portion of the line, and represent the highest levels on the sun. The images show most of the prominences as absorption markings on the disc, and some of them are so dark as to appear like clear glass in the negatives. Already in this short series several cases have been noted of the disappearance within twenty-four hours of very large masses of absorbing material.

An interesting example was photographed on May 27 at 2h. 28m. and 2h. 53m. a.m. G.C.T. The disc of the sun in these plates appears to have had a large letter S engraved upon it with great distinctness. If drawn out into a straight line, the S would measure more than 150,000 miles in length. On the following morning we examined the plates with great curiosity to see what the next letter might be! The main portion of the marking had, however, entirely disappeared, and only a few small patches remained. This marking came into being with equal suddenness, for an excellent plate taken on May 26 shows no trace of it.

While agreeing with Mr. Buss as to the occasional presence of small patches of absorbing matter interposed between a prominence at the limb and the observer, I am sorry that both our visual and photographic records are entirely at variance with him with regard to the supposed absorbing clouds overlying certain prominences, which appeared to Mr. Buss to be cut off at one common level. I have before me the K-line negatives and the drawings in Hα of the prominences of March 17 and 18, 1910, and April 26 and 27, 1911, both of which Mr. Buss has cited as instances. These prominences were observed here and photographed under almost as good conditions as can be had at 7700 feet altitude, and the photographs show a mass of detail in the higher parts, especially in the prominence of 1910. Yet there is no trace of any such appearance as Mr. Buss has described; the highest filaments rise to many different altitudes, both on the drawings and photographs.

I may perhaps mention that reproductions of our photographs of the 1910 prominence, as well as some of the solar disc showing the absorption markings, have been sent as an exhibit to the Indian Section of the Festival of Empire.

J. EVERSHED.

Kodaikánal Observatory, June 12.

Hamilton and Tait.

THOUGH I did not miss the passage in his Life of Tait to which Dr. Knott refers in NATURE of July 20 (p. 77), I forgot about it when I wrote my review. The point as to Hamilton's activity in quaternionic work is not of very great importance, but my statement is borne out by Graves's Life of Hamilton, which I read long ago, and have again referred to, as well as by the published correspondence. Tait's introduction to Hamilton took place in 1858; Graves states (vol. iii., p. 97) that Hamilton allowed himself to be diverted *in 1857* from quaternions—the task, he says, of writing the "Elements"—by the subject of definite integrals. According to Dr. Knott, Hamilton did not begin the composition of the "Elements" until a good deal later, and this view would appear from Dr. Knott's statement, and from Hamilton's own language in his letters, to be correct.

A. G.

OTHER CONTEMPORARIES OF MAN AND THE REINDEER AT MENTONE.[1]

IN NATURE, October 10, 1907, appeared a notice of the stratigraphical and anthropological results obtained from the examination of the Baoussé-Raoussé caves at Mentone. In the work at present under review we obtain the no less important geological and palæontological results. It may be said at the outset that this subsequent volume is in every sense a worthy companion to the preceding volumes, which fulfilled in an exemplary manner the many tedious requirements which modern archæology exacts from those who undertake the investigation and description of these valuable and irreplaceable records of the past. Not the least part of the debt which archæologists owe to MM. Boule, Verneau, and de Villeneuve is due to the admirable methods which they have instituted.

The volume at present under review contains a full account of the various animal bones recovered from these caves. The bones of each animal are first carefully considered, and so far as is possible a general idea is obtained of the animal as it is represented in the deposits within these caves. The information thus obtained is next checked, confirmed, and extended by comparing the Baoussé-Raoussé specimens with those contained in the various museums of Europe. A no less interesting comparison is then instituted between these extinct forms and the forms living at the present day. Attention is next directed to the exact stratigraphical position in which the bones were discovered, and from this evidence the order of arrival of the Pleistocene mammals in the Mentone district is deduced. Not content with this, M. Boule furnishes us with a series of most useful maps of Europe and the adjoining parts of Asia and Africa showing the areas from which the remains of some of the larger and more important animals have been reported. The methods employed will thus be seen to be as perfect and exhaustive as they were no doubt laborious. Measurements of bones are almost entirely eschewed, M. Boule believing, with many others, that measurements arbitrarily chosen are in no way superior to simple observation, nor are they likely in his opinion to disclose such specific characters as would be likely to be hidden from the trained and experienced eye. Instead of long lists of measurements of dubious value, the text is enriched with a large number of admirable photographs, which in some respects possess an advantage over the actual specimens themselves.

The bones recovered were obtained from the Grottes du Prince, des Enfants, and du Cavillon. They comprised parts of the skeletons of the following:—*Elephas antiquus, Rhinoceros merckii, Equus caballus*, Hippopotamus, *Sus scrofa, Bos primigenius, Bison priscus, Cervus capreolus, Cervus elaphus, Cervus samonensis, Cervus tarandus, Cervus alces, Rupicapra tragus*, and *Capra ibex*.

The presence of *Elephas primigenius* was uncertain; *Rhinoceros tichorhinus* was absent. The Equidæ were represented by specimens which, though relatively few in number, were of wide distribution, being scattered through and recoverable from all the beds. M. Boule believes that he can recognise with considerable confidence the remains of *Equus asinus*. The vast majority of the specimens, however, belong to *Equus caballus* and to the subdivision of that species which has been variously named *Equus caballus*, Linn., *Equus caballus typicus* (Cossar Ewart), *Equus robustus* (Frank). Contrary to the expectations of those who have studied the carvings and engravings of the reindeer period, neither *Equus przewalskii* nor the zebra can be shown to have been present.

Map showing the area from which the remains of *Elephas antiquus* have been reported.

Pigs were abundant. In the Mentone neighbourhood *Bos primigenius* made its appearance quite as early as *Bison priscus*, if indeed not earlier. *Bos longifrons* was absent. *Cervus capreolus* was present as a vigorous form of the existing animal. *Cervus elaphus* and *Cervus samonensis* were considerably larger than modern specimens. *Cervus tarandus* made its appearance suddenly in Mid-Pleistocene deposits; it was only found in any numbers in the Grotte du Cavillon. *Rupicapra tragus* was of a vigorous type showing affinities to the chamois of the Alps and of the Pyrenees. *Capra ibex* was represented by such a large number of specimens that M. Boule hopes to see some day a complete reconstructed skeleton of this animal at the Musée d'Anthropologie de Monaco. He considers it to be the ancestor of the Alpine goat of to-day.

This most interesting and valuable volume will thus be seen to confirm the opinion which has slowly but surely ripened to a conclusion that there has been no sudden or complete break in the evolution or history of the fauna of western Europe from Palæolithic to Neolithic times. There has further been little if any natural organic evolution in the larger mammalia from the earliest Pleistocene to the present day. Some of the animals of the Pleistocene have disappeared through changes in climatic conditions or under the

[1] "Les Grottes de Grimaldi" (Baoussé Raoussé). Tome i., Fascicule iii., Géologie et Paléontologie (suite), by Prof. M. Boule. Pp. 157-236+plates xiv-xxix. (Monaco, 1910.)

unrelenting hand of man; others have deteriorated in size and vigour as they have gradually come under the yoke. The horse, however, forms a notable exception, having from obvious reasons improved in physique and gained in strength. Such minor changes, changes of degree rather than of kind, are all that evolution can lay claim to have effected in these stubborn mammalia within the compass of some thousands of years during which Mentone has known the two extremes of climate and temperature.

Another great assistance rendered by the work of M. Boule is that he has enabled us with more certitude than was possible before to reconstruct the milieu of certain of our Palæolithic ancestors; for, from the fauna it is not difficult to realise the nature of the flora or the conditions of the climate. With the information thus obtained we can apprach the stone and bone implements which the man of that remote date has left, and deduce more confidently what were the purposes they served. A knowledge of the fauna is thus seen to be the key which will most successfully unlock many of the sealed chambers of man's past. Apart, however, from all this, the study of the extinct Pleistocene fauna possesses in itself great and abiding interest, and dull must be the archæologist or anthropologist who does not desire further knowledge concerning these early companions of man whose bones lie commingled with his in river drift and cave floor.

The book is a most valuable contribution to science, and reflects the greatest credit on everyone concerned.

WILLIAM WRIGHT.

THE TYPES OF WATER WAVES.[1]

DR. CORNISH has produced an attractive and valuable book. The volume is not the less valuable in that it is primarily descriptive, and in that the author shows great caution and reserve as regards speculative explanations. This caution is indeed amply warranted. The mathematical theory of water waves, successful as it is up to a certain point, is limited in its application by the fact that it contemplates only specially simplified conditions. In particular, owing to the restriction to *small* amplitudes, it can at present offer little in the way of explanation of various important natural phenomena, where what is technically called "turbulent" motion comes into play. Laboratory experiments, on the other hand, require elaborate and costly arrangements, which are only provided with difficulty even when a definite practical problem is in view; and in some respects the mere question of scale would impair their relevancy. There remain only observations in the open, such as the author has recorded in the present book. The extreme difficulty of these, from a quantitative point of view, is well illustrated by his discussion of storm-waves at sea.

FIG. 1.—Wave-track of Steamer on Thunersee, showing thwart-ship and diverging waves. From "Waves of the Sea and other Water Waves."

The book is made very readable by the fact that the author's interest in his subject is evidently æsthetic as well as practical or scientific. He is fascinated by the extraordinarily beautiful and varied types of wave motion which are presented by nature, and has recorded a number of these, observed at sea or on land in many parts of the world, in a series of remarkable photographs.

[1] "Waves of the Sea and other Water Waves." By Dr. Vaughan Cornish. Pp. 374. (London: T. Fisher Unwin, 1910.) Price 10*s*. net.

The book consists of three parts. In the first of these, treating of deep-sea waves, the evidence of various writers as to the dimensions of storm-waves in different ocean basins is collated, and supplemented by the author's own observations. Accurate measurements are from the nature of the case very difficult, but it appears that there is a limit to the height (from crest to trough), which different observers concur in placing at about 40 feet, whilst the limit to the length is somewhere about 600 feet. The waves are longer and higher the longer the "fetch," *i.e.* the extent of water to windward, where the waves are generated. As to the mode in which waves grow under the influence of wind in a storm, we have at present little beyond general indications. Another subject here referred to is that of the much longer and lower waves which constitute the "swell" of the ocean. To the eye this is often scarcely perceptible at sea, and the only method of accurate observations consists in timing the waves as they break on the shore, where they are exaggerated by the shoaling of the water. In this way some inferences can be made, as pointed out by Stokes, as to the distance of the seat of the original disturbance to which the swell is due.

FIG. 2.—Stationary waves caused by a weir on the River Aare, Switzerland. From "Waves of the Sea and other Water Waves."

The second part of the treatise deals with the action of sea-waves in transporting shingle, sand, and mud. This is of enormous practical importance, and can be dealt with to some extent experimentally. From a theoretical point of view it is very difficult, and we shall not attempt here to discuss the contribution which the author makes to speculation on this subject.

The concluding section gives an interesting account, with admirable illustrations, of the "bore" or abrupt tidal wave observed in the Severn and other rivers, and of the stationary waves in flowing water due to fixed obstacles. Finally, the remarkable configuration of "ship-waves," first elucidated by Lord Kelvin, is exhibited in some beautiful photographs. These show clearly the system of "transverse" waves, which were (we believe) unnoticed in the earliest tank experiments until their existence had been pointed out by theory.

FIVE-HUNDREDTH ANNIVERSARY OF THE UNIVERSITY OF ST. ANDREWS.

FROM September 12–15 next, inclusive, this celebration will be held in the ancient ecclesiastical capital of Scotland, with all the ceremony it is possible to have in the circumstances. Though the university was not founded until 1411, yet St. Andrews for centuries previously had various teaching institutions in connection with the learned religious bodies in the monasteries of the Culdees and other sects concentrated in the ancient city, the preceptors of which had been trained in the English or Continental universities, especially those of France and Italy. Steps, indeed, had been taken before this period to further the interests of the Scottish students by the founding of the Scotch College (Balliol) at Oxford by Lady Devorguill, the wife of John Baliol; whilst the good Bishop of Moray had instituted in 1326 the Scotch College in Paris. No university, however, existed in Scotland, so that her students had to study for degrees elsewhere, and in the unsettled state of the times had not infrequently to encounter difficulties and hardships—even to the occasional capture by their then hostile neighbours, the English—on their way to other countries. Such was the condition of things when Henry Wardlaw was appointed to the bishopric of St. Andrews, and as he was a man distinguished for his wide culture, munificence, and great influence, it was not long before he found an opportunity. Eight years after his appointment to St. Andrews, viz., in 1411, the thoughts which doubtless had been revolving in his mind for a long time took shape and were put in action. A *Studium Generale* was at once commenced with the aid of a staff of able teachers in the faculties of law, divinity, and arts. He drew up a foundation-charter of the university, and forwarded it by envoys to the Pope (Benedict XIII.), who endowed it by means of papal bulls with all the powers of a university in 1413—to teach science, philosophy, and medicine, and this was subsequently confirmed by King James, who was throughout a staunch benefactor to the young institution. Thus the Scottish youth were no longer compelled to seek higher instruction out of their own country.

At the celebration in September will assemble noblemen, one of whom, the Marquis of Ailsa, is the lineal descendant of Bishop Kennedy (grandson of Robert III.), the founder of St. Salvator's College, whose elaborately carved tomb is one of the sights of the college chapel; delegates from the universities of Britain, and all her Colonies and Dependencies; from America, Austria-Hungary, Belgium, Denmark, France, Germany, Greece, Holland, Italy, Japan, Norway, Portugal, Russia, Finland, Sweden, Switzerland, Spain, and Turkey. Besides others distinguished in science and literature, representatives of the various learned societies in Great Britain and her Colonies, of almost all the foreign countries mentioned, official persons connected with all the churches in Britain, officials of the College of Justice, naval and military authorities, parliamentary leaders and members, sheriffs and heads of various departments, will grace the ceremony, together with former teachers, graduates, and students of the university, and the present staff both of St. Andrews and Dundee.

The programme of the proceedings, as at present arranged, will comprise a reception by the Chancellor of the University, Lord Balfour of Burleigh, in the large temporary hall, St. Andrews, a students' torchlight procession, and a students' symposium on the evening of Tuesday, September 12. On Wednesday, September 13, a procession will be formed in the college quadrangle, and will proceed to the Church of the Holy Trinity, where a religious service will be held. Then, after an interval, the presentation of addresses will be made in the temporary hall, and thereafter an address will be given by the Chancellor. In the evening historical tableaux in the Great Hall, an illumination of the city, and a procession will take place. Lastly, a second students' symposium will conclude the proceedings of the day. On Thursday, September 14, a graduation ceremonial will be held in the Temporary Hall, at which a large number of distinguished honorary graduates in law (LL.D.) and divinity (D.D.) will be capped. Thereafter the rector, Lord Rosebery, who represents the students, and who will be escorted by a guard of honour formed of the Officers Training Corps of the university, will be installed, and will deliver his address. In the afternoon garden-parties will be held at Mount Melville, at St. Leonard's School for Girls, and probably also at the Gatty Marine Laboratory. In the evening a banquet will take place in the Bell Pettigrew Museum, which will likewise be declared open. Contemporaneous receptions by the ladies of the university will further occur, both in St. Andrews and in Dundee the same evening, so as to include all guests and hosts, and especially ladies and students. Friday, September 15, will be mainly devoted to Dundee, commencing with a reception and addresses at University College, followed by a reception by the Corporation of Dundee, and a luncheon in the Art Galleries of the Albert Institute. Thereafter, excursions to Glamis Castle, Rossie Priory, and a sail to Perth, as well as visits to places of interest in Dundee, will occupy the afternoon. The day will be concluded by a graduates' and students' dinner in the Bell Pettigrew Museum, in St. Andrews, and a students' ball in the Temporary Hall.

The fine old ruins, so full of stirring historical associations, in St. Andrews, its old Tower of St. Regulus, usually called the Square Tower, one of the oldest buildings in the land, the home of Sir David Brewster, the most renowned principal of the university, the earliest Marine Laboratory in Britain, the fine Chemical Research Laboratory, the extensive stretch of sand—east and west—with the fringe of rocks, so full of interest to the geologist as well as to the zoologist, the zoological and botanical riches of the well-known bay, and the prominent part it has taken in initiating scientific fisheries' research—all combine to render the old cathedral city, where many Scotch parliaments were held, one of great interest. The unique silver maces, and the archery medals won by the young Scotch nobles who attended the university in the olden time, and many of whom afterwards became famous in the history of the country, are other features (not to allude to the splendid golf links) of interest to the distinguished visitors to the celebration of the 500th anniversary of the university in September.

W. C. M.

NATIONAL ASSOCIATION FOR THE PREVENTION OF CONSUMPTION.

Conference on Tuberculosis.

The conference on tuberculosis, held on July 19-21, organised in connection with the exhibition sent round the country by the National Association for the Prevention of Consumption, stationed at the Caxton Hall, Westminster, was as successful as those held during the past couple of years at Edinburgh, Cambridge, Oxford, and other centres throughout the country. Indeed, in certain respects the conference, recently brought to a conclusion, was more interesting and attracted greater attention than any one of its predecessors. The announced object of the conference was to discuss Mr. Lloyd George's Insurance Bill, or rather those sections and clauses of the Bill dealing with the prevention and treatment of tuberculosis; and at the opening meeting the members had the advantage of listening to an able address given by the President of the Local Government Board, who, as he himself put it, has, amongst his numerous and multifarious interests, specialised somewhat in tuberculosis and infant mortality.

Mr. Burns set himself to describe what has been done to bring down the mortality from tuberculosis during the last few years. As is usual with him, he illustrated his points by telling examples, of which two may be taken as likely to impress those interested in this subject even to the slightest extent. The first of these he drew from military life. A little more than thirty years ago the Guards were a body of eight thousand men—none finer or so fine in the world, maintained Mr. Burns—healthy, picked men, of fine physique, yet the death-rate from tuberculosis was a fraction above twenty. To-day what do we find? A little common-sense sanitation, better ventilation, and greater sobriety amongst the men together have brought down the death-rate from tuberculosis to 3·1. As Surgeon-General Evatt insists: what has been done in the barracks it should be possible to do in civil life. Not so quickly, perhaps, but certainly in the long run.

Coming down to later times, Mr. Burns points out that to-day in London only two persons succumb to tuberculosis where twenty years ago three lives constituted the toll to this disease. Again, for every two lives so lost in London, Berlin loses three and Paris five. This is a serious matter for our French friends, and "gives one furiously to think." How can this be accounted for? Certainly not by a single factor; but Mr. Burns makes a suggestion and gives certain figures that are well worthy of consideration.

During the last ten years the fall in the mortality from consumption has been, in Great Britain, 19; Scotland, 24; Ireland, 24; Germany, 18; London, 30; Berlin, 24; Paris, 3. This period synchronises with that during which the National Association for the Prevention of Consumption has been at work—also with Mr. Burns's term of office at the head of the Local Government Board; but during the same period the drink bill per head of the population in this country has fallen from 4*l.* 12*s.* to 3*l.* 0*s.* 8*d.* In Paris, on the other hand, no such fall has been recorded. Whether this be a cause or a symptom merely, this aspect of the question must receive careful and respectful consideration. Other points were brought forward during the conference, often with great force and wealth of argument. One thing which stamped this conference as something out of the common run of such meetings was the fact that enthusiastically as each man spoke of the special branch of the subject on which he was engaged, there was none of the "pushing of wares" to the exclusion of everything else that has sometimes characterised such meetings.

The optimistic note struck by the President of the Local Government Board in his opening address was sounded again and again by later speakers, the most hopeful of whom looked forward to the extermination of tuberculosis from cattle and man alike within the next thirty-five or fifty years, maintaining that this could readily be effected if a proper apportionment of the resources at the command of those who are dealing with the disease can be arranged. The credit of the sanatorium treatment has suffered in certain quarters from the fact that careless advocates have assigned to it functions that it was not fitted to perform, whilst others, opponents, equally careless and uninformed, have not taken into account the educational function of the well-governed and properly directed sanatorium. All are agreed, of course, that it is impracticable to submit all tuberculous patients to ordinary sanatorium treatment, and that the dispensary system must be brought into play to assist and supplement the work of the sanatorium. This dispensary system has many earnest advocates, and with certain extensions and linking up with the sanatoria on one hand and the hospital on the other there lie within it great potentialities.

In connection with the section of preventive work the optimistic spirit that manifested itself throughout threw into strong relief the feeling that far more might be done in the provision of open-air shelters, for tuberculous patients attending dispensaries and continuing at work, than has yet been done. Several speakers directed attention to the luxurious sanatoria that have been erected in various parts of the kingdom, where, owing to the enormous initial cost and the great expense of administration, the charges must necessarily be prohibitive except to those well endowed with this world's goods. Are these costly buildings necessary or even desirable? they ask. If tuberculosis is to be eradicated within the next thirty or forty years, to what use can such large and solid buildings be put when they have served their primary purpose? Moreover, would not the process of eradication of tuberculosis go on much more quickly if the money spent on these palatial buildings could be directed to the provision of a large number of open-air shelters, in some cases grouped around more solidly constructed administrative blocks, in others placed at the disposal of the dispensaries for the accommodation of single patients at or near their own homes? These shelters might be very inexpensive, and, in many cases, might be destroyed as soon as they had served their purpose. More substantial and comfortable buildings for the reception of patients in the later stages of the disease, where there is little to be hoped for from treatment except alleviation of pain—buildings from which should be dissociated all names and terms likely to depress the patient may well be provided, even at somewhat substantial outlay, especially as after they have served the purpose for which they are designed they may be converted into hospitals for the reception of other classes of patients.

The question of different methods of medication is not one to be discussed at a public conference, and, very judiciously, was not taken up. Some of the speakers, however, referred to the necessity for the continuance of experimental work. Here the prophecies of the President of the Local Government Board should have some weight in determining the nature of the efforts to be made and the character and mode of financing these efforts. It is certainly unnecessary to make provision for permanent endowments for the carrying on of this work. An immediate liberal subsidy will be of far greater value in ensuring the desired results than a large sum set aside of which only the interest can be used.

As in the case of shelters, &c., the money available should be utilised to cover as much ground as possible and *at once*. Extensive and immediate treatment, both curative and preventive, and well-devised experiments carried out as promptly and on as large a scale as possible, will do far more to stamp out tuberculosis than will efforts extending over a longer period, and in the long run far more costly.

The National Association for the Prevention of Consumption has been working away quietly and systematically for some time; much of its work in the earlier days of its existence was spadework of a very unobtrusive character, and certain critics, perhaps not very kindly disposed, have from time to time been prone to grumble at what they were pleased to call its inertness. For several years past, however, such criticism has been seen to be very much beside the mark, and the London conference, which was the last of a long series, has supplied ample evidence of the valuable work that has been done by the Association, demonstrating to those most directly concerned "what they shall do to be saved" from the white plague. With the facilities now offered by Mr. Lloyd George for putting into force some of the methods recommended by the conference, with a united effort made in matters on which all are agreed, such a shrewd blow may be struck at tuberculosis as it has not received since Koch made the announcement of his epoch-making discovery—the discovery of the tubercle bacillus.

DR. JOHN BEDDOE, F.R.S.

We regret to have to record that Dr. John Beddoe, the distinguished anthropologist, died on July 19 at Bradford-on-Avon.

Dr. Beddoe, who was born at Bewdley in 1826, was the first to make exact observations on the physical characters of living races over wide areas, and he will always be regarded as the founder of our knowledge of the physical anthropology of the living populations of Europe.

So early as 1846 he began to make observations on hair and eye colours in the West of England, and though he found his first system unsatisfactory and abandoned it he resumed the work, on the occasion of a visit to Orkney in 1852, and continued these observations to the end of his active life whenever his travels brought him in contact with new peoples.

Owing to his delicate health in childhood and youth, he was cut off from outdoor games and sports, but made good use of his time indoors by devoting it to a course of wide and solid reading. The effect of this is seen in the numerous and illuminating historical and other allusions in his anthropological books and memoirs.

Abandoning the study of the law, for which he was at first destined, he found a much more congenial study in medicine. He commenced his medical studies at University College, London, and completed them at Edinburgh University, where he took his M.D. in 1853. He was house physician at the Edinburgh Infirmary for fifteen months under the direction of such distinguished physicians as Christison, Simpson, and Syme.

In 1854 the Crimean War offered him the opportunity of visiting eastern Europe as a member of a civil medical staff sent out by the War Office to supplement the work of the military staff. Here he made good use of spare time to make observations on the Turks and other Eastern races he came in contact with.

On his return from the Crimea he resolved to spend a winter of study in the Vienna hospitals, and in his journeyings to and from Vienna he collected a great deal of anthropological material in Holland, Germany, Austria, Hungary, and Italy.

In 1867 he was awarded by the Council of the Welsh National Eisteddfod a prize of a hundred guineas for the best essay on the origin of the English nation. His essay was afterwards expanded into his well-known book, "The Races of Britain."

In 1868 Dr. Beddoe was president of the Anthropological at the same time that Huxley was president of the older Ethnological Society. The amalgamation of these two rival societies into a single society, the Anthropological Institute (now the Royal Anthropological Institute), which has done so much to promote the study of anthropology in this country, was due to a great extent to the efforts of Beddoe. He also took an important part in the movement which led to the constitution of anthropology as an independent section at the British Association.

Dr. Beddoe was president of the Anthropological Institute in 1889. In 1890 he delivered the Rhind Lectures on "The Anthropological History of Europe," a work which shows his unique knowledge of the physical characters, the migrations, and evolution of the peoples of Europe. In 1905 he delivered the Huxley lecture of the Royal Anthropological Institute, and quite lately he was appointed honorary professor of anthropology in the Bristol University.

When we consider that the large amount of anthropological research done by Beddoe was carried out during the intervals of leisure in a busy professional life, we cannot help being astonished at the amount of very valuable work he has done, nor withhold our admiration for the devotion to science which enabled him to persist in it through so many years. Beddoe was a pioneer in a new line of scientific investigation, and his example has been powerful in stimulating other investigators to carry out similar work. The great survey of the hair and eye colours of the school children of Germany carried out by Virchow was without doubt due to the stimulus of Beddoe's pioneer work, and a great deal of similar work has since been carried out by other investigators. The name of John Beddoe will always occupy an honourable place in the history of anthropology.

DR. H. TIMBRELL BULSTRODE.

DR. H. TIMBRELL BULSTRODE, who died suddenly from heart failure on July 22, was one of the senior medical inspectors of the Local Government Board, having been appointed to that office by Mr. Ritchie in 1892. His death was unexpected and will be widely regretted.

Dr. Bulstrode obtained his medical education at Cambridge University and St. Thomas's Hospital. Since his appointment to the Local Government Board he had, in addition to the more routine work of the medical inspectorate, been engaged under three successive medical officers in work of a more special nature implying exceptional skill in epidemiological investigation. It is in regard to this work that his high reputation was made. Three of his reports to the Local Government Board have been presented to Parliament as command papers. Of the subjects at which he worked, that of the relationship of contaminated shellfish to the prevalence of illness, and especially to enteric fever, is particularly important. Early in the nineties of last century the attention of the Local Government Board was directed to the possible causation of outbreaks of enteric fever, as well as of cholera, by the consumption of contaminated oysters, and Dr. Bulstrode was commissioned to make a comprehensive investigation into the subject. He visited all the districts in England and Wales in which there were oyster layings, and collected all the known literature on the subject of his inquiry. His report, which was presented to Parliament in 1894, was illustrated by a series of charts which indicated the position of all the principal oyster layings in England and Wales, and the positions of sewers in their neighbourhood. The issue of this report necessarily and properly caused much damage to the trade in oysters as then carried on. Its more permanent effect has been to improve the conditions under which a very large proportion of the total oysters in this country are grown and fattened.

Dr. Bulstrode's next investigated several deaths and a considerable number of cases of enteric fever which occurred after mayoral banquets at Winchester and Southampton, and clearly traced these to the consumption of contaminated oysters. Early in the current year a report by Dr. Bulstrode was presented to Parliament dealing with shellfish other than oysters in relation to disease. This report, which is a comprehensive one, brings up to date epidemiology in association with oysters, and contains a detailed account of the principal shellfish beds of mussels and cockles. The volume, like its predecessor on oysters, is illustrated by a valuable series of charts showing the topography of the beds in relation to sewage pollution. Dr. Bulstrode attended many meetings of the Royal Commission on Sewage Disposal which had the oyster and other shellfish difficulties under consideration.

Another public health question with which Dr. Bulstrode was particularly concerned is that of tuberculosis. In 1903 he gave the Milroy lectures at the Royal College of Physicians, choosing the subject of tuberculosis. In 1905 he was associated with Dr. Theodore Williams as a representative of the British Government at the International Congress on Tuberculosis at Paris. In 1908 Dr. Bulstrode's report on sanatoria for consumption was issued and presented to Parliament. This extremely valuable work on sanatoria in England and Wales was republished by H.M. Stationery Office in a cheaper edition, the demand for it having been large.

Dr. Bulstrode, at the time of his death, was engaged in an inquiry, as a representative of the Local

Government Board, with officers of the Home Office into cases of phthisis which had been attributed to "kissing the shuttle," a practice in the cotton mills in Lancashire. His recent report on plague in East Suffolk was a further piece of excellent work, set out with characteristic detail and exactitude. All his reports will remain for a long time valuable works of reference for investigators and examples of laborious and exact inquiry.

Dr. Bulstrode's death in his fifty-third year removes from the medical staff of the Local Government Board not only a very able and conscientious public official, but a colleague who had endeared himself to the officials of his own department, and was held in high repute by local officials in England and Wales with whom his investigations had brought him in contact.

THE PROMOTION OF SCIENTIFIC RESEARCH BY THE DEVELOPMENT COMMISSIONERS.

THE appointment of the Development Commissioners marks a remarkable change in the attitude of the British Government towards research. Not only is the old *laissez-faire* policy thrown over, for the commissioners are charged with the duty of fostering decaying rural industries and trying to promote new, but they are also specifically instructed to promote scientific research and experiment so far as it bears upon agriculture. The funds placed at their disposal are considerable—a capital sum of two and a half million pounds, with an annual grant of 400,000*l.* for the five years for which provision is made in the Act—and though the big grants will be chiefly wanted for such purposes as the improvement of harbours and inland navigation, the reclamation of land, rural transport, and similar works, there should yet be a very considerable margin available for investigation and education in its widest sense.

The first report, which the Development Commissioners have just issued, shows that although they have been at work for less than a year, they have set scientific matters in the forefront of their programme; indeed, they indicate that until they have dealt with research and education they intend to postpone the consideration of projects aiming at the direct creation of employment, such as the reclamation of land, canals and light railways, and afforestation of waste land. Our deficiencies in the scientific direction and control of agriculture and other cognate industries, *e.g.* sea-fishing, are both patent and pressing. In this direction the foundations have to be laid for the future; and, moreover, there can be very little doubt but that the expenditure wil be recouped a thousandfold, because it will take effect upon the mind of the men who have to live by the industry, whereas in the case of works the expenditure is greater and the ultimate benefits to the industry as a whole more doubtful.

The commissioners have already made certain grants for research to institutions like Cambridge University (4,000*l.*), the Rothamsted Experimental Station (2,000*l.*), the Royal Veterinary College (1,390*l.*), Bristol, and other university colleges possessing agricultural departments; but they indicate that these are only interim grants for the maintenance of certain work already going on pending the framing of a general scheme of research applicable to the whole kingdom and intended to secure that every part of the wide field shall receive adequate attention. The commissioners report that they are negotiating with the Board of Agriculture for the preparation of such a scheme, and that they propose to devote about 40,000*l.* a year to carrying it out. In other directions the scientific aspect of the question seems to have been well before the commissioners, for example in the scheme for the improvement of the breeding of light horses; they have insisted that "definite provision should be made for watching and supervising its operation and so far as possible making experiments from the point of view of scientific research in eugenics as applied to horses." Again, in attacking the problem of increasing the variety of production, they "have appointed two gentlemen of scientific training to investigate by inquiry at home and abroad" the cultivation and management of the tobacco, flax, and hemp crops; and, as regards forestry, they report that education and research ought to precede any action in the direction of afforestation on a large scale.

This recognition of the foundation of all development of industries like agriculture, forestry, and fishing upon scientific knowledge and research is very welcome, and must be applauded as a most promising departure from the spirit and methods that have hitherto prevailed in English official circles. We may compare the 40,000*l.* the commissioners propose to spend with the few hundreds a year which represented all the Board of Agriculture was able to devote to the same purpose.

In this connection the British Science Guild may well be congratulated upon its action. A few years back the guild appointed an agricultural committee, which, after making many inquiries and collecting a great deal of information, produced a report showing what Great Britain did in the way of agricultural research in comparison with foreign countries and our own colonies, and giving some examples of the returns which had accrued to the industry from the application of particular investigations. This report was widely and influentially signed and presented to the Government; and the guild may be well content with the manner in which its representations have now been translated into action. Subjoined are a number of extracts from the commissioners' report.

The Development Commissioners were appointed by the King on May 12, 1910, by Royal Warrant. The commissioners include Lord Richard Frederick Cavendish (chairman), Sir Francis Hopwood, K.C.B., and Messrs. Saint-Hill Eardley-Wilmot, H. J. Davies, M. A. Ennis, W. S. Haldane, A. D. Hall, F.R.S., and Sidney Webb. At the beginning of this year the commissioners entered, with the Road Board, into the occupation of permanent offices at Queen Anne's Chambers, Broadway, Westminster.

Since their appointment, the commissioners had held nine official meetings up to March 31 last, and it is with the work done at these meetings and the preliminary business transacted by the commissioners that their first report[1] deals.

General Principles of the Commissioners' Action.

The commissioners are informed that during the period under review about 170 applications for advances from the Development Fund were made to the Treasury. Of these, twenty-four reached the commissioners officially under the Act, so that they could take formal cognisance of them.

It may be useful if they offer some general remarks on the duties entrusted to them by the Act of 1909, and the principles at which they have arrived in considering how best to carry out those duties.

Their prime duty is to consider and report to the Treasury on applications referred to them for advances from the Development Fund. All applications must in the first instance be made to the Treasury. The Act directs that when an application reaches the Treasury it is to be dealt with in different ways, according to its source. If it is from a Government department, the Treasury are to send it direct to the commissioners for examination; if it

[1] First Report of the Proceedings of the Development Commissioners for the Period from May 12, 191 . to March 31, 1911. Pp. 60. (Wyman and Sons, Ltd.) Price 3*d*.

is not from a Government department, the Treasury are to send it to the Government department concerned with the subject-matter of the application, who are required to forward it in due course with their report to the commissioners. When the application reaches the commissioners they have to consider it and state their opinion to the Treasury, with whom rests the responsibility of finally deciding whether to give effect or not to the commissioners' recommendation if it is favourable. If the Treasury approve, the money is advanced as required to the applicant—direct, if the applicant be a Government department; if the applicant be some other body or association, through the department concerned, who are then responsible for supervising the actual expenditure.

From this procedure, as laid down by the Act of 1909, three main results follow. In the first place, the commissioners themselves have no power to make grants or loans from the Development Fund; like other Royal commissions, they can only recommend expenditure, which must be finally authorised by the Government. Treasury approval is required for every penny spent from the fund. Secondly (again like other Royal commissions, or the majority of them), they have no executive power; the schemes recommended by the commissioners must be carried out either by a Government department or by some other body under the supervision of a department. Thirdly, they have no formal and official cognisance of applications from bodies other than Government departments, and cannot report to the Treasury on them, until the applications have been examined by and passed through the departments concerned with their subject-matter.

Such being in general terms the position assigned to the commissioners by the Act, it became incumbent on them to settle at an early stage of their proceedings the main principles by which they would be guided in considering, amending, and framing schemes for expenditure from the Development Fund.

The first of these principles is that, to deal satisfactorily with many of the purposes mentioned in the Act of 1909, it is absolutely necessary to work on a comprehensive policy, which shall provide for and take account of the whole of at least one of the three main administrative divisions of the United Kingdom (viz. England and Wales, Scotland, and Ireland), and shall wherever possible be based on a survey of the position and needs of the whole kingdom in relation to that particular subject. Take, for instance, the very important question of research in agricultural science. Numerous applications for advances from the Development Fund for different branches of research and pieces of research work were expected, and have, in fact, been made by bodies, institutions, and associations all over the kingdom. It seemed to the commissioners that there would inevitably be waste of energy and money if these applications were simply taken one by one as they arrived, and advances recommended to those institutions which made out a good case for themselves, irrespective of other institutions and the work done by them. It is probably neither desirable nor possible to prevent all overlapping and duplication of work, and the commissioners realise that individual investigators and institutions cannot and ought not to be dragooned into uncongenial tasks. But looking to the vast amount of work still to be done, they think that any advances from the fund for this purpose should be made on a coherent and comprehensive scheme, covering as wide an area as possible.

Agricultural research has been taken as an example, but it will be obvious that similar considerations apply to other purposes for which advances may be made from the fund. The commissioners do not lay it down as a hard-and-fast rule that in no circumstances, however special, will they recommend an advance from the Development Fund apart from an examination of all possible or probable applications of the same nature, or apart from a general scheme applicable to the whole country or a large part of it; and the necessity of such a scheme varies with the purpose for which advances are desired. But for the reasons briefly indicated above, they feel that as a rule an application should be considered not simply and entirely as a disconnected unit, but in the light of a policy which takes account of the requirements of a wider area than a single district or institution.

From the adoption of this attitude, certain practical consequences follow. In the first place, it is impossible to deal with individual applications as quickly as if they were taken one by one, without reference to general considerations. To recommend even a large number of disconnected advances is obviously a very different thing from working out or examining in detail a coherent and organised scheme which is meant to be applicable to the whole country or a large part of it—a scheme in which existing bodies and institutions would each find a place consistent with its possible contribution to the general advancement.

It follows, secondly, that the relations of the commissioners with Government departments must necessarily be of the closest nature. In any event they must be close, for all applications come either from or through a department, and all advances from the fund must be made either to or through a department. But the commissioners' policy of proceeding by general schemes necessarily means that they welcome such applications as the departments themselves may make; and for reasons similar to those which have influenced the commissioners, the departments, when confronted with the duty of reporting on a large number of disconnected applications, have perhaps felt that they would best discharge that duty by themselves putting forward a general scheme which would cover and include so far as possible the schemes of the individual applicants. The commissioners cannot consistently with their statutory duty accept such schemes without consideration, and it is not a matter for surprise if they do not always find themselves in entire agreement with the applying department. In such cases, discussion between the two bodies is the only way of settling a scheme: for on the one hand it cannot be financed without the commissioners' recommendation, and on the other (the commissioners having no executive authority) it cannot be executed apart from the department. The commissioners are happy to say that they have hitherto encountered no difficulties with public departments which full discussion has proved unable to solve.

In the third place, procedure by general schemes involving large advances to Government departments brings into clear view the difficulties and delays caused by the inevitable complication of the administrative machinery of the United Kingdom. The nature of some subjects is such as to permit of their being considered separately for separate parts of the country; yet even with such subjects more than one department may be concerned—for instance, agricultural education (as distinct from scientific research) is in different branches within the purview of both the Board of Education and the Board of Agriculture. With some subjects, on the other hand, the commissioners might wish to deal, if possible, on a scheme or schemes taking account of all parts of the United Kingdom; and in that case they might be concerned at the same time with one or perhaps two authorities for England and Wales, another for Scotland, and another one or two for Ireland.

It will not escape observation that the one case (viz. the encouragement of horse-breeding) in which during the first few months of the commissioners' existence Government departments were able to submit, and the commissioners to recommend, comprehensive schemes, is precisely a case in which some of the difficulties mentioned have been absent. There is only one authority for the whole of Great Britain. The Irish scheme had been in existence for some years, and by common consent worked well, needing only money for its extension; and the British scheme followed, generally, similar lines.

The other principles on which the commissioners proceed may be explained more briefly. In the first place, they do not think that it would be consistent with their duty to recommend an advance from the Development Fund until a fairly detailed scheme for the expenditure of the money is framed and approved.

Secondly, they do not propose, as a general rule, and subject in certain cases to considerations of practical convenience, to recommend advances from the Development Fund in relief of existing expenditure, whether from Parliamentary votes, local rates, or other sources. In their view, it was the intention of Parliament that the fund should be used to promote new work, so to speak, not to pay for work already financed from other quarters.

Thirdly, the commissioners will, in general, recommend advances only by way of loan for schemes which are expected to be directly remunerative sooner or later.

Fourthly, the commissioners take note of the provision in the Act of 1909 (s. 18) which directs that in approving, executing, or making advances in respect of the execution of any work under the Act involving the employment of labour on a considerable scale, regard shall be had, so far as is reasonably practicable, to the general state and prospects of employment.

Last, and by no means least important, the commissioners feel it incumbent on them to ensure, so far as it lies in their power, that the fund shall not go into the pockets of private individuals, and they propose to recommend no applications or schemes likely to have that effect.

Policy in regard to Agricultural Development and Forestry.

The main lines of the policy by which they propose to be governed in considering schemes for two of the most important purposes mentioned in the Act, viz., first, the development of agriculture and rural industries, and secondly, forestry and afforestation.

Having regard to the amount of the Development Fund, they propose to deal with the first of these problems by devoting their attention principally to three lines of action. They aim first at increasing the amount and quality of the product of agriculture by assisting the extension of a system of scientific investigation and research, and with it of a system of education which will, so far as possible, ensure that the results of investigation and research are known and utilised in practice; and, secondly, they aim at increasing the variety of production by placing the cultivator in a position to know whether he can add certain new crops and industries to the existing number with a reasonable probability of profit. Finally, looking at the problem from a rather different and more strictly commercial point of view, they propose to encourage, in particular, the organisation of cooperation—a subject which is expressly named in the Act.

Nothing has impressed the commissioners more than the clearness with which the fact has appeared that the first condition of any considerable progress in these ways is the creation of a trained staff. It is useless to expect that immediate results of real value can be obtained on a large scale merely by expenditure. One example is sufficient: the number of men really qualified to conduct agricultural research in this country is at present exceedingly small, and it obviously cannot be increased at a moment's notice.

The problem of increasing the variety of production is likely to raise difficult questions both of principle and practice. It is enough at this early stage to name flax, hemp, tobacco, and beet as particular crops to which the commissioners propose to give attention with the view of ascertaining whether they can be grown in this country on a commercial basis, and to possible schemes for advances from the Development Fund for that purpose. They have appointed two gentlemen of scientific training to investigate by inquiry at home and abroad, and to systematise for their use the information available in regard to the first three of these crops. In regard to beet, they propose to consider in consultation with the Government departments concerned the question whether it is possible to make an experiment on a fairly large scale designed to show, not whether beet of good quality can be grown in this country (a point which they think may be regarded as settled), but whether it can be grown at a profit.

On the subject of forestry development, the commissioners have formulated for their guidance in considering British schemes and applications the following principles:—

(a) That the first requirement for such development is effective education in forestry at suitable centres, regulated by organised research and demonstration.

(b) That no scheme of State afforestation on a large scale can be considered until investigation has shown where State forests might be economically and remuneratively provided (regard being had to the interests of other rural industries), and until a trained body of foresters has become available.

(c) That for the present applications for grants for the above purposes should include provision for the creation and maintenance of such staff as may be necessary to give practical advice and assistance to those who desire to undertake afforestation or to develop existing afforested areas.

It will be gathered that in considering their action in this, as in other directions, the commissioners have been faced at the outset with the difficulty that the number of trained men in this country capable of directing forestry operations on any large scale is at present very small. Before all else they think it necessary that this difficulty should be overcome.

Applications and Schemes.

The twenty-four applications which reached the commissioners contemplated an expenditure of 210,829*l.* annually and 208,030*l.* capital sums. Among the applications, which have been grouped by subjects, may be mentioned:—

AGRICULTURAL RESEARCH AND EDUCATION.

I.—*England and Wales.*

The Treasury forwarded to the Development Commissioners on September 2, 1910, an application by the Board of Agriculture and Fisheries for an advance of 50,000*l.* per annum for the organisation of a system to aid and develop agriculture by the provision of technical advice for farmers and by promoting scientific research and experiments in the science, methods, and practice of agriculture.

The commissioners decided to recommend that the following grants, or such proportion as might be required for the financial year, should be paid to the Board for the benefit of the institutions named below, and for the purposes indicated:—

	£
Cambridge University.—Research work	4000
Bristol University.—(1) Bio-chemical investigations on cheese; (2) Investigations on teart land... ...	500
Yorkshire Council for Agricultural Education (Leeds University).—Investigations of atmospheric impurities	210
University College, Reading.—General work on (1) Microflora of cheese; (2) Cereal selection	250
South-Eastern Agricultural College, Wye.—(1) Investigations on tobacco; (2) Mycological Department; (3) Entomological Department; (4) Investigations on hop resins	350
University College of Wales, Aberystwyth.—Botanical survey of Aberystwyth, and subsidiary inquiries ...	156
Harper Adams Agricultural College.—Research on wart disease, and finger and toe	190
Royal Veterinary College.—Investigations in respect of vaccination	1390
The Incorporated Society for Extending the Rothamstead Experiments	2000
The British Dairy Institute, Reading	60
Woburn Experimental Station	600

The commissioners further intimated to the Board that they would be prepared to recommend additional interim grants, not exceeding in the aggregate a sum of 3000*l.*, to such other of the institutions as had applied for grants, but had not at that time been dealt with by the Board. They also informed the Board that they would be ready to recommend a grant of 1000*l.* to make provision for scholarships during the financial year so soon as they were favoured with a scheme embodying the conditions under which the Board proposed the scholarships should be given. The commissioners further contemplated recommending a grant of 1000*l.* for expenses of administration when the heads of estimated expenditure, and the amounts required under each head, were supplied to them.

It may be added that the commissioners have stated to the Board that they are willing to contemplate an expenditure of 40,000*l.* per annum for research alone, apart from advisory and other work.

II.—*Scotland.*

The Scotch Education Department forwarded to the commissioners on November 14, 1910, applications from each of the three agricultural colleges in Scotland for capital grants amounting in all to 137,425*l.*, made up as follows:—

Edinburgh:		£
College buildings	... ...	35,000
Farm	... ...	12,500
Forest garden	... .	1,225
		48,725
Glasgow:		£
College buildings	. ...	35,000
Farm	... ...	15,000
Research	... ...	2,500
Forest areas	... ...	5,200
		57,700
Aberdeen:		£
Purchase of estate	... ...	18,500
Alterations for farm purposes	... ...	6,000
Forest garden	... ...	1,500
Research (buildings, &c.)	... .	5,000
		31,000

On March 2, 1911, they informed the Department that they would be prepared to recommend the Treasury to grant a capital sum not exceeding 60,000*l.* on the following conditions:—

(1) That only one half of the expenditure ultimately approved is defrayed from the Development Fund, the other half being met by fresh contributions of local authorities and persons interested, and by a contribution from the Education (Scotland) Fund (one quarter from each source).

(2) That a revised scheme and estimates of expenditure relating to each individual college should be placed before the commissioners for consideration before they report to the Treasury.

They also informed the Department that they would be prepared to recommend an annual grant of one half of the excess of the expenditure of the colleges on what may be called "extension" work (*i.e.* instruction to agriculturists in the colleges' provinces by such means as lectures, visits, &c., and similar work), over the corresponding expenditure of the year 1908–9, on the following conditions:—

(*a*) That the grant from the Development Fund shall not in any year exceed the total contributions to the colleges from the Education (Scotland) Fund.

(*b*) That it shall not in any case exceed 5000*l.*

(*c*) That the commissioners are satisfied, when the formal application is made, as to the nature and scope of the work proposed; that it comes within the terms of the Development and Road Improvement Funds Act, 1909; and that it will be properly carried out.

III.—*Ireland.*

The commissioners received on July 18, 1910, an application by the Department of Agriculture and Technical Instruction for Ireland for a grant of 15,000*l.* a year for five years for the establishment and maintenance of an agricultural station for a system of general investigation and scientific research in Ireland.

It was proposed that the station should be established in the vicinity of Dublin, the capital expenditure being estimated at 20,000*l.* and maintenance at 15,000*l.* a year.

The commissioners determined to intimate to the Department that they would be prepared to consider schemes based on an expenditure of—

(*a*) 4000*l.* per annum for a central institution for investigations and technical advice of a local character.

(*b*) 5000*l.* per annum for scientific research in animal breeding or some other subject undertaken in Ireland as part of a general scheme of scientific research for the United Kingdom.

At the end of the year the commissioners were awaiting an amended application on the terms thus indicated.

Horse and Livestock Breeding.

The commissioners received on July 26, 1910, an application by the Board of Agriculture and Fisheries for a grant of 50,000*l.* per annum, of which 5000*l.* was to be devoted to livestock other than horses, and 45,000*l.* to the encouragement of light-horse breeding in Great Britain. On November 23 the commissioners recommended the Treasury to advance 36,000*l.* for one year to the Board by way of grant, to be expended generally as follows:—

	£
(*a*) Payment of premiums to the owners of stallions	13,000
(*b*) Encouragement of the keeping of brood mares	10,000
(*c*) Free nominations for the service of mares by premium stallions	3,000
(*d*) Purchase of stallions	5,000
(*e*) Registration of stallions	5,000

The report recommended advances not exceeding 3800*l.* to cover travelling expenses, the expenses of local committees, payment of local secretaries, &c., and not exceeding 1250*l.* to cover other administrative expenses up to March 31, when the sum previously voted by Parliament to the Royal Commission on Horse-breeding was expected to become available for the Board.

As regards horse-breeding in Ireland, the commissioners received on July 18, 1910, an application from the Department of Agriculture and Technical Instruction for Ireland for a grant of 10,000*l.* per annum for five years for the extension of the Department's existing schemes. On October 29, 1910, they reported to the Treasury, recommending a grant of 10,000*l.*, to be expended roughly in the following proportions:—two-fifths on the extension of the existing schemes for the registration and purchase of stallions, two-fifths on the extension of the existing schemes of service nominations to mares, and one-fifth on a new scheme to encourage the keeping and breeding of better mares of the Irish draught type.

Forestry.

It is provided in section 1 (*b*) of the Act that forestry, as one of the purposes for which the commissioners may recommend advances, shall include:—

(1) The conducting of inquiries, experiments, and research for the purpose of promoting forestry and the teaching of methods of afforestation.

(2) The purchase and planting of land found after inquiry to be suitable for afforestation.

Believing that forestry is one of the purposes of the Act which require to be dealt with on comprehensive and national lines, the commissioners at an early stage appointed four of their number to report on the broad principles to be applied to all applications bearing on the subject.

Various schemes and applications were considered, and the situation on March 31 is summed up as follows:—

In regard to England and Wales, the commissioners have just received a comprehensive scheme from the Board of Agriculture and Fisheries.

In regard to Scotland, they have agreed to the provision of a central demonstration area—for the acquisition of which preliminary steps are being taken—and of a forestry school in connection with it, and also to the provision of small forest gardens for the local use of the agricultural colleges.

In regard to Ireland, they have agreed to advances of 25,000*l.* or 30,000*l.* for the purchase of land, and to further advances, so soon as formal and definite applications are made under the Act, for additions to staff and for the maintenance and management of small woodlands in the hands of county councils.

The Development and Improvement of Fisheries.

Among the applications from the Department of Agriculture and Technical Instruction for Ireland which the commissioners received on July 18, 1910, one dealt with the development and improvement of fisheries. For this purpose the Department asked for a sum of 50,000*l.*, made up as follows:—

	£
For the development of six specified harbours	32,500
Removal of wrecks	1,000
Motor boats	5,000
Inland towns—supply of fish	1,000
Dredger	8,500
Shell-fish	2,000
	50,000

An interim application was considered by the commissioners at their meeting held on March 15, when it was resolved:—

(a) To recommend an advance of a sum not exceeding 4000*l.* for the purchase of a dredger, on the production of satisfactory tenders for the approval of the commissioners.

(b) To postpone consideration of the application in respect of Ballinagoul until the next meeting, for the production of plans of the proposed works.

Summary and Conclusion.

It will be gathered from this brief review of their action that during the first nine months of their operations the commissioners (and also, they believe, the Government departments most concerned with the Development Fund) have been largely occupied in necessary preliminary work. Although they have received under the Act but a small proportion of the applications actually made to the Treasury, yet it must be remembered that the settlement of a comprehensive scheme for such a purpose as agricultural research is in practice equivalent to disposing of many individual applications; and for reasons already stated, that procedure, though apparently slow, is, in the commissioners' view, the only ultimately satisfactory method of dealing with schemes for several at least of the purposes mentioned in the Act.

The sums of which the commissioners have either recommended the allocation, or agreed to recommend it so soon as satisfactory schemes are framed, amount roughly to 165,000*l.* per annum, and 100,000*l.* non-recurring advances. By far the larger proportion of this expenditure, if ultimately approved by the Treasury, will go in agricultural research and instruction, viz. England and Wales 105,000*l.* per annum, Scotland a lump sum of 60,000*l.* and 5000*l.* per annum, Ireland 9000*l.* per annum.

These figures do not take account of the considerable sums, of which no definite estimate can yet be given, but for which schemes were either being prepared or were under examination by the commissioners at the close of the year, *e.g.* forestry in England and Wales, the purchase of a demonstration area in Scotland and the establishment there of a central school of forestry, the development of Irish fisheries and fishery harbours, and the encouragement of the organisation of cooperation throughout the United Kingdom. Nor do they take account of applications which had not reached the commissioners, though known as having been made, or about to be made, to the Treasury—as, for instance, schemes for the development and improvement of British fisheries and of Scotch harbours; nor, again, of possible expenditure on such projects as the revival of the flax and hemp industries, the encouragement of tobacco and beet cultivation, or the establishment of an institution for the study of rural economics.

In the first nine months of their work the commissioners, so far as they are concerned, have allocated and, as they think, rightly allocated, one-third of the annual income guaranteed to the Development Fund for five years. Out of the two-thirds which now remain they hope to provide during the coming year for considerable annual expenditure on such purposes as forestry and forestry instruction and the organisation of cooperation; and it cannot be supposed that expenditure on the purposes with which they have already dealt ought to or will remain stationary at the amounts provisionally fixed. Looking to these facts, they cannot but feel some apprehension that unless Parliament comes to the aid of the fund its position in a very few years will not be a strong one. They will, however, be far more able to form an opinion on this important question at the end of the financial year 1911–12, by which time they hope that all the applications hitherto made to the Treasury will have reached them from the Government departments, that considerable schemes known to be in preparation will have been submitted, and that the inquiries which they are making into such subjects as flax, hemp, and tobacco cultivation will have been completed, or be on the point of completion.

NOTES.

ON Saturday last, July 22, nineteen aëroplanes started from Brooklands, near Weybridge, in a race for which a prize of 10,000*l.* was offered by *The Daily Mail*. The specified route was a circuit of Great Britain, with a number of landing-places, or control stations, at each of which a descent had to be made; these places, with their distances in miles from one another, were:—Brooklands to Hendon, 20; Hendon to Harrogate, 182; Harrogate to Newcastle, 68; Newcastle to Edinburgh, 93; Edinburgh to Stirling, 31; Stirling to Glasgow, 22; Glasgow to Carlisle, 86; Carlisle to Manchester, 103; Manchester to Bristol, 141; Bristol to Exeter, 65; Exeter to Salisbury Plain, 83; Salisbury Plain to Brighton, 76; Brighton to Brooklands, 40; total distance, 1010 miles. The first section of the race was covered by J. Védrines in 19m. 48s., and ten other airmen accomplished the journey in less than half an hour. On Monday morning the following machines and pilots started from Hendon for Edinburgh, with official control descents at Harrogate and Newcastle:—J. Védrines, Morane-Borel monoplane; Lieut. Conneau ("Beaumont"), Blériot monoplane; J. Valentine, Deperdussin monoplane; G. W. Hamel, Blériot monoplane; S. F. Cody, Cody biplane; H. J. D. Astley, Birdling monoplane; C. Howard Pixton, Bristol biplane; Lieut. R. A. Cammell, R.E., Blériot monoplane; O. de Montalent, Bréguet biplane; C. T. Weymann, Nieuport monoplane; C. P. Pizey, Bristol biplane; G. Blanchet, Bréguet biplane; B. C. Hucks, Blackburn monoplane; Lieut. H. Bier (and passenger), Etrich monoplane; Lieut. H. R. P. Reynolds, R.E., Howard Wright biplane; E. Audemars, Blériot monoplane.

YESTERDAY afternoon, when we went to press, two airmen, namely, "Beaumont" and Védrines, had reached Brooklands, having completed the circuit, and it was announced that the prize had been awarded to "Beaumont." The race was a severe test of the efficiency of aëroplanes and their control by the pilots. The circuit of 1010 miles had to be completed without any airman changing his engine or aëroplane. Five parts in each aëroplane and five in each engine were stamped, and at least two parts in each case had to be in place at the end of the race, the object of the contest being to encourage the construction of trustworthy and enduring flying machines. That it should be possible for airmen to travel over such an extended course of strange country with nothing but maps and compasses to direct them is, however, a remarkable achievement, independent of the capabilities of the aëroplanes. No doubt much experimental data and mathematical investigations will be required before aëroplane architecture can reach the position of naval architecture, but meanwhile aviation engineers and pilots are bringing us nearer that conquest of the air which will be the distinguishing characteristic of the present century; and one of the historic events of this era of aërial navigation will be the trying contest which has just been concluded.

WE gather from a circular lately received that a testimonial is contemplated in honour of Sir Patrick Manson, K.C.M.G., F.R.S. The international memorial was an inception by Prof. Blanchard, of the Faculty of Medicine, Paris, and with him are associated the names of men best known in tropical medicine. It was felt, however, that it would ill become Sir Patrick's British *confrères* did they not come forward and show their special appreciation of the work he has done in the field of tropical medicine. The international testimonial is proposed to take the form of a plaquette in gold to be presented to Sir Patrick, and bronze plaquettes to subscribers, to bear an impression of Sir Patrick by a well-known artist. The British testimonial is in the first place to be the presentation of a portrait in oils, of which each subscriber of one guinea and over will receive a black-and-white reproduction; but it is hoped that, in addition, a Manson prize will be founded for bestowal as a reward for good work accomplished in the sphere of tropical medicine and hygiene. Of the success of these testimonials there should be no doubt, for the benefits conferred upon mankind by Sir Patrick Manson as the "father" of modern tropical medicine is incalculable. A new field of scientific investigation has been opened by him; the formulation of the mosquito-malaria theory has had consequences which have extended far beyond even the widely flung malaria, and opened up new channels of thought in every direction. Knowledge of the part played by vermin in the spread of disease is being extended daily as the result of Manson's work, and a new school of thought, giving a fresh direction and impetus to inquiry, has advanced science generally, and will go on bearing fruit so long as time extends.

THE organising committee of the Fourth International Conference of Genetics, to be held in Paris on September 18–23, met recently under the presidency of Dr. Viger. M. Philippe de Vilmorin, secretary of the committee, reported what had been done up to that day in preparation for the conference. Not counting the names of the principal French biologists who are members of the committee, the secretary was able to give the names of the following foreigners who have subscribed:—Baur, Giesenhagen, Goldschmidt, Pfitzer, Poll, &c. (for Germany); Agar, Bateson, Darbishire, Gregory, Miss Durham, Hartog, Laxton, Lynch, Nettleship, Paton, Punnett, Miss Saunders, Staples-Browne, Sutton, Miss Wheldale, &c. (for Great Britain); Bradley (for Australia); Fruwirth, Strakosh, Tchermak, &c. (for Austria); W. and Chs. Saunders (for Canada); Johannsen (Denmark); Balls (Egypt); Davenport, Hays, Howard, Swingle, Tower, &c. (United States); Hagedoorn, Houwink, Lotsy, Noordnijn (for Holland); Leake (for India); Strampeli (for Italy); Nilsson-Ehle, Rosenberg (for Sweden); Chodat (Switzerland); Boris de Fedtschenko (Russia); and Arechavaleta (Uruguay). Many universities and scientific societies will be officially represented. Numerous communications have been promised; short descriptions of them will be published before the meeting of the conference, and they will be published in full in the proceedings, a copy of which will be sent to each subscriber. The meetings of the conference will depend upon the number of the communications, but it seems probable that five sittings will be sufficient. The remaining time will be devoted to visits to the Museum of Natural History, the Pasteur Institute at Garches, to Verrières, the laboratories of the Sorbonne, &c. Probably there will be a reception by the French National Society of Horticulture on September 18, and one at the Hôtel de Ville on September 23.

IT has been decided to publish from the Sleeping Sickness Bureau a quarterly bulletin dealing with the Leishmania group of diseases. Dr. C. M. Wenyon, protozoologist to the London School of Tropical Medicine, will undertake this part of the work. A list of references is now in preparation and will form the first number.

REUTER's correspondent at Washington announces that on July 24 the Senate ratified the agreement between the United States, Great Britain, and Russia for the suspension of pelagic sealing for fifteen years. An article upon the fur-seal and the convention, which has now been accepted by the United States Senate, appeared in NATURE of July 13.

WE learn from *Science* that the earthquake of July 1 is reported to have done considerable damage at Lick Observatory, on Mount Hamilton. The 36-inch telescope is said to have been moved three-quarters of an inch out of place on its concrete pier, but was restored without trouble. The case of the Riefler clock was wrecked, and minor damage was done to the working parts. The chimneys of the observatory buildings were injured, and a brick structure which houses a number of astronomers was cracked so as to be unsafe for occupancy.

IN the obituary notice of the late Dr. H. Bolus in NATURE of June 8, reference was made to "his generous support of the Cape University, which owes to him the foundation of its chair of botany." Prof. H. H. W. Pearson writes to point out that though the establishment of the "Harry Bolus chair of botany in the South African College in 1903 was due in a large measure to the munificent support which Dr. Bolus gave it, there is no botanical chair in the Cape University, which is not a teaching institution."

REFERRING to the inauguration of a fund to honour the memory of the late M. J. Joubert, to which attention was directed in our last issue (p. 101), we are able to state that an influential committee has been formed, including representatives of the Pasteur Institute, the French Physical Society, and the International Society of Electricians. Joubert's collaboration with Pasteur, his work for the French Physical Society, of which he was once president and for ten years general secretary, and his researches and writings, have all made his name widely known and respected. The idea of founding a Joubert scholarship should appeal to all old colleagues, pupils, and friends of Joubert. Subscriptions may be sent, as has been stated, to M. Gauthier-Villars, 55 quai des Grands-Augustins, Paris.

THE present month is establishing a record both for the long and persistent drought and also for its high temperature. In London, July 25 was the twelfth day during the month with the thermometer above 80°, and on two days, July 21 and 22, the temperature exceeded 90°. There has been no temperature in London so high as 90° in July since 1900, and none at any period of the summer since 1906. At some places in the east and south-east of England the thermometer rose higher than in London. In France and Germany the temperature has also been excessive, shade readings of 100° being reported in places. The month was absolutely rainless in London and over the southern portion of England until July 24, when slight rain was experienced, which was followed by a thunderstorm on July 26; so long a period of drought has not occurred in July since 1887.

THE recorder of Section C (Geology) of the British Association sends the following statement of the provisional programme for the Portsmouth meeting:—Joint meetings have been arranged with Sections E (Geography) and K (Botany). The subject for discussion with Section E is "The Former Connection of the Isle of Wight with the Mainland," and with Section K, "The Relation of the Present Plant Population of the British Isles to the Glacial Period." Presidential address by Mr. Alfred Harker, F.R.S. The address on the local geology will be delivered by Mr. Clement Reid, F.R.S. The following papers have already been promised:—"On the Discovery of Remains of *Iguanodon bernissartensis* in the Wealden Beds of Brightstone Bay, I. of W., and the adaptation of the pelvic girdle to an erect position and bipedal progression,"

R. W. Hooley. (1) "Siliceous Oolites and other concretionary structures in the vicinity of State College, Pennsylvania," (2) "On the Pre-Cambrian Beds of Ontario," Prof. E. S. Moore, of State College, Pennsylvania. "Further Work in the Silurian Rocks of the Eastern Mendips," Prof. S. H. Reynolds. (1) "On some New Rhætic Fossils from Glen Parva, Leics," (2) "On the Shell-layer in Mollusca," A. R. Horwood.

In *The Times* of July 12 Mr. W. E. Roth, now Commissioner of the Pomeroon district, British Guiana, discusses modern men of the Stone age in New Guinea and North Australia. From a comparison of Mr. Goodbody's account of the strange race found in the hitherto unknown interior of Dutch New Guinea with the natives of North Australia, Mr. Roth comes to the conclusion that the latter are "undoubtedly the more primitive, in that they are nomadic and ignorant of any native fermented drink. They are certainly on a level with regard to the treatment of their women and in their eating human flesh; this, however, can hardly be regarded as true cannibalism, in that all the cases that I have met with in North Queensland were due rather to sentiment and affection, nor, indeed, did I come across a single instance where the individual—man, woman, or child—was purposely killed to be eaten."

Artists and students of anatomy will welcome the elaborate paper entitled "Les proportions du corps pendant la croissance de 13 ans ½ jusqu'à 17 ans ½ ainsi qu'à la naissance, à 6 ans ½ et à 23 ans ½ représentées en milliémes de la taille," published in parts iv.–v., for 1910, of *Bulletins et mémoires de la Société d'anthropologie de Paris*. These series of elaborate measurements of the relations of different parts of the human body are illustrated by statistical diagrams. The memoir is a fine example of the best class of anthropometrical work in which French *savants* have gained a well-merited reputation. Another similar memoir, contributed to the same journal by Drs. Chaillou and Léon Mac-Auliffe, entitled "Le type musculaire," starts with the examination of cerebral characteristics, and passes on to the consideration of living types and sexual variations. The paper deserves study by all who are interested in physical culture. After pointing out the diseases due to the sedentary life, the authors arrive at the conclusion that its hygiene resolves itself into two words—exercise and rest.

In the July issue of *Man*, Messrs. N. F. Robarts and H. C. Collyer continue their report on the excavation of the British camp at Wallington. The numerous loose unbroken flints found on the inner side of the ditch seem to have been used as missiles, and round Tertiary pebbles were employed as sling-stones. A large collection of implements used in the preparation of food was made, the most common, probably because they were the most indestructible, being saddle-back mealing stones, made of the Lower Greensand sandstone. Many tiles, resembling those from the Swiss Lake dwellings, were discovered. Though there were many flakes and cores, stone implements were scanty in number. A broken axe of diorite indicates foreign commerce. Further exploration of the large remaining portion of the ditch will doubtless provide many other similar articles, but the specimens already unearthed are sufficient to give a tolerably clear idea of the civilisation, arts, and industries of the inhabitants of this Surrey town in the first or second century B.C.

We have received a copy of No. 3 of the *Nature Photographer*, which contains excellent photographs of a merlin and her young, and of a group of the tree-fungus known as the "oyster of the woods."

The first part has reached us of a "Lepidopterorum Catalogus," edited by C. Aurivillius and H. Wagner, and published by W. Junk, of Berlin. The catalogue, of which this part deals with the Chrysopolomidæ, purports to give the name of every genus and species, with references.

After financing a natural history collecting expedition to Alaska, Miss A. M. Alexander recently supplied funds for a similar undertaking in Humboldt County, Nevada, which was duly accomplished in the summer of 1909. The results, so far as mammals are concerned, are recorded by Mr. W. P. Taylor in a report issued as No. 7 of the seventh volume of the University of California Zoological Publications. One short-tailed field-mouse is described as new.

Among the more important papers recently published in the Proceedings of the Academy of Natural Sciences of Philadelphia, reference may be made to the third portion of Mr. J. P. Moore's account of the polychætous annelids, dredged off southern California by the *Albatross*, which appeared in the April issue. The number of new forms described indicates the richness of the fauna. Later on in the same issue Messrs. Brown and Pilsbry describe the molluscs of the Tertiary Gatun beds, Isthmus of Panama.

In describing a batch of fourteen newly-born young of an electric ray (*Narcine brasiliensis*) from Florida, Messrs. Bean and Weed point out, in No. 1816 of the Proceedings of the U.S. National Museum, that these differ in colouring from their parents. The young, as shown in a striking plate, are spotted as conspicuously as a leopard, whereas in the adult the spots are much less distinct, and in some cases are formed by the agglomeration of pin-like dots. In No. 1824 of the publication cited, the same authors reclassify the so-called freshwater American sunfishes of the genus Lepomis, belonging to the peccoid family Centrarchidæ. The pharyngeal bones and teeth are largely taken as the basis of classification, and a number of examples of this part of the skeleton are figured.

In an article on the Morocco-Algerian frontier, contributed to the *Field* of July 15, Sir H. H. Johnston reproduces two outline figures of the extinct north African buffalo (*Bos* [*Bubalus*] *antiquus*), incised on rock-faces near Tiout, southern Algeria. The sketches, the age of which is unknown, appear to have been made by a people related to the modern Berbers, but living under conditions similar to those prevalent during the Neolithic or early Metal age in Europe. The horns of the buffalo seem to be of the type of those of the Indian, as distinct from the African, species, and are of immense size. On the other hand, it has been stated that the skeleton, apart from the skull, is more like that of the African buffalo; and the nasal bones appear to be of the short type distinctive of the latter. Sir Harry Johnston states that he was informed by one of the professors at the University of Algiers that other rock-pictures show this buffalo domesticated by a tribe acquainted with the use of metal; a circumstance which renders it all the more remarkable that the species should have become extinct before the time of Carthaginian and Roman history. It may be added that the intermediate characters presented by the extinct Algerian species tend to show that the proposal to separate generically (or subgenerically) the African from the Indian buffalo is unnecessary.

Systematic contributions to the *Kew Bulletin* (No. 5) comprise a list of Balsaminaceæ from the State of Chitral determined by Sir Joseph Hooker, a series of new African euphorbiaceous plants, including a new genus, Cyrtogonone, defined by Dr. Prain and a collection of new exotic fungi described by Mr. G. Massee; of the latter, two species of Balansia, *Æcidium osyridocarpi* and *Ustilago trichopterygis*, are figured, and *Æcidium cymbopogoni* is noted as a destructive pest on lemon grass in the botanic gardens at Entebbe. An article on persimmons, communicated by Mr. W. B. Hemsley, furnishes evidence for separating *Diospyros roxburghii*, a species native to east India and western China, from *Diospyros kaki*.

An appreciable supplement to what was considered to be a fairly complete list of plants for Monroe County in New York State and adjoining territories, published in 1896, has been issued in the Proceedings of the Rochester Academy of Science (vol. v.). The additions amount to more than two hundred species, of which two-thirds are native and one-third alien. No fewer than seventy-seven of the native species represent determinations made by Dr. Sargent for the genus Cratægus, as this county supplied him with a large number of critical forms; under Viola, eight new native species are scheduled. An alien that was expected and duly arrived along the railroad track is a variety of *Salsola kali*, that receives the name of Russian thistle. *Lysimachia nummularia* is noted as a weed growing on lawns.

The announcement is made in the May number of *The Indian Forester* that the responsibilities of editorship have been transferred to the president of the Research Institute at Dehra Dun, with whom, as heretofore, a board of management is associated. Among the contents is a concluding article on paper-pulp testing, contributed by Mr. W. Raitt. Dealing with grasses, two new sources are indicated as pulp prepared from "ulla," *Anthisteria gigantea*, and a Burmese consignment of "kaing" grass, *Phragmites karka*, both gave satisfactory results in the matter of colour, strength, and toughness; being in these respects superior to "bhabur," *Ischaemum angustifolium*, that is now worked in the factories. Summarising the prospects of the pulp industry in the United Provinces, the author is of opinion that large reserves of material exist, that ulla, bhabur, and spruce promise to yield the best material, while a number of trees, notably *Bombax malabaricum*, would furnish a pulp of inferior but serviceable quality.

Central America is following the excellent example set by the United States in agricultural education, and from Costa Rica we have received the first two numbers of the *Boletin de Fomento*, the organ of the Department of Agriculture. Hevea and coffee naturally come in for a good deal of attention, and sections are devoted to horticulture and agriculture; there is also a geological section. A list of Spanish works on water in relation to agriculture is given, which, though small in comparison with other lists, is much more extensive than one would have expected. The bulletins are well illustrated, and will, we hope, be found to serve a useful purpose.

The Agricultural Statistics of India for the years 1904–9 are now published in two volumes, vol. i. relating to British India and vol. ii. to the native States. The statistics are not discussed, but are given without comment; for the native States they are not always as accurate as might be desired, but the best available information has been used. For the historian and the administrator these records are invaluable, and all interested in Indian agriculture will find complete *data* as to crops, irrigated and unirrigated areas in the numerous districts, for each of the five years under consideration.

The growing importance of rice in India has necessitated a careful study of the numerous races cultivated by the natives, and as a preliminary these races have been enumerated in *The Agricultural Ledger* (1910, No. 1). The list is very extensive, and extends over two volumes, each of nearly 300 pages, but it is believed to be as complete as is at present possible. Under each variety is given a very brief description, together with references to papers or books where a fuller account may be found: thus the list is also a guide to the literature. An enormous amount of work has evidently been involved in its preparation, but the authors, Messrs. R. Abbey-Yates and E. F. Vieux, will have the satisfaction of knowing that they have saved subsequent workers much weary searching through literature that is not always easily accessible.

The report of the Egyptian Survey Department, dated July 3, states that the White and Blue Niles had been rising throughout June at a normal rate, but the level at Wadi Halfa was then 25 cms. below normal, owing to a check in the rains in Abyssinia. The forecast for the Nile flood indicated that it will probably be about 10 per cent. below the average.

The Cairo Scientific Journal for June contains two articles on the silt which is carried and deposited by the flood waters of the Nile, relating especially to the Ibrahimia Canal, one of the great artificial waterways which irrigate Middle Egypt to the north of Assiut. Samples were taken at varying depths, and seemed to show that the scour caused by a bridge unsuitably placed increases the silt which is deposited in the canal downstream of it to a considerable extent. The matter is one of great importance to irrigation in Egypt, and too little attention has hitherto been given to obtaining accurate results, so that the work of Messrs. Bury and Pollard is of definite value.

In the same number Mr. A. Lucas treats of "hashish," or Indian hemp, *Cannabis indica*, the forms in which it finds its way into Egypt; the manner in which it is consumed, and the methods of detecting it with certainty. Its introduction into Egypt is prohibited, and very large quantities (amounting to 23,000 kilog. in 1909) are seized every year by the Custom House officials and the coastguard officers, but the demand is widespread, and it is obtainable practically in every village. From the number of ways in which this injurious drug is prepared for consumption, in the form of sweetmeats or confections, and the large amount that is still introduced into the country, such investigations are of the highest importance, especially in a country where the adulteration of foods is not controlled, as in Europe.

In the July number of *Petermann's Mitteilungen*, Dr. Peucker gives an account of the proceedings of the International Aëronautical Conference, held at Brussels on May 26 and 27, in so far as they affected maps. Resolutions were passed in favour of the scale of 1 : 200,000 as far as possible, though in special circumstances other scales might be desirable; each sheet should include a degree square, and the sexagesimal system should be employed: geographical names should be in the language of the country represented. In the compilation of detail and employment of conventional signs full latitude was given, but some delegates expressed the desire that high-tension electric cables should be indicated.

The Hydrographer's report for 1910 has been issued, containing a brief summary of the surveys which have been carried out by the Admiralty during the year. Five ships were employed in home waters and seven abroad, off

British Columbia, Australia, Borneo, the west, south, and south-east coasts of Africa, the Straits Settlements and Australia, and off Newfoundland. Two ships of the Royal Indian Marine were employed on the Marine Survey of India, off Burma, and the west coast of India. Among much work classed as miscellaneous, a systematic determination of the magnetic variation in the North Sea was carried out in March by the officers of four cruisers, which resulted in obtaining good values at sixty-two positions. Considerable irregularity was also located near the Shetland Islands, and also near the coast of the British Isles. Further experiments were carried out at Chatham with the Field-Cust tide-recording apparatus for use at sea, and very satisfactory results were obtained.

THE Journal of the Meteorological Society of Japan for May contains, in addition to several articles in Japanese on interesting subjects (*e.g.*, "Fogs on the Korean Coast," "Variation of Barometric Pressure in Japan," &c.), original articles in other languages. One of the latter is on "Wireless Telegraphy in the Service of Japanese Meteorology," by Mr. T. Saki. Japan is frequently visited by typhoons, and the most dangerous are those which originate in the Pacific. By arrangements made since May, 1910, the central office at Tokio receives ordinary and special codified radiograms from men-of-war and vessels of the great Japanese shipping companies, from distances even as far off as 180° E. longitude (40° E. of Tokio), and dispatches warning telegrams to ships at sea. These messages will be of great value both for storm-warning purposes and for improving our knowledge of the behaviour of those destructive storms.

IN *Climatological Service* of the U.S. Weather Bureau (District No. 11, California), Prof. A. G. McAdie publishes a paper on forecasting the supply of water for the summer from the depth of snow, which is of considerable interest to engineers, farmers, and others. Observations of the depth of snow and of rainfall have been made since 1870 at Summit, a station on the Southern Pacific Railway, at a height of 7017 feet, where 86 per cent. of the precipitation falls as snow. The average depth of snow (mean of ten seasons), the average rate of its melting, and the depth for the present season, are shown by a diagram. A model (shown in the paper) is also made use of for comparing the actual curve of melting snow for any given season with the mean curve. By means of this design and the tables, the probable date of the snow's disappearance, and the consequent cessation of water supply from this source may be determined. The author points out that the wind is probably the greatest factor in reducing the depth of snow, and he refers to the difficulty of determining the water equivalent for given depths. The "packing" process plays an important part; samples taken near the top and bottom of a snow bank give very different results.

DR. H. A. MIERS, F.R.S., principal of London University, delivered the eighteenth Robert Boyle lecture before the Oxford University Junior Scientific Society on May 20, and selected as his subject the growth of a crystal. The lecture has just been issued by Mr. Henry Frowde, price 1*s*. net. To the elucidation of the problem of crystallisation nearly the whole of the researches which Dr. Miers had carried on with the aid of a small but zealous band of students during his tenure of the Waynflete chair of mineralogy at Oxford had been devoted, and his lecture, therefore, took largely the form of a valedictory address, in which he recounted the nature of those researches and summed up the progress made in our comprehension of the constitution of crystallised matter as the result of them. Dr. Miers had early realised that mere idle speculation was futile, and that it was of primary importance to observe a crystal while actually growing, and had devised for the purpose apparatus which he brought with him to Oxford; with it he made the interesting discovery that the layer immediately in contact with the crystal is denser than the liquid as a whole. In conjunction with Miss Isaac he investigated the conditions governing crystallisation from a saturated solution, and at his instigation Mr. Barker studied the growth of one crystallised substance on another, and found that congruence of molecular structure was the factor that determined parallelism of growth. Dr. Miers referred to Prof. Lehmann's discovery of liquid crystals, and to the theory of crystal structure put forward by Mr. Barlow and Prof. Pope, and, in conclusion, pointed out that advance in a subject such as crystallisation, which lay near the confines of several branches of science, depended to no small extent upon the assistance of other workers beyond the fence.

UNDER the title "Men of Note in Aëronautics," the July issue of *Aëronautics* gives a biographic notice of Mr. R. F. Macfie which should do much good in bringing home to English readers the side of aviation to which little attention is given in daily papers. The extracts from Mr. Macfie's diary will, indeed, be a revelation to the uninitiated reader of the difficulties encountered by the early pioneers of artificial flight, which include destruction of aëroplanes, repeated interviews with War Office officials, followed by refusal of permission to fly, delays of three days at Custom houses, permission refused at Pau after having previously been granted, interviews with municipal authorities resulting in further refusals, loss of machine in transit, its recovery in a terrible state of ruin, delay in sending engines, short flights, then permission withdrawn, machine damaged by bad weather, then partially burnt. In spite of the present popular enthusiasm, there are many workers in aviation who not only do not receive the recognition they deserve, but are, on the contrary, handicapped by every kind of discouragement.

THE Circolo Matematico di Palermo is a society which during the twenty-seven years that have elapsed since its foundation in 1884, has gradually developed into an international mathematical society. It is interesting to note how different nationalities were represented at the time when its last report, for 1910, was drawn up. Out of a total of 745 members, we find that the countries contributing not fewer than 10 members may be classified as follows:—Italy, 275; United States, 119; Germany, 111; France and colonies, 54; Austro-Hungary, 49; Russia, 24; Great Britain and Ireland, 17; Sweden, 16; Denmark, 13; Belgium and Switzerland, each 11. The membership for the whole British Empire, including India, only numbers 24, the same as for Russia. It need scarcely be pointed out that the large preponderance of Italian members is in great measure attributable to the local character of the society, but leaving the figures for Italy out of account, the remaining statistics may afford some indications of the relative importance attached by different countries to an international movement for the advancement of higher mathematics.

THE annual report of the Royal Prussian Meteorological Institute ("Bericht über die Tätigkeit des königlich Preussischen Meteorologisches Instituts, 1910") has been issued. The administrative report shows that satisfactory progress has been maintained with routine work both at the institute and at the Potsdam Observatory. A number of scientific papers by members of the staff or by observers in connection with the institute are printed as appendices. Several of these deal with questions of thermometer and rain-gauge exposure. Among the remaining papers we may mention a detailed summary of the observations of cloud motion over Hildesheim, extending over the period 1904–8, by Th. Bötel, observer at Hildesheim, and a report by W. König of the heavy rainfall experienced in Germany during the first few days of August, 1910. Appendix xi. reports on the comparison of the standard barometers and magnetic instruments of Potsdam Observatory with those of de Bilt, Paris, Val Joyeux, and Pavlovsk, carried out by Dr. W. Kühl in conformity with resolutions of the International Meteorological Committee. Further papers on magnetic comparisons are contributed by Prof. Ad. Schmidt and Dr. O. Venske. Prof. Schmidt also contributes a paper on the detailed magnetic survey of east Prussia, a region of great magnetic disturbance. This is accompanied by a chart of isogonic lines for the epoch 1911·0

IF the collimator and telescope of a spectrometer are so placed that their axes coincide, and a block of plane parallel glass is placed between the collimator lens and the telescope lens, no deviation of the image of the collimator slit is produced. If the upper part of the glass block is provided with a prism-shaped cavity which contains a liquid having an index of refraction which differs from that of the block, the upper part of the image of the slit will be deviated by an amount proportional to the difference of the two indices of refraction. Now the deviation of a narrow pencil of homogeneous light on passing through a lens is proportional to the distance of the point of the lens on which the pencil falls from the axis of the lens. By making the light which has passed through the liquid pass through a lens at the proper distance from the axis, the deviation due to the liquid may therefore be compensated. It is on this principle that the Féry refractometer is constructed. The block of glass containing the prism-shaped hollow for the liquid the index of refraction of which is required, is enclosed in a small water tank the sides of which are plane convex lenses. The tank and contents can be moved horizontally across the field by means of a screw, and the distance through which they have to be moved to make the resultant deviation zero, is found to be proportional to the difference of refractive indices of glass and liquid. In the instrument as constructed by Messrs. Hilger, the range of refractive index is from 1·3300 to 1·6700, with a degree of accuracy of nearly 0·0001. The reading is direct, and by heating the water in the tank to different temperatures the effect of temperature on the index of the liquid may be determined. A measurement can be obtained with 1 c.c. of liquid.

THE second issue of *Le Monde*, which is described as a monthly illustrated encyclopædia, being an anthology of the reviews of all countries, has reached us. Copies may be obtained in this country from Messrs. Nilsson and Co., 16 and 18 Wardour Street, London, W., at the price of three francs. Among other contributions to this issue we notice translations into French of Mr. H. H. Suplee's article in *Cassier's Magazine* on the determination of altitudes reached by aëroplanes, and an article from *The Times* on the great ocean liners which now connect Europe and America.

WE have received from Prof. C. Ulpiani a reprint of a paper from the *Atti della Società Italiana per il Progresso delle Scienze*, 1910, discussing the work of the United States Bureau of Soils, especially the applications of physical chemistry to the soil.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR AUGUST:—

Aug. 1. 7h. 11m. Jupiter in conjunction with the Moon (Jupiter 1° 13′ N.).
7. 22h. 46m. Uranus in conjunction with the Moon (Uranus 4° 28′ N.).
8. 18h. 0m. Mars at quadrature to the Sun.
10. 1h. 0m. Venus at greatest brilliancy.
10–12. Maximum of the Perseid Meteors.
12. 21h. 0m. Mercury at greatest elongation E.
13. 6h. 0m. Saturn at quadrature to the Sun.
16. 15h. 53m. Mars in conjunction with Saturn (Mars 0° 21′ N.).
16. 20h. 2m. Saturn in conjunction with the Moon (Saturn 4° 2′ S.).
16. 20h. 12m. Mars in conjunction with the Moon (Mars 3° 40′ S.).
19. 19h. 0m. Venus in Aphelion.
21. 1h. 20m. Neptune in conjunction with the Moon (Neptune 5° 36′ S.).
22. 14h. 0m. Venus stationary.
25. 11h. 50m. Venus in conjunction with the Moon (Venus 10° 23′ S.).
28. 22h. 0m. Jupiter in conjunction with the Moon (Jupiter 1° 41′ N.).

DISCOVERY OF ANOTHER COMET (1911*c*).—A telegram from the Kiel Centralstelle announces the discovery of a comet at the Geneva Observatory (U.S.A.) on July 20. At 9h. 52m. (Geneva M.T.) the comet's position was

R.A. 22h. 13·6m., dec. 20° 57′ N.,

and it was moving in a north-westerly direction. A second observation was made on July 21 at the Lick Observatory, and at 9h. 53·1m. (Lick M.T.) the position was

R.A. 22h. 13m., dec. 21° 34′ 40″ N.

This position precedes the Great Square, and forms, roughly, an equilateral triangle with α and β Pegasi; it transits at about 1 a.m. According to the Lick observers, the comet was of about the tenth magnitude, and was moving in a N.N.W. direction.

THE KIESS COMET, 1911*b*.—A number of observations of comet 1911*b* appear in No. 4512 of the *Astronomische Nachrichten*, where the magnitude is variously recorded with values varying from 4·0 to 8·5. The object is blue or green, and has a faint tail, which on a photograph taken at Simeïs on July 9 was 0·5° long, in position angle 285°.

Later observations have made it possible for Dr. Kobold to improve his elements and obtain an ephemeris which practically agrees with the observations; these he publishes in a supplement to No. 4513 of the *Astronomische Nachrichten*.

Ephemeris (12h. M.T. Berlin).

1911	α (true) h. m.	δ (true) ° ′	log r	log Δ	mag.
July 26	4 15·0	+30 3·3			
,, 28	4 9·9	+28 57·7	9·9515	9·8582	5·8
,, 30	4 4·2	+27 40·2			
Aug. 1	3 57·5	+26 3·5	9·9755	9·7742	5·4
,, 3	3 49·7	+24 5·6			

Perihelion occurred on June 30, so that the comet is now receding from the sun; but it is approaching the earth, and later, in August, will come within 0·2 of an astronomical unit. It should then provide a striking spectacle, especially to those situated in the southern hemisphere, in the early morning sky. At present its calculated magnitude is about 6·0, but when nearest the earth the comet should increase in brightness to about magnitude 3·5. The present position lies about half-way between ι Aurigæ and the Pleiades, and on August 3–4 the comet should be very near to the latter asterism.

WOLF'S COMET, 1911*a*.—Observations of this faint comet are recorded in No. 4512 of the *Astronomische Nachrichten*. M. Javelle, observing at Nice on July 5, found it to be a star-like object of less than magnitude 14·0, having a faint nebulosity about it. M. Kamensky finds that the correction to his ephemeris is about −0·5s. and −6·3″, and asks observers to communicate their positions to him.

THE RADIAL VELOCITY OF THE SUN, AND DOPPLER'S PRINCIPLE.—In No. 5, vol. xxxiii., of *The Astrophysical Journal* Mr. A. Cotton has a paper dealing with the legitimacy of applying Doppler's principle, purely and simply, to determine the radial velocity of the sun's parts from the measured displacements of the lines in the solar spectrum. He shows that the fact that the sun is surrounded by an extensive, turbulent atmosphere, in which densities and thermic qualities of vastly different magnitudes coexist, is sufficient to call for prudence when applying a simple, single interpretation to the displacements.

PECULIAR STELLAR SPECTRA AND SELECTIVE ABSORPTION IN INTERSTELLAR SPACE.—We have just received No. 51 of the Lowell Observatory Bulletins, in which Dr. Slipher discusses evidence for the existence of some material in interstellar space which differentially absorbs star radiations.

A spectrum of β Scorpii displayed a sharp K line, whereas all the other lines in this "Orion"-type spectrum were diffuse and broad; and while the latter show a Doppler displacement equivalent to a range of 240 km., the K line gives no sign of shift.

Further research indicated that σ, δ, and π Scorpii exhibit the same phenomena, and in this are like δ Orionis, ζ Ophiuchi, ι and η Orionis, o Persei, and other binaries. Apparently the matter wherein this calcium absorption takes place is, in each case, independent of the star, and the theory at once suggests itself that it takes place in an absorbing medium lying between us and the stars. Evidence for this accumulates in other directions; and the matter is one of fundamental importance to which the attention of astrophysicists must soon be directed. Dr. Slipher asks for cooperation; as a preliminary, the examination of all the spectra of "Orion"-type stars in existence would indicate those in which the independent behaviour of the calcium, and maybe the sodium, lines was marked.

FRENCH ASTRONOMICAL WORKS.—Readers of French will find that "Quelques Heures dans le Ciel," a franc "paper back," by the Abbé Th. Moreux, gives a very complete, lucid, and well-illustrated *résumé* of present-day astronomy. The chatty freedom with which the various points are explained will attract the beginner, and the illustrations will considerably assist his comprehension.

Those who wish to practise astronomy will find the Commandant Ch. Henrionnet's "Petit traité d'Astronomie pratique" a useful summary and guide. The author describes the books and the instruments used, the simpler methods employed, and gives a brief statement of the interesting things in various constellations. Gauthier-Villars publish the book at 1.75 francs.

THE MANCHESTER MEETING OF THE INTERNATIONAL ASSOCIATION OF SEISMOLOGY.

THE meeting of this association, which was held in Manchester on July 18–22, proved to be one of considerable interest and importance. The time spent on business and administration was less than at preceding meetings, so that more was left for original communications and discussions.

On the opening day, the Vice-Chancellor of the University of Manchester received the delegates in the Whitworth Hall, and during the day a telegram was received from the President of the Board of Education in the following terms:—

"His Majesty's Government heartily welcome your association, and wish success to their deliberations. They rejoice to see the attempt to organise seismology internationally, which was initiated by the British Association under the influence of Dr. Milne, bearing fruit, through your proceedings on British soil."

Amongst the communications received, probably the most important was the description by Prince Galitzin of his new instrument for measuring the vertical component of the motion of the soil. The instrument shown at the meeting has been acquired for the observatory at Eskdalemuir, where it will be set up as soon as a proper foundation can be built.

Mr. Oddone showed an ingenious and simple apparatus for measuring the elasticity of rocks, and Mr. Wiechert's communication on the constitution of the interior of the earth gave rise to an interesting discussion.

An instrument was also shown at the meeting constructed by the Cambridge Scientific Instrument Company, with which it is intended to count the number of waves which strike the shore in a given time in order to test whether the period of these waves is the same as the period of the microseismic disturbances. This instrument has already been taking records on the coast of Northumberland, under the superintendence of Mr. Morris Airey.

There was a reception in the Town Hall on one of the days of meeting, which was well attended, and a dinner was given by the university on the last evening.

Saturday, July 22, was given up to excursions, and at the invitation of the director of the Meteorological Office and of Mr. and Mrs. J. Walker, nearly twenty foreign delegates visited the new magnetic and meteorological observatory at Eskdalemuir.

The foreign delegates both privately and publicly expressed their gratification at the presence of Dr. Milne, and, in addition, British men of science were well represented, amongst others by Sir George Darwin, Profs. Lamb, Love, Knott, Mr. Oldham, and Dr. Shaw.

Prince Galitzin was elected president, and Mr. Lecointe vice-president, for the next period of three years, dating from April, 1912.

The opening address delivered by Prof. Schuster on July 18 is subjoined.

Some Problems of Seismology.

Since our last meeting important changes have taken place in our Central Bureau. Increasing age has compelled Prof. Gerland, to whose strenuous efforts the foundation of this association is mainly due, to resign the directorship of the seismological station at Strassburg. Prof. O. Hecker, who has been appointed in his place, has thereby become the director of the Central Bureau, and you will agree with me that no better choice could have been made. The excellence of his work is well known to you, and since he has entered into his new office he has with characteristic energy already done much to make the bureau more efficient for its international work. You will have an opportunity of showing your confidence in him when we decide on the locality of the Central Bureau for the next period of four years, as though we have no official voice in the choice of the director, it lies in our power to move the seat of the Central Bureau at any meeting of the general assembly if such a course seems desirable in the interests of our work.

Our association primarily deals with the study of the causes of earthquakes and of their effects, but the interest which the public shows in our investigations is mainly due to the sympathy roused by the human suffering which follows the trail of these seismic catastrophes. At present we feel helpless, though perhaps not altogether hopeless, in the face of the destructive convulsions of the earth. The problem of constructing buildings which can withstand shocks of earthquakes does not enter into our programme, but it has been asked, and the question will be raised during the present meeting, whether there are any preliminary indications which would allow us to predict the occurrence of a dislocation of the soil and take precautions to mitigate to some extent its power of destruction. Remembering how meteorologists have succeeded in preventing loss of life at sea by predicting the course of cyclones in the Indian Ocean or the Gulf of Mexico, we might be tempted to hope that similar warnings may help us to fight the dangers of an earthquake. I am afraid that the cases are not quite analogous, and even if our knowledge should allow us in the future to form predictions of equal certainty, the dangers accompanying such predictions may overbalance its benefits. The precautions which can be taken in a harbour against an approaching storm are of a comparatively simple character, and the meteorologist is therefore justified in warning us against a probable storm which does not appear; but would the seismologist be justified in creating a panic and dislocating trade by predicting an earthquake which failed to take place? We can easily forgive the meteorologist who forecasts the weather as "fine to doubtful and stormy"; but should we forgive the seismologist when he forecasts the approaching seismic condition of our town as "calm to unstable and collapsing"? Perhaps it may seem to you that I am wandering beyond the range of practical science even in alluding to this subject; nevertheless, the fear of creating panics by premature forecast is one which has already cast its shadows in advance, and I am informed that insurance companies in this country have shown some irritation by the early publication of the indications of a destructive earthquake which has taken place in a distant part of the world.

To the man in the street the question whether a thing is large or small is all-important; to the scientific man it matters not at all; and a great part of our deliberations will deal, not with catastrophes, but with microscopic movements of the soil, movements so small that the vibrations due to the traffic in a city compare with it as the waves of the ocean with the ripples on a pool. At the last meeting of the general assembly, four years ago, you appointed a committee to investigate these microseisms. I need not remind you that there are two types of short waves which are frequently observed. One of them has independently been traced in different countries, and by several observers, to the action of the wind, which seems to create waves over an extended land surface just as it does over the ocean. The second type of vibration, which occurs in periods of from five to ten seconds, is more difficult to trace. It has been suggested that the vibrations are due to the impact of waves on the shore against which the wave strikes. For the purpose of testing this hypothesis, an instrument has been set up on the coast of Northumberland (partly paid for by the funds of this association) which automatically counts the number of waves which in a given time strike the shore. The instrument, which was designed by the Cambridge Scientific Instrument Company, Ltd., will be exhibited at this meeting. It has been set up and looked after with great ability by Mr. Morris Airey, and we are already able to say that it will fulfil its object, though the observations at present are too few to allow us to draw any conclusions.

While we rightly attach much value to the systematic investigation of minute disturbances, we must not forget to keep in mind the source and origin of all dislocations of the soil. The recent advances in physical science render it imperative to review our position with regard to this fundamental question.

In our youth we were taught that the earth, once a molten and fiery globe, had gradually cooled down, leaving the inside still hot, but gradually cooling and contracting. This contraction of the nucleus was looked upon as the primary cause of geological dislocations. But now do we stand at present? In the breaking up of radio-active products we find a source of heat which—if the amount of radium and thorium in the interior of the earth is not decidedly less than that which is found near the surface—would not only balance the earth's loss of heat by radiation, but actually increase its average temperature. Though reasons may easily be found why the surface layer of the earth may be richer in radio-active products than the core, I think that we are nevertheless driven to the conclusion that the earth is now, and has been for a long time, in thermal equilibrium, and that shrinkage by cooling does not account for any of the more recent displacements. Why, then, should not the earth long ago have settled for itself all seismic questions, and have come to rest in a comfortable state of equilibrium? After the four or five million years which it has had to calm down, we might have expected that everything should be quietly arranged in uniform layers round the centre of the earth. Instead of this regular distribution of matter, we have not only mountain chains, but also the depressions and elevations which cause the distribution of land and water over the globe.

The causes of these inequalities have long interested geologists and mathematicians, but the wider discussion of the stability of the whole structure on which we live has only recently come into prominence. The subject is a most difficult and intricate one, and a most important contribution towards its elucidation has appeared within the last few weeks. In an essay to which the Adams prize of the Cambridge University has been adjudged, and which, I think, will become a classical guide to all who intend to pursue the subject, Prof. Love has treated the problems of geophysics with masterly ability and lucidity. I wish it had been possible to arrange—perhaps it is still possible—for Prof. Love to give you an account of his investigations, and in his presence it would be impertinent in me to explain, as otherwise I might have been tempted to do, the main conclusions at which he has arrived. I must therefore content myself with directing attention to the great importance of this work, and alluding to one suggestion contained in it which more particularly touches a subject with which this meeting is concerned.

The important work of Prof. Hecker, confirmed since by others, has allowed us to trace the tidal deformation of the earth, and has brought to light the curious result that the earth appears to resist a change of shape less in the north and south than in the east and west direction.

Prof. Love, having failed to account satisfactorily for the effect in other ways, suggests that the want of symmetry in the rigidity is apparent only, and that the observed effects are caused by the attraction of the tide wave in the North Atlantic and its accompanying excess pressure on the sea bottom. In the investigation of the tidal deformation of the earth, our work overlaps that of the International Geodetic Association, and a communication from that body will have to be considered by us. In other directions our work closely touches that of the geologist, and there may be points of contact with other parts of geophysics, such as meteorology and terrestrial magnetism. This interdependence of different branches of science will force us before long to consider our relationship to other international associations.

The extreme specialisation which finds expression in the formation of so many different societies and associations is an evil which may be a temporary necessity, but which we should try to mitigate so far as possible. There ought to be a connecting link which draws us away from the minute elaboration of detail and towards the great problems that ought never to leave the mind of a man of science. But what is this connecting link to be, and what are the bonds which are to unite it to bodies of such varied interests and constitutions? I have formed my own opinion, but I am afraid on this occasion to enter on to ground which may be controversial.

In concluding these few words of introduction, I feel that I express your wishes by thanking the Vice-Chancellor, who has found time among his many heavy duties to come here to welcome you.

THE PROGRESS OF CANCER RESEARCH.

THE tenth annual meeting of the Imperial Cancer Research Fund was held on July 20 at the Royal College of Surgeons, the Duke of Bedford presiding. The presidents of the Royal Colleges of Physicians and Surgeons, Sir Wm. Church, Sir Douglas Powell, Sir John McFadyean, Sir Henry Morris, Sir John Tweedy, Dr. Sidney Martin, Mrs. Bischoffsheim, and many other supporters of the fund were present. Sir Wm. Church, in moving the adoption of the annual report, gave an outline of Dr. Bashford's statement of the progress of knowledge of cancer, from which we give some extracts below. In seconding the resolution, Sir Henry Morris directed attention to the widespread influence exercised by the investigations of the scientific staff. This was evidenced in one way by the number of distinguished voluntary workers attracted to the laboratory from abroad, not only from all European countries, but also from America, Australia, and Japan, and in another way by the number of learned societies at home and abroad which invited the director to address them. Thus Dr. Bashford had visited, among other centres, Berlin, Heidelberg, Toronto, Paris, Budapest, Christiania, and Utrecht. Its influence was felt in a third way by the large increase in the number of centres engaged in the investigation of cancer in the laboratory. The other business was purely formal.

A feature of this year's work is the extension of experimental investigation to rabbits, in which animal a carcinoma of the mamma and a sarcoma of the subcutaneous tissue have been discovered, the latter being capable of propagation.

Statistics.

It will be remembered that the policy pursued in regard to the statistical investigation of cancer has been to supplement the national statistics, and, if possible, to add to their utility by special inquiries, but not to endeavour to overlap or in any way to replace them. This collaboration and coordination, which does not exist in the case of organisations for the investigation of cancer in other countries, where independent statistical inquiries have been undertaken with the voluntary assistance of the medical profession, has been of the greatest importance in England and Wales by preventing profitless overlapping, and in effecting real advances in the accurate statistical knowledge of the incidence of cancer.

The application of the law of age-incidence for cancer to short-lived as well as to long-lived animals reinforced the other reasons for obtaining it, and suggested that knowledge would be advanced by more detailed information about the age-incidence of cancer in the several organs of man as distinct from its dependence on the age-distribution of persons. The tabulation of the new data for the years 1901–9 brings out the fact that the increase during this period is referable to certain anatomical regions and not to others. Thus, for males, the main increase falls on the alimentary tract, especially the stomach. The liver and gall-bladder and the skin show no, or only a slight, increase. For females, the increase, although it falls mainly on the alimentary tract (stomach and intestines), affects also the mamma, while the uterus, ovary, liver and gall-bladder, rectum and skin, show little or no increase. It is also of importance that the recorded mortality from cancer of the generative organs has not increased at the same rate as that for other organs, and that most of the increases affect the higher age-periods predominantly. For the first time it is fully demonstrated that it is wrong to make statements of a disquieting nature about the increase of cancer in general. While it is evident that several of the differences brought out by the figures can be explained by more accurate diagnosis and by transference of the seat of the disease from the secondary to the primary situations, as illustrated, *e.g.*, by the relation revealed between cancer of the liver and gall-bladder and the alimentary tract, this may not account fully for other features. In particular, the increase recorded for the mamma in women and the tongue in men requires further study and elucidation.

The analysis also shows that the incidence is very unequally distributed among the several situations, and, indeed, that the whole curve of incidence may be different for different organs. A progressive increase up to the highest age-periods is characteristic of the face, lip, mouth, bladder, urethra, and breast only. The other organs show a distinct diminution in the highest age-periods; but it is not yet possible to determine whether this curve indicates a liability rising to a maximum followed by a diminution, or is merely the result of deaths being still ascribed to other causes in the case of cancer of internal organs in aged people. The proportion of total deaths ascribed to the ill-defined cause of old age is 65·6 per 1000 as compared with 65·7 for cancer, and it must be borne in mind that the increases recorded for cancer affect principally the higher age-periods, and that the average age of the population is increasing.

The study of the occurrence of cancer in mankind and in domesticated animals in widely separated parts of the globe has shown that the practice of peculiar customs (involving the subjection of particular parts of the body to chronic irritation), provokes the disease in situations and organs from which it is absent when these customs do not obtain. It is reasonable to suppose that the frequency of cancer would be diminished if such practices as the use of the kangri in Kashmir, the chewing of betel-nut, the eating of very hot rice in China, were discontinued. It is also reasonable to assume that the introduction into England of these exotic customs would greatly increase the frequency of cancer in this country. So definite is the evidence of the mediate causation of certain forms of cancer by chronic irritants, that the possibility of variations in the cancer death-rate must be admitted as regards particular organs and regions of the body. The possibility of a variation of the main incidence of cancer in conformity with changes in certain customs must also be admitted. That irritation is really an important causative factor of cancer is an assumption which is justifiable only for certain forms of cancer occurring in particular regions. The knowledge of the irritants to which different species of animals and the individual tissues of the same animal are susceptible is of very considerable importance. The acquisition of this knowledge will doubtless require extensive study, and it is advisable to approach this study in man statistically, and advisable to have data of the incidence of cancer in persons pursuing different occupations. This information will be embodied in the next decennial supplement to the reports of the Registrar-General.

Heredity.

The breeding experiments which have been in progress for many years have been alluded to in several earlier reports. They have now yielded upwards of 2000 mice of known ancestry and age. 562 females were available for a study of the influence of heredity on the development of cancer of the mamma when an analysis was made on October 24, 1910. The investigations show that heredity plays a part in the development of cancer of the breast in mice. At all age-periods the disease is more frequent when the mother, or either grandmother, or all three had died from cancer of this organ.

Apart from its bearing upon heredity, the obtaining of such mice was most important for furthering the experimental investigation of the genesis, nature, and, should it be necessary, artificial production of cancer, and for attempting to define the reasons for its apparently greater frequency in some geographical areas than in others.

While it is at present impossible to explain how the liability is transmitted, it can be averred with certainty that it does not consist in the inheritance of a soil more suitable for the growth of cancer in general. It can only be inferred, with some probability, that it is a local or circumscribed tissue predisposition, in virtue of which the mammary tissue is prone to pass from mere proliferative reaction into continuous or cancerous proliferation. Further, hereditary predisposition is only one of the factors in play, for it has been found that chronic inflammatory changes are remarkably frequent in the mammæ of female mice of the laboratory. Other factors still unrecognised may exist.

Individuality and Cancer.

The study of the parallel behaviour of normal and cancer tissue, both as regards absence of continued growth and the nature of the immunity reactions induced, when cancer is transferred from one animal to another of a strange species, showed that cancer had all the properties which distinguish the normal tissues of one species from those of another species. Recent experiment has carried knowledge much further. The fact that transplantable tumours grow in normal animals as well as they do in spontaneously affected animals shows that the latter do not present a soil for the growth of cancer substantially different from that presented by normal animals. When this result is contrasted with the almost invariable success of transplanting a portion of its spontaneous tumour into the animal so affected, and the almost invariable failure of implantation of any spontaneous tumour into other spontaneously affected animals, the demonstration is complete that each tumour is peculiarly and genetically related to the individual in which it arises. This conclusion is drawn from studying the growth of tumours under the different conditions just enumerated, and is supported by the results of elaborate experiments on inducing resistance or immunity to the inoculation of cancer-cells under these different conditions. The results of these two lines of inquiry agree also with the fact that resistance has not been induced either with an animal's own tumour or its own normal tissue. The individuality of cancer would thus appear to have been placed at last beyond all further discussion. It has long been maintained in various forms on the basis of deductions drawn from histological (microscopical) examination of the tissues at the site of the primary lesion, and from the nature of dissemination, but this interpretation of the findings has been as vehemently combated. The combination of the results arrived at by microscopical investigation and experimental study appears to terminate any need for further discussion. A long step has thus been taken in defining the direction in which the future investigation of cancer is alone likely to be profitable.

The Nature of Cancer.

It follows from the argument pursued in the preceding paragraphs that a closer definition of the nature of cancer will involve an analysis of the relation obtaining between the individual developing cancer and the tumour.

In all previous reports guarded reference has been made to the mediate relation obtaining between chronic irritation and certain forms of cancer. The indefiniteness in the way of directing attention to the relationship has been deliberate. In the first place, it is due to an effort to elucidate those forms of cancer with which irritation is most constantly associated without considering other forms in which the particular irritants concerned do not play a part. In the second place, it is due to the fact, already frequently emphasised, that these irritants have nothing in common beyond their association with cancer. The varied investigations of the past nine years have added a knowledge of new forms of irritation. It has become more and more evident that irritation, effective in one case, may be, and often is, quite ineffective in another.

It has been ascertained that every fresh transplantation effects a disturbance of the cancer cells. They are thrown into a state equivalent to regeneration from which they tend to recover, as analogous as possible to reactive proliferation when naturally occurring.

Ever since the beginning of these investigations it has been maintained that the mere cultivation of cancer had important, if only indirect, bearings upon its nature and genesis. Thirty-five of the tumour-strains have now been growing for more than three years, *i.e.* for longer than a mouse lives, while fifty other strains have been grown for extended periods. The one feature all these tumour-strains have in common is the power of continuous growth which they possess, in spite of the most divergent structure, and of extremes in the rate of growth varying from an almost explosive rapidity to one much inferior to that of embryonic tissue, as determined by weighing experiments.

It can be shown that there is a constancy in the behaviour of a tumour-strain and a variability which is individual. The variations which occur are similar to those which distinguish the eighty-five different strains from one another. They are not mainly induced by the environment, but arise spontaneously; otherwise all strains would approach a common type, which they do not. The demonstration of the occurrence of these variations under artificial conditions permits of the inference that they could also occur under natural conditions, and yields objective evidence of the validity of the conclusion that the cancer-cell is a biological modification of the normal cell endowed with many inherent properties of the latter. The objection at once suggests itself that these variations during prolonged propagation are secondary, and do not necessarily indicate corresponding primary changes as responsible for genesis; but this objection cannot be maintained against the facts that the potentiality for variation has been demonstrated, as has also the tenacity with which the several varieties are adhered to.

Immunity and Therapeutic Investigations.

The dissemination of cancer has been studied experimentally both by injecting cancer-cells directly into the blood-stream and by implanting them in internal organs. It has been found possible to produce the lesions of dissemination in these ways both in the absence and in the presence of a primary growth, and what is more important also, to prevent them. Problems difficult of solution in the mouse, because of its small size and the short duration of its life, can now be studied in the more favourable circumstances obtaining in the rabbit, the extension of experiments to this animal being a new feature made possible by the successful propagation of a sarcoma from rabbit to rabbit.

Nothing but harm can result from the premature application to the treatment of the human subject of methods found to modify the growth of propagated cancer in animals. The methods which induce an *active* immunity to propagated cancer have been tested on thirty-three mice with natural cancer, and have given no evidence of powers either to hinder growth and dissemination or to prevent recurrence of spontaneous cancer after surgical removal.

The successful treatment of animals bearing propagated cancer by means employed to induce *passive* immunity has been described by other investigators. Some of these methods have been tested in the laboratory, but have not yielded positive results. It becomes increasingly evident that the therapeutical treatment of cancer is not to be sought for along these lines.

A considerable number of cases of natural healing of spontaneous malignant new growths have now been observed in mice affected with spontaneous cancer. The changes leading to natural cure appear to depend, as in propagated cancer, on an altered condition of the cell and its contents rather than on an alteration in the general condition or constitution of the affected animal. Means must be devised for elucidating the nature of the change in the cell before curative measures can be discovered.

Since these investigations were first contemplated by those responsible for their inauguration, the provisions made for the investigation of cancer have greatly altered in this country. Whereas nine years ago, apart from special provision for treatment being supplied by a number of hospitals, there existed for the investigation of the disease only one other laboratory in addition to the Imperial organisation contemplated by the founders of this fund. To-day a number of other laboratories exist throughout the country, both in London and the provinces. England and Scotland are now provided with a greater number than any other country in comparison with their size and population. Whenever an opportunity has occurred of furthering the particular investigations upon which these institutions have been engaged, assistance has been rendered by supplying material from the laboratory and by the Imperial Cancer Research Fund in many other ways. The responsibilities thrown upon the workers of the Imperial Cancer Research Fund are not diminished, but rather increased, by the multiplication of institutions engaged in the investigation of cancer.

THE BOARD OF EDUCATION'S SCIENCE EXAMINATIONS AND GROUPED COURSE CERTIFICATES.[1]

As is well known, the Board of Education for some time past has been considering the reorganisation of the existing system of science examinations conducted by the Board, in the hope of lessening the somewhat heavy cost of these examinations and of securing greater educational efficiency. The conclusions arrived at by the Board have recently been published in a circular, accompanied by a covering letter from Sir Robert Morant, in which is summarised the principal changes which the Board has decided to bring into operation in the session 1911–12.

The general principles governing the action of the Board in respect to the proposed alterations are given in the following extract from Sir Robert Morant's letter:—

"The examinations were instituted in circumstances widely different from those of the present, at a time when no other machinery for promoting scientific or technical instruction was generally available; and they have in the past contributed greatly to the diffusion of scientific and technical knowledge throughout the country. But during recent years there has been a great development in the teaching of the subjects covered by the examinations in evening and technical schools, the organisation of which is necessarily affected by the nature of the examination tests available; and the Board have had to consider under what conditions a system of science examinations, conducted not by the teachers of the schools but by an external body, has any claim to continued existence, and how the working of the system so far as it is retained can best be coordinated with and made to supplement the work of the teaching institutions themselves."

It is evident that the Board recognises the very great difference between the general educational conditions in

[1] "Science Examination and Grouped Course Certificates." Board of Education Circular, No. 776, June 20.

force when the examination system was initiated and the conditions prevailing at the present time, and that extensive changes are necessary in order to bring these examinations into harmony with modern developments of educational thought and practice. The Board clearly realises that the annual examination must not be the dominant factor in education. The examination must be subordinate to the teaching. Further, the yearly test, to be of any value, must be mainly an "internal" one, in which the teacher plays an important part. At the present time, the examinations conducted by the Board are purely "external" examinations, carried out by an outside body which is out of touch with the teacher and the students, and necessarily unacquainted with the actual conditions under which the educational work is carried out.

The Board, however, is not yet prepared, "as regards all students, to hand over entirely to the teaching staffs . . . the functions which the Board at present discharge in regard to the testing and certification of the attainments of individual students, although a partial transfer of such responsibility has now become possible." In the future, the Board will leave the examination of, and the issue of diplomas to, full-time day technical institution students to the teachers concerned, subject to regulations to be previously submitted to and approved by the Board. Full-time day students will not in general be permitted to attend the evening science examinations. The examination of all first stage evening or part-time students is also handed over to the institutions. Further, "the Board intend to invite the assistance of some teachers in technical schools as members of the examining boards to be constituted for the reorganised examinations."

Coming to the examinations themselves, the principal changes enumerated in the circular are the following:—

(*a*) A number of the examinations formerly held by the Board will be discontinued. These examinations are mainly in subjects which have attracted comparatively few candidates in the past (*e.g.* nautical astronomy), and in certain branches of natural science, such as botany and biology, which have usually been taken only by candidates reading for university degrees. The examinations to be retained by the Board are divided into five groups as follows:—

(1) *Group A.*—Pure and Applied Mathematics:—Practical plane and solid geometry, pure mathematics, practical mathematics, theoretical mechanics (solids), and theoretical mechanics (fluids).

(2) *Group B.*—Engineering:—Machine construction and drawing, applied mechanics (materials and structures), applied mechanics (machines and hydraulics), heat engines, building construction, and naval architecture.

(3) *Group C.*—Physics:—Heat, magnetism, and electricity.

(4) *Group D.*—Chemistry:—Inorganic chemistry and organic chemistry.

(5) *Group E.*—Mining and metallurgy:—Coal mining, metallurgy.

It may, perhaps, be regretted that the Board proposes to cease its examinations in subjects such as agriculture, hygiene, and physiology, in view of the national importance of these subjects, the rapid development of public interest in them, the increasing provision of facilities for instruction, and the absence of any generally recognised and easily accessible system of examinations in these subjects if the Board's examinations be withdrawn.

(*b*) Up to the present the Board has held four examinations in each subject, arranged as follows: 1st stage, 2nd stage, 3rd stage, and Honours. In the future, the Board will not conduct elementary examinations corresponding to the first stage, as it is felt that these examinations are now unnecessary, the "inspection" by the officials of the Board on their visits to the classes being sufficient to test the efficiency of the teaching. The Board will only hold two examinations in each subject, termed "Lower" and "Higher" examinations respectively. The standard of the Lower examination will be approximately equal to that of the present Stage II., while that of the "Higher" examination will be intermediate between Stage III. and Honours.

The main objections which may be urged against the withdrawal of the Stage I. examinations are:—(1) The present Stage I. syllabuses are a valuable guide to many teachers, especially perhaps to those interested in the more directly technical subjects and to those employed in the smaller, isolated technical schools; (2) the lack of uniformity in the elementary stages of technical instruction caused by the absence of syllabuses followed by schools all over the country, thus hindering the transfer of students from one institution to another. These obvious disadvantages may probably be best overcome by consultation between the representatives of the teachers and the Board of Education inspectorial staff, with a view to arrive at a common measure of agreement respecting courses, curricula, and the standard of work to be aimed at, especially in the earlier years of a student's work.

(*c*) Practical examinations, such as those in chemistry and metallurgy, will be discontinued, but candidates for admission to the Higher examination in subjects other than practical geometry, mechanics, &c., "will be required to furnish a certificate of having completed a satisfactory amount of laboratory work, and to submit his laboratory note-books signed and certified by the teacher."

Elaborate regulations, which will probably be found somewhat burdensome in actual practice, are outlined in the circular with regard to "grouped course certificates and diplomas, and conditions of endorsements." The Board will not, in general, issue certificates to students who have passed a given single examination. The Board will, however, endorse certificates or diplomas granted by school authorities upon the satisfactory conclusion of well-balanced courses of study, and "they trust that a certificate or diploma, endorsed by the Board under the prescribed conditions, will be recognised by all concerned as having at least a definite minimum value and standard."

"Grouped courses" are classified by the Board into two main classes: (1) evening or part-time day courses, (2) full-time day courses. Each of these is again subdivided into three groups: (*a*) junior courses (14 years to 16 years of age), (*b*) senior courses (16 years to 18 years), (*c*) advanced courses (18 years to 20 years).

Generally speaking, the proposed regulations as outlined in the circular mark a distinct advance upon the arrangements in force at present. In the main, the alterations are in the direction of freedom for the teachers, a greater elasticity permitting more modifications to suit local educational and industrial requirements, and the placing of examinations in a relatively less important position. The circular holds out to technical teachers the promise of speedy action by the Board of Education in regard to two important matters which they have long pressed upon the attention of the authorities at Whitehall, namely, the cooperation of the teachers in the drawing up of syllabuses and the conduct of examinations, and the improved organisation and coordination of all grades of technical education.

J. WILSON.

THE BRIGHTON CONFERENCE OF THE MUSEUMS ASSOCIATION.

THE attendance at the Brighton meeting of the Museums Association, held on July 10–15, was large and representative, delegates being present from forty-two museums at home, as well as from the American Museum of Natural History (New York), the Australian Museum (Sydney), and the Deseret Museum (Salt Lake City, Utah). The presidential chair was occupied by Mr. H. M. Platnauer, of York. Mr. Platnauer was one of the original founders of the Museums Association, which was inaugurated at York twenty-two years ago.

In his presidential address Mr. Platnauer strove to answer the question "What is a museum?" and showed by his remarks that he conceived all museums, whether of science, art, or history, to have a broad and educational function. He deprecated the idea that a provincial museum should be purely local, would not agree that the function of an art museum is merely to make a pleasurable appeal to the emotions, and suggested that museum arrangements should convey the facts of natural evolution and human progress by exhibits arranged in more than one dimension of space.

Mr. H. S. Toms had prepared an account of the Brighton Museum, with special reference to developments since the last meeting of the association in Brighton twelve years ago. It was plainly indicative of great progress, and embodied some very useful practical hints on the care of collections.

Mr. J. A. Charlton Deas introduced the subject of national art loans to municipal museums, pointing out the great and growing need for making the artistic treasures of the nation more accessible to the dwellers in the provinces.

The value of museum guides, catalogues, and other publications was dealt with by Mr. Thomas Sheppard under the title "Pastimes for Curators." He described the manner in which the eighty or more publications issued by the Hull Museum had been prepared, and showed how they kept public interest in the collections alive and frequently led to desirable acquisitions.

Dr. J. A. Clubb read a paper on the purpose and arrangement of an index museum, in which the idea was elaborated of making the entrance hall of the museum a philosophic introduction to those fields of human knowledge covered by the museum collections. The validity of the word "index" in this connection came in for some criticism, but it was generally agreed that some form of introductory collection, broad in conception and treatment, is an absolute necessity in all large museums. By the multiplicity of their collections and specimens such institutions bewilder the uninitiated visitor, who should be enabled to get a clear grasp of what the institution is aiming at by some lucidly sketched outline.

As a new departure in the work of the association, a public lecture was given during the conference. The lecturer was Dr. F. A. Bather, F.R.S., who took for his subject "Open-air Folk Museums." The lecture consisted chiefly of a description of the open-air museum founded at Skansen, Stockholm, by Arthur Hazelius. Dr. Bather gave an outline of the object of such museums, and emphasised the urgent need for promoting some such scheme in Sussex, and thus preserving the fast disappearing relics of its extremely picturesque past.

A further paper by Mr. W. Ruskin Butterfield on folk museums dealt specially with the material at present available in Sussex, and showed how rich Sussex still is in picturesque old dwellings, involving much delightful folklore.

Mr. Arthur Smith showed how collections of photographs might serve the purpose of recording the history and progress of the surrounding district. Many places have collections of photographs and prints secured merely for the purpose of what may be called a survey, but Mr. Smith emphasised the fact that this is not sufficient. Photographs ought to be taken so as to show clearly, for instance, the original and altered condition of a street or building, so that a person looking at them may realise the nature and extent of the change which has taken place.

Evolution in archæology was dealt with by Mr. R. A. Smith, of the British Museum, who described the succession of developmental characters exhibited by such articles of human manufacture as stone implements, pottery, brooches, and primitive British coinage in a lucid and informing manner. He strongly advocated the arrangement of antiquities on evolutionary lines wherever possible.

The evolution of English pottery during the eighteenth century was the subject of a paper by Mr. H. Stuart Page. He argued that the adoption of an intelligent system of classification on lines which he set out in some detail would enable the involved story of English pottery to be illustrated by a carefully selected series of examples showing the gradual development in materials, processes, and technique. It was a matter for speculation how long the English potters would have continued contentedly in their antiquated methods of producing coarse heavy ware but for the introduction of Oriental china, brought into the country by tea-drinking habits. The beauty of this ware —all the more emphasised by the rudeness of the English production—created a remarkable infatuation, and the English potters sought to rival it. Their history then becomes one of laborious costly experiment, absorbing lives and fortunes. Ignorant of chemistry, they were, in fact, groping in the dark. The eventual result, however, was the acquisition of a technical skill which, whatever be the artistic quality, holds its own among the ceramic productions of the world.

Mr. E. Rimbault Dibdin read a paper on the functions and scope of a municipal art museum, in which he showed that there exists in England a very confused idea of the way in which to make an art museum of value. He urged that special efforts should be made to attract curators and directors of art institutions, and to assign a special day to the discussion of the questions of function, scope, conservation, arrangement, lighting, and the hundred and one other practical problems which face the administrator of art collections.

A small trade exhibition organised in connection with the conference was of considerable practical interest to curators.

During the meeting visits were paid to the Worthing Museum and Library, to the Booth Museum, to Hastings Museum, to Sedlescombe Museum, and to Battle Abbey. The association concluded its business by accepting the invitation of the Board of Agriculture and Technical Instruction for Ireland to meet in Dublin in 1912, and by unanimously electing Count Plunkett, director of the Irish National Museum, through whom the invitation was conveyed, to the presidential chair for the ensuing year.

THE FRENCH AEROTECHNICAL INSTITUTE.

ON July 6 the Aërotechnical Institute of the University of Paris, which has been founded by the generosity of M. Henry Deutsch de la Meurthe, was inaugurated at St. Cyr. Its object is entirely scientific, and is to study all problems of aviation and aërostation relative to the support of bodies in the air, both at rest and motion, from the double point of view of theory and practice. Under the presidency of the vice-rector of the Paris University, with M. Deutsch de la Meurthe and the dean of the faculty of sciences of the Paris University as vice-presidents, the council includes all the famous names in French aëronautics, as follows: MM. Armengaud, Barthou, Baumès, Blériot, Bouttieaux, Cailletet, Carpentier, Eiffel, Estienne, Hugon, Janet, Jouguet, Kapferer, Kœnigs, Le Cornu, Loreau, Maurain, Marchis, Painlevé, Picard, Sauvage, Soreau, Surcouf, Urbain, Voisin, Weiss.

The area occupied by the buildings and grounds is 72,000 square metres, of which the principal part has been reserved for building purposes. The remainder includes a strip 25 metres by 900 metres, with an additional piece of some 462 metres in length, which has been conceded by the Minister of War. Moreover, 4000 metres have been set apart for the erection of aëroplane sheds, workmen's houses, &c.

In the central hall are the following:—

(1) A large fan, two metres in diameter, fitted with various adjustments, and an aërodynamical balance for measuring wind-pressures on surfaces.

(2) A wind tunnel furnished with a fan for the study of the reaction of the air on surfaces, the air-current being capable of maintaining a uniform speed of 20 metres a second.

(3) An aërodynamical balance.

(4) A wind tunnel similar to that built by Col. Renard for studying the stability of model hulls or planes.

(5) An apparatus for measuring the friction of various surfaces moving through air of various pressures at gradually increasing speeds.

(6) A dynamometrical installation for measuring the thrust of stationary propellers.

(7) An installation for the study of helicopters.

(8) A protected chamber for testing the resistance of propellers at very high speeds. (Although it would be difficult to attain to bursting speed, it will be possible to run them at a considerably higher rate of revolution than the normal.)

(9) A test bench for motors.

In the chemical laboratories researches will be made in the study of light gases, of fabrics for balloon envelopes and aëroplane coverings, and of varnishes.

The physical laboratories will be concerned with the improvement and application of instruments used in aërial navigation, and the physical properties of light gases.

The photographical section will be occupied in obtaining records of experiments made; a special department will test all materials used in the construction of flying-machines and dirigibles; and the usual meteorological instruments are provided.

The power-house contains two compound vertical steam engines, one of 120–150 horse-power, and the other of 30–40 horse-power, driving dynamos of 200–300 amperes and 160 amperes respectively.

In the grounds is an experimental track 1400 metres long, quite straight, and perfectly flat save for 80 metres at one end which has a slope of 10 mm. in the metre to facilitate the start of the rolling platforms, and a rise of 5 mm. in the metre at the other end to assist stopping and returning them.

The rails are 12 metres in length, welded two together by an aluminothermal process so as to give 24 metres without a joint. The current is conveyed to the carriage by live rails raised on oak standards about 0·7 metre high on each side of the track, the return being made through the track-rails themselves.

Four rolling platforms are to be provided, each designed and fitted for its special work. The first measures the vertical and horizontal components of air-pressure on planes and curves, both simple and compound, and determines the position of the centre of pressure at various angles of incidence. This has been already built. The others under construction are to comprise two for propeller testing (one for large dirigible propellers and the other for aëroplane propellers to obtain their thrust, speed of rotation, the power absorbed, and their mechanical efficiency), and one for measuring the resistance of the different parts.

Platform No. 1 weighs, including the motor of 1100 kgs., 4900 kgs. The iron chassis is 6·12 metres long, 2 metres wide, and is rounded in front. The motor-bed is carried in the centre. Two axles 3·60 metres apart carry the chassis, which projects 1·86 metres in front and 0·66 metres in rear. This inequality is for the purpose of putting additional weight on the front axle, which tends to be lifted during experiments with large horizontal surfaces. For the same reason the axis of the motor is nearer the front axle than the back axle. The wheels of cast steel are one metre in diameter. The steering swivels run in ball-bearings, and special arrangements are used to prevent lateral play. A system of brakes engaging additional rails at the end of the track brings the platform to a standstill. All the platforms are to be fitted with the following instruments:—

(1) A registering chronograph for the number of turns of the axles.

(2) A registering cinemometer, giving the speed at every point along the course.

(3) Dynamometers.

(4) A wattmeter registering the motive power at every point.

The platform at present in use can easily obtain a speed of 33 metres a second.

As open-air experiments are not always desirable or possible, a whirling table has been installed in a circular building 38 metres in diameter. The axis of the planes or propellers tested on the end of the arm will be 16 metres from the centre, thus describing a circle 100 metres in circumference. There are two motors, one of 20 horse-power, which turns the arm, and another of 25–30 horse-power, which is connected up with any propeller undergoing tests.

There only remains to mention the library, on behalf of which an appeal is made for gifts of books, pamphlets, and prints, and the bulletin of the institution, in which will be published from time to time the results of the work accomplished.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—At its last meeting for the session, the University Court, with the concurrence of the Senatus, resolved to increase the teaching power of the University by the institution of the following:—a third lectureship in engineering; a second lectureship in zoology, with special reference to protozoology; a new assistantship and a new assistant demonstratorship in physiology; two new assistant demonstratorships in geology; and a new demonstratorship in physical chemistry and radio-activity.

The resignation by Captain Lyons, F.R.S., of his lectureship in geography was accepted with regret. It was agreed to intimate the vacancy, and to take steps for the appointment of a new lecturer before the beginning of next session.

The resignation by Sir Robert Wright of the office of principal and professor of the West of Scotland Agricultural College brings into operation a provision by which the University and the College, through a joint committee, take part in the appointment of the new professor. The committee will meet for the purpose during the summer.

Professorships of medicine, surgery, obstetrics, and pathology in connection with the Royal Infirmary, and in addition to the existing chairs, have been sanctioned by his Majesty in Council, and will be filled up in time for next session.

THE Nevada State University, says *Science*, has received 50,000*l*. from Mr. Clarence Mackay, of New York City, and several of his friends, for the construction of a library and administration building.

THE annual meeting of the Midland Agricultural and Dairy College, Kingston, Derby, will be held at the college on Monday, July 31, when the report on the year's work will be presented, and the Duke of Devonshire will address the meeting and present the diplomas and certificates awarded to students during the past session.

IT is stated in *Science* that all the qualified men in this year's graduating class in the College of Agriculture of the University of Wisconsin have secured positions, and the requests for teachers are still coming in. The demand is especially strong from agricultural high schools both in Wisconsin and other States. Many of the requests are for men who have been brought up on farms, have had some teaching experience, and also have had a thorough course in agriculture. The demand for such instructors in agriculture for high schools is very much greater than the supply. Even as early as four weeks ago most of the seniors had accepted positions as farm managers, as research assistants, or as teachers of agriculture in colleges and secondary schools. The average salary of the men who will teach next year in agricultural schools is 250*l*.

IN referring, in the issue of NATURE for March 2 (vol. lxxxvi., p. 30), to the centenary of the University of Christiania, which was founded by King Frederic IV. in 1811, we were able to give the important items of the interesting programme of events which has been arranged for the occasion. The following representatives of British universities and other institutions had, up to July 13, been chosen to attend the celebration, which begins on September 4 and lasts until September 8:—University of Bristol, Prof. I. Walker Hall; University of Cambridge and the Cambridge Philosophical Society, Sir George Darwin, K.C.B., F.R.S.; University of Durham, Rev. H. Gee; University of London, Dr. H. A. Miers, F.R.S.; the Royal Society, Sir J. Rose Bradford, Sec.R.S.; the British Academy, Prof. W. Paton Ker; the Royal Institution, Prof. H. E. Armstrong, F.R.S.; the Victoria Institute, Dr. J. W. Thirtle; Victoria University of Manchester, Prof. C. H. Herford and Sir William J. Sinclair; University of Oxford, Prof. W. J. Sollas, F.R.S.; University of Aberdeen, Prof. D. W. Finlay; University of St. Andrews, Dr. H. M. Kyle; University of Edinburgh, Lord Edward T. Salvesen, K.C.; the Royal Society of Edinburgh, Mr. James Currie; University of Glasgow, Prof. J. Ferguson; Queen's University of Belfast, Prof. J. Symington, F.R.S.; University of Dublin, Rev. T. B. Willson; the Royal Irish Academy, Prof. C. Marstrander.

LORD HALDANE distributed the prizes at Mill Hill School on July 22 and delivered an address. He said the British nation is now taking a wider view of education. A great deal has been learnt from the Continent and from hard experience. "For two years and a half," said Lord Haldane, "I have been chairman of a Royal Commission on University Education. How much longer we shall have to sit before we have dealt with the whole of the material we have to survey I do not know." The Commission has shown two things—first, that the nation is waking up about education, and that very great advances are being made; and, secondly, that those advances have come none too soon, because other nations have been making advances. This nation has come to learn that education is one and indivisible. Organisation is the order of the day, and without it nothing can be done. Schoolmasters are functionaries of a very important order; they have to mould the national life of the generation that is coming on. The world is moving forward. There used to be a tradition, said Lord Haldane later, that our great public schools were very much behind the great secondary schools of the Continent, but as schools of character English public schools are not to be beaten.

UPON the recommendation of the Development Commissioners, the Treasury has decided to make an advance from the Development Fund to the Board of Education to enable the Board to make additional grants in aid of farm institutes. Such an institute should serve as the headquarters for the miscellaneous and itinerant work of the county agricultural staff, and should also provide accommodation for central courses of instruction in agriculture and kindred subjects and for demonstration. These central courses might include, for example, (1) a sixteen or twenty weeks' winter agricultural course for the sons of small farmers who have acquired some practical experience on the land since leaving elementary schools; (2) shorter courses in dairy work, poultry-keeping, and the like during spring and summer; and (3) vacation courses for teachers of rural subjects in local continuation courses. The grant in aid of the provision or enlargement of a farm institute will not exceed 75 per cent. of the total cost, while the grant for maintenance will be limited to 50 per cent. of the total cost. On educational grounds, the Board regard it as essential that there should be a farm and garden in connection with the institute, which should not only be used for the internal teaching, but should also serve as an object-lesson to the farmers and gardeners of the county. In some cases a small holding might be added. These should be conducted on business principles, but some annual deficiency will generally be entailed by their use for educational purposes. The grants are not to have the effect of reducing the amount of any expenditure at present incurred by a local education authority out of the rates or other local resources upon work of the type to be aided, or the amount of any contribution by the authority to the educational work conducted by the agricultural colleges.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 17.—M. Armand Gautier in the chair.—A. **Haller** and Ed. **Bauer**: Syntheses of substituted β-diketones, of ketonic ether-salts, and of enolic ethers by means of the sodium derivatives of ketones. The interaction of the sodium derivative of isopropylphenyl-ketone with benzoyl chloride gives two isomeric benzoyl compounds, one, the diketone dibenzyl-dimethyl-methane, from which a monoxime is readily prepared, and the other the enolic form, not combining with hydroxylamine. Other examples of similar reactions have been worked out. Chlorine and iodine compounds give different reactions in some cases.—A. **Lacroix**: The alkaline rocks of Nosy komba (Madagascar).—Ch. Ed. **Guillaume**: The modifications undergone by nickel steels after prolonged heating and on the action of the time. These measurements show the necessity of a preliminary tempering of nickel steels used in the construction of instruments of precision, and the possibility of calculating by extrapolation during a period of several years the length of a standard invar bar maintained between certain limits of temperature.—Paul **Sabatier** and A. **Mailhe**: Some new preparations of the benzylamines and of hexahydrobenzylamine. The general method employed consists in acting with ammonia gas upon the vapour of an alcohol at 300° C. to 350° C. in presence of a catalytic oxide, such as thoria. With benzyl alcohol the chief products of this reaction are benzylamine and dibenzylamine. Pure benzylamine, obtained by this method, treated with hydrogen at 170° C. to 180° C. in presence of a very active nickel gives ammonia, toluene, and hexahydrobenzylamine. The latter base was isolated, and its properties are described.—M. **Bernstein** was elected a correspondant in the section of medicine and surgery in the place of the late M. Engelmann.—M. **Borrelly**: Observations of the Kiess comet (1911*b*) made at Marseilles Observatory with the comet finder. Observations of the comet and comparison stars are given for July 9, 12, 13, 14, and 15. The comet appeared as a globular nebula with a condensation at its centre, and was about the 8th or 9th magnitude.—M. **Esmiol**: Observations of the Kiess comet made at the Marseilles Observatory with the Eichens 26 cm. equatorial. Observations given for July 13 and 15.—Ernest **Esclangon**: Observations of the Kiess comet (1911*b*) made with the large equatorial of the Observatory of Bordeaux. Positions of the comet and comparison stars given for July 10 and 11. The comet appeared as a nearly round nebulosity of about 2′ diameter.—Observations of the Kiess comet (1911*b*) made at the Observatory of Besançon with the 33 cm. bent equatorial. Positions given for July 10, 11, 12, and 13.—A. **Petot**: The extension to geodesic lines of a kinematic property of the right line.—Ruben **Mallton**: The construction of integral functions of irregular growth.—A. **Korn**: An important class of asymmetrical nuclei in the theory of integral equations.—H. **Vergne**: A theorem in hydrodynamics.—MM. **Melchissedec** and **Frossard**: The mechanical theory of some tubes producing sound.—A. **Leduc**: Internal pressure in gases. Formulæ of state and the law of molecular attraction.—M. **Hanriot** and F. **Raoult**: The magnetisation coefficients of gold. A comparison of the magnetic properties of the brown gold (previously described by the authors) and ordinary gold into which the brown gold is converted by heating shows that they are distinct varieties of the same metal.—G. **Chavanne**: Isopyromucic acid. Its behaviour towards oxidising agents. Dibromomaleic and bromoxymaleic dialdehydes. Dibromomaleic aldehyde,

$$OCH—CBr=CBr—CHO,$$

is obtained by acting with bromine upon monobromisopyromucic acid, and treatment of the bromine addition compound thus obtained with bromine and water.—Ph. **Barbier** and R. **Locquin**: The transformation of some substituted paraconic acids into the isomeric cyclopropanedicarboxylic acids. This transformation is effected by the action of thionyl chloride upon the dry acid dissolved in one and a half times its weight of benzene, and maintained at the temperature of the water-bath for twelve hours. This new reaction will be studied with other lactones.—G. de **Gironcourt**: The cheeses of Touareg. This native cheese is remarkable for the small proportion of water it contains. It keeps well for long periods of time, and can be carried great distances without change.—MM. **Vermorel** and E. **Dantony**: Sulphur capable of being moistened. A method of treating sulphur for agricultural purposes.—A. de **Varenne**: The destruction of Cochlyis of the vine.—Pierre **Lesage**: The characters acquired by plants watered with solutions of common salt. The addition of the salt causes a reduction in the size, a yellowish coloration, and a reduction in the duration of the cycle of growth.—G. **Perrin**: The prothallus of Equisetum.—A. **Guilliermond**: The mitochondria of plant cells.—C. L. **Gatin**: The influence of the tarring of roads on the growth of the trees of the Bois de Boulogne. In certain cases only, where the road is much exposed to the sun and where the traffic is heavy, could the tarring of the road be proved to have a marked deleterious effect on the trees.—Edmond **Perrier**: Remarks on the preceding communication, pointing out the serious damage done to the trees in the Jardin des Plantes by the adjacent tarred road.—B. **Roussy**: The existence of a very simple geometrical law of the body surface of a man of given dimensions, demonstrated by a new method. Detailed instructions are given (with two diagrams) for determining two magnitudes called by the author the mean perimeter and the total mean peripheral height. The surface of the skin is shown to be equal to the product of these two quantities.—Raphael **Dubois**: Fluorescence in luminous insects.—L. **Mercier** and R. de **Drouin de Bouville**: The disease of the crayfish of the lake of Nantua: a criticism of the views of M. Dubois.—F. **Rogoziuski**: Researches on the glycogenic property of glucosamine.—A. **Daniel-Brunet** and C. **Rolland**: The influence of sex and of castration upon the quantity of lipoids in the bile of cattle.—Stanislas **Meunier**: An example of pluvial decalcification realised in the course of the lower Tertiary epoch.—Louis **Laurent**: The presence of the genus Atriplex in the Tertiary flora of Menat (Puy-de-Dôme).

CAPE TOWN.

Royal Society of South Africa, May 19.—Mr. S. S. Hough, F.R.S., vice-president, in the chair.—R. **Marloth**: Some new South African succulents and other plants. Among the plants described in this paper are three species of special interest, viz., one of Cytinus, one of Borbonia, and one of Anacampseros. The Cytinus is noteworthy as it constitutes a second species of Rafflesiaceæ for South Africa; the Borbonia is of economic importance, being the source of a colonial tea, viz., "rooibosch-tea," and the Anacampseros is another example of mimicry-plant, of which eight species were described in previous papers.—Miss D. L. **Bleek**: Note on the language of Bushmen tribes north of the Orange River. All words and sentences taken down from Bushmen south of the Orange River show that they spoke one language, with dialectical variations. North of the Orange River, however, in the Langeberg and adjoining Southern Kalahari, we find a different language, that of II n Bushmen, closely allied to that of I Xam Bushmen (those south of the river); the difference in the vocabulary, and still more in the grammar, of these two tribes is too great to be called a mere dialectical variation. In the Northern Kalahari the so-called Masarwa are found, people living exactly as Bushmen do, though said to be mixed in type. The South African Museum has a series of gramophone records taken from pure Masarwa, in the heart of the Kalahari region, which the author has transcribed, and which, in spite of the instrument not having recorded clicks clearly, gave valuable evidence that the language belongs to the Bushman family.—L. **Péringuey**: Note on the result of investigation of a Strand Looper rock-shelter, with exhibition of the objects found. The cave which it was decided to excavate is, properly speaking, a rock-shelter, filled with an accumulation of kitchen refuge, blown sand, &c. The excavation was carried through a depth of nearly 14 feet of this material, when it was found necessary to stop, owing to the dampness of the detritus. The cave was originally discovered by Mr. C. J. Whitcher, who carried on some excavation first, and very kindly allowed the museum to proceed with further exploration work. This cave proves to have been a necropolis, a considerable number of skeletons having been found at different depths. In the pelvic bone of a young child (or female) was found embedded a small stone chip, part of the point of an arrow, probably poisoned. Most of the skeletons are in a greatly advanced stage of decay. Some are plainly Strand Loopers, but others were found which are not Strand Loopers; they are of greater and more robust stature, and would appear to be half-bred, or perhaps Kaffirs, yet the mode of burial is the same, but the skulls of this "larger race" are not entire, nor could all the fragments be found. A feature of the hitherto unrecorded burial rites is the placing of flat stones, occasionally painted, on the hunched-up body resting on its side. One of these stones has polychrome paintings of the Bushman type, but unlike any of these paintings, in this one the eye, and an attempt at facial delineation is noticeable. The evidence of the bone and stone implements found in this sepulture not only indicates that the two industries prevailed simultaneously, but that implements of palæolithic and neolithic type were also coeval. It can now be said that in South Africa the hiatus which in Europe, or in the Palæarctic region, separates the palæolithic from the neolithic, is now proved not to have existed.—T. **Burtt-Davy**: Observations on the inheritance of character in Zea Mays. In Red Cuzco and some other breeds of red maize, the red colouring matter is confined to the pericarp, and is therefore a fruit character; it does not appear in the first cross between a white male and a red female. In a red dent breed the red pigment occurs in the aleurone layer; it is therefore a seed character; it is dominant to whiteness. When this breed is crossed with a white sugar breed the results in the second generation are approximately:—Red: starchy, 56·25 per cent.; sugary, 18·75 per cent. = 75 per cent. White: starchy, 18·75 per cent.; sugary, 6·25 per cent. = 25 per cent. A single grain has been seen, in which the starchy character appears in one half, the sugary character in the other. The number of rows on a maize ear, within certain limits, is subject to fluctuating variations, which may perhaps be affected by season or food supply, or both. When an 8-row type is crossed with an 18-row type, both characters disappear in the heterozygous form, and an intermediate type is produced, in which there are 10, 12, or 14 rows, 12 rows greatly predominating. A white-cobbed breed crossed with a red-cobbed produces a red-cob in the first filial generation. Result of reciprocal cross is the same.—E. **Nevill**: The early Babylonian eclipses of the sun. On the fourteenth line of Tablet No. 35968 of the British Museum Collection, Mr. King has deciphered the record:—"On the twenty-sixth day of the month Sivan in the seventh year the day was turned into night and fire in the midst of heaven. . . ." From collateral evidence contained on the tablet, the author supports Mr. King's contention that the phenomenon referred to is a total eclipse of the sun, but differs from Dr. Cowell, who has identified it with the eclipse of B.C. 1062, July 31. The author has examined the features of some seventy eclipses which occurred between B.C. 1250 and B.C. 950, the extreme limits of date which seems to be compatible with the inscription, and finds that three of these only appear to satisfy the prescribed conditions of having been visible from the neighbourhood of Babylon at a time of year corresponding with the twenty-sixth day of the month Sivan, viz., those of —1217 June 5, —1123 May 18, and —956 May 31. The identification of this eclipse is of importance as bearing on the theory of the moon's motion, as well as in relation to doubtful points concerning the chronology of the earlier kings of Babylon.—T. **Muir**: Sylvester's axisymmetric unisignants.

THURSDAY, AUGUST 3, 1911.

ZOOGEOGRAPHY.

Bartholomew's Physical Atlas, vol. v., Atlas of Zoogeography: a Series of Maps Illustrating the Distribution of over Seven Hundred Families, Genera, and Species of Existing Animals. Prepared by Dr. J. G. Bartholomew, W. Eagle Clarke, and P. H. Grimshaw. Pp. viii+67+36 plates+xi. (Edinburgh: J. Bartholomew and Co., 1911.) Price *2l. 12s. 6d.* net.

THE fifth volume of "Bartholomew's Physical Atlas" is devoted to "Zoogeography"—that is, as the word clearly indicates, the science of the distribution of animal-life over the world's surface. Little was known and still less was understood about this branch of zoology in former years. But when the "Origin of Species" began to be discussed it was quickly perceived how closely the localities of animals and plants are connected with their affinities, and how important "zoogeography" is to the student of animal and vegetable life. Linnæus and his immediate followers did not understand this. They thought that such terms as "East Indies" or "Brazil" were quite sufficient indications of the locality of an animal. But, as the science of zoology advanced, authors became gradually more particular as to their localities, and nowadays unless the place of origin is exactly known a specimen loses at least half its value. In early days the faunal character of each geographical area was supposed to depend entirely on its climatic and physical peculiarities. This idea, however, has been abundantly proved to be incorrect. In many cases tracts of the world's surface exactly similar in climate and in other physical conditions can be shown to be entirely different as regards their animal life. It was not until the theory that the descent of animals is accompanied by modifications of their structure became appreciated that any correct views were put forward on the laws of their geographical distribution. The authors of the present work describe the commencement of this new period as follows:—

"The first attempt to map out a set of zoogeographical regions, based upon the actual distribution of species, and apart altogether from purely geographical considerations, was made by Dr. P. L. Sclater. This eminent zoologist, who is, fortunately, still living, read a paper before the Linnean Society of London, in June, 1857, entitled 'On the General Geographical Distribution of the Members of the Class Aves.' Taking as his basis the Passerine, or 'Perching' Birds, he proposed the division of the earth into six great regions, which he defined geographically, and whose area in square miles he roughly estimated. At the same time, he furnished a tabulated statement of the number of species found in each region, and gave an indication of the peculiar and characteristic genera. As this paper was an epoch-making one, and as its divisions correspond very closely with the main regions adopted in most of the schemes since proposed, it is perhaps desirable to quote the main features before proceeding further."

The authors then proceed to enumerate the six great "regions" into which Dr. Sclater had proposed to divide the earth's surface for zoological purposes, adding in each case a short description of their boundaries and estimated areas, also a rough calculation of the number of species of birds then known to be found in each of them. These six regions were as follows:—(1) The Palæarctic region (embracing Europe and North Asia, and the northern part of North Africa); (2) the Ethiopian region (Africa, except the portion north of the Sahara); (3) the Indian region (southern Asia and the adjacent islands); (4) the Australian region (Australia and the Pacific Islands); (5) the Nearctic region (North America); and (6) the Neotropical region (South and Central America).

The publication of Dr. Sclater's article induced many other zoologists to state their views on the subject. Günther, Blanford, Huxley, Heilprin, and Blyth were among the number. Many of them agreed more or less with Dr. Sclater's proposals, but offered criticisms on particular points, and suggested emendations of his nomenclature. But in 1876 appeared Dr. Wallace's classical and important work, "On the Geographical Distribution of Animals," which combined all that had been previously known on the subject with the knowledge acquired by the travels and experiences of this great naturalist. In this work Dr. Wallace absolutely adopted Dr. Sclater's division of the world into six great regions and his nomenclature, only suggesting that the name of the "Indian" region should be changed to the "Oriental" region, an improvement which subsequent authors have been generally willing to agree to.

Dr. Wallace, after fully considering the question, states decisively his reasons for adopting the six zoological regions proposed by Dr. Sclater as follows:—

"So that we do not violate any clear affinities or produce any glaring irregularities, it is a positive, and by no means an unimportant advantage to have our regions approximately equal in size, and with easily defined, and therefore easily remembered, boundaries. All elaborate definitions of interpenetrating frontiers, as well as regions extending over three-fourths of the land-surface of the globe, and including places which are the antipodes of each other, would be most inconvenient, even if there were not such great differences of opinion about them. There can be little doubt, for example, that the most radical zoological division of the earth is made by separating the Australian region from the rest; but although it is something useful and definite to know that a group of animals is peculiar to Australia, it is exceedingly vague and unsatisfactory to say of any other group merely that it is extra-Australian. Neither can it be said that, from any point of view, these two divisions are of equal importance. The next great natural division that can be made is the separation of the 'Neotropical' region of Dr. Sclater from the rest of the world. We should thus have three primary divisions, which Prof. Huxley seems inclined to consider as of tolerably equal zoological importance. But a consideration of all the facts, zoological and palæontological, indicates that the great northern division (Arctogæa) is fully as much more important than either Australia or South America, as its four component parts are less important; and, if so, convenience requires us to adopt the smaller rather than the larger divisions."

Convinced by these weighty arguments, the authors of "Zoogeography" adopt the six Sclaterian regions without exception, and use them throughout their work, making only the change of the name of the "Indian" region into the "Oriental" region, as was suggested by Dr. Wallace. They take these six regions one after the other, and describe their extent, the best mode of their division into subregions, their most obvious physical features, and the chief zoological characteristics which distinguish them. One of the more difficult points to be considered is the relation of North America to the Palæarctic region. So similar in many respects are their faunas that Heilprin had proposed to unite them under one name as the "Holarctic" region, which has met with approval by Huxley, Newton, Lydekker, and other writers. But after discussing the question, our authors follow Wallace in rejecting Heilprin's proposal, and give good reasons for doing so.

The third and most important part of the present work is the zoological section, to which we must now direct attention. It is obvious that an exact knowledge of the general distribution of animal life must be based on a thorough acquaintance with the particular distribution of each species. But, as is well pointed out in the present work, the distribution of animal life in many areas "has not been investigated in sufficient detail to afford the necessary data, and in such cases it is impossible to define the range of species with precision." Moreover, in many groups of animal life, especially in the lower forms, the species are so multitudinous, and as yet so little known, that they cannot be used for such a purpose. But all the higher forms, such as mammals, birds, reptiles, and amphibians have been dealt with in this work, besides the more important families of fishes, and a selection of the better-known groups of insects and molluscs. The zoological portion of the letterpress of "Zoogeography" occupies some forty-four pages of two columns each, and seems to be very complete, though it involves a mass of details, which it must have been a hard task to put together and to arrange in order.

Following this portion of the work is a "bibliography," containing the titles of the separate books and the principal articles published in journals relating to zoological distribution. This, we think, though useful as it is, might have been improved by the addition of the names of the leading authorities on the faunas of each of the different parts of the world, something like that which was given by Dr. Sclater in his presidential address to the Biological Section of the British Association at Bristol in 1875. It must be admitted, however, that such a list, though of much value, would have somewhat inconveniently increased the bulk of the "bibliography."

We now come to the maps, the most important feature in the work, which have been planned to illustrate the distribution over the world's surface "of more than seven hundred families, genera, and species of existing animals." It is to be regretted that the extinct forms of animal life have been altogether unnoticed, as they serve to explain in some degree the anomalies of the present state of distribution. That the task of inserting them would have been serious it must be confessed. We observe that the dodos (Dididæ) have been mentioned. But we think that a few words might also have been devoted to the moas (Dinornithidæ) of New Zealand, the rocs (Æpyornithidæ) of Madagascar, and to other forms which have only recently become extinct. Taken as a whole the thirty-six plates of the atlas are excellent, and fully sustain the claim of the great firm which has produced this handsome volume to issue nothing but first-class work.

In books of this kind, accompanied by a large number of illustrations, there are often slight discrepancies between the plates and the descriptions of them in the text. We find nothing of this sort in the present work, in which it is obvious that the main object of the text has been the description and explanation of the illustrations. In fact, we consider that Mr. Bartholomew and his enterprising firm deserve the greatest credit for the production of the fifth volume of their "Physical Atlas," which, we are sure, will long remain the leading authority on "zoogeography."

CENTRAL ASIA.

L'Asia Centrale: noti di viaggio e studi di un Diplomatico giapponese. By Nisei Tocugiro (Nishi Tokujiro). Translated by L. Nocentini. Pp. xxx+317. (Turin: Unione Tipografico-Editrice Torinese, 1911.) Price 4.50 lire.

THE distinguished Sinologist, Prof. Lodovico Nocentini, has translated into Italian an interesting Japanese work on the geography, ethnography, and political conditions of Central Asia, which was written a quarter of a century ago by Mr. Nishi Tokujiro (or Tokujiro Nishi, as we should say), then First Secretary of the Ministerial Council at Tokyo. The translation, with additions and notes by the translator, which bring it up to date, has now been presented to the Italian Geographical Society, with a preface by the president of that body, Signor Cappelli. Mr. Nishi has been prevented by other work from adding new material to the book himself.

In 1880 Nishi Tokujiro, then attached to the Imperial Legation at St. Petersburg, left on his homeward journey by way of Central Asia, passing through Russia and Chinese Turkestan on the way, and this volume, produced in 1885, was the result of his *noti di viaggio* and general knowledge. When published it would, had it been translated promptly, have been of great interest, and even now, with the addition of Prof. Nocentini's notes, it is valuable as a general account of Central Asia. For non-Italian readers, however, its value is somewhat discounted by the unscientific transliteration of all names, whether Russian, Chinese, Turki, or what-not, into a guise which, though it may reproduce the correct sounds of the originals to an Italian reader, is confusing to those of other nations, who have to re-transliterate into the forms familiar to them. What English or German reader, to take instances, would at once recognise in "Coccienco" the Russian name Kochienko, in "I-'r O-scen" the Chinese Yi-erh Wo-shen, in "Cucia" or "Cuccia" the town of Kucha, or even in "Culgia" that of Kuldja? And ought the town of Piotr-Alexandrovsk to be literally translated into Italian as "Pietro-Alessandro"? In England we do not talk of "Coachienco," "Yee-erh, " "Cootcha," or "Peter-Alexander" (though we might have sixty years ago), and nowadays the strictly scientific "Kočyenko," "Kuldža," or "Kuča," would be perfectly well understood here. In this matter of transliteration the Italians (like the French in dealing with Arabic names) are half a century behind the times. This book will be read, out of Italy, only by those who have some knowledge of Central Asia and its languages, but do not necessarily know even enough Italian to recognise the name of the author of this book in its Italian form, "Nisci Tocugiro."

Mr. Nishi's work was a very complete description of the lands and peoples of Central Asia, so far as counting of heads goes, but not a particularly thorough one. Its historical sections are the best, but its great interest lies simply in the fact that it was the work of a Japanese so early as the eighteenth year of Meiji. Even then the relentless advance of Russia in Asia was being noted by the watching Japanese, and the resources and possibilities of her Asiatic dominion were being "sized up" by the unimportant traveller Nishi, who was significantly, on his return to Japan, attached to the general staff. Who knows but even then the Japanese were beginning to prepare for the inevitable struggle, which came twenty years later, just when the dominion of all Asia seemed about to fall irrevocably into Russian hands? Mr. Nishi had no great belief when he wrote in the ability of China or even England to stop Russia. He seems to shrug his shoulders over the vain English protests against the advance of the colossus of the north, which emanated in "Mervous" succession from our Foreign Office for twenty years, and ended with the "Penjdeh incident" (Signor Nocentini calls the place "Pange"), which seemed to make our weakness patent to all the world. The ally of 1902 did not seem very admirable to a Japanese in 1885. We have, however, got over our "mervousness" now that Russia is brought up short by the great mountain-barriers, and indeed it is not probable that we ever had any real justification in trying to stop her advance into Turkestan. Her taking of Merv was much more inevitable than our taking of Mandalay, and she only went beyond bounds when she took Penjdeh and the Kushk valley from Afghanistan. The real danger of war which then ensued was a signal to her to stop, for we know now, since Japan has shown us, that Russia's power is all "bluff"; she had no more wish for war with us in 1885 than with China over the question of Kuldja in 1880, or with Japan in 1903. In 1880 China met her bluff with greater bluff, and in 1903 Japan took her at her word, with the result that the history of Asia has entered on a new phase, incredible had it been, prophesied in 1885, even to the self-confident countrymen of Mr. Nishi.

Signor Nocentini brings the political part of the book fully up to date, even including an account of Dr. Stein's discoveries and the text of the Anglo-Russian agreement relative to Tibet. We see from this that the prohibition of the sending of scientific expeditions to Tibet by either Russia or England expired in 1910. But in view of the disturbed condition of Tibet owing to the Chinese invasion, it is not probable that any such expeditions will be sent there for some time yet.

The typographical and ethnological details have not been brought up to date. The mountains stand where they stood in 1885, and the Jaxartes has not yet again changed its course, while the ethnic peculiarities of Kirghiz, Uzbegs, Sarts, Eleuths, and Dungans remain the same, so this does not matter. But details of the population of the cities and of the dislocation of Russian troops in Asia in 1881 have now merely an antiquarian interest.

Nevertheless the book is a very interesting one, and is well worth persual by those who study the subject. What the future of this huge land will be, who can say? The Japanese war has probably put a stop to all Russian advance for many a year to come, unless a parliamentary China should foolishly (thinking herself, in Babu-wise, the equal of Japan) try to oust Russia from northern Manchuria. In that case China will lose much, while Japan will look benevolently, this time, upon Russia's chastisement of her. Then we English would be well advised to insist that Russia, whatever else she may take, shall leave Chinese Turkestan in Chinese hands. Otherwise a fresh attack of "mervousness" may arise, if Russia is in Kashgar and Khotan.

If there is no war between Russia and China within the next few years, the Russians will be able to devote their rather intermittent energies to the development of the enormous territory that is already theirs. Railways are a necessity to her military hold of Central Asia, and there are lines yet to be built which are of great strategic importance, though they may not "pay" for a century. A railway from Orenburg through Akmolinsk to Semipalatinsk is projected, and another line should run from Tashkend to Krasnoyarsk, by way of Aulië-ata, Vyernyi (where the recent earthquake took place), Sergiopol, Semipalatinsk, and Barnaul, with a branch to the Ili valley, and, if China will permit, on to Kuldja. This line would bind Turkestan to eastern Siberia, and enable troops to be railed from Samarkand to Irkutsk direct. But the country to be traversed is mostly steppe, and the immediate value of the line would only be military, as in the case of the existing Orenburg-Tashkend railway. So Russia will be condemned indefinitely to pour out millions of roubles into the wilderness (and the contractors' pockets), and only a century hence will the slow work of the present day bear fruit in a great and mighty country, the home of millions of peaceful and hard-working Russians—a new Canada.

The future of China, who can prophesy? But it is improbable that a century hence China will have allowed the Japanese to retain their control of southern Manchuria, or even Korea, and the islanders may be driven back to their home, even as we were expelled from France in the fifteenth century. History always repeats itself in similar cases. But Japan will have done her work well, and the notes made by Nishi Tokujiro in his journey twenty-five years ago would have shown us then, had we had ears to hear or eyes to see, that already Japan was studying the huge continent at her door, and weighing the possibilities that might come forth from it in the fulness of time.

It remains only to say that the book is "bound" only in paper covers, and falls to pieces directly it is cut. We presume that Italians send their books to the binders before they read them. L4.50 seems a high price for a book of 300 pages that has no binding and no illustrations. Unlike the French, the Italians understand the value of an index, and this book has a good one.

LUCIANI'S HUMAN PHYSIOLOGY.

Human Physiology. By Prof. L. Luciani. Translated by Frances A. Welby. Edited by Dr. M. Camis. With a preface by Prof. J. N. Langley, F.R.S. In two vols. Vol i., Circulation and Respiration. Pp. xiv+592. (London: Macmillan and Co., Ltd., 1911.) Price 18*s*. net.

THE rapid progress in the science of physiology makes it increasingly difficult for any single individual to give a comparatively complete presentation of the whole subject. In consequence of this fact, the larger text-books are usually written by several authors. While there are many advantages in this method, a loss of unity in the treatment of the subject inevitably results. Luciani's work gives a more detailed account of the subject than the majority of text-books of single authorship, and thus occupies a place intermediate between the larger works and those of moderate size.

The arduous labour of translation has been carried out very efficiently, the English version being clear, accurate, and eminently readable. The translator has also had the advantage of the assistance and advice of Dr. Aders-Plimmer on chemical subjects, and of Mr. W. L. Symes on many technical difficulties. The references to the literature of the subject appended to the various sections of the work form a very useful feature. The editor, Dr. M. Camis, has rendered these more complete by the addition of the chief recent English and American physiological papers. These references will undoubtedly offer valuable guidance to senior students of physiology desirous of extending their knowledge of physiology beyond the limits of their text-books.

The present volume, which extends to 600 pages, deals with the general physiology of living matter, the physiology of blood, the circulation, respiration, and lymph.

The introduction gives a brief but masterly account of the general objects and domain of physiology. The first three chapters deal with the structural features, the chemical and physical basis of living matter, its fundamental properties, and the conditions by which it is influenced. The third chapter closes with an interesting account of the hypotheses of Pflüger, Hering, and Verworn regarding the nature of the processes which take place in living substance.

The fourth chapter deals with the formed constituents of blood. The historical development of the subject is excellently epitomised. The general physico-chemical characters of the blood as a whole are next described. A brief account of the methods used in determining the rate of coagulation might have been added with advantage. The morphological elements of blood are then described. The plate showing absorption spectra is somewhat diagrammatic, methæmoglobin and acid hæmatin being represented as having identical spectra.

An excellent account of the chemical and physical properties of blood plasma, and of the theories of its coagulation, forms the main subject-matter of chapter v. The chapter concludes with an account of the effects of bleeding, transfusion, and the bactericidal and immunising properties of blood.

An exceptionally detailed account of the historical development of our knowledge of the circulation of the blood is given in chapter vi. The author ascribes the discovery of the true course of the circulation to Cesalpinus rather than to Harvey, differing in this respect from the large majority of physiologists. In the preface to this volume, Prof. Langley has given the chief reasons for critical caution in studying Prof. Luciani's views on this subject.

The mechanics of the heart and blood flow are fully discussed in chapters vii. and viii. The discussion of the myogenic and neurogenic theories of cardiac rhythm given in chapter ix. offers an excellent example of the author's skill and impartiality in presenting the evidence for and against rival views. The account given embodies the most recent work on the subject, including that of Carlson on *Limulus polyphemus*.

Chapter x. provides an excellent account of the vaso-motor nervous mechanism. Chapter xi. is devoted to the chemistry and physics of respiratory exchanges. A most interesting review of the historical development of the subject is given, both from the chemical and physiological points of view. A description of Haldane's method for determining the oxygen capacity of blood might have been appended to the account of the methods for the extraction of the gases of the blood.

The nervous and chemical control of respiratory rhythm form the subject-matter of chapter xiii. Some interesting recent observations by Italian workers, throwing new light on the mode of production of certain forms of polypnœa in muscular work, are recorded. A somewhat fuller discussion of recent views on the chemical regulation of respiration would have been welcome.

The present volume concludes with an excellent account of the physiology of lymph and lymphatic organs.

The book is singularly free from errors; yet in a text-book of this extent minor errata inevitably occur. The following may be mentioned with the view of aiding to some extent in the preparation of a table of errata. On p. 25 "cornea" is used instead of "stratum corneum"; on p. 109 "carbon bisulphide" should be replaced by "ammonium sulphide"; on p. 333 "afferent" by "efferent"; and on p. 415 "inspiratory" by "expiratory."

The present edition is a distinct advance on the earlier issues, the more recent additions to physiology being fully given. Such are some of the chief characteristics of this book. So brief a review as the foregoing necessarily leaves unmentioned many other important features. The book is a remarkable achievement, especially in view of the fact that it is the work of a single author, and appears to the reviewer to possess special qualities and merits, which entitle it to a high place amongst the existing English text-books of physiology. The issue of the remaining three volumes will be eagerly awaited by all who have studied the present volume.

ABBE'S THEORY OF IMAGE FORMATION IN THE MICROSCOPE.

Die Lehre von der Bildentstehung im Mikroskop von Ernst Abbe. Edited by Otto Lummer and Fritz Reiche. Pp. xii+108. (Braunschweig: F. Vieweg und Sohn, 1910.) Price 5 marks.

AN account of Abbe's theory of the microscope image given by so distinguished an optician as Prof. Lummer cannot fail to arouse a large amount of interest among all students of optical theory, as well as among workers with the microscope. It demands the more attention in that it is professedly a reproduction of Abbe's theories as propounded by himself. Lummer tells us that in the winter of 1887, in company, among others, with Winkelmann, Czapski, Rudolph, and Straubel, he attended a series of lectures given by Abbe in Jena, and it is clear that he enjoyed exceptional opportunities of becoming acquainted with Abbe's views and his manner of regarding microscope theory.

The work, we are told, is founded solely on the carefully preserved notes of these lectures. One question only, it was thought, needed to be reviewed from the modern point of view: Is the Fresnel-Huyghens secondary-wave interference theory a satisfactory basis for the discussion of the phenomena, or will the more modern theory of Kirchhoff and Maxwell lead to some modification of the conclusions arrived at? It may be answered at once that Lummer attacks the problem of image formation by limited beams from the latter point of view, and shows that it leads to identical results with the former.

The intrinsic interest of the book is very great, and the methods employed are most instructive, both in the establishment of general principles and in their application to the special cases which arise in microscope imagery when periodic structures are viewed by transmitted light. Thus, in the latter case, the determination of the distribution of light intensity in the image plane requires an integration over the plane of the structure viewed, and over that of the actual or virtual aperture. By variation of the order of integration the authors are able to bring out clearly the part played by the different "diffraction spectra" in the formation of the image. The same thing is shown in a different manner more fully, and still more clearly, in Lord Rayleigh's well-known paper of 1896, "On the Theory of Optical Images, with special reference to the Microscope."

The special cases here dealt with are those of a single luminous slit, two parallel slits, self-luminous or viewed by transmitted light, and a single slit of finite breadth, with or without phase difference; finally, in a separate chapter the case of a grating is considered, and the effect discussed of limiting the image-forming rays to certain of the grating maxima. In dealing with images formed by transmitted light, the case of oblique illumination is also treated. The source of light is supposed either at a finite or infinite distance, but, as might be anticipated, there is no special discussion of the case of "critical" illumination. Throughout, the treatment is not for a circular aperture, but an aperture of special form is assumed to simplify the integration.

The main interest of the volume, however, lies in the light it throws on the manner in which Abbe derived his well-known theory. From this point of view we must confess that we find the book a little disappointing. It is not easy to agree with Prof. Lummer as to the necessity, or even the desirability, in this book, of devoting space to showing how far the older theory is in agreement with more modern views, and this is not the only feature which tends to produce a sense of uncertainty as to how far the account given can be regarded as a direct reproduction of Abbe's presentation of the subject. What admirer's of Abbe's work would wish to have is a close and faithful transcript of Abbe's own development of the theory, with the minimum of variation from the line of argument he may have followed. The volume is, however, inspired by a true enthusiasm for Abbe's teaching, and a just appreciation of the value of his work, and the future historian of science will be indebted to Prof. Lummer for the trouble he has taken to present in a manner worthy of its origin the material at his disposal.

THE NUTRITION OF THE ALGÆ.

Die Ernährung der Algen. By O. Richter. Pp. viii+192. (Leipzig: Dr. W. Klinkhardt, 1911.) Price 12 marks.

SINCE the appearance in 1905 of the second part of Oltmann's work on the morphology and biology of the algæ, so large a number of memoirs on the nutrition of the algæ have appeared, that Dr. Richter has thought it worth while to collect them into a volume for the *International Review of Hydrobiology and Hydrography.* The references are grouped under three headings—(1) the significance of chemical elements and certain chemical compounds in the physiology of nutrition; (2) the influence of various chemical and physical factors of the nutrient substratum on the form and development of the algæ; and (3) an appendix on the influence of temperature and light on the algæ with reference to their culture.

It is not possible to give anything like an adequate account of the numerous investigations which are brought under review. After a brief discussion of the metallic elements which are of importance to the algæ, the non-metallic elements and compounds are considered. Reference is made to the evolution of oxygen in carbon dioxide assimilation and the various methods by which it can be quantitatively determined. Engelmann's well-known bacterial method and Beyerinck's method of using luminous bacteria are spoken of by the author as "two of the most elegant methods for the demonstration of the evolution of oxygen." Beyerinck found that luminous bacteria, when placed in contact with algal filaments, are phosphorescent when oxygen is being evolved, but cease to be luminous in its absence.

In reference to Bokorny's observations on Spirogyra and Zygnema in support of Baeyer's hypothesis that formaldehyde is the first product of carbon dioxide assimilation, the author concludes that, in view of their far-reaching scientific importance, it is necessary that these investigations should be repeated with absolutely pure cultures of algæ. This appears to be so much the more desirable as Treboux, working with pure cultures of some of the lower algæ, was unable to obtain starch formation either with formaldehyde or methylal. Dr. Richter very properly lays stress upon the great importance of pure cultures in these experiments in order to prevent the contamination with carbon dioxide produced by fungal or bacterial growths, which may completely vitiate the results. He fully discusses the results obtained by various observers upon the assimilation of organic nutrient substances, such as glycerine. Many algæ seem to prefer organic compounds containing nitrogen; others prefer carbohydrates. Among the former are diatoms, and indeed these organisms seem to have a preference for albuminoid food substances.

The second part of the book is taken up with a consideration of the papers dealing with the poisonous action of various chemical compounds, the influence of narcotics, the deleterious effects of different species of algæ upon one another, and the reactions of the nutrient material upon their growth and development. The poisonous action of minute traces of metals, termed by Naegeli oligodynamic, is illustrated by some interesting experiments made by the author to show the deleterious influence exerted by coins when placed in contact with diatom cultures on agar. In discussing the effects of light and temperature on the algæ, the author shows clearly that variation in intensity has a very marked effect on their growth and on the formation of various organs.

The book may be commended to students as a very useful summary of the important researches bearing upon algal nutrition and the various factors by which it is controlled. Very few of the problems, of course, are peculiar to algæ (they are problems of plant nutrition generally), and the book is to some extent lacking in completeness, because, in his desire to confine himself strictly to algæ, the author has neglected many papers dealing with plant nutrition, which are just as applicable to algæ as to other plants.

There is a very full index, both of subjects and of authors, together with a good table of contents and a list of nearly five hundred references.

H. W.

POPULAR ASTRONOMY.

(1) *Star-Lore for Teachers: Suggestions for the Teaching of Astronomy by direct Observation, Experiment, and Deduction.* By B. Lowerison. Pp. 67; interleaved for notes. (London: The Clarion Press, n.d.) Price 1s.

(2) *The Star Pocket-book; or, How to Find Your Way at Night by the Stars. A Simple Manual for the Use of Soldiers, Travellers, and other Landsmen.* By R. Weatherhead. With a foreword by Sir Robert Ball. Pp. 80. (London: Longmans, Green, and Co., 1911.) Price 1s. net.

(3) *Les Progrès Récents de l'Astronomie (III.—année 1909.)* By Prof. Paul Stroobant. Pp. 174. (Brussels: Hayez, Rue de Louvain, 1911.)

(1) IF the automatic response to the stimulus of the starry heavens has not forced a man to acquire enough astronomical knowledge to instruct his pupils intelligently in star-lore, that man has no business to be a teacher of the subject. Lacking the capacity or desire to observe and find out for themselves, we fear that such misplaced persons will gain little from this book.

The information is tabloidal, sometimes even awkwardly abbreviated, and the compilation bears internal evidence of the lack of that fuller knowledge so essential in anyone who professes to direct the teacher.

The motive is worthy, and as the book was written "for love" we should, perhaps, modify the criticisms that suggest themselves at once. But *gamma* is not the brightest star in Corona (p. 29), nor is Sirius a notable Algol variable, as might be deduced from p. 40; and objection may be taken to "astrology" as a translation of "L'Astronomie."

The children under the author's tuition probably enjoy their astronomy lessons immensely, and he is to be congratulated upon the modest but effective equipment so thoughtfully provided for them. We would that other teachers could be induced thus to recognise the wonderfully educative potentialities of astronomy, but we fear that, despite the excellent intention, this small book can do but little to further the recognition.

(2) As a practical naval instructor, Mr. Weatherhead was asked to lecture to a number of army officers on the use of the stars as guides in night marches, and he now gives the general public the benefit of his admirable notes. A brief introduction, directions as to how to identify the chief stars, and a key to the nomenclature of them, are followed by some excellently clear charts showing the brightest, most conspicuous groups. A few tables and examples make it clear how to find north or south by three of the simplest methods. All interested in the stars apart from their

physical features will find the pocket-book instructive and interesting.

(3) Dr. Stroobant's annual summaries of the most important results obtained in astronomical research each year are models of concise and careful compilation, in which the general reader, as well as the professional astronomer, will find much to interest and instruct.

Limitations of space forbid any extensive *résumé* or discussion of the various sections here, but, whether it be in solar physics or in astronomy of position, it would be difficult to point to any result of value that is not included. In the present volume, as one would naturally expect, Halley's comet is given a prominent place, the bringing together of the most important observations and results occupying about sixty pages; the history of the 1909–10 apparition is brought up to the end of July, 1910, and illustrated by several photographs and charts. W. E. R.

OUR BOOK SHELF.

Inorganic Chemistry for Schools. By W. M. Hootton. Pp. viii+408. (London: Edward Arnold, n.d.) Price 3*s.* 6*d.*

The author of this volume has exercised a considerable amount of ingenuity in illustrating his subject by reference to many of its most interesting technical applications. His own knowledge is evidently extensive and up-to-date, and it is therefore all the more to be regretted that he should have adopted a method of teaching which is radically bad and indefensible. As in so many other cases of the kind, he has evidently sacrificed sound method to the demands of those who require "a sufficient preparation for the London Matriculation (new syllabus), Northern Universities Matriculation, and Army Entrance Examinations in chemistry," compressed into a two years' course, and has adopted a system which approaches perilously near to "cramming" pure and simple.

Formulæ are introduced on p. 48, but the pupil has to take them as *ex cathedra* pronouncements until on p. 261, almost at the close of his course, he receives a faulty explanation of the way in which they may be deduced. In the meantime, he must be puzzled by being told, on p. 51, without any explanation, that "phosphorus pentoxide (P_4O_{10}) is a white powder easily soluble in water." It would scarcely be possible to conceive a more direct violation than this of the maxim which forms the opening words of the preface, that "It is demanded of a school course of chemistry that it shall train the reason"! The imperfections of his own reasoning is shown by a statement on p. 267 that "according to Avogadro's theory, the atomic weights of elementary gases are numerically equal to their densities." Such a statement, if reproduced by his pupils, and applied by them to mercury, sulphur, and phosphorus, should go a long way towards securing their failure in the examinations for which this book is intended to prepare them. Such errors would be impossible if the author had consulted the original papers or the "reprints" by which they are now rendered so easily available.

The same lack of accuracy and absence of all historic sense is shown in a very picturesque way on p. 46, Fig. 14, where Lavoisier is represented as heating mercury in a long-necked retort by means of coal-gas, and with the help of the burner invented several decades later by Bunsen. In a book so faultily designed and containing such errors, the inclusion of diagrams of electric furnaces for the manufacture of calcium, of carbide, and of carborundum, is a very inadequate compensation. Such a volume cannot be recommended.

East and West. Comparative Studies of Nature in Eastern and Western States. By S. D. Kirkham. Pp. x+280. (New York and London: G. P. Putnam's Sons, 1911.) Price 7*s.* 6*d.* net.

The title refers to the two horizons of the American continent so widely distant that there is the greatest difference in the scenery and organic life representative of the States situated on the Atlantic and Pacific slopes. Primarily it is the author's desire to interest his countrymen in the natural beauties of the land of their inheritance. He presents a dozen sketches of typical scenes or associations with which he is familiar. The descriptions are taken from localities in the States of New York or Massachusetts, on the east, and from the States of California and Arizona on the west, where the author has evidently spent some time in leisurely observation. Cape Ann, Long Island woods, Chaparral and Arizona gardens are sufficiently explanatory as to their situation; other localities described are the forest-clad waterways in the Adirondacks, the "finger-lakes"—so called on account of their configuration—in New York State, and the Elysian fields, situated in this case in the Santa Inez valley in California.

The sketches or impressions relate almost entirely to natural artistic effects, plant associations, or the habits of birds; they will appeal with special force to the traveller who has trodden paths remote from civilisation. To English readers many of the names of birds and plants will be a puzzle; chickadee, road-runner, phœbe, and vireo are strange; similarly madrona, bay berry, and hobble bush require translation. An appendix of scientific names would add materially to a better understanding of the text. It is evident that the author has found greater diversity and brilliancy in the plant- and bird-life in the western States, for which reason the later sketches are the more attractive and illustrative.

Columbia University Contributions to Anthropology. Edited by Franz Boas. Vol. ii., Kwakiutl Tales. By Franz Boas. Pp. viii+495. (New York: Columbia University Press; Leyden: E. J. Brill, Ltd., 1910.)

This volume is the first to appear of a projected annual series under the general editorship of Dr. Franz Boas, and forms, with tales previously published by him, a large mass of material for the study of the myths of the Kwakiutl, who live between River Inlet and Cape Madge, on the coast of British Columbia. There are here many interesting parallels to legends of Japan, Australia, and other distant lands, as well as racial and local tales, often humorous, of culture-heroes and sorcerers, and naïve explanations of the origins of dances and ceremonies, and of animals and natural objects. The usefulness of the collection could have been much increased, especially for readers not familiar with American-Indian lore, by multiplying the footnotes, and by an introduction such as Dr. Boas himself supplied to Teit's "Traditions of the Thompson River Indians," for, as pointed out by him elsewhere, the traditions and organisation of the tribe are mutually explanatory, and here we have the traditions only.

The first tale, for example, has no notes, and yet the general reader can scarcely be expected to know that the victor who takes unawares an adversary more powerful in magic is a tribal culture-hero, and that the double-headed serpents forming the belts and canoes of the rivals are each the dread sisiul, which has a horned snake's head at each end, and a two-horned human head in the middle. It is an unlucky mischance, in a volume otherwise so carefully produced, that four lines which should begin p. 451 are printed at the top of p. 452, and it is only appreciation of the great value for reference of a series for which we are heartily grateful to Dr. Boas and his university that prompts us to beg that no future volume shall, like this, be without an index.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Nature of γ Rays.

DR. E. VON SCHWEIDLER pointed out in 1905 that an effect (such as ionisation by α rays) due to a finite number of independent events would be subject to fluctuations. The mathematical theory of the different experiments which have been made to exhibit this with light, α and β rays, has been developed by Mr. N. R. Campbell.

One of us began some preliminary experiments in 1908 at the Cavendish Laboratory to detect discontinuous effects with γ rays. Two forms of apparatus have been used in our experiments. In the first, two similar cylindrical ionisation vessels were placed close together with their axes directed to the source of the γ rays—some radium.

If the γ rays have a spherical wave front, the two similar vessels, being symmetrically placed with respect to the source, should be equally effected by the γ rays, though the resulting ionisation due to the equal effects may not be the same. If, on the other hand, the γ rays are any type of corpuscular radiation (in the Newtonian sense) made of a finite number of particles, the effect in the ionisation vessels would be unequal over short periods of time. To compare the number of ions produced in the two vessels, the electrodes were connected to an electrometer, one vessel being positively, the other negatively, charged. The positive and negative currents from the two cans were balanced as closely as possible for long periods of time, and so there was no large steady drift of the electrometer. The quartz fibre electrometer (Proc. Camp. Phil. Soc., xv., p. 106, 1909) showed fluctuations in the balance.

In the second apparatus a box-shaped ionisation can with a central plane electrode was used. The positive ions formed in one half of the can were received on one side of the flat electrode, the negative ions from the other half of the can on the other side of the electrode. Large fluctuations were observed when the source of γ rays was placed in the plane of the electrode outside the can. This experimental result would be explained if (1) the γ rays from radium are projected particles, or (2) if the number of ions produced in air by a constant source of γ rays is subject to fluctuations.

We are continuing the experiments with the view of determining what part each of these factors plays in producing the fluctuations observed.

The Occurrence of a Fresh-water Medusa (Limnocnida) in Indian Streams.

MR. S. P. AGHARKAR, lecturer on biology in the Elphinstone College, Bombay, who has been kind enough to undertake the collection of fresh-water invertebrates on behalf of the Indian Museum, has recently sent me several specimens of a medusa from small streams in the Western Ghats. Although they were taken at so great a distance from the west coast of India, it is important to note that these specimens were obtained from a river-system which flows across the Indian Peninsula and reaches the sea more than 500 miles away on the shores of the Bay of Bengal. Mr. Agharkar writes as follows:—

"The Medusæ were collected in deep pools of the Koyna and Yenna rivers (tributaries of the Krishna). I was not able to get the hydroid form. I was told that the Medusæ (called flowers or wheels by people) occur regularly in these rivers every dry season. Probably they are present all the year round, only they are swept away by the current during the rainy season and a short time after that. During the dry season, when the stream becomes more or less a succession of deep pools, they become very marked."

In the structure of the manubrium and digestive system, the position of the gonads, the structure of the tentacles, and the form of the umbrella these medusæ agree precisely with *Limnocnida tanganyicae*. As regards generic identity, there can, indeed, be no doubt, and there is nothing in the specimens before me to suggest even a specific difference. They are not, however, in a particularly good state of preservation, having suffered somewhat in the post, and the question of specific identity may be left unanswered until after an examination of fresh specimens, which I anticipate no difficulty in obtaining at a suitable season. In the meantime, I should be extremely grateful for well-preserved specimens of Limnocnida from Africa in order that an actual comparison may be made.

Indian Museum, Calcutta, July 7.

Standard Time in Portuguese Territories.

I BEG to inform you that Standard Time will be in use from January 1, 1912, throughout Portuguese territories, as follows:—

h.	m.	
8	0	E. Macao, Portuguese Timor.
5	0	E. Portuguese India (provisionally 5h. 30m. E.).
2	0	E. Portuguese East Africa.
1	0	E. Portuguese West Africa.
0	0	(Greenwich, or West Europe).—Portugal, St. Thomé and Principe Islands, Whydah.
1	0	W. Madeira, Portuguese Guinea.
2	0	W. Açores and Cape Verde Islands.

This observatory remains entrusted with the determination and the telegraphic transmission of Standard Time to the whole country, to the Lisbon time-ball, and to the time station at the Meteorological Observatory, Ponta Delgada (St. Miguel, Açores).

I take this opportunity to state also that the most trustworthy geographical latitude of this observatory is lat. N. 38° 42′ 30·5″ (prime vertical, meridian, and zenith telescope series of observations from 1872 to the present, printed or unprinted), and that the designation "*Lisbon, Tapada,*" is now the most suitable for it, being similar, for instance, to "Florence, Arcetri," or "Naples, Capodimonte."

For two years a new astronomical observatory has been in existence and at work at Lourenço Marques; the geographical coordinates are (transit pier):—

Lat. S. 25° 58′ 4·9″ ± 0·2″ (meridian observations by Captain Gago Coutinho).

Long. E. 32° 35′ 30·4″ ± 0·05″ (moon culminations, simultaneously here, and geodetic connection with the Cape).

Altitude (top of pier), 59 metres.

CAMPOS RODRIGUES.

Observatorio Astronomico de Lisboa, Tapada-Lisboa-Portugal, July 25.

Obsolete Botanical and Zoological Systems.

WOULD some naturalist with a taste for bibliography be so good as to mention books which contain tables of obsolete botanical and zoological systems? Agassiz's "Essay on Classification" and the article on Zoology in the "Encyclopædia Britannica," ninth edition, furnish useful examples, but more are desired.

L. C. M.

LOLO AND BORDER TRIBES OF WESTERN CHINA.[1]

THIS book deals mainly with the little-known Lolo and neighbouring tribes in western China, who are believed to represent some of the pre-Chinese aborigines of that empire. The journey into the steppes of Tibet, which gives the title to the book occupies less than a sixth part of the volume, and is based upon notes by the late Lieutenant J. W. Brooke, upon his journey along the well-known route from Koko Nor to Nagchuka. Foiled in his attempt to enter Central Tibet in 1907, Lieut. Brooke, on the advice of Mr. Fergusson, turned his attention to the Lolo country in western China to the north of the Yangtse, and the present volume is issued as a memoir of that adventurous young traveller, who met a tragic death at the hands of the wild Lolos. In Mr. Fergusson, the resident missionary of Chengtu, the capital of Szechuan, Lieut. Brooke has found a sympathetic and competent editor, whose own notes indeed form the most important part of the book, based as they are upon a long personal acquaintance with those regions.

FIG. 1.—Lolo Chief hostages. From "Adventure, Sport, and Travel, on the Tibetan Steppes."

The warlike Mantze tribes, now settled in China, preserve the tradition of having come from Tibet, and this is generally supported by their physical features, their language, customs, and religion, as they are professedly lamaists. The part of Tibet, however, to which they are assigned by Mr. Fergusson is not clearly evident. They are stated to be "emigrants from Gari, a place north of Siklim [*sic*], near Camba Dsung . . . on the upper slopes of the Brahmaputra." Possibly the deserted town of Ge, near Khamba Jong, to the north of Sikkim, may be intended. The Tibetan legend of its desertion has been recorded by Lieut.-Colonel Waddell in his "Among the Himalayas" (p. 196), and is in keeping with a possible emigration to China.

The Lolo tribe and its affinities are less well known. This tribe, or rather the series of tribes bearing this general title, occupies the more inaccessible mountains in western China, on both sides of the Yangtse, in the provinces of Szechuan and Yunnan. It is the former section of the tribe which is dealt with here. The aggressive turbulence of this wild tribe has prevented travellers from penetrating the country to any great distance, though it and its people are not so wholly unknown as is represented in this book. M. P. Vial, in his "Les Lolos" (Shanghai, 1898), Colborne Baber, T. de Lacouperie, Colquhoun, and latterly Dr. Logan Jackson, in his "Back Blocks of China," have contributed to advance our knowledge of the subject; but Mr. Fergusson now adds much that is both new and interesting. These wild Lolos have hitherto preserved their independence, though in order to repress to some extent their habitual bloody raids into settled Chinese territory, hostages are taken from the frontier villages for their good behaviour.

FIG. 2.—Takin (*Budorcas sp.*). From "Adventure, Sport, and Travel, on the Tibetan Steppes."

"These hostages are representative chiefs who take turns of imprisonment to go pledge for the good conduct of the tribes. These chiefs are paid a nominal sum by the Chinese Government for thus serving a period in durance, and after serving a term of three

[1] "Adventure, Sport, and Travel on the Tibetan Steppes." By W. N. Fergusson. Pp. xvi+343. (London: Constable and Co., Ltd., 1911.) Price 16s. net.

months they are allowed to be relieved by other representative men of their tribes." The accompanying photograph depicts some of these hostages, who may be taken as types of the tribe.

The people live in rude huts and seldom build substantial houses, like the settled Mantze. Whilst termed "Lolo" by the Chinese, they call themselves "Nosu," alternatively spelt "Nossu" and "Nesu." The former appellation appears to us to be the same that is applied by the Tibetans to these and other savage tribes on their borderland, namely "Lalo" (spelt *kla-klo*). Their features seem to us to resemble those of the head-hunting Indo-Mongolian tribes of Assam, called "Nāga" by the Indians. They are said by Mr. Fergusson to be "certainly not" Tibetan. Their mode of tying up the hair (see Fig. 1) is suggestive of that of the Lepchas, whose non-Tibetan and proto-Malayan affinities have been indicated by Lieut.-Colonel Waddell.

Lieut. Brooke won the distinction of being "the first Englishman to shoot" that rare Eastern antelope, the takin (*Budorcas sp.*: see Fig. 2), and to study it in its haunts, of which we have here a detailed description.

Mr. Fergusson furnishes a detailed map of the southern part of the country plotted out by himself, a valuable contribution to Chinese geography.

RUBBER CULTIVATION.[1]

TO students of African rubber, the volume (1) by Dr. Cuthbert Christy will prove of considerable value. Dr. Christy was for a considerable time connected with the Mabira Forest Rubber Company, Uganda, and had many opportunities of obtaining first-hand information regarding the environment most suitable for Funtumia, the yields of rubber obtainable, and the chemical and physical problems associated with the coagulation of the latex. The author first gives a general account of the African rubber industry, and shows the fluctuation in exports of raw rubber from the Gold Coast, Sierra Leone, Southern Nigeria, Liberia, the French Ivory Coast, Togoland, the Kameruns, the Belgian Congo, and East Africa. There is, however, nothing which would lead one to expect that Africa will henceforth increase its crop of raw rubber, despite the large number of vines and trees which have been planted during the last few years.

A considerable amount of information is given on the botany, life-history, and structure of *Funtumia elastica*, Stapf, known in the early days as *Kickxia elastica*, Preuss. It appears that in Uganda this tree loses most of its leaves during the dry, hot period of January to March. It is, however, never quite leafless. Young shoots are produced and old leaves fall more or less freely at all seasons of the year. The trees flower from November to December, and the fruits are mature six months later. The author is of the opinion that the wind-blown seeds carried beyond the limits of the forest never produce permanent plants, owing to the long grass covering the country outside the forest areas. In the scrub formation (Acanthus) the seeds appear to have a better chance. The permanent Funtumia trees are found largely in belts where the forest is hilly; though these belts are usually well-defined, their distribution appears to be influenced by water-level conditions. In Uganda the trees appear to grow in large groups varying from family parties to large belts and areas several square miles in extent; in some cases the growth is entirely made up of this species, but in other cases the species is scattered.

Photograph by E. Brown.

FIG. 1.—Chagwe Forests, Uganda. An area cleared of underwood and seed sown at stake. Nearly all the trees in view are *Funtumia elastica*. From "The African Rubber Industry and *Funtumia elastica*."

After discussing the distribution, climate, and soils for Funtumia, the author goes into detail regarding other species of Funtumia—*Funtumia latifolia*, and *Funtumia africana* the latex from which, however, possesses very little rubber, though it may be used.

[1] (1) "The African Rubber Industry and *Funtumia elastica* ('Kickxia')." By Dr. C. Christy. Pp. xvi+252. (London: John Bale, Sons, and Danielsson, Ltd., 1911.) Price 12*s.* 6*d.* net.
(2) "The Physiology and Diseases of *Hevea brasiliensis*, the Premier Plantation Rubber Tree." By T. Petch. Pp. iv+268. (London: Dulau and Co., Ltd., 1911.) Price 7*s.* 6*d.* net.
(3) "The Whole Art of Rubber Growing." By W. Wicherley. Pp. 154. London: West Strand Publishing Co., Ltd., 1911.) Price 5*s.* net.

even intentionally, by natives for adulteration. The chemical and physical characters of the latex and the methods of coagulation have received attention by Dr. Christy in Uganda, and his chapters on these subjects provide much interesting matter. The book is, however, one which must necessarily appeal to a limited section owing to the relative unimportance of the species dealt with as sources of rubber. It is true that Funtumia has supplied large quantities of Lagos-silk rubber in the past, and will continue to do so for many years to come. Nevertheless, it is a species which does not lend itself to cultivation; wherever it has been tried—in Ceylon, Malay, Samoa, New Guinea, &c.—its growth has been so slow and the yields so small that planters have abandoned all hopes of ever cultivating the tree profitably.

(2) This a book which deals with a very special side of the rubber industry, and is mainly of interest

FIG. 2.—High-tapping Funtumia (Mabira Forest). From "The Whole Art of Rubber Growing."

to planters in the East, and to students of mycology elsewhere.

After giving a general introductory statement on the structure of *Hevea brasiliensis*, its latex and rubber, and the tapping systems employed on plantations, the author comes to the special part for which he is qualified to deal, viz., plant sanitation from the mycological point of view. Leaf diseases—*Helminthosporium heveae and Gloeosporium heveae*—are dealt with, and the result of an examination of fallen leaves is described, it being shown that conspicuous defoliation was not due to these diseases. Among root diseases, the author pays particular attention to *Fomes semitostus*, which is now reported from most estates in Ceylon, Malaya, Sumatra, Java, and even Africa; to the Brown root disease—*Hymenochaete noxia* and to *Sphaerostilbe repens*, and he deals also with numerous miscellaneous fungi observed by himself and others on the roots of this particular tree.

Stem diseases are dealt with in a separate chapter. *Phytophthora Faberi* is described as a parasitic fungus affecting the stem and fruit of *Hevea brasiliensis*; it has also been associated with cocoa, with which rubber trees are often interplanted. Pink disease—*Corticium salmonicolor*, B. and Br.—formerly extensively known in Java as *Corticium javanicum*, Zimm., is also described. This disease appears to originate generally in the fork of the tree or where several branches arise close together from the main stem; it has caused considerable damage, especially in Java and Malaya. A new stem canker, *Coniothyrium sp.*, is reported to have made its appearance on a Ceylon estate in 1909; this apparently appears on young green shoots, the first sign of its appearance being the production of hard, yellowish patches due to the development of a corky layer under the epidermis. Stem diseases of seedlings and the sterilisation of nurseries also receive attention.

Some abnormalities in Hevea in the form of twisted seedlings, nodules, and twisted stems (fasciation) are well illustrated, and should prove of interest to teratological students.

Much of the information has already been published in Ceylon, but this should not seriously detract from its value. References to literature on each subject are freely given, and in this way the reader is enabled to secure further detail if he desires to do so.

It is to be regretted that this book deals only with diseases due to fungi and bacteria. The book would have been much more useful to planters and to others in Europe had it taken into consideration the numerous animal pests which at the present time are a source of great anxiety to all cultivators of rubber trees. It is the only book of its kind, and should find a place in the library of all who wish to maintain an interest in tropical agriculture.

(3) Mr. W. Wicherley's booklet covers a series of general problems connected with *Hevea brasiliensis*, *Manihot glaziovii*, *Ficus elastica*, *Castilloa elastica*, *Funtumia elastica*, and three of the new Manihots. The majority of the essays have already appeared in the London Press. The writer acknowledges his indebtedness to the officials of the Ceylon Botanic Gardens, and pays a tribute to past and present officers for the work they have done in connection with this cultivation.

The statistics given of planted acreages and probable future yields (p. 144) are, in our opinion, calculated to give a wrong impression; the acreages now under rubber are, and the future annual crops will be, much larger than those suggested by the author.

There are some interesting illustrations, especially those showing high tapping of Funtumia trees in Uganda, and of methods of tapping adopted on trees of *Manihot dichotoma*. The book deals almost exclusively with matters relating to plantation subjects, and will be found useful by the general reader who is anxious to acquire a general knowledge of this section of the industry.

THE COAST OF NORTH DEVON.[1]

THIS is a book which should be in the hands of all who are interested in the scenery of the British Isles, and especially of those who intend to visit any of the holiday resorts on the northern or western coasts of Devon. It is not an ordinary guide-book, and it is not a geological treatise, but a description and explanation of some of the most picturesque and interesting coast scenery to be found in England or Wales.

[1] "The Coast Scenery of North Devon." Being an Account of the Geological Features of the Coast-line Extending from Porlock in Somerset to Boscastle in North Cornwall. By E. A. Newell Arber. Pp. xxiv+261+2 sketch maps. (London: J. N. Dent and Sons, Ltd., 1911.) Price 10s. 6d. net.

It includes all information necessary as to the best means of seeing the different parts of the coast-line, and all the geological information that is requisite for understanding the structure of the country, the flexuring of the rocks, and the features which the cliffs present. Mr. Arber points out that one of the special features of this coast is the number of coastal waterfalls. "By this term," he says, "we imply waterfalls cut by streams in their passage over the sea-cut cliffs to the beach. Several of these coastal falls are of considerable height, and form striking landmarks on the coast. Their features, however, are so varied that no two of them are exactly alike in all respects. They show all stages in the evolution of a waterfall from its birth to its senile period of old age and decay."

Mr. Arber divides his subject, that is to say, the coast-line, into six districts, beginning with the most easterly, near Porlock, in Somerset, and ending with the most southerly, near Boscastle, in Cornwall. He mentions the best headquarters for each, and then describes the rocks seen in the cliffs, the ridges and headlands, the streams, and the waterfalls, all of which are illustrated by excellent photographs, fifty-nine in number, and two of these, reproduced in Figs. 1 and 2, will show the reader what kind of scenery is to be found in the area described.

The chief peculiarity of this area is that the two main watersheds are, roughly, parallel to the coast, and seldom more than three miles away from it. We have consequently the curious arrangement of a number of streams rising near the coast and flowing inland, and of a still larger number of short streams flowing from the watersheds to the cliff-line, over which most of them fall in one or more cascades. The explanation of this arrangement is that the sea has invaded and destroyed the country which originally lay outside the main watersheds, and is now advancing on the actual watershed ridges. This is illustrated by a clear map of the whole drainage system of the area.

Mr. Arber writes, on p. 20, as if there were only one watershed, and it is true that there are secondary watersheds which nearly unite them, but, as a matter of fact, there are two main watersheds separated by the Valley of the Taw, and it is doubtful if they were ever united. The Exmoor ridge may have been prolonged indefinitely westward, while the Hartland watershed must always have been truncated by the continuation of the Taw valley along the floor of Barnstaple Bay, before the recent depression or subsidence enabled the sea to advance so far over the western land.

This comparatively recent subsidence is a very important factor in the explanation of the present peculiar drainage system, and of the features presented by the coast-line, but Mr. Arber has not laid sufficient emphasis upon it. He refers to it in several places, but he also refers to what he terms the "recent elevation" of some parts of the coast, leaving the reader to infer that the one movement was as recent as the other. He should have made it clear that the upheaval which lifted the "Raised Beaches" to their present position, or rather to a still higher level, was antecedent to the subsidence which is indicated by the drowned valleys and the submerged forests. When the book reaches a second edition Mr. Arber will do well to add a short account of the Pleistocene history of the country to his introductory chapter.

Of the coast near Hartland Point Mr. Arber writes that it includes some of the wildest and grandest cliff scenery to be met with in the whole of Devon, and that as regards its coastal waterfalls he believes it to be quite unique so far as Britain is concerned. One

FIG. 1.—The valley of Milford Water and the head of the First Fall, from the cliffs above Speke's Mill Mouth, looking east (Hartland District). From "The Coast Scenery of North Devon."

of these waterfalls is that of Milford Water, and is shown in Fig. 1. This, moreover, is only the first fall of the stream from a level of about 160 feet above the sea; below it is a cañon, in which are three smaller falls before the stream reaches the beach. Fig. 2 is a side view of the same fall from below, showing the synclinal flexure of the rocks at this point, and the manner in which the stream turns at right angles along the syncline. After going for 132 yards to the south it again turns west across the strike of the rocks, a curious and interesting instance of the relation of stream channels to rock structure.

Part ii. of the book deals with some features of special geological interest, these being the marine erosion of folded rocks, sea-dissected valleys, and the evolution of coastal waterfalls. The author points out that the usual text-book explanation of bays and promontories along a sea-coast is not always the true one. They do not always coincide with the outcrops of softer and harder rocks. Some of the irregularities of the Devon coast seem to be due to the influence of previously existing physiographic features, the bays coinciding with the sites of valleys and the promontories with the dividing watershed ridges. Others are due to the influence of the flexures, and he finds that the anticlines are more stable under the action of sea erosion than are the synclines, while on land under the action of subaërial agencies the reverse is the case.

FIG. 2.—The First Fall of Milford Water and the synclinal fold, looking north. From "The Coast Scenery of North Devon."

Mr. Arber has certainly succeeded in showing how many points of interest there are along this piece of coast-line, both for the geological student and for the intelligent tourist. A. J. J.-B.

NOTES.

THE present summer is establishing a record for its high temperatures, and in many places for its persistent drought. At Greenwich the mean temperature for July was 68·3°, which is 4·6° above the average for the past sixty years. The mean of the day temperatures was 81°, and of the night temperatures 55·5°. There were nineteen days during the month with the shade temperature above 80°, and three days above 90°. This is the greatest number of days in July above 80° since 1868, and the third highest number since 1841. The highest shade temperature during the month at Greenwich was 95·6° on July 22, and the only two instances of a higher temperature at any period of the year are 97·1° on July 15, 1881, and 96·6° on July 22, 1868. There were seven days after July 20 with the thermometer in the sun's rays about 150°, and on July 22 the black bulb thermometer registered 161°. The duration of sunshine for the month was 331 hours, which is nearly 100 hours more than the average. No rain was measured until July 24, the period of drought being the longest in July since 1887. The aggregate rainfall for the month was 0·26 inch, which fell on three days. This is the driest July since 1864, and there is no other July so dry since 1841. At Bath, July was absolutely rainless. The reports received by the Meteorological Office give the following additional high temperatures:—On July 21 the thermometer registered 90° both at Oxford and Margate, on July 22 94° at Margate, on July 29 93° at Bath and 91° at Oxford. The type of weather was anticyclonic almost continuously throughout the month, and the region of high barometer readings extended over a large part of western Europe, where exceptionally high temperatures occurred almost throughout the month. At Rochefort the thermometer registered 93° on July 6, at Lorient 95° on July 7, 97° on July 8, and 99° on July 9. On July 14 the temperature at Rochefort was 100°, and at Stockholm 95°. Paris had a temperature of 96° on July 22 and 23, Frankfurt 100° on July 23. From July 24 to 29 several stations in France and Belgium had temperatures from 95° to 98°. Some exceptionally severe thunderstorms occurred during the month; on July 28 1·1 inches of rain fell in fifteen minutes at South Kensington, and on July 29 2·14 inches fell in 2½ hours at Kilkenny.

FOR the moment the remarkable archæological discoveries in Corfu have thrown other work in the eastern Ægean into the shade. But in various parts of this area, in the Greek mainland and islands, much progress has been made, the results of which are described in an interesting article in *The Times* of July 31. The Greek Archæological Society has restored the Propylæa on the Athenian Acropolis; repairs have been carried out at Mycenæ; and the museum at Olympia has been converted into a safe receptacle for its treasures. The French Mission at Delos has unearthed images of Egyptian and Syrian gods which illustrate the adoption of foreign cults into the religion of Greece; and some progress has been made at the island of Levkas (Santa Maura), which Dr. Dörpfeld believes to be the Homeric Ithaca. The British School has been at work on the Menelaion, the tomb of Menelaus and Helen at Sparta. Phylakopi, in Melos, the seat of an early trade in weapons of obsidian, has yielded some good vases imported from Crete. An appeal is now made for help towards the explorations in Macedonia, conducted by Messrs. A. J. B. Wace and M. Thompson, where important results in the examination of prehistoric, classical, Byzantine, and mediæval antiquities may be confidently expected.

PROF. CZERMAK, of the Brünn High School, who died on July 11 at the age of seventy-seven years, left, says the *Revue Scientifique*, a million crowns to the Vienna Academy of Sciences.

IT is announced in *The Times* that M. Ernest Mercadier, formerly director of studies at the École Polytechnique, died on July 27 in his seventy-sixth year. M. Mercadier entered the French telegraph service in 1859, and held the post of director of telegraphs during the siege of Paris, when he likewise organised the military telegraph service. After the war he became professor of physics at the École Supérieure de Télégraphie, and in 1881 he was appointed director of studies at the École Polytechnique, where he remained until the end of the year 1903. He was an honorary member of the Institution of Electrical Engineers and of the International Society of Electricians.

We regret to learn that Mrs. Helena B. Walcott, wife of Mr. Charles D. Walcott, formerly director of the United States Geological Survey, now secretary of the Smithsonian Institution, was instantly killed in a railway accident at Bridgeport, Connecticut, on July 11. Mrs. Walcott had been ardently and actively interested in the scientific work of her husband. In 1888 she accompanied him to Newfoundland, where they worked out together the key to the succession of the Cambrian formations of the North American continent. They then crossed to Wales and studied the classical Cambrian sections. For eighteen seasons she accompanied Mr. Walcott on his expeditions in connection with geological researches in various regions of eastern and western United States and Canada. Since his appointment as secretary of the Smithsonian Institution she had been greatly interested in the development of the United States National Museum and in the general study of museum systems. Possessed of unusual charm of person and manner, Mrs. Walcott's death is a heavy blow to a large circle of friends and acquaintances.

The fifth annual meeting of the Italian Society for the Advancement of Science will be held in Rome on October 12–18, under the presidency of Prof. G. Ciamician. The sections of the association, with their presidents, are as follows:—mathematics, astronomy, and geodesy, Prof. G. Castelnuovo and Prof. A. Di Legge; physics, Prof. P. Blaserna; applied mechanics and electrotechnics, Prof. C. Ceradini; pure and applied chemistry, Prof. E. Paternò; mineralogy and geology, Prof. R. Meli; geography, Prof. E. Millosevich; zoology, anatomy, and anthropology, Profs. G. B. Grassi, F. Todaro, and G. Sergi; pure and applied botany, Prof. R. Pirotta; physiology, Prof. L. Luciani; pathology, Profs. A. Bignami and E. Marchiafava; history and archæology, Profs. G. Beloch and L. Pigorini; philology, Prof. I. Guidi; social science, Prof. M. Pantaleoni; philosophy, Prof. P. Ragnisco. Several lectures on subjects of wide scientific interest will be delivered to general meetings of the association as a whole, and others to joint meetings of sections concerned with related subjects. Full particulars may be obtained from the secretary, to whom contributions for the sections should be addressed, Prof. V. Reina, Via del Collegio Romano 26, Roma.

In the first part of the second volume of the Museum Journal of the University of Philadelphia we find an interesting account of an exploration of the remarkable ruined city of Chichen Itza, in Yukatan. The place is familiar to students of Central American archæology from the enthusiastic accounts of Stephens with Calderwood's drawings, the photographs and measurements of Maudslay, and the sketches of Holmes. These, however, only imperfectly represent the decoration scheme, and for the frescoes and wall sculptures the only existing record is the fine series of water-colour drawings by Miss Adela Breton, who with rare devotion has succeeded in reproducing the beautiful work of the ancient artists. These drawings are as yet unpublished, and all students of art will join in the hope that arrangements may soon be made for their publication.

It is a good omen for the scientific value of the reports of the recent census of India, which are now in process of compilation, that Mr. E. A. Gait, the census commissioner, has prepared for the use of the provincial superintendents an abstract of several important reviews by eminent Continental anthropologists of the report by Sir H. Risley on the census of 1901. These criticisms are of much importance, and direct special attention to certain problems for the solution of which the reports of the last census may be expected to supply valuable material. Of special interest are the suggestions of Herr Baelz on the peculiar skin patches which seem to be a race characteristic of the Mongolians; Walcher's review of the results of artificial changes in the skull form; and Surgeon Captain E. P. Maynard's remarkable discovery among some coolies at the tea gardens of Assam of a curious form of melanoglossia which seems to be peculiar to certain of the Munda tribes of Chota Nagpore, and may be of great importance in identifying the modifications of this ethnical type.

In vol. iv., part iii., of the Transactions of the Hull Scientific and Field Naturalists' Club Mr. T. Pickersgill describes a remarkable collection of Roman coins made at South Ferriby by the well-known Thomas Smith, locally known as "Coin Tommy," which has recently been acquired by the Hull Municipal Museum. South Ferriby, lying on the direct route between Lincoln and York, was obviously a place of considerable importance in Roman times, and the interest of this collection lies in the fact that its 2600 specimens practically cover the whole period of the Roman occupation of north Lincolnshire. It begins with a coin of the Emperor Trajan (A.D. 98), and extends to the time of Honorius (A.D. 395–423), in whose reign the Romans finally withdrew from Britain. The collection includes the coins of thirty-nine emperors and members of their families, several of the wives of the emperors being represented. Mr. Pickersgill gives a full catalogue of these coins, with details of their mintage, and supplies two sheets of photographic reproductions of the most typical specimens, a valuable monograph which will be of interest to all numismatists.

In *The Eugenics Review* for July (x., No. 2) Sir Thomas Oliver directs attention to the disastrous effects of lead-poisoning on the race, particularly among potters. Lead-poisoning, insufficient definitely to cripple the workers, has a disastrous effect on the reproductive organs; females who work in lead before marriage miscarry twice, and females working in lead after marriage miscarry three times, more frequently than those engaged in ordinary housework. A high percentage of children born alive to lead workers die shortly after birth and during the first few months of life. Some of the worst effects of lead-poisoning are to be seen among the small pottery manufacturers of Hungary, of which Sir Thomas Oliver gives a graphic account.

Under the title of "The Hunted Otter," the Animals' Friend Society, Kingsway, W.C., has published a pamphlet urging the total prohibition of otter-hunting. While all, we hope, will support the proposal to establish a close time during the breeding season, it by no means follows that public opinion will demand the entire abolition of the sport of otter-hunting.

The Victorian Naturalist for June contains an obituary notice of the late Mr. A. O. Sayce, who was appointed demonstrator and assistant lecturer in bacteriology in Melbourne University six years ago. In addition to bacteriology, Mr. Sayce devoted special attention to crustaceans, on which he wrote numerous papers, the most important being one on the new malacostracous genus Koonunga. In recognition of the value of his work, Mr. Sayce was elected some years ago an associate of the Linnean Society of London.

In the July number of *The Museums Journal* Mr. C. O. Waterhouse directs attention to the urgent need for a very great extension in the space allotted to the study series of insects in the natural history branch of the British Museum—a subject which appears to have been in some degree overlooked during the recent discussion with regard to the disposal of the ground at the back of the building. At present the collection is housed in rooms originally described as workshops, where it is crowded to an almost unimaginable extent. The writer pleads for two new galleries for the entomological study series, and gives two alternative plans for such extension. In the second of these it is suggested that the present main front of the building should be continued to Queen's Gate, and the continued galleries used for public exhibition, with a further extension from the present west tower, at first northward and then westward, so as to form an open quadrangle facing Queen's Gate, the entomological collections to occupy the second floor of the latter part of the extension.

Two incidents of prime importance are recorded in the report of the U.S. National Museum at Washington for the year ending June 30, 1910, namely, the practical completion of the new buildings and the transference of a large portion of the collections, and, secondly, the reception of the natural history collections made by the Roosevelt expedition to East Africa in 1909. The latter are estimated to comprise more than 11,000 specimens of vertebrates and a large number of invertebrates, as well as several thousand plants and a few ethnological objects. It is claimed that the collection of East African mammals is probably more valuable than any similar series in any other museum. "Its importance lies not so much in the number of new forms as in the fact that it affords an adequate basis for a critical study of the mammal fauna of East Africa, and the establishment or rejection of the large number of forms which have been described, especially in recent years, from insufficient material."

In the July number of *The Zoologist* Prof. McIntosh, of the Gatty Marine Laboratory, St. Andrews, records the results of a number of experiments made in Ireland and Scotland for the purpose of ascertaining whether salmon and trout are liable to injury by the turbines so frequently used in Irish mills, many of which revolve at a very high rate of speed. So long ago as 1892 a number of similar experiments were instituted by Sir Thomas Brady, who was of opinion that very few fry survived an experience with a turbine, believing that the great majority were killed at once as they went through, their bodies dropping into the deep water as they were struck. The experiments of Prof. McIntosh give a much more favourable aspect of the matter from the point of view of the fish. It is stated, for instance, that "in all the experiments, which were twenty in number, one feature was marked, viz. the comparative ease with which healthy trout in the turbine-pits kept free from the vortex caused by the action of the turbine. They appeared to go through the turbine only when they pleased or by accident. Moreover, when circumstances were favourable, they swam out of the turbine-pit to the head-race, and thus . . . could have passed up-stream to the nearest by-wash, if such existed."

Directing attention to the varying descriptions of the manner in which fruit dispersal is effected by species of Geranium, Prof. W. Sorensen communicates the results of his own observations in the current Bulletin (No. 2) of L'Académie Royale des Sciences et des Lettres de Danemark. The details commonly overlooked are the existence of an aborted ovule, the detachment of the seed, the position of the lines of dehiscence, and the devices by which in certain species the seeds are retained temporarily in the open pericarp. The species *sibiricum* and *molle* are described as illustrative examples of the two methods of pericarp shedding, and the peculiar features of *dissectum* are noted.

A consideration of vegetative changes and the agencies inducing them, forming the subject of a presidential address delivered before the Association of American Geographers by Prof. H. C. Cowles, is published in *The Botanical Gazette* (March). Under physiographic agencies the author discusses regional and topographic successions; biotic factors are examined under the headings of humus, shade, and human agency. As an example of occasional plant plasticity, it is noted that the Douglas spruce may be a xerophytic pioneer, and then persist through successive stages of forest development, culminating in a mesophytic formation; throughout each stage it may be dominant, and yet it shows no striking change in leaf habit.

Rice cultivation in Siam provides the subject of an article contributed by Dr. C. C. Hosseus to the *Tropenpflanzer* (vol. xv., No. 6). Many varieties of rice are recognised by the Siamese, most of which fall under the common species *Oryza sativa*. In addition, three other species can be distinguished; *O. praecox* is a "wet" rice, yielding a grain very similar in its qualities to that of *O. sativa*, but is also cultivated on the mountain slopes; *O. glutinosa*, as its name implies, yields a glutinous grain, that is cooked by the tribes of the interior in bamboos, acquiring thereby a distinctive flavour; the fourth species is the "hill" rice, *O. montana*, less nutritious than ordinary rice, but preferred by the Laos tribes.

Bee-keepers should find much to interest them in No. 447 of the Farmers' Bulletin, published by the U.S. Department of Agriculture, under the title "Bees," and written by Dr. E. F. Phillips, the official expert on bee-culture. Full instructions are given for the installation, equipment, and management of apiaries, with notes on the production of honey and wax; in fact, the bee-keeper will find information on all points connected with his trade or hobby.

The mycologist of the Board of Agriculture, Trinidad, Mr. J. B. Rorer, describes a bacterial disease of plantains and bananas in the island (*Phytopathology*, i., No. 2, p. 45). The disease causes the leaves, progressively from below upwards, first to become yellow, then to droop, and finally to break off, and eventually the terminal bud is attacked, and the plant dies and rots down to the ground. The vascular bundles are filled with bacteria, pure cultures of which were obtained, and inoculations of them into healthy plants reproduced the disease.

The flowers of Chaucer form the subject of an article by the Rev. H. N. Ellacombe now in course of publication in *The Gardeners' Chronicle*. In the issue of July 22 it is pointed out that although the box is an indigenous tree, it never had an English name, "box" being an Anglicised form of the Latin *buxus*. Chaucer mentions cedar, but apparently never saw a specimen. The same issue includes an illustrated account of the rock-garden in course of construction for the Royal Horticultural

Society at Wisley. The rocks are Wealden sandstone, some of the rocks weighing as much as a couple of tons. A large moraine forms one of the subjects of interest, below this being a bog-garden, watered from the source which supplies the moraine.

THE poultry investigations at the Maine Experiment Station are well known, and the recently issued bulletins will be read with interest by those engaged in similar work elsewhere. Messrs. Pearl, Surface, and Curtis have compiled an account of the common poultry diseases in a bulletin which must be regarded as one of the most useful yet issued for the practical man. The symptoms are clearly described, and such remedies as are known are indicated. In a more technical publication Dr. Pearl continues his discussion of the inheritance of fecundity in the domestic fowl.

THE Boyle lecture on the fertility of the soil delivered by Mr. A. D. Hall before the Oxford University Scientific Club has now been issued as a separate reprint. It is shown that Boyle and some of his contemporaries discussed the question of soil fertility, and especially the part played by nitre. The investigation was widened by Daubeny, professor of botany and rural economy in Oxford, and the real founder of a science of agriculture in this country, and in recent years has been shown to be even more complex by the intervention of the micro-organic flora of the soil. The factors determining fertility are, however, being slowly disentangled and brought under control.

THE German Mineralogical Society, which now consists of 158 members, under the presidency of Prof. F. Becke, of Vienna, at its annual meeting in September last decided on the publication of a journal, to be called the *Fortschritte der Mineralogie, Krystallographie, und Petrographie*, and the first number has just made its appearance, under the editorship of Prof. G. Linck, of Jena. It is an imposing volume of nearly 300 pages, and contains fourteen articles by distinguished members of the society. One of the earlier ones is by Prof. Baumhauer, on "Geometrical Crystallography," in which he deals with the "Law of the Complication and the Development of Crystal-faces in Zones rich in Faces," and discusses the most important recent contributions to crystallographical literature from this point of view. Then there are two articles by Prof. Mügge, of Göttingen, and Prof. F. Becke, the president, on "Twin-Crystals," in which many recent descriptions of new twin-forms are discussed and correlated, including the important work of Dr. Stefan Kreutz on twins of calcite. Another interesting and important article is that by Dr. Albert Ritzel on the "Rapidity of Crystallisation and Solution," in which the facts concerning the different speeds of growth of a crystal in different directions, and the corresponding differences in the times taken by a solvent in dissolving the material from the different faces of the crystal are carefully compiled from all the recent work on the subject, and the general results discussed. These examples will suffice to show the value of this new publication, which reminds us very much of the annual reports published by the Chemical Society, but goes further in including a considerable number of text-figures, and in embodying original results obtained by the authors themselves. We heartily congratulate the German Mineralogical Society on its venture, and shall look forward to seeing a continuation of these excellent articles, presenting in an interesting form the essence of the progress made in the subjects included in the purview of the society.

WORKS are now in operation for improving a section of the navigable channel of the Mississippi, and at the same time developing the water resources of the river by the construction of an hydro-electrical plant, consisting of a power-house designed to contain machinery driven by turbines capable of developing 120,000 horse-power. This power-station lies about midway between Kansas City and Chicago, and 140 miles north-west of St. Louis. The site of the works is at the foot of the Des Moines rapids. These rapids now are only navigable at high stages of the river, and at other times vessels have to pass round them by means of a canal having three locks. When the works are completed there will only be a single lock, of dimensions sufficient to accommodate vessels of much larger size than those which now navigate this part of the river. The works include a concrete dam 1560 yards in length and 40 feet high, and the pool above formed by the dam will constitute a reservoir extending for forty or fifty miles.

AN instructive study of the mouth of the Scheld by F. Müller appears in the June number of the *Zeitschrift fur Erdkunde*, in which the form and character of the river mouth, its tidal conditions and its development during the past five centuries, are detailed. The various towns are described, and in some cases illustrated, to show their varying fortunes during the same period. Similar studies of some British coastal settlements would form a profitable object for geographical research in this country. In the same number Prof. K. Kretschmer describes a number of early manuscript maps in the Bibliothèque Nationale at Paris, and analyses them.

THE demarcation of boundaries in Africa continues steadily, one of the most recent being that between Tunis and Tripoli. A French party carried out a geodetic and topographical survey of a zone 10 kilometres wide from Ras Ajedir on the Mediterranean coast to Ghadames, of which the position was determined to be lat. 30° 7′ 48·7″ N. and long 7° 9′ 57·9″ W. of Paris, or some 27 kilometres east of Duveyrier's original determination; the mean altitude of the oasis was found to be 340 metres above sea-level. This information, given in the April number of *La Géographie*, is supplemented in the May number by a description of the route by L. Pervinquière, who was detailed to study the geology of the country traversed.

THE Survey of India has just published an account of explorations made by Kinthup, a native of Sikkim, in Bhutar, and on the lower Tsang-po, in 1886–7. He was despatched in July, 1880, with a Chinese Lama, from Darjeeling to Tibet by the late Captain Harman, and, after being detained in slavery in the Pemakoi country, finally succeeded in returning to India. He travelled along the Tsang-po, or Brahmaputra River, from the point where it turns southward towards India to the village of Mrii Padam, which he gives as about thirty-five miles from the British frontier. Though followed under very unfavourable conditions, the line of the river is probably indicated with fair accuracy, and goes part of the way towards filling the gap which has hitherto existed in our knowledge of the course of this great waterway.

NEW isothermal charts of Africa have been drawn for the atlas which is being prepared in the Survey Department of Egypt for use in Egyptian schools, and Mr. J. I. Craig gives those for January and July in the May number of *The Cairo Scientific Journal*. Temperatures have been reduced to sea-level, the gradient being taken as $-0{\cdot}6°$ C. per 100 metres in the equatorial zone, and as $-1°$ C. per 100 metres in the drier region of North Africa, on the basis of kite observations at the Helwan Observatory. With the recent values employed the isotherms run somewhat differently from their courses as shown in earlier charts. In July the highest temperature, 34° C., lies almost wholly to the east of the Nile, the greater part of the Sahara falling between that isotherm and that of 32° C.; and in Central Africa the isotherm of 26° C. extends southward to about latitude 17° S. in the basin of the Zambezi.

THE meteorological chart of the North Atlantic and Mediterranean for August (first issue, July 13), published by the Meteorological Committee, is of special interest in connection with the recent prolonged drought. The weather charts for July 6–12, and the useful summary which accompanies them, show that throughout that period a well-developed anticyclone dominated the situation over the eastern part of the ocean and western half of Europe; the temperature rose at places above 90°, and even to 84° in Iceland. For six out of the seven days this system of high barometric pressure lay practically motionless over these islands, and at the close of the period reports indicated the continuance of anticyclonic conditions of weather on the ocean.

IN an article in *Symons's Meteorological Magazine* for July, entitled "The Disappearance of Evening Cloud at Full Moon," Mr. W. Ellis, F.R.S., endeavours (owing to a recent reference to the subject) to refute the opinion held by Sir J. Herschel and others that the full moon possesses the faculty of clearing away clouds. This fallacy, like that of the artificial production of rain, is difficult to eradicate from the public mind. Mr. Ellis has shown from the Greenwich observations that a maximum cloudiness in the forenoon and a minimum in the evening represent the usual climatic variation. A change from a cloudy to a clear state in the evening sky is much more likely to attract attention when occurring near to full moon, and this is the opinion of leading meteorologists of the present day. Dr. W. N. Shaw (Quart. Journ. R. Met. Soc., April, 1902) suggests a physical explanation of the phenomenon, viz. that a floating cloud loses heat by radiating into space more heat than it receives from the earth beneath; the water globules consequently evaporate, and the cloud will vanish. "Any effect of direct radiation of the moon may be quite properly disregarded." A more recent opinion in the same sense (to which we have before referred) is contained in Mr. J. R. Sutton's paper on the lunar cloud period (Trans. South African Phil. Soc., December, 1907).

AN article by Mr. D. Owen in *The Electrician* for July 7 places in a very clear light the importance which now attaches to the "lively dance of bright spots," first noticed by the English botanist Brown, in any liquid containing minute particles in suspension when illuminated from the side. Sixty years ago the observation attracted little attention, but recently, through the improvements which have given us the ultra-microscope, the experiments of M. Perrin and the theoretical work of Dr. Einstein, the study of the Brownian movements has thrown considerable light on the properties and motions of the ultimate particles of which matter is composed.

SEPARATE copies of several of Prof. Righi's recent papers have reached us, and to one of them, which deals with the effect of a magnetic field parallel to the axis of a vacuum tube on the electric discharge through the tube, we should like to direct special attention. If such a tube with aluminium disc electrodes 15 cm. apart is covered outside with tin foil and placed in a magnetising solenoid, Prof. Righi finds that a potential difference of 3000 volts between the electrodes, which is insufficient to cause a measurable discharge in the absence of a magnetic field, will maintain a current through the tube with a field of 1250 gauss in the neighbourhood of the positive electrode, or a field of above 5000 gauss in the neighbourhood of the negative. He is disposed to attribute the phenomena to the production of electrons at the walls of the tube by the magnetic field, and is engaged in further work to test this hypothesis.

THE remarkable influence of borax in raising the rotatory power of mannitol has been known for nearly forty years, but the exact origin of this effect has been open to question, although the combination of the mannitol with the boric acid appeared the most probable explanation. It is therefore a matter of satisfaction that the compound should at last have been isolated and analysed. As described by Messrs. J. J. Fox and A. J. H. Guage in the June number of the Chemical Society's Journal, the compound is formed, according to the equation

$$C_6H_{11}O_6+H_3BO_3=H_2O+C_6H_{15}O_8B,$$

by dissolving mannitol and boric acid in hot alcohol, filtering, and allowing to stand. The mannitoboric acid slowly separates in compact, colourless prisms, melting at 89·5°, but dissociates again when attempts are made to recrystallise it.

THE tenth volume of the Transactions of the English Ceramic Society (part i.) contains as a frontispiece a portrait of the president, Mr. H. Johnson, whilst a portrait of the first president, Mr. William Burton, is issued as a frontispiece to vol. i. The new issue includes two important technical papers on electricity for potters' machinery, by Mr. Odelberg, and on liquid fuel, by Mr. Kermode; these may be regarded as additions to a series of papers of which those on gas-firing were noted in these columns recently. Attention may also be directed to a paper by Dr. J. W. Mellor on the constitution of the kaolinite molecule, and to a paper on colour and its measurement by Mr. J. W. Lovibond. The value of the work done by this society in emphasising the importance of scientific methods in one of the leading industries of the country can scarcely be overestimated.

THE extension of the system of multiple evaporation in the manufacture of sugar has been limited by the fact that whilst the evaporation may be effected safely under normal and reduced pressures of steam, the sugar begins to decompose when steam under pressure is used. A report on the effect of high temperatures on cane sugar in solution, by Noël Deerr, issued from the Experiment Station of the Hawaiian Sugar Planters' Association, describes an investigation of considerable technical and scientific importance. It is shown that sugar inversion begins to be important at 110°, but may be checked by the addition of alkali; this causes the juice to darken, but much of the colour disappears when the alkali is neutralised, and the coloration in no way corresponds with loss of sugar. The conclusion is drawn that the local juices may be relied upon to stand half an hour's heating at 120° without loss of sugar, whilst under careful control and observation a temperature of 125° (or even 130° for shorter periods) is permissible. This conclusion is important, not only by reason of economy in evaporation, but also because a temperature of 125° is sufficient to produce almost instant sterilisation, an effect that cannot be produced with any certainty at 100°. A point of considerable scientific interest, dealt with incidentally in the paper, is the reciprocal interconversion of dextrose and lævulose when the solutions are heated either alone or in presence of alkalis.

MESSRS. GEORGE ALLEN AND CO., LTD., are about to publish a work on "Bushman Folk Lore," by W. I. Bleek and L. C. Lloyd. The volume will be fully illustrated with numerous specimens of Bushman drawings, and will contain a preface by Dr. G. McCall Theal.

OUR ASTRONOMICAL COLUMN.

COMET 1911*b* (KIESS).—The numerous observations of Kiess's comet which appear in Nos. 4513–5 of the *Astronomische Nachrichten* agree in describing it as a nebulous mass some 2·5 to 5′ in diameter, with a condensation some 40″ to 50″ across, but no definite nucleus. The estimates of the magnitude, as one would expect of such an object, vary considerably, but about July 10 the magnitude was approximately 8·0.

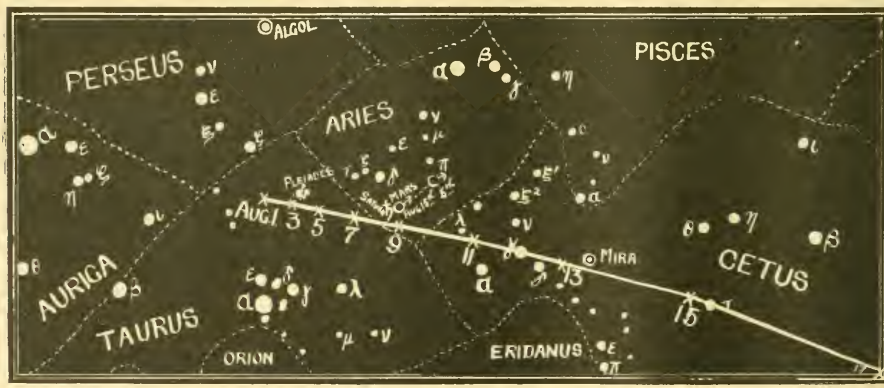
A forty-two minutes' exposure, made in a slit spectrograph attached to the reflector of the Königstuhl Observatory, on July 11, showed 390 μμ to be the brightest band. The radiation 388 μμ was fainter, and its companion of shorter wave-length fainter still. While the 390 μμ line extended to a distance of 1½′ from the condensed centre, the much fainter line 407–470 μμ, with a maximum at 472 μμ, extended only to about ½′. The bands 398–410 μμ and 423 μμ were extremely faint, and no continuous spectrum was shown on the plate.

Dr. Wolf adds that, as seen in the 12-inch refractor on July 8, the head showed a distinct dark space behind its centre, and a cone of matter was seen to be streaming out from the front of the coma. A brief observation by Herren Helffrich and Massinger showed a curved tail at least 1° long, but very faint.

Elements computed by Messrs. Einarsson and Meyer agree well with the corrected elements published by Dr. Kobold, and, with an ephemeris, appear in No. 4515. The following ephemeris is abstracted from that given by Dr. Kobold in No. 4514:—

1911	α (true) h. m.	δ (true)	log r	log Δ	mag.
Aug. 3 ...	3 49·7 ...	+24 5·6			
,, 5 ...	3 40·1 ...	+21 29·4 ...	9·9993 ..	9·6711 ...	5·0
,, 7 ...	3 28·2 ...	+18 6·0			
,, 9 ...	3 13·0 ...	+13 29·3 ...	0·0226 ...	9·5442 ...	4·5
,, 11 ...	2 52·8 ...	+ 7 2·7			
,, 13 ...	2 25·2 ...	− 2 1·6 ...	0·0452 ...	9·4013 ...	3·9
,, 14 .	2 7·2 ...	− 7 43·6 ...	— ...	9·3708	
,, 15 ...	1 46·9 ...	−14 15·8 ...	— ...	9·3439	
,, 16 ...	1 22·5 ..	−21 16·9 ...	— ...	9·3267	
,, 17 ...	0 54·0 ...	−28 26·1 ...	0·0670 ...	9·3212 ...	3·6

The positions in regard to the surrounding stars are shown approximately on the accompanying chart, the bottom line roughly corresponding to the mean horizon for London; after August 17 the distance from the earth begins to increase, and the comet also becomes invisible in these latitudes, its declination on August 18 being 35° S.



Apparent Path of Comet 1911*b*. August 1–17, 1911.

BROOKS'S COMET, 1911*c*.—Numerous observations recorded in No. 4515 of the *Astronomische Nachrichten* show that the magnitude of comet 1911*c*, during July 20–23, was about 10 or 11. Dr. Hartwig reports it, on July 22, as an irregular mass 2·5′ in diameter, with a faint 0·5′ condensation of the eleventh magnitude.

In the supplement Dr. Ebell gives provisional elements and a daily ephemeris extending to August 24. The elements give the time of perihelion as November 11, 1911, so that for some weeks we may expect the comet to brighten up, on account of both its decreasing distance and its increasing activity.

Ephemeris (12h. M.T. Berlin).

1911	α (true) h. m.	δ (true)	log r	log Δ	mag.
Aug. 4 ...	21 56·4 ...	+29 42·0 ...	0·2760 ...	0·0264 ...	9·4
,, 8 ...	21 48·8 .	+32 21·2 ...	0·2632 ...	0·0020 ...	9·2
,, 12 ...	21 39·7 ...	+35 6·7 ...	0·2500 ...	9·9783 ...	9·1
,, 16 ...	21 28·7 ...	+37 56·6 ...	0·2363 ...	9·9557 ...	8·9
,, 20 ...	21 15·6 ...	+40 48·2 ..	0·2221 ...	9·9345 ...	8·7
,, 24 ..	21 0·2 ...	+43 37·8	0·2074 .	9·9151	8·5

Not only is this comet becoming brighter, its position for observation in these latitudes is improving. Its apparent path is from Pegasus towards α Cygni, and the last position given here is very near ξ Cygni; thus for some time it will transit, with a small zenith distance, not far from midnight.

HORARY NUMBER OF METEORS VISIBLE.—Mr. Denning's publication, in No. 4515 of the *Astronomische Nachrichten*, of the horary number of meteors visible for every night in the year comes at an opportune moment, for the outstanding feature of his comprehensive table is the heavy preponderance of meteors per hour in late July and early August. The numbers are deduced from the Bristol observations made during 1866–1911, and give the horary number for one observer watching a clear, moonless sky uninterruptedly. From a glance at the table the average number per hour for the first six months of the year would not exceed six; but early in July an increase sets in, which culminates in sixty-nine per hour on August 10, and averages nearly twenty-four per hour for the whole month.

CHARTS FOR THE SOUTHERN HEAVENS.—Dr. Ristenpart announces in No. 4514 of the *Astronomische Nachrichten* the publication of charts of the southern heavens by the Santiago Observatory. Five series, including fifty charts, will cover the sky between the south pole and declination 19° S., and series 1 and 2 (90° to 67° south) are now ready.

THE CIRCUIT OF BRITAIN BY AËROPLANE.

THE most remarkable race the world has yet seen is over, and Naval-Lieutenant Conneau, flying a Blériot monoplane under the name of "Beaumont," has won the 10,000*l.* offered by *The Daily Mail* for the circuit of Britain—a total distance of 1010 miles in 22h. 28m. 18s. of actual flying time, or just under 45 miles an hour.[1]

The basic idea of the race was to test the trustworthiness of the competing aeroplanes. With this end in view, five parts of the machine and five parts of the engine were marked, viz. the wings, rudder, elevator and fuselage, two cylinders, and various portions of the crank-case.

Two of each of the five parts thus marked had to be in place throughout the race. The motor was marked with an electric needle, the fuselage with burnt-in letters, and the other parts with wired-on lead seals, their position being indicated with red paint on the fabric to assist the examiners at the various controls.

The course was divided into five sections, which were again divided, with the exception of the first and last, into controls, as follows:—*Section* 1.—Brooklands-Hendon (20 miles. *Section* 2.—Hendon-Harrogate (182 miles), Harrogate-Newcastle (68 miles), Newcastle-Edinburgh (93 miles). *Section* 3.—Edinburgh-Stirling (31 miles), Stirling-Glasgow (22 miles), Glasgow-Carlisle (86 miles), Carlisle-Manchester (103 miles), Manchester-Bristol (141 miles). *Section* 4.—Bristol-Exeter (65 miles), Exeter-Salisbury Plain (83 miles), Salisbury Plain-Brighton (76 miles). *Section* 5.—Brighton-Brooklands (40 miles).

Provision was thus made for the competitors to experience every kind of country, while the climate provided, as the event proved, every kind of weather. Twelve hours' resting time on the ground in a control had to be taken in Sections 2, 3, and 4, and no competitor was allowed to start in any of the Sections 3, 4, and 5 unless the full resting time had been taken in the previous section. This wise provision was made to ensure that the competitors had some rest and were not over-driven in the round. The times were taken from the start from one control to the arrival at the next, any stoppages in between counting as flying time, while any resting time taken in any section over and above the twelve hours specified was also counted as flying time.

On Saturday, July 22, the start was made at 4 p.m. from Brooklands. Of the original thirty entrants, twenty-eight were possible starters on the day; but only twenty actually went to the post, and only seventeen got away. Lieut. Porte (Déperdussin monoplane) and F. C. Jenkins (Blackburn monoplane) both fell just after starting, smashing their machines, fortunately without injury to themselves, while Gordon England (Bristol biplane) could not get sufficient altitude to leave the ground. The rest reached Hendon, Védrines making the fastest time, 19m. 48s., winning thereby the right to go first on Monday.

Monday was perhaps the most remarkable day of the race. At the earliest dawn the machines began to fly away to the north, and when night fell they were scattered all along the line from London to Edinburgh. Before noon Védrines and "Beaumont" both reached Edinburgh, where Valentine (Déperdussin monoplane) landed soon after four in the afternoon. Hamel (Blériot monoplane) arrived at Newcastle, Cody (Cody biplane) at Harrogate, and the rest lay between Harrogate and Hendon.

Tuesday night saw both the leaders at Bristol, Valentine at Glasgow, Hamel at Edinburgh, and Cody near Durham. On Wednesday, at a few minutes past two in the afternoon, the race was won, "Beaumont" beating Védrines on time by 1h. 9m. 47s. This result was chiefly due to the fact that the latter mistook the way at Bristol and alighted on the wrong ground, breaking a stay in doing so, and much precious time was lost before he was able to reach the actual aërodrome. Both arrived with all their marks intact.

There is nothing astonishing in the fact that they so far outdistanced the rest of the competitors. They are both acknowledged pilots of the very first rank, with great experience in cross-country flying, while their machines and motors were the pick of their types.

[1] Up to the time of going to press no official times have been issued.

"Beaumont's" Blériot monoplane was of the usual cross-country type, fitted with a 50 horse-power Gnome motor and a Normale propeller. Its total supporting area is 17·5 metres; span, 8·9 metres; length, 7·65 metres; and weight, 230 kilos.

Védrines's Morane-Borel monoplane is very similar to the Blériot, except in its landing chassis, the arrangement of the elevator, and the camber of its wings. In plain view also its wing tips are rounded from front to rear instead of from rear to front like the Blériot. It was fitted with a 50 horse-power Gnome motor and an Intégrale propeller. Its total supporting area is 17·5 metres; span, 9·3 metres; length, 6·7 metres; and weight, 200 kilos.

As aviators steer their way by map and compass, the winner naturally had, owing to his nautical training, a considerable advantage. The chief landmarks to the flyer are rivers and lakes, roads, railway lines, the contours of villages and towns, and the masses of deep colour afforded by woods. Good artificial guides are smoke columns in isolated positions, kites or balloons carrying flags, and white-washed sloping roofs of prominent buildings. A good map must be masterly in its omission of unnecessary detail, and must show distinctly the varying heights of the country and the landing places. One difficulty is the absence of trustworthy news, from the aviator's point of view, as to the weather 100 miles ahead. The opinion of the average man, who has no conception of what constitutes good flying weather, and is not equipped with any apparatus for sounding the air, is quite worthless. As flying becomes commoner we shall, no doubt, see a national system of meteorological stations linked up by telephone or wireless telegraphy. Charts of the atmosphere will be in common use so soon as regular services from point to point are established. Profs. A. L. Rotch and A. H. Palmer have foreseen this, and have just issued a pioneer work giving charts of the conditions prevalent at various times of the year in the vicinity of the Blue Hill Observatory, Mass., especially designed for the use of aeronauts and aviators.

Compasses for aëroplane work have only recently been made practicable. One of the most trustworthy is that invented by Mr. E. H. Clift, and it was largely used by competitors. The difficulty hitherto has been the iron and steel work, the framing, motor, wire stays, and so forth that are used on every aëroplane. A deflection, sometimes as great as 30°, is consequently set up, which has to be corrected by "swinging," that is to say, the head of the machine is moved to every point of the compass in turn, and the errors noted and brought to their lowest dimensions by means of magnets and soft iron balls and bars. Errors are then tabulated and reduced to a curve, which can be plotted to accord with the direction of flight. From this it can be seen that compasses are still far from perfect, and are thrown out by the movement of metal parts, their breakage, or removal.

In reviewing the race, one is inclined to regret that the biplanes showed up so badly. The cry has gone out that the biplane is dead. This, of course, is sheer nonsense. One of the finest machines built is the Curtiss biplane; the Wright biplane holds all the duration records in America; the Bréguet biplane holds the record for weight-carrying; the Cody biplane may not be very fast, but it is stable and trustworthy; the Bristol biplane went round the European Circuit in very creditable time; and the Roe biplane has shown what can be done in the way of speed. The monoplane for scouting, for racing, and perhaps for ease of transport, has proved itself superior, but the biplane has many points in its favour which cannot be disregarded. Another machine one would have wished to see do better was the Etrich monoplane, flown by Lieut. Bier with Lieut. Banfield as passenger, which, as the outcome of years of labour, is probably the most scientifically constructed monoplane, both from the aëronautical and engineering point of view, in existence. It broke down, like many others, from engine trouble.

People viewing the race from a distance, or by the more convenient method of newspapers, are inclined to entertain the idea that man can now get up and soar away to the ends of the earth on his lawful occasions with very little trouble, but they reckon without all the vital factors that make for success. First and foremost is the mechanic. Oily and dirty, often starving, usually exhausted to the point of collapse from want of sleep, he follows where the machine leads him. No other but he can tend his own machine; he knows its ways, its moods, and its weaknesses. The touch of his deft fingers removes all cause of complaint and freshens up every flagging part. Then he stands back, watching the white wings sail up into the sky; and they are scarcely out of sight before he takes the road again in his car to follow, anxious, fretful, but enthusiastic, to where his master leads. This is a side of flying as heroic as that of the pilot and as necessary, but gaining no applause and no glory.

A big race is won by everything being of the best—picked pilot, picked machine, picked motor, picked mechanics, and perfect organisation. If one fails, all fail. And here, perhaps, our English temperament fails. Nothing in flying is "good enough," as we are inclined to think; *it must be the best.*

THE BIRMINGHAM MEETING OF THE BRITISH MEDICAL ASSOCIATION.

THE proceedings in the Section of Electro-therapeutics and Radiography of the meeting of the British Medical Association, held in Birmingham on July 25–28, were of scientific as distinguished from purely medical interest. A form of treatment is being introduced in which the ions composing the drugs are sent into the diseased part—skin, nerve, joint—by means of the electric current, that is, by kataphoresis. For instance, a preparation of salicylic acid is ionised by the current, and thus introduced into a nerve—facial or sciatic—in a case of neuralgia with a directness and intensity not attainable by the method of solution in the blood. The consensus of opinion at the discussion was that this, the latest, form of medication was exceedingly useful, not only in neuralgia, but in many joint affections. The speakers agreed that we had yet a great deal to learn, as, for instance, how deeply the ions can penetrate and how many milliamperes it is best to employ.

The utility of this method in cases where the drug which has to be used would disturb digestion, is very obvious, and it is also probable that the drugs introduced by the method of ionisation act more energetically than if they had reached the part through the blood and lymph.

Sir Oliver Lodge addressed the section on the theory of electrical conveyance through solids, liquids, and gases. In solids, he said, the travelling electrons, which were negative in charge, moved through the solid matter; in liquids the electrons, which seemed to be charged negatively and positively in about equal numbers, travel along with the more mobile matter, whereas in gases the current seemed to consist of positive electrons moving independently of the molecules of the gas.

If we rarefy a gas—remove a great many of its molecules or allow it to expand until it fills a much larger space—the electrons are accelerated, and this acceleration is accompanied by a fine shimmer of light, and in certain cases by sound—a cracking noise. The kathode rays are due to the rush of electrons suddenly stopped by a metal plate or target. Sir Oliver concluded by demonstrating his well-known electric valve, a device whereby he permits electrons only of one sign to accumulate, and rejects the others by a series of ingenious "traps." In this way he can, for instance, dose plants with electricity of one kind only, a treatment which has given the most encouraging results in the ripening of wheat, tomatoes, and other vegetables on quite a large scale.

The joint meeting of the Section of Therapeutics and Dietetics with that of Anatomy and Physiology was for the purpose of discussing the problems associated with the work of Prof. Chittenden, of the department of physiological chemistry at the University of Yale, U.S.A. Prof. Chittenden holds, as the result of observations on a large number of persons selected at random, that the usually accepted quantity of protein food for the adult, 118 grams in the twenty-four hours, is excessive. One series of experiments extended over 130 days, so that the charge of insufficient data cannot be brought against the Yale researches. Prof. Chittenden gives about 70 grams, or less than half the German standard, as sufficient; and his contention is that, because the majority of mankind take much larger quantities of protein food, we have no right to assume that this has a scientific basis. He believes the time has come for dietetics, as for all else, to be studied by the methods applicable to other scientific problems.

It is admitted by the Yale school that the amount of nitrogen in food is no measure of our energy requirements, and that, provided we obtain from fats and carbohydrates the amount of potential energy necessary for the daily kinetic output, then the minimum of protein constitutes what we might also call the optimum. Chittenden's work is so well known in this country through his book "Economy in Nutrition" that it need only be said that, as regards analysis of the food and excreta, it is as careful and complete as could be desired. Although it may be proved that the subjects of his experiments were perfectly vigorous on their restricted diet, one failed to learn from Prof. Chittenden what were the bad results of taking more protein than the 70 grams. He said it "stimulated metabolism generally"; but, as one speaker pointed out, this is not in itself a bad thing, as the more active tissue-change is, within limits, the better is the physical and mental health of the individual.

Some speakers who followed in the discussion held that the usual quantity of protein ingested did no harm whatever, while others asserted that protein in excess of Voit's quantity of 118 grams gave rise to excessive intestinal putrefaction and toxæmia, with raised blood-pressure and gouty arterio-sclerosis.

The diets of poor Orientals are not to be quoted as exemplifying the benefits of a low protein intake, since they are indigestible and dietetically insufficient in many ways. The low stamina and frequent anæmia of these races is due to the deficiency in absorbable nitrogen, and an improvement is noticeable so soon as these people are able to afford the more generous *régime* of the European.

According to Dr. Provan Cathcart, the quality, and not the quantity, of the protein is the important matter physiologically, for the nearer the composition as regards the constituent amino-acids approaches that of the tissue-protein of the animal being fed, the less will there be of nitrogenous waste from that animal. Thus dogs wasted less nitrogen when fed on dog-flesh than on any other kind of protein.

In a paper by Dr. Fraser Harris on some physiological aspects of mine rescue apparatus, there were several points of scientific as distinguished from medical interest. For the last two years a committee of the South Midlands Coal Owners' Association has been investigating the various types of self-contained breathing apparatus for saving life in mines after explosions and underground fires. All the following types of apparatus were examined:—Aerolith, Draeger, Fleuss, Meco, Weg, Hall-Rees, and bellows and helmet. Each has its characteristic feature: in the Aerolith liquid air evaporates; the Draeger, Meco, and Weg supply pure oxygen, compressed under 120 atmospheres, at the rate of 2 litres a minute; in the Fleuss one breathes into a large bag in which sodium hydrate in sticks absorbs the carbonic acid gas. The Hall-Rees is used chiefly for submarine work, and in it oxygen is liberated from sodium-potassium peroxide, in which the carbonic acid gas is simultaneously absorbed.

A point for which the committee was not prepared was that the helmet is far from an ideal mechanism. To a person who has never worn a helmet or done hard work in a metal case, which entirely covers the head and face, the helmet seems the very thing required; but he soon finds that the face becomes excessively hot from the absence of ventilation, and the glass window becomes dimmed from the non-evaporated moisture, and, most serious of all, one's range of vision above and to the sides is very limited. This limitation of vision is particularly serious when one is crawling on hands and knees, which in mines it is often necessary to do. The enclosing of the whole head in a helmet diminishes one's power of hearing, a matter of some consequence, since the possible warning of falls from the roof cannot be heard. The committee favoured half-masks and nose-clips, with motor goggles rather than helmets. In order to make the helmets smoke-tight round the face, an indiarubber tyre has to be inflated, and in the cases where this does not fit the wearer a good deal of pain is experienced from the pressure.

Physiological observations on men wearing different forms of apparatus were carried out during this investigation, as it was clearly important to discover whether the wearing of the apparatus and the doing of hard work in them for upwards of two hours at a time was or was not injurious to the volunteers. The investigations were conducted in the experimental mine attached to the mining department of the University of Birmingham. This represents on a reduced scale all the typical workings found in a mine, and it is so constructed that it can be filled with smoke and its atmosphere made irrespirable, or can have steam driven into it so as to saturate the air, but leave it respirable.

The men, then, worked in three sorts of atmospheres:—

(1) With air at the ordinary temperature.

(2) Hot, moist, and irrespirable atmospheres, in which the wet bulb was about 80° F.

(3) Hot, moist, but respirable atmospheres with the wet bulb about 90° F.

The men varied in age from twenty-five to fifty, in height from 5 feet 7 inches to 6 feet 6 inches, and in weight from about 55 to 89 kilos. The men were weighed naked before and after a test, and the gross loss of weight so ascertained. The losses in weight varied from such figures as 226 grams to 1700 grams in two hours; they bore no definite relationship to the body-weight in any given case.

The loss of carbonic acid gas was ascertained by weighing the regenerators, or absorbents, before and after the experiment, the increase in weight giving the moist carbonic gas absorbed. Such figures as 52·7 grams of CO_2 in 30 minutes and 180·5 grams in 130 minutes were obtained. The CO_2 excreted depends on such a large number of conditions—mass of body, temperature, temperament, amount of work to be done, nature of food, light or dark surroundings, &c.—that it is best to express it per kilo. of body-weight per hour, and when this is done it is seen that the weight of moist CO_2 excreted is represented by a figure not greater than 2, and rarely so low as 0·5 gram. In other words, the amount of carbonic acid gas eliminated in unit time per unit of tissue is very much the same for all the men (12) subjected to the same external condition. There was a remarkable uniformity in the average weights of the gas excreted in all the four types of apparatus worn in rotation by all the experimenters, thus:—in the Fleuss, 1·25; Meco, 1·28; Weg, 0·86; Draeger, 1·14.

The observations on the pulse did not elicit anything very interesting, for, as was to be expected, the heart-beat was markedly accelerated. The minimum number of beats added per minute was 16, the highest 58, but it was satisfactory to know that in all cases the heart had returned to its normal within fifteen to twenty minutes after the test was stopped.

As regards the respiration, nothing more than a physiological hyperpnœa was observed in any case; true dyspnœa was never seen, even at the end of two hours' hard working. No bad effects of the inhalation of pure oxygen as observed by some physiologists in the case of the lower animals were noticed. The very absence of dyspnœa under conditions of oxygen deficiency may become a danger. It is usual for men to suffer from violent and embarrassed breathing when their supply of oxygen begins to run out, but a small proportion, about 10 per cent., appear to be seized with cardiac syncope instead of dyspnœa. The importance of this is that, suppose such a man is the last of a team, then, if his oxygen runs short, he simply falls down unconscious without giving any warning to his companions. He may be left behind in the smoke, as he is unable to call out to them that anything is wrong. The members of the committee, in view of an accident of this kind, point out the danger of allowing only two men to form a rescue-team and enter an irrespirable zone. The committtee was greatly struck with the enervating effects of moist heat on the workers. The report contains the following sentence:—"We were impressed by the rapid onset of fatigue, particularly mental, in very hot and moist atmospheres (group 3). When the wet bulb is higher than 85° F. or so, a man, especially if he has hard work to do, is overcome by irresistible lassitude. He becomes irritable, as well as indisposed to mental exertion. We think this partial mental enfeeblement a fact of some consequence, inasmuch as a person fatigued by hard work in a rescue apparatus in a hot and moist atmosphere might, in some situation requiring promptness of decision, coolness of judgment, the accurate recollecting of instructions, plans, &c., not prove himself equal to the emergency.

The heat developed in the regenerators was such that the men had the skin of the back burnt on more than one occasion. Temperatures of more than 200° F. were registered in the regenerators, and 135° F. was attained by the outside of the bag of the Fleuss. Undoubtedly one of the sources of this heat is that from the chemical combination ($2Na.OH + CO_2 = Na_2.CO_3 + H_2O$) which is slowly dissipated in the hot atmosphere. The last point of interest is that the temperature of the circulating oxygen in hot atmospheres became so high as to burn the throat. Now this temperature was rarely higher than 100° F., and yet it produced great discomfort, while we know that the air in a Turkish bath can be breathed without discomfort even when the temperature is as high as 200° F. The difference is that in the rescue apparatus it becomes saturated, whereas in the Turkish bath it is kept as dry as possible. The dry, although hot, air allows the water to evaporate from the mucous membrane, and so carry off heat in a latent state; but the saturated air circulating in the apparatus permits of no evaporation, and consequently of no corresponding loss of heat.

At an honorary degree celebration of the University of Birmingham on Thursday, July 27, a number of distinguished persons received honorary degrees in connection with the visit of the British Medical Association, and the following speeches were made by the principal (Sir Oliver Lodge) in presenting them to the Vice-Chancellor:

The president of the Royal College of Physicians of Edinburgh, physician to the Royal Edinburgh Infirmary, lecturer on medicine in the Extra Academical School of Medicine, and reader of the address in medicine at the present meeting of the British Medical Association, Dr. Bramwell is the author of many splendid works on medical subjects, in particular of a monumental atlas of clinical medicine, which have made his name known all over the world and will perpetuate his memory. An indefatigable worker, a brilliant clinical teacher, and one of the best known and esteemed physicians in the British Islands, I present for the honorary degree of Doctor of Laws

Byrom Bramwell.

The city of Birmingham has for many years believed strongly in local self-government and strenuous civic administration. Recently it has assumed enlarged responsibility, and in this expansion it gratefully acknowledges the assistance and high encouragement it has received from the President of the Local Government Board a man who, during his term of office, has consistently shown active and practical and powerful sympathy with the struggling period of more than one expanding or federating municipal enterprise; while the future housing of many a community will benefit by his energetic insistence on foresight in planning and thoroughness in drains.

We of this University, closely connected as we are with the city, wish to join in expressing to him our cordial good feeling and gratitude.

Fortunately the present occasion gives to this feeling an opportunity of expression quite apart from any kind of political or social controversy. For the medical faculty represented to the Senate that in his capacity as head of the department which is concerned with the sanitary administration of this country, the Member for Battersea has constantly cooperated with the medical profession in their efforts to improve public health and has given his powerful assistance to those municipalities which are trying to ameliorate the sanitary conditions of the areas under their control. A man of exceptional vigour and of health, both in mind and body, which he devotes without stint to the service of the community, I present to you for the honorary degree of Doctor of Laws

The Right Hon. John Burns.

The presence of Dr. Chittenden in our midst enables us to offer a welcome to a representative of our great kindred across the seas, with whom we are on terms of the most affectionate alliance—strengthened as it is, or as we trust it soon will be, by a permanent treaty of arbitration dealing with any and every difficulty such as may sometimes arise even between close friends.

Dr. Chittenden is professor of physiological chemistry at Yale, and director of the Sheffield Scientific School of Yale University, where his researches have led him to advocate a much less plentiful diet than is usually found to give satisfaction. He was for ten years president of the American Physiological Society. He is already Doctor of Philosophy and Doctor of Science, and is well known as the author of important works on the physiology of nutrition, which have been based on researches to which he has devoted the labour of many years. He has come to Birmingham by invitation to open a discussion in the Section of Therapeutics, which has attracted much interest.

Prof. Chittenden is welcome as a distinguished representative of American university teachers, and we are honoured by enrolling his name on the list of our honorary graduates. I present to you for the degree of Doctor of Laws

RUSSELL HENRY CHITTENDEN.

Among all the movements of our time fraught with benefit for the human race, surely the conquest of the broad belt of the earth from the diseases which ran riot there, and the fitting for white habitation of those sun-favoured regions, is among the most promising.

We do not forget that our Chancellor has exerted himself to promote the activity of officers of the Crown in this direction, and to-day we have the pleasure of welcoming one of the enthusiastic pioneers in this endeavour.

Sir Francis Lovell, Baronet, C.M.G., Fellow of the Royal College of Surgeons, has held high office in our colonies, especially in the West Indies, and has been entrusted with various missions on sanitary questions for the Colonial Office. He served his country first in the then deadly district of Sierra Leone, and subsequently was for many years chief medical officer and president of the General Board of Health and member of the Council of the Government, first of Mauritius, and then of Trinidad and Tobago. His active services abroad lasted from the early 'seventies into the present century, and now continue during his holidays, for he devotes his well-earned leisure to the promotion of the study of those diseases which render tropical climates fatal to Europeans and cause a high rate of mortality among the native populations.

As dean of the London School of Tropical Medicine, and as president of the Section of Tropical Diseases at this meeting of the British Medical Association, I have special pleasure in presenting

FRANCIS HENRY LOVELL.

James Alexander Macdonald is Doctor of Medicine of the Royal University of Ireland and physician to the Taunton and Somerset Hospital. He is the chairman of council of the British Medical Association, and was for three years chairman of the representative meeting of that body. He is also a member of the General Medical Council, in which he sits as a direct representative of the medical profession. His work in the association, and the important offices he has so ably filled, mark him out for the distinction which the University desires to confer upon him. For the honorary degree of Doctor of Laws I present to you

JAMES ALEXANDER MACDONALD.

The University rejoices at the opportunity of welcoming on this occasion many representatives of foreign nations, with all of which we cordially desire to be, not only at peace, but to be linked by ties of friendship and mutual effort—all harmoniously working together for the increase of civilisation and the welfare of the human race. Two of these representatives I shall have the honour of presenting on this occasion. Dr. Oppenheim, Doctor of Medicine and titular professor of the University of Berlin, is a neurologist of great distinction and the author of many important books on his subject. He has opened a discussion in the Section of Neurology at this meeting. His reputation extends all over the world and is of the highest kind. He is the author of a text-book which has been translated into many languages and is accepted as a standard work. His standing and repute as a scientific physician are such that no honour we can confer can enhance his dignity. I present for our honorary degree

HERMANN OPPENHEIM.

Of the self-governing Dominions of the Crown we welcome a representative in Dr. R. A. Reeve, Bachelor of Arts, Doctor of Medicine, who is professor of ophthalmology in the University of Toronto, and was for many years dean of the faculty of medicine there. He enjoys a wide reputation in Canada as a specialist in diseases of the eye, and the position he occupies is sufficiently attested by his having been elected president when the association met in Toronto in 1906. As a distinguished representative of the Dominion of Canada, the University is proud to add his name to its roll of graduates. I present to you

RICHARD ANDREWS REEVE.

In the person of the eminent surgeon Dr. Strassmann we recognise another representative of a great and friendly nation, and to him the introductory remarks prefixed at the presentation of our honorary graduate Dr. Oppenheim equally apply.

Dr. Strassmann is titular professor and assistant to the chair of obstetrics and gynæcology in the University of Berlin, the author of many monographs on various subjects in his department, and an accomplished operating surgeon. He is visiting Birmingham by invitation to take part in the proceedings of the Section of Obstetrics and Gynæcology, in which he has this morning opened a discussion. The University welcomes him as a shining example of sterling ability in his branch of practice, and empowers me to present for the honorary degree of Doctor of Laws

PAUL STRASSMANN.

The professor of pathology in the University of Cambridge is a friend of many of us, and a man regarded with affection wherever he is known, whether in Edinburgh, in Cambridge, or in Birmingham; for Sims Woodhead is no stranger to this University, which he has indeed served in the capacity of an external examiner. He is an M.D. of Edinburgh, the editor of *The Journal of Pathology*, the author of a manual of practical pathology, and for some years was superintendent of a research laboratory in Edinburgh University. Moreover, he is a member of the Royal Commission on Tuberculosis, and has carried out an enormous amount of experimental research in connection with that subject. Little of this work is known to the public, and the University is glad to recognise it by enrolling among its honorary graduates the name of

GERMAN SIMS WOODHEAD.

SCIENTIFIC ASPECTS OF THE UNIVERSAL RACES CONGRESS.

IT appears that the idea of a Universal Races Congress first originated with Prof. Felix Adler, of New York, but its realisation is due to the untiring energy and enthusiasm of Mr. Gustav Spiller. The avowed object of the congress was "to discuss, in the light of science and the modern conscience, the general relations subsisting between the peoples of the West and those of the East, between so-called white and so-called coloured peoples, with the view of encouraging between them a fuller understanding, the most friendly feelings, and a heartier cooperation." Invitations to attend the congress were scattered profusely, and delegates were appointed by a very large number of Governments and institutions, and there was an attendance of more than two thousand members. Rarely, if ever, have so many different nationalities and varieties of mankind been gathered under one roof. From this point of view the congress was an undoubted success; the bringing together of this heterogeneous assembly was no small task, and it cannot be doubted that the spirit of friendliness that permeated the congress, and the introduction to one another of varied peoples with similar or analogous aims, were all to the good, and will have permanent beneficial results.

The main work of the congress consisted of speeches and resolutions, as well as of the papers which were published before the meeting in a volume of nearly five hundred pages entitled "Inter-racial Problems" (P. S. King and Co.). These were taken as read, but many of the writers had a further opportunity of stating their views. The official meetings of the congress were held on July 26–29 in the large hall of the University of London, a room which, unfortunately, has bad acoustic properties. As a very large number of persons were invited or volunteered to speak, the time given to each was necessarily limited, and in consequence most of them spoke very rapidly, and often not distinctly; various languages were employed, and the oppressively sultry weather made it difficult to concentrate attention. The conditions were not favourable to a real discussion, and the proceedings were necessarily more of the nature of orations, sometimes perfervid, on a multiplicity of topics. On the previous Tuesday, however, an attempt was made to organise discussions on "The effects of miscegenation on intelligence and character," and "The influence of environment in forming and changing racial characteristics." These two problems and "the general problems of the conditions of progress" were also discussed on the Wednesday morning.

Prof. F. von Luschan in his printed paper states that "As long as man is not born with wings, like the angels, he will remain subject to the eternal laws of Nature, and therefore he will always have to struggle for life and existence. . . . Nations will come and go, but racial and national antagonism will remain; and this is well, for mankind would become like a herd of sheep if we were to lose our national ambition and cease to look with pride and delight, not only on our industries and science, but also on our splendid soldiers and our glorious ironclads." In his speech he humorously admitted that he was swimming against the stream of the congress, which was certainly the case. Dr. Haddon maintained that Dr. von Luschan had only partially stated the case; he assumed that it was largely on account of his weakness and social habits that man diverged from the other anthropoids; the least advanced peoples are, if anything, over-socialised, and all through human history progress depends upon the balance between individualism and collectivism, between self-help and mutual aid. Mr. John Gray, in opposition to the sentiments of many present, frankly stated that all men were not equal and never would be, nor was it desirable that they should be; but, on the other hand, equal opportunities should be given to all, so that the more capable should not be stifled. Drs. von Luschan and Haddon agreed that there were practically no pure races still existing, and that a discussion of races was not suitable for a congress such as this, as it was mainly of academic interest; the former went so far as to state that the old Indo-European, the African, and the east Asiatic all branched off from the same primitive stock, perhaps hundreds of thousands of years ago, "but all three forming a complete unity, intermarrying in all directions without the slighest decrease of fertility." This does not, however, mean, as some would have liked to believe, that there is no racial difference between men.

Prof. Lyde printed an informing paper on the climatic control of skin-colour. Most anthropologists admit this control, which, however, has not yet been sufficiently studied, nor are the very numerous exceptions yet accounted for. Colour has long been recognised as but a very secondary factor in race discrimination, and it was distinctly pointed out that the question of race was a purely zoological problem, and must be solved by zoological methods. Nearly every speaker confounded peoples with races, but perhaps this is inevitable among those who have not had a biological training; this confusion of terms is manifest in the first printed paper on the meaning of race, tribe, nation, by Dr. Brajendranath Seal, who speaks of a "national race" of complex elements. He also says "We may arrange the types of physical race . . . (1) . . . by a modified genealogical tree (with devices for intercrossing and retrogression), or by symbols and formulæ analogous to those of organic chemistry (as in arranging isomers, polymers, &c.) . . . (2) . . . in space (or more simply on a plane surface) the distance along different directions marking the degree of affinity as estimated by three (or two) groups of correlated characters. . . . A third way would be to conceive an ideal type as the goal towards which the normal development of the organism is tending, and to place the actual types round this as a centre, at distances corresponding, more or less, to their approximation to the ideal." Anyone who has tried to make an arrangement of human types on a plane surface will appreciate how impossible it is to do so in anything like a satisfactory manner; but who is to decide what is "the ideal type" (or does he mean "ideal types"?) "to which the normal development of the organism is tending"? He adds:—"Though the third method is not quite feasible, an occasional application of this test of normal or standard development is a useful corrective."

It is scarcely to be expected that this suggestion, if it were carried out, would lead to much precision, as we cannot be sure of what we are going to develop into. A classification of existing types must necessarily be static, a phylogeny (assuming that the requisite data are available) is dynamic, an ideal type is mainly a matter of sentiment, a goal is prophecy which belongs more to the domain of philosophy than to that of science. Later he says "No view of civilisation is sound or adequate which considers Race and Racial types statically, and not dynamically as growing, developing progressive entities"; however this may be, ethnologists will not entirely agree with Principal Seal when he says "There are other phenomena which are abnormal, pathological, implying degenerative transformation of structure or function. Cannibalism, promiscuity, Morgan's consanguineous marriage, group marriage, infanticide, black magic, &c., are of this class. In the first place they are far outside the line from the ape to the civilised man . . . and secondly, natural selection would ruthlessly weed out stocks in which such impulses would be normal. It follows, therefore, that, when such phenomena appear, as they undoubtedly do, among savages or primitive folk, they are not part and parcel of their normal physico-psycho-social type, but are phenomena of degeneration or retrogression in those peoples."

There are one or two other papers dealing with anthropological subjects, among which may be noted a valuable essay by Dr. C. S. Myers on the permanence of racial mental differences. Prof. Earl Finch writes on the effects of racial miscegenation, and he presents "some facts tending to prove that race blending, especially in the rare instances when it occurs under favourable circumstances, produces a type superior in fertility, vitality, and cultural worth to one or both of the parent stocks." This view was maintained, on the whole, in the preliminary discussion on the Tuesday, the manifest exceptions to the statement being explicable mainly by the unsatisfactory social conditions of half-breeds—in other words, the problems of miscegenation are sociological rather than physiological. In a paper on the instability of human types Prof. Franz Boas summarises his observations on European immigrants into New York, to which the attention of readers of NATURE has already been directed. He makes the very remarkable statement that "the child born in America, even if born only a few months after the arrival of the parents, has the head-form of the American born." The investigations of Prof. Boas were referred to by others as demonstrating the uncertain character of physical traits in racial problems and the rapid effect of the environment; a tendency, however, is observable for others to go beyond the conclusions arrived at by Prof. Boas. It was pointed out that so far Prof. Boas has not given us his methods, nor has he stated what precautions he has taken to control the personal equation of his numerous assistants; a further possibility of error lies in the working up of the statistics. Doubtless this information will be given in his final report.

The ethnologist will find various interesting facts and conclusions in some of the other papers, more especially those dealing with the negro in Africa and America. A lantern demonstration on the methods of racial discrimination and classification was given by Dr. Haddon on Thursday evening. There was also organised in connection with the congress an exhibition of nearly two thousand photographs, &c., representing a large number of peoples, and including a series of coloured drawings of types painted expressly for the occasion by Mr. Norman H. Hardy. A large number of books and pamphlets dealing with ethnological subjects were also on view. The exhibition of illustrations and literature was a great attraction, and was of great educational value. Considering the very few people connected with the congress who knew or cared about scientific matters or methods, the scientific results may be considered as fairly satisfactory.

THE INSTITUTION OF MECHANICAL ENGINEERS.

THE summer meeting of the Institution of Mechanical Engineers was held at Zurich and northern Switzerland, commencing on Monday, July 24. In addition to the meetings for the reading and discussion of papers, an extensive programme of visits to works and hydro-electric power stations had been arranged, and formed an important part of the meetings. The works visited included those of Brown Boveri, Esher Wyss and Co., Oerlikon Machine Works, Sulzer Brothers, and the Swiss Locomotive and Machine Works. The power stations at Rheinfelden, Laufenburg, Wangen, Schaffhausen, Beznau, and Löntsch were also included. The institution dinner was held on July 25. Brief notices of the papers read are given below, and a fuller abstract of a paper on high-pressure water-power works will appear in a later issue.

A paper on electric traction in Switzerland was presented by Mr. E. Huber-Stockar, of Zurich. It may be found astonishing that progress in electric traction has not been greater in Switzerland when one considers that it is necessary to buy all the coal supply from foreign countries, and that a large amount of water-power is still undeveloped. Further, Switzerland has had certain railways electrified at a comparatively early date, and might have been expected to go onward on this basis, especially as applied electricity is highly developed in the country generally. Economy of operation is having a decisive weight, and makes the problem, as it is presented, difficult. The railways already electrified, or about to be electrified in the near future, are such that the smoke nuisance would be an almost prohibitive feature with steam traction, as in the case of the Simplon tunnel, or where the capabilities of steam are near exhaustion, as in the case of the St. Gothard Railway. There are two gauges in use, 1·435-metre "normal" and 1-metre "narrow." There has been but slow progress in normal-gauge railways since 1883, and rapid progress in narrow-gauge railways since 1887.

The author describes very fully several typical Swiss railways and the methods of operation. Reference is made to the valuable scientific work which has been carried out by the Schweizerische Studiencommission für electrischen Bahnbetrieb. This society has investigated such problems as the elucidation of the question of general railway electrification under Swiss conditions. The merits of the several systems, the cost of plant and of operation, and the comparison of steam and electricity for definite lines or groups of lines. The electrification of the St. Gothard Railway, to be carried out in the near future, has been well prepared by the work of this society.

Railway electrification is making noteworthy rather than rapid progress in Switzerland. As regards system, single-phase current of low periodicity (15) and high contact-line voltage, varying from 5000 to 15,000, according to circumstances, is being sanctioned by experience and by authority. All electrification in Switzerland is directly connected with the utilisation of water-power. The heavy variations of load and the rapid seasonal variations in the fresh-water supply make water storage desirable, and even imperative.

A short survey of the practical development of the Diesel oil engine up to the present day was given by Mr. F. Schubeler, of London. It will be remembered that the characteristics of the Diesel principle are compression in the working cylinder up to the ignition temperature of the fuel (about 500 lb. per square inch and about 1000° F.) and the use of an independent multiple-stage air-pump for raising the pressure of the injection air to 600 or 850 lb. per square inch; the injection air is used for the introduction of atomised air into the cylinder. The extreme high pressures and temperatures of the Diesel process put a limit to the dimensions of the cylinders, which will scarcely exceed 30 inches in diameter. Assuming 150 revs. per min. and the ordinary Otto cycle, this corresponds to an approximate cylinder output of 300 to 400 horse-power. It is not desirable to have more than six cranks; hence, in dealing with large powers, it becomes necessary to seek means of increasing the specific cylinder output. For this there are three possibilities:—(1) by carrying out the single-acting Otto cycle machine as a double-acting one; (2) by adopting the single-acting two-stroke cycle process; (3) by adopting the double-acting two-stroke cycle process. The first method approximately doubles the cylinder output; the second produces the same result, but necessitates the provision of special scavenging pumps; the third theoretically quadruplicates the cylinder output, but in practice about 3·4 may be secured.

For small and medium size units the single-acting Otto cycle takes the preference. Such machines have worked for periods of six to eight weeks without interruption, even in cement factories and mills. The two-stroke cycle shows a somewhat higher consumption of fuel, amounting at least to the percentage of the energy absorbed by the air-pump; it has, however, a more favourable turning moment, and guarantees better starting and better conditions for regulation, which is specially important for direct coupling with alternators. The space required is smaller, and the engine is lighter and cheaper. There are many difficulties involved in the problem of the double-acting Diesel engine, and the author deprecates the proceeding at once to the double-acting two-stroke cycle without first gaining experience with the single-acting engine. Some firms have already claimed to be able to carry out a double-acting two-stroke marine engine. The results obtained with such engines are unknown to the author, and he feels somewhat doubtful whether success has already attended such efforts. Attempts have been made to build Diesel locomotives. The adoption of the Diesel engine for motor-cars and aëroplanes does not seem to be very promising.

Dr. Alfred Amsler, of Schaffhausen, described two new types of transmission dynamometers. The first of these is of the torsion type, and is intended for measuring the power transmitted to or from high-speed machines. The dynamometer couples the shaft of the driving engine direct to the driven machine, and consists essentially of a shaft the angle of twist of which gives a measure of the torque. To measure the angle of twist three discs are used, one fixed to one end of the shaft and the other two fixed to the other end. A transparent celluloid rim is attached to the first disc, and has divisions cut on it; each of the other two discs has a radial slit. The scale divisions are strongly illuminated, and may be clearly read through the slits when the shaft is running. An impression is given to the eye every revolution, and at high speeds these impressions become a continuous stationary image.

The other type of dynamometer is intended for use with slow-running machines of variable resistance. Two pulleys are placed close together on a common shaft, one being fixed to the shaft and the other pulley runs loose. The pulleys are connected by means of two cylinders fitted with pistons and charged with oil. The drive from the source of power is communicated to one pulley by belt, and the machine under test is driven by belt from the other pulley. In operation, the oil in the cylinders is put under pressure corresponding to the torque being transmitted. The shaft is hollow, and serves to make communication between the cylinders and a pressure gauge, the readings of which give a measure of the torque.

A paper on rack-railway locomotives of the Swiss mountain railways was read by Mr. T. Weber and Mr. S. Abt, of Winterthur. Switzerland has a total of 120 steam locomotives, as well as 45 electric locomotives and motor coaches arranged for working with rack gear. The total length of the rack railways is 87 miles. The whole of the systems of racks which are in use have been designed in Switzerland. The Abt system has been most adopted, and consists of flat-toothed plates, of which two or three, according to the tractive power, are bolted together on chairs in such a way that the tooth of one plate in regard to the other is displaced one-half or one-third of the pitch. The pitch is 4·7 inches, and the rack ensures a quiet motion and permits the trains to work at high speed.

A paper descriptive of the Zoelly steam turbine was presented by Mr. H. Zoelly, of Zurich. This turbine is of the impulse type, and as made at the present time has eight stages for turbines running at 3000, twelve stages for 1500, and sixteen stages for 1000 revolutions per minute. The first diaphragm plate of the high-speed turbines has nozzles which extend for a portion of the circumference only in the bottom half of the diaphragms, whilst in the other diaphragms the nozzles usually extend completely round the circumference. In the case of large units, steam is admitted through channels extending completely round the circumference for all stages. Governing is effected by throttling the live steam. The efficiency of this type of turbine will be evidenced by the following results for a 4000-kw. turbine:—steam consumption per horse-power-hour at full load, 9·36 lb.; at about three-quarter load, 9·58 lb.; at almost half load, 9·84 lb.; at about one quarter load, 10·12 lb. A set of two marine Zoelly turbines, each of 7500 horse-power, has been installed recently in the torpedo-boat destroyer G. 173 of the Imperial German Navy.

Prof. Franz Prášil, of Zurich, communicated the results of some of his tests on Francis turbines and on Pelton turbines. It is of interest to note that both types have developed in the direction of increase of horse-power per unit since 1900, and have now reached as high as 10,000 horse-power per wheel. The Francis turbine is applied with success to falls of 3·3 to 492 feet, the Pelton wheel to falls of 131 to 3116 feet. There has been steady improvement in the construction of the turbines, in the efficiency of the automatic governing, and in the safety mechanism.

In the case of four Francis turbines in open-wheel pits and working under heads of 4·4 to 10·4 metres, the efficiency was found to be more than 85 per cent. at about 80 per cent. of full load. Five Francis turbines in spiral wheel cases gave results showing that efficiencies of 85 per cent. and more are attainable in this style of turbine. The heads in the latter case ranged from 12 to 147 metres.

Four Pelton wheels were tested under falls ranging from 90 to 850 metres. At about 55 per cent. of full load all four turbines showed efficiencies lying between 84 and 85 per cent. The most favourable efficiencies varied between 84 and 89 per cent. The efficiency was lower than 80 per cent. only under loads which were 25 to 30 per cent. of the full load.

In regard to efficiency, there is not to be expected much further advance in the future. The problem of governing can still be considered as not yet completely solved, since there still appears in view a series of applications which will influence the further development of this problem.

THE BELFAST HEALTH CONGRESS.

THE annual congress of the Royal Sanitary Institute, which was held at Belfast on July 22–29, proved a great success; and if the papers dealing with the scientific research side were few, those dealing with the administrative side of preventive medicine amply made up for this deficiency. It is only possible in this short article to indicate those contributions which were of special interest and importance.

In a paper upon the non-nitrification of sewage in sea-water, Messrs. Purvis, McHattie, and Fisher recorded the results of many experiments, which demonstrated:—"That even after seventy days' incubation of 10 per cent. sewage in sea-water, with every facility for complete aeration, there was no production of nitrates or nitrites, and that the free-ammonia figure was increased in the sewage and sea-water at the end of forty-two days. The most obvious explanation of these facts is to assume that the sea-water destroys the useful nitrifying organisms. With regard to the continuous presence of free-ammonia, even after fifty-two days' incubation, it is of interest to note that it supports the suggestion of Kenwood and Kay-Menzies as affording a valuable clue to the contamination of sea-water by sewage."

Drs. T. Houston and T. Rankin contributed an important paper upon the diagnostic value of blood reactions in epidemic cerebro-spinal fever and allied conditions, and they maintain that their observations show that the cerebro-spinal cavity is the proper place to attack the causal organism—the Meningococcus—by means of an anti-serum.

Dr. Williams, the medical officer of health of the Port of London, contributed a paper on plague precautions in reference to the destruction of rats. After discussing the various means of destroying rats aboard of ships, and testifying to the unsatisfactory results obtained from pathogenic bacterial methods, he records the results of experiments on the lethal qualities of air containing 3 per cent. sulphur dioxide gas. These experiments indicate that rats and beetles are killed within from two to three hours of exposure to such air.

In a paper on the viability of *B. typhosus* in water and its isolation therefrom, Drs. J. Wilson and C. Dickson conclude that uncultivated *B. typhosi* (viz. those actually present in the urine and fæces of "carriers") may be recovered from water after a period of three weeks and two days, when conditions closely resembling those found in nature are imposed. "Dr. Houston was unable to recover uncultivated typhoid bacilli from water at a later period than one week from the time of addition, and states that 'less than a month's storage of a raw river water is apparently absolute protection against typhoid fever.' Our experiment shows that Dr. Houston's statement should be accepted with reserve."

Dr. King-Kerr, in an interesting and suggestive paper on the prevention of typhoid fever, dealt with the experience of Belfast. As recently as ten years ago the death-rate from typhoid fever in Belfast was a very high one (1·04 per 1000 in 1901), whereas for the past three years the rate has been only 0·05. Dr. King-Kerr explains that several factors were found to have exercised a powerful influence in this reduction, and that their coming into operation was followed by a marked, definite, and even immediate fall in the death-rate. These factors were the substitution of water-closets for privies, the stoppage of the sale of cockles, the establishment of an additional fever hospital, the sterilisation of the infected hospital sewage, and the more complete isolation of typhoid patients. The decline in the typhoid, zymotic, and general death-rates coincides with these operations.

In a paper on municipal hospitals, Dr. P. Boobbyer directed attention to experiments extending over fifteen years, which had been carried out at Nottingham, to test the value of the open-air treatment for all classes of acute specific diseases, including small-pox, scarlet fever, diphtheria, measles, whooping-cough, pneumonia, erysipelas, and even enteric fever. He was moved to make this experiment in the first instance by the reputed liability of isolation hospitals to favour the spread of many (and often complicated) cases in confined atmospheres. "During the past few years it has been our constant practice to nurse the more severe cases of the diseases mentioned above, as far as possible, in the open air, in bell tents with open sides, in the freely ventilated corridors between the various ward blocks of the hospital, or in the covered approaches to the latter. Cases of an acute and septic character certainly clear up more speedily in the open air than in closed wards. In no single instance, so far as I have been able to discover, has any untoward result accrued from the exposure."

The State endowment of motherhood, a paper by Dr. Eric Pritchard, aroused considerable interest. He advocated that the mother should be endowed in her capacity of mother in order to mitigate the evil effects of poverty and labour upon the woman advanced in pregnancy; and he impressed the importance of the adequate provision and training of midwives in the principles and practice of infant feeding and management. The whole object of maternity endowment should be centred in efforts to safeguard the interests of the infant before and immediately after birth, and these interests would be best studied by an efficient midwifery service, supplemented by the domiciliary visits of properly trained health visitors, both before and after birth; and both midwives and health visitors should be empowered to dispense free benefits of food, clothing, or other necessity which they might think proper for the welfare of the State's new citizen.

Mr. A. J. Martin's advocacy of a "National Health Week" met with much acceptance. We cannot expect to awaken all at once a sustained interest in matters of health, but it is practicable during one week in the year to secure for them a fair measure of public attention. "Health week" may fittingly start with Health Sunday. "If the clergy will but awaken and stir the conscience of the nation, and bring home to all their congregations a sense of their personal responsibility for their own health and that of their families and neighbours, the Press and other agencies for moulding public opinion may be trusted to do the rest. The Press of this country has again and again given proof of its readiness to work for the public health. Only a few months ago one of our great papers devoted columns day after day to a campaign against tuberculosis. Still more recently leading journals have taken a strenuous part in the agitation for wholesome bread.

"Our local authorities are largely occupied with health work. Let them for one week in the year take their constituents into their confidence. Let them hold one or more public meetings to discuss the special needs of the town or district, the work already accomplished, and that which still remains to be done.

"And then the schools. Throughout Health Week let the regular teaching in hygiene be supplemented, at least for the elder children and their parents, by one or more lectures from local medical men—lectures, not crammed with dry scientific facts, but brimful of that romance in which the pages of sanitation abound.

"I would also enlist the aid of the trade unions, the cooperative societies, the friendly societies, the funds of which are so cruelly depleted by preventable disease—every body of men, in short, who care for the well-being of their fellow men, and are willing to work for it."

The difficulties to be overcome should not be underestimated, but they need not be exaggerated. Hospital Saturday and Hospital Sunday in this country, and Tuberculosis Sunday in the United States, have shown the way. From small beginnings they have grown into great national institutions; and if the cure of disease has a claim on our sympathy and support, how much the more has its prevention?

THE FIFTH INTERNATIONAL DAIRY CONGRESS.

THE fifth International Dairy Congress met at Stockholm on June 28, and was closed on Saturday, July 1. There was a large attendance of members, and some interesting discussions arose on the various subjects contained in the programme.

The meetings were held in the two chambers of the Houses of Parliament, and to facilitate the procedure, the subjects under discussion were divided into two sections. In Section 1 the production of milk was the main subject of discussion, whilst in Section 2 attention was directed to the treatment and use of milk. It is not possible to follow in detail the discussions which took place on practically all the subjects which were dealt with by the two sections, so a short account of the questions placed before the congress, and a *résumé* of the conclusions or recommendations arrived at, will be given. The first question was on the effect of the different fodders on the quality of milk and dairy products; six reports had been presented, and abstracts published and issued to members. The discussion of this subject made it clear that there is still a great deal of uncertainty as to whether or not food can cause an increase of fat in milk. Kellner (Möckern—Leipzig) reported that feeding experiments which had been carried out under his direction proved that the use of palm-nut cake meal caused a rise in the amount of fat in the case of cows with a high milk yield.

Bøggild (Copenhagen) recalled the experience of Danish farmers some twelve or fifteen years ago, when it was found that palm-nut cake meal raised the percentage of fat in milk. The rise was not maintained and the use of palm-nut cake meal fell. The influence of the season should not be overlooked in these cases, for in some years the increase in the fat content of milk seemed to be due to this factor.

Further evidence of the possibility of increasing the fat in milk was given by several speakers, and Nils Hansson, in a very able paper, pointed out that it may be necessary to abandon the view that food has no quantitative influence upon the fat of milk. The part played by foods in influencing the flavour of milk was discussed, and particularly the bacteria from feeding stuffs. The entrance of organisms into the milk, either directly or indirectly, through fæcal matter, was considered important.

The interest displayed in this subject resulted in a *résumé* being prepared by Martini, Kellner, and Ostertag, and communicated to the next day's meeting. The final conclusions of the congress were that it is evident from practical observations and from scientific researches, particularly those of Kellner, that certain foods exercise an influence upon the quantity of fat in milk in the case of cows having a high milk yield, but that the following questions still need an answer:—(1) From what period does the influence of the food make itself felt? (2) To what degree is this influence maintained? (3) Does the addition of certain foods exercise an equal influence upon the quantity of fat? (4) Is the quantity of fat obtained by the use of these specific foods remunerative?

The second question dealt with the influence of the different fertilisers on forage plants with regard to the quality of milk and dairy products. Orla Jensen (Copenhagen) gave an account of a long series of experiments which he had conducted. The results proved, however, to be largely negative, and in spite of slight and irregular changes in the milk salts, and the coagulation of the milk, it was concluded that the chemical effect of the fertilisers was very little indeed. The effect of bacteria coming from fodder upon milk, particularly when associated with digestive disturbances, is very considerable and of far-reaching influence, in the making of cheese particularly. This being the case, the necessity for the strictest cleanliness in the cowshed and in the dairy, the adequate cooking of the milk, and the retention of healthy cows only, become once more the recommendations of those best fitted to advise. Unfortunately there was little discussion upon this question; in all probability the subject had not been investigated by others.

The third question dealt with a subject which is much discussed at the present time in this country, and the conclusions of the congress as noted below ought to prove conclusively that we are neglecting one of the best means of improving our milk supplies at practically no cost. The question was as to the importance of control associations (milk record societies) for the production of milk. Benno Martini (Gross Lichterfelde) criticised the manner in which these associations are generally run, and the conclusions which are often drawn from the results; but he agreed as to their usefulness in bringing the importance of the careful testing of each cow in the herd before the farmer himself, and this in many cases was first done when a travelling tester visited the farm. Every other speaker, and they were of all nations, had praise for the control associations, and if any evidence were needed that their operations resulted in the rise in quantity and quality of milk, it was furnished in abundance.

Funder (Christiania) reported on a condition of affairs in Norway which somewhat resembles that in England, namely, the reluctance of the farmers, especially the smaller ones, to join the associations, and the objection to the travelling tester staying at the farm.

The opinion of the congress is well expressed in the following resolution, which was passed:—

"Judging from the good results obtained in Sweden, Denmark, Germany, Finland, and Austria, the fifth International Dairy Congress declares that milk record societies exercising a control of the feeding of the cows furnish one of the best methods of raising good animals of a milking strain, and assist in the reduction of the cost of milk.

"The congress directs attention to the great importance of such control societies in initiating a rational, economical, and balanced mode of feeding, and in propagating the sound experience which has been gained in the keeping of animals."

The veterinary control of live stock as regards the production of milk was the fourth subject dealt with, and the discussion showed that very strong views were held as to the necessity of veterinary inspection of cows. The question of the food for cows from which special "infants'" milk is obtained, and the tests to which the milk should be subjected, were also discussed. It was agreed that when a change from dry to green food was made, it must be done gradually, and also that the milk from cows on good pasture was permissible for the feeding of young children, and could be recommended. The congress did not, however, feel that there was unanimity in the proposals which had been made, so it was finally decided that a special commission should be appointed to draw up regulations for the veterinary control of milk, and to submit them to the next International Dairy Congress.

The following were elected to the special commission:—Poels, Rotterdam; Regnér, Stockholm; C. O. Jensen, Copenhagen; Martel, Paris; Trotter, Glasgow; Bougert, Berlin; Ostertag, Berlin; Winkler, Vienna; Zschokke, Zurich; Malm, Christiania; Happich, Dorpat; Fettick, Budapest; Fiorentini, Milan; with power to add to their number.

A recommendation was made to the milk associations of the various countries to appoint committees, which should work with the object of getting the control system introduced into all public and private ventures.

The fifth subject dealt with the supervision of the milkers and attendants, and the visiting of them in their homes by a regularly appointed medical man was urged. Cleanliness in the habits of dress of the milkers was also strongly recommended.

In the second section of the congress the subjects dealt with have a more practical and less scientific bearing, with the exception of the seventh subject, noted below. The sixth subject, for example, treated of what demands should be made in the case of new milk intended for direct consumption, of condensed milk, and of dried milk. The congress passed a number of strong recommendations, which, if they could only be carried out, would be of the greatest possible benefit to the consumer, but to the producer they would necessitate a heavy expense and a consequent increase in the cost of the milk.

Subject number seven placed before the section was a question dealing with analytical methods to be employed in testing milk and dairy products. In addition to the ordinary fat determination, and the taste and smell, it was advocated that a test for dirt should be made also the reductase test (Barthel), the fermentation test (Walter), and the leucocythemia test (Walter) and the catalase test. The alcohol boiling test and a determination of the acidity were also advised.

No unanimous resolution was adopted, but the general feeling of the congress seemed to be that the above-mentioned tests could be used with most satisfactory results, whether the milk was intended for direct consumption or for the manufacture of butter, cheese, &c.

The ninth subject, which dealt with cheese control, attracted a large amount of attention from representatives of countries exporting cheese. It was resolved by the congress that it should be left to the next congress to fix what can be regarded as the normal amounts of dry matter and fat in cheese. The permanent committee was charged with the task of undertaking the necessary preliminary work. It was also recommended that margarine cheese should not be made up in form of the ordinary types of commercial cheese.

The question of the training and instruction of the *personnel* of dairies was closed with an invitation to the societies of each nation to draw up methods and conditions of instruction.

Finally the congress resolved that it is absolutely indispensable, for the avoidance of misunderstandings, that in all dairy publications the metric units of measure and weight should be used, and for temperatures the degrees centigrade.

At the conclusion of the congress most of the members paid a visit to Orebro, where the twenty-first General Swedish Agricultural Exhibition was held. These exhibitions are held once in five years in different parts of Sweden. The show, somewhat spoilt by rain on the first day, was excellent. The members of the Dairy Congress had then an opportunity of taking part in one of four different excursions. Those who were interested chiefly in agricultural and educational matters visited Ostergötland and Scania, and were rewarded by a most interesting and instructive trip.

THE BRITISH PHARMACEUTICAL CONFERENCE.

THE forty-eighth annual meeting of the British Pharmaceutical Conference was held at Portsmouth on July 25–27 under the presidency of Mr. W. F. Wells. The presidential address dealt mainly with pharmaceutical legislation, incidentally directing attention to the fact that the laws regulating the practice of pharmacy in Germany and France afford better protection and greater privileges for pharmacists than the British and Irish laws. Mr. Wells deprecated the practice of Irish boards of guardians of purchasing drugs of inferior quality at competitive prices, and expressed the opinion that a large proportion of the damaged drugs imported from abroad went to public institutions, the governors of which paid more attention to price than to quality.

For the first time in its history, the meeting was this year divided into two sections, the "science section" and the "practice section." In the former section eighteen papers were contributed, the larger number of which were of purely pharmaceutical interest.

Mr. H. Finnemore and Mr. G. E. Town contributed a short note on *Bartsia odontites*, a very common wayside plant of the natural order Scrophulariaceæ. It is well known that this plant is avoided by cattle, and bearing in mind the haphazard methods in which our knowledge of the use of medicinal plants has emerged, and also the fact that plants botanically related often contain similar chemical constituents, it occurred to the authors that this relative of digitalis might possibly be worthy of pharmacological and chemical study. A quantity of the plant was extracted with alcohol, but Dr. Laidlaw, who tested the action of the solution on frogs, found that it had no poisonous or digitalis-like effect. A crystalline matter which separated from the alcoholic solution was identified as mannite.

Mr. H. J. Henderson described an experiment in peppermint culture in the shade. The plants were grown on the bank of a stream at Hitchin, and some of them reached a height of 50 inches; the stems were stout, and the leaves correspondingly large. It was found, however, that the lack of sunlight, due to the shadow cast by the trees on the opposite bank, prevented the production of the hairs bearing the oil cells, and reacted powerfully on the yield of oil, this being only 0·1 per cent. from the fresh herb. The yield of oil from ordinary plants grown on the same farm was 0·409 per cent.

Mr. E. H. Farr and Mr. R. Wright contributed a paper in which they described experiments carried out with the view of testing the accuracy of the statement, which is frequently made, to the effect that in the conversion of opium into extract or tincture the quantity of morphine shown by the official assay of a sample of opium is always greater than the amount found in the finished product. The authors find this statement to be correct. In seven samples of opium worked upon, the loss of morphine varied between the limits of 0·8 per cent. and 9·0 per cent. of the whole, with an average for the whole series of 4·78 per cent. The loss appears to be due to occlusion of the alkaloid, rendering its complete extraction by water or alcohol a matter of practical impossibility, or to some other factor which has hitherto escaped recognition.

Mr. H. Deane, in a communication on extract of Indian hemp, demonstrated the variability of this extract as supplied by the manufacturers. He suggested a modification of the official process of manufacture by which an extract consisting practically of pure resin would be obtained.

Mr. R. R. Bennett suggested that an iodine standard should be officially adopted for *Thyroideum siccum*. The majority of pharmacologists are agreed that the activity of thyroid is dependent upon the combined iodine present, but the author finds that the combined iodine present in commercial preparations varies considerably. The percentage of iodine in dry thyroid prepared from a series of sheep's thyroids obtained direct from the slaughter-house varied from 0·21 per cent. to 0·096 per cent., the average value being 0·158 per cent. The author thinks that an iodine standard of 0·15 per cent. might be adopted without unduly harassing the manufacturer.

Mr. John C. Umney contributed a note on *Podophyllum emodi*. At the request of the Indigenous Drugs Committee (Calcutta) he conducted a series of experiments upon the drug, collected under different conditions and at different seasons. He finds that the resin obtained from the rhizome collected after flowering is much richer in podophyllotoxin than the sample he examined some years ago, and that it contains about twice as much podophyllotoxin as the resin of *P. peltatum*.

A paper on the composition of diabetic foods, by Mr. F. W. F. Arnaud, gave rise to a vigorous discussion. The author gave the results of the analysis of twelve different samples of gluten bread and flours, the products of seven manufacturers, which showed that the products of one manufacturer alone were satisfactory. Nine of the products contained from 40 per cent. to 70 per cent. of starch. The author cannot confirm the statement, frequently made in advertisements, that the starch has been altered, either by the qualitative iodine test or the microscope. A sample of an expensive diabetic food was found to consist of ordinary flour which had merely been heated. In the course of the discussion it was suggested that the conference should take some action with a view to the repression of the sale of ordinary bread and flour as specially prepared diabetic foodstuffs, and it was finally decided to refer the paper to the executive with the object of considering whether the attention of the British Medical Association should be directed to the facts disclosed.

In a paper on white precipitate, Mr. G. D. Elsdon described a method for the estimation of mercury. He confirms the statement made on previous occasions that the sulphide method gives results that are sometimes too high, but contends that the process is, in respect to its accuracy, no worse than the others in general use, and is to be preferred on account of its speed and simplicity. He also described a method of analysing white precipitate ointment for the purposes of the Sale of Food and Drugs Acts.

Mr. H. Finnemore communicated a brief note on solution of sodium ethylate. This liquid becomes brown on keeping, the change in colour being due to the action of the alkali on the acetaldehyde present in absolute alcohol. The use of methyl alcohol in place of ethyl alcohol is suggested; a sample of solution of sodium methylate showed no trace of discoloration after two years.

Other papers read in the science section included a note on the constitution of commercial bismuth subchloride, by Mr. J. B. P. Harrison; notes on arsenates of strychnine and strychnine hypophosphite, by Mr. D. B. Dott; and a paper on the moisture and ash contents of medicinal extracts, by Messrs. K. C. Allen and T. Brewis.

In the Practice Section a paper on the education of the pharmacist was read by Dr. F. Beddow. He expressed the opinion that the present system of educating the pharmacist is not an ideal one from the teacher's point of view, since a large majority of students do little or nothing until they are old enough to sit for their final examination; they try to compress all their work into a few months, the result being a process of cramming. So far as possible, educationists would like to minimise the importance of the examination and increase the importance of the education; and in Dr. Beddow's view the proposed pharmaceutical curriculum (NATURE, February 23, p. 564) is a step in this direction, for it substitutes to some extent proof of education for examination.

A paper was also read by Mr. E. F. Harrison on secret and proprietary remedies, and at the close of the discussion a resolution was passed calling upon the Government to institute an inquiry into the sale of these products. The position of pharmacists under the proposed national insurance scheme was also discussed.

Sir Edward Evans was elected president for the ensuing year, and an invitation to hold the next meeting of the conference at Edinburgh was accepted.

THE SCENTS OF BUTTERFLIES.[1]

AMONG all the country sights of spring, summer, and early autumn, I suppose there is none more familiar than that of the common white butterflies. They are to be seen, as we know, everywhere; haunting woods, hedgerows, lanes and gardens, crossing heaths and meadows, and visiting at times not only parks and squares, but even streets in the heart of London. Of these insects there are in this country, as is no doubt known to many of you, three especially abundant kinds. One of these is the large cabbage white; the other two species are smaller. These two latter kinds are much alike when seen on the wing; but on a closer view they are easily distinguished, the most obvious mark of difference being the presence in one of them of greyish-green streaks, following the course of the so-called "veins" or "nervures," on the under surface of the hind wing. From this character the form in question gets its common name of the "green-veined white." If anyone will capture a male green-veined white (easily distinguished from the female by the much slighter spotting of the male's upper surface), and will brush the upper surface of the fore or hind wing with a camel-hair pencil, he will become conscious of a strong agreeable odour like that of the so-called "lemon-plant." On further examination he will find that this perfume emanates from the wings of the butterfly, and is strongly perceptible on the brush with which the wings were rubbed. The rubbing process has, of course, dislodged large quantities of the minute scales with which the wings of this insect, like those of butterflies and moths in general, are clothed; and these dust-like scales, adhering to the brush, have in some way or other carried with them the characteristic odour of the butterfly. A similar scraping or rubbing of scales from the under surface of the wings does not emit the odour, nor is it found in association with any scales from either surface of the female.

We find, then, that in this butterfly the perfume attaches to the scales in one particular situation, namely, the upper surface of the wings of the male insect. This fact obviously suggests that we should examine these particular scales in order to find out whether they present any differences from the scales which appear to be odourless. On applying the microscope to the scraping which carries the scent, we find at once an answer to our question. The great majority of the scales are of the ordinary well-known kind, consisting of an elongated flattened lamina, provided at one end with a short quill-like footstalk by which they are attached to the membrane of the wing, and frequently showing at the other extremity a more or less marked indentation. But among these will be found certain scales of an entirely different appearance. These latter scales in the insect before us are somewhat heart-shaped, carrying a long footstalk which ends in an almost circular disc, and tapering at the other extremity to a point. But the greatest peculiarity of these special scales is to be found in the plume-like structure which crowns their apical portion. Under a low power of the microscope the appearance is that of a tuft of fine transparent hairs, strongly suggestive of the vibratile cilia which are so familiar in animal and vegetable histology; but these hair-like processes, unlike the cilia, have no faculty of active movement, and under a high power they bear rather the aspect of minute tubes, in many cases seeming to be open at their free extremity. On examining a similar scraping from the under surface of the male, or from either surface of the female wing, we find only scales of the ordinary kind; the special "plume-scales," as they have been called, being invariably absent. Inasmuch, then, as the characteristic fragrance is found only in scrapings which contain the plume-scales, we are justified in concluding that these remarkable structures act as carriers of the perfume.

So far we have considered only one species of butterfly, the common green-veined white; but the question will naturally be asked—what about other butterflies, the other common whites, for example? Is this flowery perfume a peculiarity of one species only, or is the property of emitting a fragrant odour shared by other related insects? In order to answer this question, let us suppose that we make a series of trials on the second species of smaller common white, the small cabbage or garden white, as it is usually called. Here, again, no trace of a flowery odour is discoverable in the female or in scales from the lower surface of the wings in the male; but, as before, the upper surface of the wings in the latter sex will be found to be scented, and, also as before, the scent will be found to adhere to the scales removed by scraping or brushing from the upper surface. Examining the scented scraping microscopically, we find that here, too, are a number of plume-scales mixed in with scales of the ordinary type. These

[1] Discourse delivered at the Royal Institution on Friday, March 3, by Dr. F. A. Dixey, F.R.S.

plume-scales bear a family resemblance to those of the previous species, but are easily distinguishable from them. In fact, it is quite as easy, perhaps easier, to discriminate between the two species of the common white by comparing two scales measuring not much more than one-tenth of a millimetre in length, as it is to tell them apart by examining entire specimens of both insects.

We conclude, then, that the scent-producing function is essentially similar in the two kinds of smaller common white. But it is to be observed that the endowments of the two in this respect, though similar, are not identical. The scent of the green-veined white (*Ganoris napi*) is, so far as my experience goes, always present and easily recognisable, this being the reason why I chose it for first mention. But with the common garden white (*Ganoris rapae*), the case is different. You will probably find some male specimens with no appreciable scent at all; others with the scent so faintly developed that you may be doubtful about its presence; in none, probably, will the scent be nearly so strong as in the case of the green-veined white that we began with. Moreover, the character of the perfume differs. It has been not inaptly compared to sweetbriar, and it is at all events quite distinct from that of its near relation *Ganoris napi*. Extending our observations to the large cabbage white (*Ganoris brassicae*), we find a plentiful supply of plume-scales of quite a different aspect, these being very much longer, tapering gradually from base to apex, and showing none of the elegant heart-shaped outline that we saw in the other two species. The regularly disposed fringe or plume of the smaller whites is here also replaced by a kind of untidy bundle. These scales, again, are present only in the male, and only on the upper surface of fore and hind wing. What about the scent? It cannot be said to be entirely non-existent, but it is certainly the case that anyone of average olfactory powers may examine many male specimens of the large white without being able to detect any characteristic odour whatever. In some individuals, however, it is unquestionably present, though it is, as a rule, only to be appreciated with difficulty. But when detected it is like a faint whiff of violet powder, or, as has been happily suggested by Dr. Longstaff, orris-root.

There is in Africa a well-marked genus of white butterflies which goes by the name of Mylothris. The members of this group are in many respects much like the common whites of our own country; they are, however, as a rule somewhat brighter in appearance, many of them having a touch of vermilion, orange, or some shade of yellow at the base of the wings close to the body. This is more frequent on the under surface, but in many cases it is seen on the upper side as well. The genus also differs from our common whites in usually possessing a distinct marginal row of dark spots. The figures shown on the screen, which were photographed in colour from nature, were prepared for another purpose; they give, however, a good idea of the general features of the group.

Now all the species of Mylothris which I have had the opportunity of examining during life possess a strong and fragrant odour, which is developed under just the same conditions as in the butterflies we have already discussed. That is to say, it belongs to the male alone, and in that sex is confined to the upper surface of the fore and hind wings.

The scent of *Mylothris agathina*, a species which is abundant in many parts of Africa south of the Sahara, appears to me to be exactly that of sweetbriar. It is a good deal like that of our garden white (not the green-veined species), but very much more intense. Indeed, so powerful is it, that I have more than once perceived it when the butterfly was held in the hand at some considerable distance.

There is a pretty species of Mylothris which I found rather common at East London (South Africa). It has been named *trimenia*, after the distinguished naturalist who presided for many years over the South African Museum at Cape Town. It has a graceful, floating flight, and the hindwings in the male are of a delicate lemon-yellow. The general attractiveness of this insect is increased by its pleasant fragrance. This is quite different from the odour of its congener *agathina*, though at least equally powerful. It is not easy to describe, but may perhaps best be compared to the scent of sweet-pea or clover, with a suggestion of orange-peel or lemon. The females of both these species of Mylothris are destitute of odour. The curious shape of the male scent-scales, which is tolerably uniform throughout the genus, is shown in an outline diagram.

In a couple of months' time our country lanes will be enlivened by the presence of a butterfly known no doubt to many of you as the "orange-tip." This very pretty insect is much like one of our common whites, but may be distinguished by the elaborate green mottling of portions of the under surface—a feature of colouring which causes the butterfly to be almost invisible when it settles with closed wings on the head of an umbelliferous plant. This green mottling is found in both sexes, but the male has in addition a large patch of bright orange at the apex of the forewing. Whether this butterfly is scented I am unable to say, as I never happen to have had the opportunity of examining live specimens since I began to search for butterfly odours, but the male certainly possesses plume-scales of the same general character as those of the common whites, though differing, as will be seen by reference to the diagram, in points of detail. I should be glad to receive information as to its power of scent-production from any of you who may make the acquaintance of the butterfly during the coming spring.

Though I have at present no information on this point as to our English orange-tip, I have been able to test several foreign species which are somewhat like it in aspect, and are not very far removed from it in point of affinity. These belong to the genus Teracolus. One of these Teracoli, called *omphale*, common in Africa, has a scent which I compare to that of Philadelphus, commonly called "Syringa," or perhaps more exactly to that of the white lily, together with a more aromatic constituent suggesting at one time chocolate, at another, musk. A second African orange-tip, *Teracolus achine*, has a scent, not always present, which reminds me of honeysuckle. The scent of a third African species, *Teracolus auxo*, in which the general coloration is yellow instead of white, recalls that of jasmine or Philadelphus.

Closely allied to these tropical and subtropical orange-tips is a group in which the orange apical patch is replaced by a brilliant crimson. The South African representative of this group has a scent which comes nearest to the garden heliotrope, commonly called "cherry-pie." In yet another group we find, instead of orange or crimson, an apical patch of glossy purple. The only species of purple-tip which I have had an opportunity of examining in the living condition is also possessed of a sweet, flowery scent somewhat different from that of the last.

Many more examples of these perfumed white butterflies could be given, but I should only weary you by multiplying cases. For our present purpose it is sufficient to say that among the butterflies that are fairly close relatives of our common whites, the odours, though not universal, are very frequently present; that they vary much in character and intensity, though possessing in common an agreeable quality and a likeness to the perfume of certain vegetable products, particularly to the scent of flowers. They are almost without exception confined to the male sex, and to the upper surface of the wings, and they are almost invariably found in connection with the peculiarly specialised scales that we have learned to distinguish as "plumules." The only exception to the latter statement that I know of among this particular assemblage of butterflies is the yellow African orange-tip, *Teracolus auxo*, in which I find no plume-scales, though it has a flowery odour which in some specimens is really strong.

Apart, then, from a few possible exceptions, we have certainly established a relation between the presence of plume-scales and the emission of a flower-like odour. What is the nature of this relation? To answer the question let us examine the plume-scale itself a little more closely. This diagram shows a typical form of plume-scale taken from one of the common African whites, *Belenois thysa*. This butterfly, which somewhat recalls one of our common whites, though generally larger, and still more closely resembles *Mylothris agathina* lately mentioned, has a strong, sweet odour like that of roses. The scale consists of a flattened plate, or lamina, rounded at the base and sharp at the apex. At the middle of the base is attached a slender footstalk, at the end of which furthest from the lamina we find another flattened structure, in this species shaped like a cheese-cutter, which may be called the "accessory disc," or simply the "disc." From the apex of the lamina arise the cilia-like processes, which may conveniently be termed the "fimbriæ." This may serve as an example of a form of plume-scale commonly found in the white butterflies or Pierinæ, but the scale in all its parts is liable to considerable modification; and, indeed, it may be said with truth that in no two species are the scent-scales exactly alike. The diagrams will show how very diverse are the forms assumed by the plumules of these white butterflies; but in all of them may be observed under various shapes the lamina, fimbriæ, footstalk, and accessory disc. The scale is formed of chitin, a substance which constitutes the outer covering, or external skeleton, as it is called, of many insects, and which when met with in bulk is of a hard and horny consistence, as may be seen, for instance, in the forewings or "elytra" of beetles. Chitin is practically a dead material, and there is no trace to be found in the scale of any protoplasmic or living matter. The granules which are present are probably pigment granules, the presence of which in the ordinary scales imparts to the wings their characteristic colour. So far we have discovered no apparatus to which we may attribute the production of perfume.

But now let us examine the means by which the scale is attached to the membrane of the wing. The point, or rather surface, of attachment is the accessory disc, which fits into a cup-shaped depression in the wing-membrane, which cavity, however, is generally not large enough to admit the whole of the disc. In many species can be seen an orifice in that part of the disc which is enclosed, when the scale is *in situ*, within the cup-shaped cavity or socket just mentioned. And when the fimbriæ are examined with a very high power, an appearance is seen in many species which suggests that their free extremities are not closed, but open; that they are, in fact, minute tubes which put the interior of the scale into communication with the outer air. Now can we discover any means by which, say, a vapour entering the disc by the orifice in its buried portion can be conveyed through the scale and find its way out through the patent extremities of the fimbriæ? It certainly appears that we can. Within the disc there is generally visible a chitinous structure which often bears the appearance of a convoluted tube; the footstalk which forms a bridge between disc and lamina is apparently not solid, but pervious. The lamina itself consists of two delicate chitinous layers, one of which may be called dorsal and the other ventral, enclosing a flattened cavity which contains a certain amount of interstitial material. This latter takes various forms in different species, but very often presents the appearance of a longitudinal striation, which in all probability betokens the existence of fine parallel channels or passages traversing the interior of the lamina side by side from base to apex. This longitudinal striation is frequently obscured by the accumulations of granular pigment; but in many cases there is a comparatively clear area near the apex where the striæ can be fairly well made out, and where they can be seen to correspond in number and position with the individual fimbriæ. There is, then, much reason to suppose that the cavity of the lamina is more or less completely divided into channels which communicate in one direction with the fimbriæ, and so, through the orifices of the latter, with the outer air; and in the other direction through the footstalk with the disc, and so through the aperture of the disc with the socket of the wing-membrane and its underlying structures. We have, therefore, some warrant for considering the scale to be a piece of apparatus not indeed for the manufacture, but for the distribution of scent; and to get some insight into the mode of production of the latter, it is evident that we must pursue our researches into the structure of the wing itself.

It was noticed by Weismann more than thirty years ago, and more recently by Günther, that in the hypodermis, as it is called, or cellular layer immediately underlying the homogeneous surface-membrane of the wing, there occur certain cells which appear to be specialised for the production of a secretion. These cells were described and figured by Günther under the name of "Drüsenzelle," or "gland-cells." In this diagram, which is copied from one of Günther's figures, we see two of these "gland-cells" in direct connection with the sockets in the wing-membrane into which fit the footstalks of two scales partly seen in section. These scales are not plume-scales, for they possess no disc; but if secreting cells are found, as here, in connection with scales of the ordinary kind, there seems to be no reason why we should not also find them in relation with plume-scales, supplying in that position the living and working protoplasmic element by means of which the scent-bearing secretion is elaborated. The clear spaces in these cells of Günther's figure are rather suggestive of the oil or fat vacuoles seen especially in growing cells of adipose tissue; and it may be conjectured that the scent-bearing secretion is of the nature of a volatile oil. In the case of the ordinary scales the secretion may still be oily. Probably most of us know how difficult it is to wet a butterfly's wing with water. This is no doubt partly due to the mechanical conditions involved in the coating of minute scales, but it is possible that, as in the case of the plumage of aquatic birds, some additional power of resistance to wet is afforded by the presence of an oily secretion, which may be conveyed to the surface by the scales of ordinary character. It is also possible, as has been suggested by Weismann, that the secretion formed in connection with the ordinary scales may bear an odour, though of a different nature from that of the plume-scales, and, at least in many cases, imperceptible by our senses. All this is a matter of more or less probable conjecture, and it is very clear that there is a good deal more work to be done before we can be sure that we know all about the various functions of the scales and their associated structures.

Before we go on to the next part of our subject I should like to call your attention to some figures that will be thrown upon the screen of various forms of plume-scales. In these figures the chitinous sculpturing of the scale will be seen. It differs in character from species to species, but in all there is more or less visible a longitudinal striation of the lamina, which we have seen reason for interpreting as an indication of channels along which pass the odoriferous secretions or exhalations from the gland-cells buried in the substance of the wing to the fimbriæ and so into the open.

The question will no doubt have occurred: are these plume-scales the only structures by which the scents of butterflies are distributed? They are by no means the only ones. There are many other methods of distribution of these flower-like odours, some of which we can find without going beyond the group of so-called white butterflies, or Pierines. Visitors to the south coast of England in the late summer and autumn months can hardly have failed to notice a very active butterfly of a fine bright orange colour with a dark border, which is especially given to haunting fields of lucerne and clover. This is the butterfly commonly called the "clouded yellow," one of the most conspicuous of the whites, or, as we ought rather to say, the Pierine butterflies. In this insect we should search for plume-scales in vain; but on examining in a male specimen the front edge of the hindwing where it is overlapped by the forewing, we find on the upper surface a patch of scales distinguished from their surroundings by their lighter colour. The microscope shows that these scales are of a different shape from those of the rest of the wing, and are packed much more closely together; moreover, instead of lying nearly flat upon the wing, like the tiles on a roof, they are set up on end, sometimes almost at a right angle. When the wing membrane is denuded of scales and examined with a high power, the situation of the patch is easily recognisable by the crowding together of the sockets for the insertion of the footstalks, and also by the fact that tracheæ, or air-tubes, are seen to be leaving one of the main "veins" of the wing and supplying this particular area, breaking up into smaller branches as they go.

In ordinary circumstances the scent of the clouded yellow is not easily detected; but if in a living specimen the scales be scraped off one of the patches that have just been described, they will in many cases be found to have an odour which is somewhat like that of the garden heliotrope, or "cherry-pie." The South African clouded yellow, which is much like ours, though quite distinct, has a similar patch and a similar odour. The scent-producing apparatus in these clouded yellow butterflies presents many features of interest; in the first place, the scent-scales are crowded together into one small area, instead of being generally distributed over the wing-surface as in the common whites. Then the scales are quite unlike plume-scales, having neither fimbriæ nor accessory disc, while the footstalk is short and quill-like, instead of being long and flexible as in the plume-scales. They are, indeed, quite of the type of the ordinary scales, except that they differ a little in size and shape from the scales of their immediate surroundings. The distribution of tracheæ, or air-tubes, to the site of the scent patch is noteworthy, and so also is the fact that in ordinary circumstances the patch is covered by the overlap of the forewing, which acts like a sliding lid. It may reasonably be conjectured that this arrangement ensures economy of the perfume. The production of the scent is confined to a limited area, and its escape is prevented under ordinary conditions by the overlapping edge of the forewing. When emission of the scent is required, a slight separation of the fore and hind wings gives it exit. The special distribution of tracheæ may be a provision for pumping air into the patch from below, and so supplying a *vis a tergo* to assist the escape of the perfume.

Many other butterflies possess similar patches of scent-distributing scales. They are generally, though not always, so placed as to be covered up in the ordinary position of the insect. In some instances there are two patches on each side, one on the upper surface of the hindwing, the other on the under surface of the forewing, these being so arranged that they exactly cover one another when the butterfly holds its wings in the normal position. It is to be observed that in these patches the rule is for the scent-scales to be of the same general character as the ordinary scales of the wing, though they may differ much from the latter in shape, size, and arrangement. The patches seldom contain plume-scales, and, when fitted with a sliding lid, I believe it would be correct to say that they never do.

The question may be asked: is it not necessary that the scent should be economised in the case of the plume-scales quite as much as in the case of the definite patches? No doubt it is; and a little further consideration of the typical plume-scale may show us how this is effected. The plume-scales, it is true, being as a rule generally distributed over the wing, cannot be shut down under a lid; but they are frequently scattered among ordinary scales which are a good deal longer and larger, and which may act as coverings to the individual scales, though there is no general covering for the whole. Then again, as we have seen, the plume-scale has an accessory disc and a long footstalk. The disc with its internal chitinous structure may act as a reservoir for the scent; it will be remembered that in many cases it appears to contain a convoluted tube. The footstalk seems to be flexible, and it often shows one or more sharp bends in its course. These bends may impede the passage of the scent from the reservoir in the disc to the lamina and fimbriæ, and the butterfly may be able, by some movement of its wings, to bring about a straightening of the footstalk and a consequent liberation of the odour. At any rate, it is probably significant that the apparatus of accessory disc and long flexible footstalk belongs to the plume-scale alone.

There is a handsome butterfly, common in Africa, which is not far removed in affinity from our well-known "brimstone." This butterfly, which is known as *Catopsilia florella*, has in the male a strong fragrant scent. Now *Catopsilia florella* possesses on the hindwing a patch of special scales which is somewhat similar in aspect and position to the scent-patch in the clouded yellow. But, curiously enough, the characteristic scent appears to proceed, not from the patch on the hindwing, but from another structure altogether. This is a beautiful silky fringe of long hair-like scales which are set along the edge of the forewing on its underside, and are covered as a rule by the overlap of the hindwing. When the wings are parted and the fringe spread out, a scent is exhaled which appears to both Dr. Longstaff and myself to be like that of jasmine or tuberose. The portion of the wing which forms the seat of this silky fringe, as well as that underlying the scent-patch of the hindwings, is furnished, like the patch in the clouded yellow, with a plentiful supply of air-tubes, proceeding to it from the adjacent "vein." In the case of the patch in *Catopsilia florella*, the ramifications of these air-tubes seem to form a fine polygonal network, each mesh of which surrounds the socket of a scent-scale. A similar appearance may be seen in the scent-patch of one of the Teracoli (*T. fausta*), and probably in that of others.

Sessile scent-patches, which may or may not be accompanied by silky fringes, occur in many other species of the brimstone-like section of Pierines, and in several of these, including both Asiatic and American species, a flowery odour has been detected both by the late Mr. de Nicéville and by Dr. Longstaff. An observation which would be of great interest, but which, so far as I am aware, has not yet been made, would be to compare the odour diffused by the fringes with that conveyed by the sessile patches in those species where both these forms of apparatus occur together.

An accumulation of hair-like scales, no doubt serving as scent-distributors, may also be seen in another genus of Pierines (*Dismorphia*) which is remote in affinity from those butterflies which have just been considered. But these odoriferous tufts or fringes are by no means confined to the Pierines. In the very different group of Satyrines, to which our common brown hedgerow butterflies belong, the males of some species possess fringes or tufts which are clearly similar in function to those of their distant cousins, the Whites. In one of these, an African species, I found that the odour produced was like that of vanilla chocolate. Another species of the same genus, a native of India, was named by Wood-Mason and de Nicéville *suaveolens*, from its pleasant fragrance. The vanilla odour was found by the same two observers in several other Indian butterflies belonging to different groups.

Some Satyrines have plume-scales which are not unlike those of the Pierines, but differ in seldom, or perhaps never, possessing an accessory disc. At the utmost they may show a slight dilatation of the articulating end of the footstalk. Plume-scales much like those of the common browns are also found in the Fritillaries, which belong to the great group of Nymphaline butterflies.

There is yet another kind of scent-scale, specialised in form. This is the well-known "battledore" scale, present in the male of many of the small blue butterflies belonging to the subfamily of Lycænids. These battledore scales are provided with apertures on their general surface which no doubt serve, like the apertures of the fimbriæ in the plume-scales, for the escape of the odour into the outer air. The ribs apparent in the "battledore" are in all probability homologous with the longitudinal channels seen in the Pierine plume-scale. These in Mylothris, as we have seen on the screen, take the form of ribs as definitely marked as those of the Lycænids.

So far, all the scents with which we have been concerned are of a kind that is agreeable to our own senses. But there is another sort of odour which is also commonly present, especially in the butterflies of tropical and subtropical regions, and which, instead of being pleasant to the human sense, is disagreeable or even repulsive. The Acræas, which are mostly reddish or brownish butterflies with small dark spots; the Euploeas, large butterflies which often show a brilliant purple gloss like that of our own purple emperor; the Papilios, of which a good example is the black and yellow swallowtail butterfly of the Cambridgeshire fens, have many of them an odour which may be called disgusting. Musty straw, stable litter, rabbit-hutches, acetylene, bilge-water, these are some of the substances to which the odours of these unsavoury butterflies have been compared. In some cases, as in the instance of the agreeable perfumes, the seat of these evil-smelling odours has been found in patches or tufts of specialised scales or hairs; in others the scent appears to be emitted from the general wing-surface. But in no instance, so far as I am aware, has any structure like a plume-scale been found guilty of emitting anything but a pleasing fragrance. A very remarkable difference between the scents pleasant and the scents unpleasant is this: that the former kind usually, though not invariably, is confined to the male sex; while the latter kind is common to both sexes, being often, indeed, stronger in the female.

It has, no doubt, occurred to you to ask: has the presence of these scents any particular significance with regard to the needs of their possessors; and if so, what? And why should the agreeable scents be so commonly confined to the one sex, while the repulsive odours are shared by both?

The second question helps us to answer the first. With regard to the scents of the disagreeable kind, which are probably often accompanied by a nauseous flavour, there is good reason to suppose that they are in effect a means of protection from insect-eating enemies. We have much actual evidence bearing upon the point. Evil-smelling butterflies, like the Acraeas or the well-known *Limnas chrysippus* (a large brown butterfly common throughout many parts of Africa and Asia), are often conspicuous, slow-flying, and given to courting observation rather than to avoiding it. These are all marks of butterflies which are more or less immune from attack by birds; and it may be added that the frequency with which many of them are copied by other butterflies gives further reason for the conclusion that they enjoy protection in virtue of their distasteful qualities—a protection which other butterflies are enabled to share by resembling them in outward appearance.

Now, granted that the avoidance of attack by birds is the object of the repulsive scents, we should, of course, expect to find them present not in one sex only, but in both alike. And this is precisely what we do find; moreover, since it is well recognised that the preservation of the life of the female is more important than that of the male for the welfare of the species, we should expect that if there is a difference between the sexes in the intensity of the odour, that difference would be in favour of the female. This, again, is borne out by observation in a number of cases. Where both sexes are repulsive, the female, as a rule, is the more repulsive of the two, and therefore (as a consolation) the safer from attack.

So much for the odours unpleasant. Now let us turn to the other kind, the fragrant flower-like perfumes with which we dealt at the outset. These, we saw, are frequently associated with specialised scales which are the exclusive property of the male sex. We cannot say quite so much for the odours themselves, for though in the great majority of cases they belong to the males alone, yet the females are not left entirely destitute. Fritz Müller many years ago found evidence of sweet scent in a female white butterfly, and since then Dr. Longstaff has detected in the females of several species a fragrance not unlike that of the male, but usually much weaker. Still, we may certainly say, speaking generally, that the pleasant odours show a vast preponderance in favour of the male. This suggests that they must have some significance in regard to the relations between the sexes; and, indeed, there can be little or no doubt that, as was first pointed out by Fritz Müller, these scents are employed by the males in courtship as a means of attraction; they may also perhaps serve as a means of recognition. That their employment is occasional, and not constant, appears from the fact that they are so often furnished with a provision for keeping them confined until wanted. There is, so far as I am aware, no direct evidence that they are more plentifully liberated during courtship; but to anyone who has observed the persistent fluttering of white butterflies about and around each other under those circumstances, it can hardly fail to occur that the fanning wing-movements of the male must have the effect of encouraging the evaporation and diffusion of the odour; also perhaps of aiding its escape from the disc through the footstalk and so into the lamina of the plume-scale. The flowery scents would thus come under the head of those features which have been called by Prof. Poulton "epigamic": characters, that is, which, like the splendid plumage of some cock-birds, are believed to further the cause of matrimony. If this interpretation be correct, it is most interesting to find that the æsthetic preferences of butterflies in the matter of scents are so much like our own. In other insects, as well as in many of the higher animals, we find attraction exercised by odours that to our senses are disgusting. Butterflies themselves are not exempt from a depraved taste where food is concerned; the best bait for the purple emperor is well known to be a piece of putrid meat. But in matters of love-making, the butterfly seems to resort for his means of fascination to methods which recall the human lover with his gifts of flowers and boxes of vanilla chocolate.

The evil odours tend to be somewhat persistent. In some cases they may be detected for a long time after the butterfly is dead and stiff. The agreeable scents, on the other hand, are usually evanescent, becoming imperceptible very soon after the insect has ceased to live. On one occasion I was able to detect the lemon-plant odour of a green-veined white when the butterfly had been dead for eleven days, but this is probably an extreme case. Both kinds of odour may be present in the same species; when this is so, it is commonly found that the first impression given by the butterfly is a disagreeable one, the pleasant constituent only becoming apparent when its distributing apparatus is specially exposed. These cases of a double odour follow the same rule of repulsive scents being common to the two sexes, and agreeable perfumes being confined to the male.

This finishes what I have to say on the subject of the scents of butterflies. I am conscious that I stand in need of your indulgence; as, from the force of unavoidable circumstances, I have had but a short time in which to prepare this lecture. But, "qui s'excuse, s'accuse," and I trust that in spite of its sketchy and imperfect character the discourse to which you have just listened may have succeeded in quickening the interest that most of us feel in these very attractive objects of nature, and in giving fresh emphasis to the fact that the study of insects in general, and of butterflies in particular, is capable of shedding light upon questions of high importance in the science of biology.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. Hugh Gunn, formerly Director of Education of the Orange Free State, has accepted an invitation from the Government of Western Australia to act as adviser and organiser for the university which that State is founding at Perth.

Mr. W. H. McMillan has been appointed to the newly founded chair of mining at University College, Nottingham. Prof. Heaton has been appointed principal of the college in succession to the Rev. J. E. Symes, who has resigned.

Among the bequests of M. Marino Corgialegno, a naturalised British subject, who died on April 26, are:—40,000*l.* to institute a school at Athens on the lines of Eton or Harrow, "sharing in the desire expressed to me by his Majesty King George that education in Greece should be rendered more perfect by the establishment of a public or secondary school upon the model of the English public schools, where boys will receive a regular course of teaching as well as of good breeding"; 40,000*l.* for a school for craftsmen at Argostoli, in the island of Cephalonia; 15,000*l.* for technical scholarships; 10,000*l.* each for a school for girls in Cephalonia, for schools or gymnasia in Argostoli, for a public library at Argostoli, for the Agricultural Society at Athens, for a polyclinical hospital in Athens, and for the Society for the Propagation of Useful Books.

The Educational Science Section of the British Association will meet at Portsmouth, under the presidency of the Right Rev. J. E. C. Welldon, Dean of Manchester. The president in his inaugural address, which will be delivered in the section on Thursday, August 31, will treat of educational problems of the day. His address will be followed by a discussion on the overlapping between secondary schools and universities and other places of higher education, which will be opened by Prof. A. Smithells, F.R.S., and Prof. R. A. Gregory. On Friday, September 1, there will be a discussion on the place of examinations in education, with papers by Mr. P. J. Hartog, Miss Burstall, Dr. T. P. Nunn, and Mrs. Dr. White. The discussion will be opened by Mr. A. A. Somerville and Mr. W. D. Bentliff. A discussion on grammatical terminology will be opened by Prof. E. A. Sonnenschein and Mr. P. Shaw Jeffery. On Monday, September 4, the subcommittee on mental and physical factors involved in education will present its report, which will deal with the question of feeble-mindedness in children. There will be a discussion on the diagnosis of feeble-mindedness, with papers by Dr. Abelson, Dr. C. W. Saleeby, and Dr. Tredgold, followed by a discussion on the education of feeble-minded children, with papers by Mrs. Burgwin, Miss Dendy, and Dr. Auden. Prof. J. A. Green will also read a paper on backward children. On Tuesday, September 5, there will be a discussion on practical education in the Dockyard and Naval Schools, with papers by Mr. George Dawe, headmaster of the Dockyard School, and Mr. W. H. T. Pain, of H.M.S.

Fisgard. The discussion will be opened by Dr. C. W. Kimmins. A paper on the study of German will also be read by Mr. G. F. Bridge, and a paper on school books and eyesight by Mr. G. F. Daniell.

A "MEMORANDUM on Physical Training in Secondary Schools" has just been issued by the Board of Education, and is obtainable from Messrs. Eyre and Spottiswoode, price 2*d*. That physical education at the secondary-school age is of primary importance scarcely needs to be insisted on, but it is well to have the large generalities of such education set forth, as here, in a coherent exposition. The secondary school covers the adolescent age of boys and girls—the age when growth is very rapid and the transit to manhood and womanhood demands all the care and knowledge that the best informed teacher can provide. The present memorandum does take some account of this, but does not emphasise it quite so much as the trainers of male and female youth might properly expect. Under the "objects of physical training"—it is a pity that the term "physical education" is not uniformly used—Sir George Newman gives a good summary of the nervous basis of training and the value of training in promoting "habits of discipline, obedience, ready response, and self-control." Doubtless, physical education, being a special department of mental education, *can* be used to generate such "habits"; but why insist on the merely passive aspect of education? The end of education is not to produce habits of obedience or ready response except as means to the greater end of personal self-sufficiency and independence of character. Self-development is as important as self-control, and presupposes it. But Sir George Newman is not unaware of this, for he says, "undue emphasis should not be laid upon the disciplinary effects of physical training." He justifies the Swedish system on the whole. He gives general directions as to length of lessons, the place of physical education in the time-table, and the qualifications of the teachers. "Especially as regards children and young people, physical training is not a mere matter of technical expertness." "Girls should, of course, be taught by women." Any system should be practised under the general supervision and with the constant cooperation of the medical officer of the school. The memorandum is really a memorandum, and should be to every secondary-school teacher a constant reminder of the principles and risks of physical education.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, July 24.—M. Troost in the chair.—H. **Deslandres**: Remarks on the movements of the solar prominences. The author regards the upper layer of the solar atmosphere as being ionised and under the action of a magnetic field. This field causes movements in the solar ions, especially those rising and falling. The theory explains easily all the observed peculiarities of the velocity of rotation in the prominences and the upper layer. In the present paper some further consequences of this theory are developed, and a scheme of research suggested for its control.—A. **Laveran** and M. **Roudsky**: Concerning the action of oxazine (triaminophenazoxonium chloride) on trypanosomes. The selective action of the centrosomes of the trypanosomes for oxazine, noted by Werbitzki, takes place both *in vitro* and *in vivo*. The disappearance of the centrosomes in *T. brucei*, and the fact that this morphological modification can be transmitted by heredity, is confirmed. Other species are similarly affected, but to varying degrees. The virulence of the trypanosomes submitted to the action of oxazine is reduced.—R. **Zeiller**: A Triassic flora discovered at Madagascar by M. Perrier de la Bâthie.—Emile **Belot**: The period of rotation of Venus. The observed period of rotation of Venus has been recently given by M. Bigourdan as twenty-nine hours. The author points out that in a communication to the academy in 1906 he gave a general formula from which this period was deduced to be 28h. 12m.—M. **Giacobini**: Observations of the Brooks comet (1911*c*) made at the Observatory of Paris. Data given for July 22 and 23. The comet appears as a rounded nebulosity 35″ to 45″ diameter, with a well-defined central nucleus. Magnitude 11·5 to 12.—L. **Picart** and F. **Courty**: Observations of the Brooks comet (1911*c*) made at the Observatory of Bordeaux with the 38 cm. equatorial. Data given for July 22 and 23. Comet showed a clear nucleus about tenth magnitude.—Witwold **Jarkowski**: An approximate law for the ascent of an aëroplane.—Marcel **Brillouin**: Polymorphism and molecular orientation.—G. **Sagnac**: Some paradoxes concerning the optical actions of the first order of the translation of the earth.—A. **Cotton**: Circular dichroism and rotatory dispersion.—G. **Bruhat**: The study of rotatory dichroism of a definite organic compound (diphenyl-*l*-bornyldithiourethane).—E. **Besson**: The asymmetry of the positive and negative ions relatively to the condensation of water vapour. An attempt to record photographically the results described by C. T. R. Wilson.—H. **Buisson** and Ch. **Fabry**: The amount of energy necessary to produce the unit of luminous intensity. Working with a Heraeus quartz mercury vapour lamp, the number of watts radiated per mean spherical candle was found to be 0·31 for the violet (4538), 0·018 for the green (5460), and 0·031 for the yellow (5780).—M. **Herschfinkel**: The action of the radium emanation on thorium salts.—Ettore **Cardoso**: The densities of the coexistent phases (orthobaric densities) and the diameter of sulphur dioxide in the neighbourhood of the critical point. Part of a series of researches on the law of the rectilinear diameter at temperatures near the critical point. The influence of agitating the liquid under experiment is clearly shown in the results.—L. **Tchougaeff** and P. **Koch**: An anomaly of the molecular refraction in the series of the substituted gloximes.—L. **Gay**: The notion of an expansibility pressure.—Victor **Henri**: Study of the ultra-violet radiation of quartz mercury vapour lamps. The ultra-violet rays from a mercury lamp increase very rapidly with the watts used, this increase being especially rapid in the neighbourhood of 209 watts. The action on citrate of silver papers is parallel with the bactericidal action upon the coli bacillus, and the yield of such a lamp when used for sterilising purposes may be very conveniently controlled by such papers.—G. **Massol** and A. **Faucon**: The latent heat of fusion and specific heat of the fatty acids. The discrepancy previously noted between the latent heats of fusion and solidification of formic, acetic, and propionic acids is now shown to occur with lauric acid. The possible causes of this difference are discussed.—G. **Darzens** and F. **Bourion**: The action of thionyl chloride upon metallic oxides. In numerous cases in which the action of thionyl chloride upon metallic oxides was studied the chloride behaved as a mixture of chlorine and sulphur dichloride. Since the latter is easier to prepare and purify, its use for chlorinating oxides is preferable.—Marcel **Guichard**: The extraction of the gases from copper by a chemical reaction, and the estimation of oxygen. Methods are described for converting copper either into the iodide or oxide, and recovery of the gases contained in the metallic copper. The limits of error of the two methods are indicated.—Georges **Dupont**: The catalytic preparation of some substituted ketohydrofurfuranes. Some examples of the hydration of some acetylenic pinacones by the catalytic action of a dilute solution of mercuric sulphate.—Frédéric **Reverdin**: The nitration of the ortho-, meta-, and para-nitrobenzoyl-*p*-anisidines.—Marcel **Delepine**: The sulpho-ether salts or thionic esters R.CS.OR′.—H. **Colin** and A. **Sénéchal**: The action of acids on the catalytic oxidation of the phenols by ferric salts.—R. **Locquin**: α-Methyl-laurenone, a new ketone derived from camphor. Baeyer and Villiger have shown that one of the products of Caro's reagent on camphor is a lactone, $C_{10}H_{16}O_3$. A compound $C_9H_{14}O$ has been isolated in the course of researches made to determine the constitution of this lactone, and this compound is shown to be a tetramethyl-*cyclo*pentenone. It is a methyl derivative of the laurenone previously described by Tiemann.—Th. **Nicoloff**: The ovule and the embryonic sac of the Plataneæ.—A. **Guilliermond**: The formation of the chloroleucites at the expense of the mitochondria. P. A. **Dangeard**: Complementary chromatic adaptation in plants. A. **Magnan**: The digestive surface of the ventricule and the muscular arrangement of the gizzard in birds.—Jacques **Pellegrin**: The distribution of the soft-water fishes in Africa.—Paul **Marchal**: Spanandria and the obliteration of sexual reproduction in Chermes.—M. **Bordas**: Considerations on the reagents employed for the determination of blood stains in legal medicine. Remarks in confirmation of the views put forward in a recent paper by A. Sartory on the unsatisfactory nature of various colour reactions in use for the detection of blood stains.—Y. **Manouelian**: Researches on the pathogeny of arterio-sclerous lesions.—L. **Launoy** and C. **Levaditi**: Mercurial treatment of experimental syphilis of the rabbit and of Brazilian spirillosis.—Albert **Berthelot**: Researches on the intestinal flora. Isolation of the micro-organisms which specially attack the ultimate products of the digestion of proteids.—Em. **de Martonne**: The principles of morphological analysis of erosion levels applied to the Alpine valleys.

CALCUTTA.

Asiatic Society of Bengal, July 5.—B. C. **Mazumdar**: The Stambhesvari. Mr. Mazumdar identifies the goddess Stambhesvari, whose name is to be found in the copper-plate inscriptions of Kulastambhadeva and Ranastambhadeva, with a goddess still worshipped by some aboriginal tribes.—D. **Hooper**: Phosphorus in Indian foodstuffs. This paper is the result of an inquiry, made in collaboration with Major E. D. W. Greig, into the diet of patients suffering from epidemic dropsy in Calcutta in 1909–10. The amount of phosphorus in the form of phosphoric anhydride is given in several samples of rice, wheat, and other cereal grains, as well as in animal foods, farinaceous foods, vegetables, nuts, and fruits consumed in India.—W. **Kirkpatrick**: Folk songs and folk lore of the Gehara (Kanjars).

CAPE TOWN.

Royal Society of South Africa, June 21.—Dr. Marius Wilson in the chair.—E. P. **Phillips**: A note on the principal systematic work and publications dealing with the South African Proteaceæ. The first recorded publication of a member of this order was by Clusius in 1605. In 1720 Boerhaave attempted a systematic study of the order, but it was not until 1809 that a really scientific monograph was published by Salisbury; in the following year appeared the classic work of Robert Brown. The standard work on the order is a monograph by Dr. Meisner, which appeared in De Candolle's "Prodromus" in 1856, where 279 species are described. The writer undertook to revise the order, and has recorded between 300 and 400 species of the genera Diastella, Salisb., and Orothamnus. Pappe, sunk by Meisner, have been re-established, and one new genus, Spatallopsis, Phillips, founded.—J. **Moir**: The spectrum of the ruby, part ii., and the artificial ruby. By examination of the ruby with better instruments, the complete spectrum of eight hair lines has been discovered; they are best seen in the artificial ruby, which is identical with the natural ruby in all respects, and when free from flaws is actually superior to the natural gem.—J. **Moir**: Notes on the spectrum of the precious emerald, and other gem stones. The emerald spectrum contains three very distinct hair lines in the red. Sapphires have no hair lines in their spectrum. Artificial emeralds are green sapphires, and have an indefinite spectrum, as is also the case with the following:—rubellite, spinel, amethyst, fluor, aquamarine, rose-quartz, lepidolite, and topaz. The almandine spectrum has been re-examined.—J. R. **Sutton**: A note on the land and sea breezes of South Africa.

FORTHCOMING CONGRESSES.

AUGUST.—Centenary of the Foundation of the University of Breslau.

AUGUST 12–18.—First International Congress of Pedology. Brussels. President: M. Alexis Sluys. Secretary: M. Vital Plas, 35 Avenue Paul de Jaer, Brussels.

AUGUST 13-[illegible].—Prehistoric Society of France. Nimes.

AUGUST 31–SEPTEMBER 6.—British Association. Portsmouth. President: Sir William Ramsay, K.C.B., F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

SEPTEMBER 4–6.—Centenary of the University of Christiania. President of Festival Committee: Prof. Brögger.

SEPTEMBER 9–20.—International Congress of the Applications of Electricity. Turin. President of the Committee of Honour: H.R.H. the Duke of the Abruzzi. Honorary Secretary of the Committee: Signor Guido Semenza, Via S. Paolo 10, Milano. International Secretary: Col. R. E. Crompton, C.B., R.E., Crompton Laboratory, Kensington Court, W.

SEPTEMBER 12–15.—Celebration of the Five-hundredth Anniversary of the University of St. Andrews.

SEPTEMBER 18–23.—International Conference of Genetics. Paris. President: Dr. Viger. Secretary: M. Philippe de Vilmorin.

OCTOBER 2–7.—Third International Congress of Hygiene. Dresden. General Secretary: Dr. Hopf, Reichsstrasse 4, Dresden.

OCTOBER 12–18.—Italian Society for the Advancement of Science. Rome. President: Prof. G. Ciamician. General Secretary: Prof. V. Reina, Via del Collegio Romano 26, Roma.

OCTOBER 15–22.—Tenth International Geographical Congress. Rome. President: Marquis Raffaele Cappelli. General Secretary: Commander Giovanni Roncagli, Italian Geographical Society, Rome.

DECEMBER 27.—American Association for the Advancement of Science. President: Dr. C. E. Bessey, University of Nebraska. Permanent Secretary: Dr. L. O. Howard, Smithsonian Institution, Washington, D.C.

CONTENTS.

THURSDAY, AUGUST 10, 1911.

GYMNOSPERMS.

Morphology of Gymnosperms. By Prof. J. M. Coulter and Prof. C. J. Chamberlain. Pp. xi+458. (Chicago: The University of Chicago Press; London: Cambridge University Press, 1910.) Price 16*s.* net.

In 1901 Profs. Coulter and Chamberlain published a short treatise on the Gymnosperms, forming the first volume of their "Morphology of Spermatophyta." Their present work takes the place of this volume, and is practically a new book, designed on a far more liberal scale than its predecessor. The number of pages has grown from 188 to 458, and the illustrations have increased in an even greater proportion. The extension of the book is in no small degree due to the original researches of the authors and their pupils; the special contributions from the Chicago laboratory have amounted to twenty-six since 1901.

"The present account, therefore, is based upon our own work, supplemented by the work of other investigators, rather than a compilation from literature, supplemented by occasional personal observations" (preface).

A striking feature of the book is the prominence now given to palæobotanical evidence.

The book is an invaluable record, admirably illustrated, of our present knowledge of the older type of seed-plants; on reading it one is enabled to realise in what respects essential progress has been made, and where, in spite of the accumulation of detail, there has been little real advance. The latter, less favourable position exists, in the reviewer's opinion, in respect of the Conifers, in which the most fundamental points of morphology and affinity still remain obscure.

The book begins with an account of the Palæozoic class, Cycadofilicales, a name which the authors prefer to the more modern designation, Pteridospermeæ, now generally adopted in England and France. The authors are certainly well-advised to include a description of the Pteridosperms in their book, though some botanists have thought it best to keep these fern-like seed-plants of the Palæozoic apart from the Gymnosperms, on the ground of their manifestly primitive characters. In this book there is a tendency to minimise the peculiar features of the Pteridosperms, which mark them off as an archaic group. The entire absence of anything approaching to a strobilus separates them, among other characters, from all Gymnosperms except the female plant of Cycas. In any case, however, the close relations between the seed-ferns and the true Gymnosperms are undisputed and of fundamental importance.

The Cycadofilices were recognised as a distinct group before their reproductive organs were discovered. The authors scarcely do justice to this rather impressive instance of the successful use of anatomical characters in determining systematic position; they say:—

"The striking anatomical feature of the Cycadofilices is the association of secondary wood with a fern-like vascular system. There was no occasion, on this account, to remove Cycadofilices from Pteridophytes" (p. 2).

No one who knew Williamson's work was likely to found a new group on such a basis; other considerations, as, for example, the close agreement between the leaf-trace strands of Lyginodendreæ and those of Cycads carried much more weight; the authors appear in this instance not to have consulted adequately the original memoirs. They do full justice, however, to the importance of the work done in recent years on morphological anatomy, especially that of the vascular system:—

"Vascular anatomy has emerged as a subject organised upon a morphological basis, and its value in supplementing the older morphology cannot be overestimated" (p. 4).

Though open to some criticism in detail, the account given of the Pteridosperms is on the whole an excellent summary, and will be welcomed by readers who are not familiar with special works on palæobotany.

The interesting question of the constant absence of an embryo in all Palæozoic seeds hitherto investigated is discussed. This has been regarded as the normal condition, the development of the embryo not having begun until after the seeds were shed, and then having passed over at once into germination. The authors, on the other hand, incline to the view that all Palæozoic seeds investigated were abortive, having been shed prematurely. The fact that nearly all the seeds observed are at the same stage of development, and the usual presence of normal pollen in the pollen-chamber scarcely seem consistent with this view.

The remark that the seeds of Pteridosperms

"are very far from being primitive in structure, and are no more suggestive of the origin of seeds in general than are the seeds of existing seed-plants" (p. 34),

appears just, and indicates how much remains to be learnt in this field.

In discussing the relations of the Pteridosperms to the ferns it is pointed out that "Filicales are probably so ancient that all of our evidence is relatively modern" (p. 55).

"The gap between the homosporous Primofilices (or their unknown ancestors) and the seed-bearing Cycadofilicales is an enormous one, including the evolution of both heterospory and the seed" (p. 57).

The authors divide Gymnosperms into Cycadophytes and Coniferophytes (the latter name too glaringly hybrid to be acceptable). They include the Cycadofilicales in the former, which is not Nathorst's arrangement, as erroneously stated on p. 59. The two great phyla are regarded as "both differentiating from the Cycadofilicales or each arising independently from the progenitors of the Cycadofilicales" (p. 59). This is a little confusing, for on the former alternative the Cycadofilicales would have differentiated from themselves. It would have been better to leave the Cycadofilicales (Pteridosperms) as an independent ancestral group, lying at the root of all the other branches.

Chapter ii. is devoted to the Bennettitales, the characteristic Mesozoic Cycadophytes, remarkable for their anticipation of the angiospermous flower.

The authors have been misled by the synonymy in one instance, for they describe *Williamsonia angustifolia* and Wielandiella as distinct plants, whereas they are merely two names for the same thing (pp. 66 and 86). A more serious error is the statement that Nathorst confirms the view that the flowers of the Yorkshire Williamsonias are *bisporangiate* strobili (p. 76). Nathorst's conclusion is that these flowers were monosporangiate (unisexual).

The derivation of the Mesozoic Bennettitales from the Palæozoic Cycadofilicales will be generally accepted, but the statement that "the bisporangiate character of the strobilus is probably to be explained by the bisporangiate character of the fronds of those Cycadofilicales which gave rise to Bennettitales" (p. 87) is more open to question. We have at present no evidence of the existence of bisporangiate fronds in the Palæozoic group; neither is it necessary to assume their existence in order to explain the association of stamens and carpels in the same flower.

Chapter iii., on the Cycadales, is no doubt the best account we have of this important and fascinating family. A large number of original observations, by members of the Chicago School of Research, are embodied, and there are some very fine new figures.

Dioon edule, a Mexican Cycad, said to attain an age of 1000 years, has now been added to the list of species in which fertilisation by motile spermatozoids has been observed.

The statement that the Cycadales are "probably not so old as either the Ginkgoales or the Coniferales" may need revision. Our records are scanty, but carpels scarcely distinguishable from those of recent species of Cycas are known as far back as the Lias.

In the chapter on the Palæozoic Cordaitales there is not much room for novelty, for here our knowledge has advanced but slowly of late. The current views of their affinities are adopted. The related phylum of the Ginkgoales (chapter v.), of which there is only one survivor, the maidenhair tree, is regarded as retaining certain primitive features in common with the Cycadophytes, while it has advanced more in the direction of the Coniferales, and has developed certain peculiarities of its own (p. 217).

Chapters vi. and vii. are on the Coniferales, which, from their extent and variety, naturally demand a fuller treatment than any other group. The account given is excellent, and contains much of interest, but one realises that the Conifer problem still remains to be solved.

The class is divided into Pinaceæ and Taxaceæ, but it is very doubtful whether even this first grouping is natural, for the Podocarps among the Taxaceæ seem to have little to do with the Yews, while they have much in common with the Araucarians among Pinaceæ.

Perhaps too much is made of the supposed special antiquity of the Abietineæ (firs). The arguments in support of the primitive nature of this tribe are not altogether convincing.

In stating that the Taxaceæ have not been recognised further back than the Cretaceous (p. 349), the authors ignore Nathorst's suggestion that the Rhætic genera Stachyotaxus and Palissya may be early representations of the Podocarps.

The heterogeneous group of the Gnetales forms the subject of chapter viii. We think that more stress might have been laid on the possible affinity, originally suggested by Wieland, between Welwitschia and the Mesozoic Bennettitales. The hermaphrodite flowers and monadelphous stamens occurring in Welwitschia are striking points of agreement with the extinct group.

The account of the three extremely diverse genera which make up the Gnetales is of much interest, and contains various details hitherto not readily accessible to the student. The relationship of such isolated types, with no known fossil history, necessarily remains obscure.

The final chapter, on "Evolutionary Tendencies among Gymnosperms," previously published in part as a separate paper, sums up the main results. The diagram on p. 409 gives a good idea of the probable evolutionary connections of the various groups, though in one or two points it is not quite consistent with the statements in the text. Though the reviewer does not agree with quite all the authors' conclusions, he is in entire sympathy with their principle that

"the relative position of any form in a scheme of classification can be determined only by averaging all its characters; and its relative age in a scheme of phylogeny can be determined only by the sure testimony of history" (p. 425).

D. H. S.

THE EVOLUTION OF OUR ISLANDS.

The Building of the British Isles, being a History of the Construction and Geographical Evolution of the British Region. By A. J. Jukes-Browne, F.R.S. Third edition, rewritten and enlarged. Pp. xv + 470. (London: E. Stanford, 1911.) Price 12*s*. net.

THIS new edition of Mr. Jukes-Browne's well-known book makes it virtually a manual of the geology of the British Isles. The photographic illustrations bring the relations of the rocks clearly home to us, and many of them are works of art, such as Prof. Reynolds's view of chalk and lavas at Garron Point (Fig. 61), and Mr. R. F. Gwinnell's Miocene folding at Lulworth (Fig. 63). The numerous maps, suggesting the relations of land and water at various epochs, suffer, as all such maps must do, from our ignorance of details. The sweeping boundaries of continents and the generalised forms of firths and sounds are perforce unlike anything that we now know upon the earth. Printed explanations on the maps would greatly aid the reader, such as "area of Bunter pebble-beds," "Lake-basin," and so forth. There is a mysterious dotted line on Fig. 19, for which one must search the text, while much guidance is required for the lines and colours on Fig. 57. The result may, however, be regarded as happy, if the casual reader is sent through a lengthy chapter, to find there a summary of the latest researches, and evidence of a critical mind that looks eastward across Europe. Mr. Jukes-Browne does not hope to satisfy everyone. He gives us a marine Lower Devonian series across south-west Ireland (Fig. 19), the Glengarriff Grits being supposed to represent the deposits of a land-locked bay. He carries the Upper Senonian sea (Fig. 53 and p. 333) boldly into Scotland, Wales, and central Ireland, though flints are scarce in the surface-deposits of some of the areas thus invaded, and though they are not likely to have been carried away by subsequent marine action (compare p. 426). The rapidity of the oscillatory movements in Cretaceous times is properly insisted on, if we are to regard the chalk as a deep-water rather than merely as a pure-water deposit.

The consideration given by the author to the conditions under which successive series were formed is well seen in his comparison of the Bunter pebble-beds with the alluvium of the Helmand River (p. 234), or in his very interesting discussion of the Pliocene and Pleistocene deposits (pp. 404–61). The references to recent literature show how keenly he has watched the progress of research. We thus have Mr. Hickling's views on the Permian affinities of the outliers of sandstone near Dumfries, which are often supposed to be of Triassic age (p. 208); Prof. Watts's suggestion (p. 379) of the Eocene age of igneous rocks in the English Midlands; and Mr. Bernard Smith (p. 237) on the "skerries" of the Keuper marls. Anyone who has become attracted by the varied surface of our islands, or even by the scenery of a single county, will find his views enlarged when he follows Mr. Jukes-Browne into the past. He will at once feel the complexity of the subject, and the vast range of the events that have determined the present forms of hill and dale. After reading a few pages, a healthy reaction sets in against the superficial physical descriptions in which we all are liable to indulge. No one can read "The Building of the British Isles" without becoming again a student. The author's expressions of personal opinion will stimulate inquiry rather than remove all doubt. This is the manner of the true scientific teacher, and we feel that Mr. Jukes-Browne has made new claims on our regard.

To enjoy a book so full of detail, one must see and remember the country it describes. In ten years, in holidays of a few days at a time, the geologist may learn a great deal of the aspect of our islands. To anyone who has happily crossed the open country, from the rocky coves of Cornwall to the heather-covered slopes above the Moray Firth, or from the sunlit dunes of Donegal to the grey mud-flats near the Nore, these pages will make a singular appeal. Perhaps we may read into the book a good deal obtained from other sources, since it presupposes a general knowledge of the great tectonic movements that have affected the European area. In spite of what we have said, it is intended primarily for the geologist.

Every British or Irish geologist, moreover, will find points that he will like to criticise. Why, for instance, should stratified gravels be difficult to understand (p. 440) on the hypothesis that they result from the washing of boulder-clay? Does not the melting ice supply the very agent for their stratification? A "very deep basin" would not be required (p. 128) for the accumulation of the Cornstone series in Wales, but only a continuously subsiding floor. The omission of the Snowdon area from the description of the Ordovician rocks of North Wales seems surprising (pp. 68 and 69), and no stranger would suspect the immense part played by volcanic action in originating the scenery between the Conwy and Llanberis. Other geologists, however, must now enjoy the book, and discover their particular grievances to the author, who has done so much to help them. G. A. J. C.

TECHNICAL THERMODYNAMICS.

Applied Thermodynamics for Engineers. By Prof. W. D. Ennis. Pp. viii+438. (London: Constable and Co., Ltd., 1910.) Price 24*s*. net.

THIS is by far the most comprehensive book published in the English language on the subject of technical thermodynamics. It contains an account, brief but lucid, of the transformations of heat and mechanical energy which occur in almost every conceivable industrial process. As evidence of this widespread treatment, it is only necessary to mention that among the processes discussed are the development of power in the internal combustion engine, in the steam engine, in the hot-air engine, air and gas compressors, distillation plant, mechanical refrigeration, fusion and liquefaction of gases. To the discussion of these various topics Prof. Ennis brings experience gained in the mechanical engineering side of the Polytechnic Institute of Brooklyn, and it is clear that in his study of these problems he has made a digest of recent work on the subject of gases and vapours. His style of writing is graphic, forceful—but eccentric in so far as he seems actually to seek opportunities for splitting the infinitive; in fact, he does so no fewer than four times in the first five pages of the book, and after that we gave up counting.

A useful feature is the appendage to each chapter of a brief synopsis of its contents, together with a bibliography of the authorities quoted. Problems are added for the use of students, but the author does not commit himself to their solution, a cautious step in a first edition.

Prof. Ennis's immediate aim is expressed in the following words:—

"Thermodynamics is physics, not mathematics or logic. This book takes a middle ground between those text-books which replace all theory by empiricism and that of the other class of treatises which are too apt to ignore the engineering significance of their vocabulary of differential equations. We here aim to present ideal operations, to show how they are modified in practice, to amplify underlying principles, and to stop when the further application of those principles becomes a matter of machine design."

The author may fairly be said to have carried out these intentions successfully, in spite of the necessarily considerable labour which must have gone to the compilation of so compressed a treatise.

It is not possible to discuss at length the methods followed by the author even in a section of the subjects he deals with, but some call for passing notice. Thus, he introduces early the idea of increasing specific heats of gases, and uses a formula of the form $k=a+bT$, which he applies to the calculation of entropy. He shows that when expansion follows the path (called a "polytropic" path) $pv^n=$ constant, the rate of heat absorption or emission is directly proportional to the temperature change, and the author therefore deduces that the "specific heat" *must* be constant along any such path. This seems confusing when it is realised that this particular proof rests on the hypothesis of a constant specific heat, but investigation shows the confusion to be due to a somewhat loose use of the term "specific heat." This may prove a stumbling-block to some readers. After a careful and necessarily compressed account of the basic thermodynamic laws, the author gives an account of the properties of entropy, and of the limitations to be observed when non-reversible cycles are being studied. He rightly points out that many of the most important engineering processes are not even "cyclic," to say nothing of their not being "reversible." He remarks—

"A careful distinction should be made at this point between the expression $\int\frac{dH}{T}$ and the term 'entropy.' The former is merely an expression for the latter under specific conditions . . . perhaps the most general statement possible for the second law of thermodynamics is that all actual processes tend to increase the entropy; as we have seen, this keeps possible efficiencies below those of the perfect reversible engine." He concludes, however, that "most operations in power machinery may, without serious error, be analysed as if reversible; unrestricted expansions must always be excepted. The entropy diagram to this extent ceases to have an automatic meaning."

We seem here to be getting nearer to the desired harmony between the various views, as to the nature of entropy and its utilisation, which have been expressed in the past. Brief as the author has found it necessary to make his description of the action in a gas producer, he has been able, we are glad to see, to consider the important case where exhaust products are employed instead of steam as a "heat reservoir," and he gives on p. 153 an interesting diagram comparing the two alternatives, which should prove very useful in practice.

It may be a surprise to some readers to find that, contrary to the usual custom, the internal combustion engine is dealt with before the steam engine; but since the study of gases is easier than that of vapours, it is in reality a rational sequence to adopt. The section on the steam engine is very complete, and includes an account of wire-drawing, condensation, steam-jacketing, superheating, compounding, the use of turbines, boilers, drafts, fans, chimneys, stokers, economisers, pumps, and injectors. It would have seemed rash to forecast that so many subjects could be treated in one book, but the author has succeeded in including all this, and more, in his four hundred and forty pages.

In conclusion, we have no hesitation in welcoming the book as a valuable addition to the literature of the subject. It will be of special use to scientific engineers, to practical physicists, and to that growing student class which aspires to become the one or the other.

THE SOURCES OF EDUCATIONAL THEORY.

The Child's Inheritance: its Scientific and Imaginative Meaning. By Dr. G. Macdonald. Pp. xii+339. (London: Smith, Elder and Co., 1910.) Price 12s. 6d. net.

THIS book, which some readers will find prolix and whimsical, but all must acknowledge to be eloquent and sincere, seeks the ideal form of the educational process as a development of the child's racial inheritance.

"In the understanding of the child's inheritance both the poet and the biologist are worth deep and close study, not because they are necessarily antagonistic, but because, if they understood each other better, the gain to education would be incalculable."

For this reason the author directs us to Wordsworth's "Prelude" and Weismann's theory of the continuity of germ-plasm as the best sources of educational doctrine. The synthesis is original, and Dr. Macdonald is probably right in thinking that Weismann "would find his place somewhat unexpected while standing as the poet's squire." He would possibly be still more astonished at his proximity to William Blake, who is also repeatedly quoted.

Dr. Macdonald has published elsewhere a lecture on "The Sanity of William Blake." The citations in the present work certainly indicate that a teacher with the right temperament may learn much professional wisdom from the mystical poet. With the aid of these oddly consorted authorities the author discusses the nature and interaction of the child's endowment and environment. The former is "the old world within"—the epitome, as Haeckel taught, of phylogenesis. The latter is "the new world without," which, by imitation, by suggestion, and in other ways, moulds the plastic substance of the child's mind. Examining in further detail the interplay between these fundamental factors, the author finds two processes or aspects of mental growth to be of the first importance—expression and imagination. The chief means of expression is "the service of the hand." The discussion of this topic is rather one-sided, but is nevertheless an interesting and valuable contribution to a subject of much present importance.

The chapter on imagination—described as "that something in the child which recognises the shining light in all things living"—gives occasion for some not ill-founded criticisms of existing views of man's nature and of educational practices based on them. The chapter headed "Faith and Recreation" contains an admirable doctrine of the functions and value of play. In an intermediate chapter "On Specialisation," the author is led by his favourite thesis that mental life is more than "an assembly of various functions" to combat vigorously any form of specificity in education. It is perhaps unfortunate that a criticism of education, which, though ill-balanced and occasionally extravagant, must on the whole command respect, should lead to this position. For many of us feel that vocational education, properly understood, is the most hopeful means of giving the child effective possession of his inheritance.

T. P. N.

SPECULATIVE COSMOGONY.

Essai de Cosmogonie tourbillonnaire. By E. Belot. Pp. xi+280. (Paris: Gauthier and Villars, 1911.) Price 10 francs.

THE preface to this volume of speculative cosmogony will not raise much hope in the mind of the orthodox or sceptical man of science. "Faisant table rase de toutes les méthodes actuelles de la mécanique céleste spécialement créées pour des astres isolés . . . il doit chercher par la pure logique appuyée sur l'expérience comment ces corps ont pu réaliser *tous* leurs mouvements actuels. . . ." The advice is too sweeping to be readily accepted. The phenomena which the one new theory is to explain are so varied and numerous that suspicion is at once aroused against the arguments employed.

A hypothesis that, in a short chapter of twenty-seven pages, is to account for "les alignements d'étoiles, les étoiles doubles, multiples; les amas d'étoiles; les nébuleuses amorphes, planétaires, annulaires, elliptiques, les étoiles nébuleuses, les nébuleuses spirales, les courants d'étoiles" must be well grounded to stand any reasonable chance of general acceptance. And when this hypothesis is also to explain the solar periodicity and equatorial acceleration and the masses, mean distances, and inclinations of the planets, even the most credulous mind must pause before giving adhesion to the new views. It is true that in the law of gravitation an explanation of a vast number of diverse phenomena was sought. But gravitation could be and has been triumphantly put to the supreme test of prophecy. The alternative law put forward by M. Belot as replacing gravitation in an earlier stage in the evolution of the present cosmos can be put to no such test. At the best it can be shown more or less satisfactorily to lead to the present condition of affairs and to suggest views about some phenomena other than those commonly held.

The suggestion that a spiral nebula is revolving in the direction of the increasing radius of its arms may be verified by the spectroscope, but such a discovery would not in any real sense prove the truth of the theories of M. Belot. Neither facts nor arguments of sufficient weight have been brought forward to call for very serious consideration of his views.

Put very briefly, M. Belot's account of the evolution of our solar system amounts to this. Some 90,000,000 years ago a vortex-tube, moving through space at a speed of about 75,000 kilometres per second, encountered a slowly moving mass of nebulous gas. In the subsequent disturbance huge vibrations were set up in the vortex which led to the throwing off of successive portions forming the planets of the system. In a matter of two years the nova formed by the collision had expanded into the solar system, and in the manner of this expansion, coupled with a one-sided development of the planetary portions, lies the meaning of the present constants of our system.

M. Belot seeks by ingenious methods to justify certain curious empirical laws which he has found to fit the rotation-periods, inclinations, and mean distances of most of the planets. In these empirical laws and the many facts about different parts of the solar system which M. Belot has gathered together will probably lie the chief interest of the book to serious students of cosmogony.

For those who are unable to read the book as a whole but desire to gather the views of the author, a very complete account is given in the last chapter of the book. M. Belot, in his insistence on the importance of the energy of initial translatory motion upon the evolution of our system, may have brought into deserved prominence a factor which other cosmogonists have overlooked. It is true that it hardly seems to fit in with the fact that increasing stellar velocity generally accompanies increase in age, while the extremely high velocities required by M. Belot seem out of the question. Still, the idea may prove a useful addition to cosmological speculations. The second great point of the book—the need and use of a universal *dualisme* to explain the phenomena of the heavens—does not seem likely to be fertile of useful results. It leads the author to the following fantastic comparison between the celestial and the organic world:—

"Le tourbillon qui pénètre dans la nébuleuse se met à vibrer dans le choc; à chacune de ces vibrations correspond une émission de matière, qui se mélangeant à celle de la nébuleuse, va constituer l'embryon planétaire. Puis dans la nébuleuse se dessine un vaste ovoïde à l'intérieur duquel se trouvent enfermés tous les noyaux de planètes directes; pendant leur croissance ces noyaux sont reliés à la nébuleuse par de longs filaments tourbillonnaires, véritables cordons ombilicaux amenant les aliments cosmiques aux deux pôles de chaque œuf planétaire"!

BRITISH LICHEN FLORA.

A Monograph of the British Lichens: a Descriptive Catalogue of the Species in the Department of Botany, British Museum. Part ii. By Anne L. Smith. Pp. v+409+59 plates. (London: Printed by order of the Trustees of the British Museum, and sold by Longmans and Co., B. Quaritch, Dulau and Co., Ltd., and at the British Museum (Natural History), 1911.) Price 20s.

THE appearance of the second volume of the "British Museum Catalogue of British Lichens" has been looked forward to eagerly by lichenologists for some time. This fact will be realised when it is recalled that the first volume, written by Crombie, was reviewed in these columns so long ago as 1894. Crombie was one of the last of the more prominent lichenologists to protest against the dual nature of the lichen thallus. The author of the new volume, however, belongs to the modern school, and we therefore find the algal constituents of the lichens given their correct names. The gonidia are thus more accurately defined, and the determination of the genera is greatly facilitated.

The descriptions of the species are given in terms which will be more easily understood than the very technical words used in the previous volume, and it is clear that they have been compiled with very great care, for as a rule they are very much to the point.

The introduction of keys here and there is also of great use. The first volume was illustrated by a number of drawings in the text, all of which, with the exception of the last six, were made by Nylander. The new volume has at the end fifty-nine plates which form a very valuable part of this catalogue. The figures of the lichen habits and the sections of the apothecia are really excellent, but the sections of the thallus are in most cases too diagrammatic to be of any use. In the glossary we miss any reference to the very important and not uncommon soredia.

The ecological study of the lichens is of the greatest interest, but until now it has been hampered by the absence of a complete and modern flora. It is to be hoped that botanists will now attempt more thoroughly to study the physiology of the distribution of lichens. Everywhere, on trees, on solitary rocks, on the tops of hills and mountains, towards the Arctic and Antarctic limits of plant life, the lichens form practically the only vegetation present. But this vegetation shows, though on a small scale, of course, all the gradations, from the small tree-like Cladonias of the "lichen-forest" to the minute crustaceous lichens which occur on the bare rock faces, there forming very often a typical interrupted "desert-vegetation." Numerous xerophil and hygrophil, and even hydrophil formations, can be distinguished, which are characterised by the regular association of certain definite species. But all ecological work must be based on an accurate knowledge of the species under examination, and we must therefore be glad that this lichen flora is now complete. The author is to be congratulated on having successfully carried out a very arduous bit of work.

O. V. D.

MODERN CUBA.

Cuba. By Irene A. Wright. Pp. xiv+512. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 10*s.* 6*d.* net.

It is a somewhat thankless task to write a book upon an island like Cuba, which, although large and tropical, is devoid of really grand scenery, and the original natives of which have vanished without a trace, whilst the colonial population has made no history in comparison with other Latin-American countries. The conquests of Mexico and of Peru were dramatic; they and the rest have retained a large native population full of interesting problems; they all had their wars of independence; they combined or split, and kept themselves in evidence by countless revolutions or wars of mutual conquest; and not a few of them have attained an important position among the nations of the world. Cuba, from the time of its discovery until a few years ago, was a Spanish colony, the usual unhappy condition of which concerned none but the mother-country. It is the "Pearl of the Antilles" simply because it is so large and marvellously fertile. Its history means recent politics, and such are difficult to write upon.

The author has resided for ten years in Cuba as a journalist, either on the staff of some local newspaper, or as agent of the Cuban Department of Agriculture, or lastly as editor of a magazine devoted to the commercial industries of the island, in which capacities she travelled largely through its provinces to write up, or down, as the case may be, some mine, plantation, or other concern.

After the overthrow of the Spanish *régime* in 1898 followed the four years' military administration by the U.S.A. Thanks to the vigorous cleaning-up of the devastated country and enforced quietude, everything assumed a brighter outlook until the American Government withdrew, leaving Palma as the first president of the new republic. Then followed the inevitable internal strife, those who were out wanting the jobs enjoyed by those who were in. It was no longer Cubans against Spain, but Cubans against each other. The prevailing condition is perplexing. Of the two million inhabitants, more than 11 per cent. are foreigners. This foreign-born element consists mainly of Spaniards (80 per cent.), the rest of Chinese, former African slaves, Americans, and various other nations in much diminished proportion. The Cubans themselves are for the most part the island-born descendants of white stock, but inextricably mixed with black and brown.

The foreigners hold at least three-fourths of all the valuable lands, and the commerce also is in their hands, but as uitlanders they have no voice in the government, although they pay most of the property taxes and, at least directly, the Customs duties, whilst the Cubans represent the governing class, or rather they fill the Government offices. As usual in these Latin republics, the numbers of the politically active natives are small, the overwhelming mass being petty traders and labourers, who take no interest in a strife which they do not understand. They prefer being left in peace, but they take up arms and become patriots merely because as men in arms they may forage.

The staple industries are sugar and tobacco, and as these pay best other agricultural pursuits are rather neglected, so that in parts this fertile island can scarcely feed itself. There is a chapter on tobacco, interesting for its history, but this is culled from some other work; and the reader will learn nothing about the working of such a plantation, or, let us say, the life-history of a Havana cigar, from seed to finish, a story which would be more attractive, even to non-smokers, than the information that "modern implements, intelligent and scientific irrigation are bound to increase quantity, without impairing quality in the least."

The bulk of the book, illustrated with some seventy well-executed photographs of scenery, building, town and country life, is devoted to the description of several journeys, interspersed with remarks upon commerce, industries, and local history. A long residence in the island, and the active interest taken in its politics during stirring times, entitle the writer to take sides in her expressed opinions. The chapters on home life, days in Habana, rice with beans, foreigners in Cuba are vividly true of Hispano-American life, and sketched by one who has not merely peeped but lived behind the curtain.

NEW TEXT-BOOKS OF CHEMISTRY.

(1) *A Course in Qualitative Chemical Analysis.* By Prof. C. Baskerville and Dr. L. J. Curtman. Pp. ix+200. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 6*s.* net.

(2) *Elementary Chemical Theory.* By J. M. Wadmore. Pp. xi+275. (London: Methuen and Co., Ltd., n.d.) Price 3*s.* 6*d.*

(3) *Physikalisch-Chemische Praktikumsaufgaben.* By Prof. G. Kümmell. Pp. vii+71. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 1.60 marks.

(4) *Inorganic Chemistry.* By Prof. F. S. Kipping, F.R.S., and Prof. W. H. Perkin, F.R.S. Pp. xiv+750. (London and Edinburgh: W. R. Chambers, Ltd., 1911.) Price 7*s.* 6*d.*

(5) *Outlines of Experimental Chemistry.* By Dr. E. B. Ludlam and H. Preston. Pp. iv+95. (London: Edward Arnold, 1910.) Price 2*s.*

(1) AT first sight the volume on qualitative analysis by Messrs. Baskerville and Curtman appears to follow the old, familiar arrangement, in which individual tests are followed by simple schemes of separation. But on closer inspection one comes across at the end of each scheme a series of notes in small print, which seem to us to be the really valuable part of the book. These notes, whilst they destroy to some extent the apparent simplicity of the analytical tables, acquaint the student with facts which he usually has to learn from experience, viz. that reactions are modified by their environment and that few separations are quite complete. Anomalous results are thus anticipated, and the pitfalls, into which a belief in the infallibility of tables often leads, are avoided. Importance is attached to careful manipulation, and to the use of solutions of known strength for examination, so that the student may become accustomed to forming a rough estimate of the composition of a mixture. It should be added that the book does not profess to teach manipulation, and there are no detailed descriptions of apparatus or laboratory operations.

(2) This is a book on chemical theory for use in schools, that is, one dealing with laws and hypotheses in an elementary way. Such a study naturally implies a fairly extensive quantitative as well as qualitative knowledge of chemical facts. Assuming that the schoolboy knows his facts, such a book as Mr. Wadmore's should be of real assistance to him in systematising his information. Moreover, the emphasis laid on quantitative results and the method of plotting them as curves is a process which should be early assimilated. On the other hand, such a book as this will have to be used with the utmost discrimination, for it is not every schoolboy, even in the higher forms, who will be in a position to grasp the real significance of Pasteur's work on asymmetry, the meaning of optical activity, the use of the phase rule or the nature of osmotic pressure.

The subjects on the whole are well selected, and the material is put together in a simple and attractive form. We have one criticism to offer. Some of the historical references are so curtailed as to be quite valueless, and might, for any purpose they serve, be omitted. "He [Marignac] was misled by the erroneous hypothesis of an English doctor, Prout"; but what the erroneous hypothesis was is not stated. "It occurred to no one, however, to make a special investigation of this point [constancy of composition] till . . . Berthollet denied it"; but what Berthollet's views were, or why he denied it, is left untold. "Attention was originally directed to this [diffusion] by the chance observation that hydrogen could escape through a fine crack in a gas jar." This was certainly not the chance observation, and it would have been remarkable if anything else had happened. It may be true that Dalton's quantitative results were inaccurate; but it is a novelty to read that he "cooked" them (p. 12).

(3) This small volume of seventy pages is intended, as its name indicates, to serve as a practical guide to physical chemistry. It contains exercises in chemical statics and dynamics, thermo-, photo-, and electro-chemistry, the latter forming nearly half the volume. No fault can be found with the arrangement or character of the exercises; but it may be doubted if the meagre descriptions of the operations would enable any student to carry out a single determination without either previous experience or the constant supervision and help of the demonstrator. In short, the descriptions afford little more than might be found in any ordinary text-book in which these subjects are discussed. A comparison with such a book as Dr. Findlay's at once reveals its shortcomings in the all-important matter of descriptive detail.

(4) This is practically two books, an elementary and a more advanced text-book, which are published separately, and also in one volume. The first, or elementary part, covers the subject-matter required by the matriculation examination of London University; the second part is intended for students who are working for a pass degree. The object, so the authors state in the preface, of thus combining two stages of a student's chemical course, is to avoid the necessity in which a student entering a college finds himself of procuring a different and much larger text-book. For the advanced book usually takes him back to the beginning of the subject in which "some of the new matter which he requires is scattered here and there in the earlier chapters dealing with the non-metals, most of it is contained in the chapters on the metals, but in both cases there is generally the further difficulty that it is not differentiated from the more advanced matter required in his third year."

It is no doubt true that the schoolboy has to go to some expense in stocking his library with more advanced text-books when he enters on a university course. This seems almost inevitable, and the process necessitates a certain discontinuity of treatment, and, to some extent, a repetition of previous information. It has obvious disadvantages no doubt, but also perhaps less obvious advantages. It is with the object of avoiding the former that the authors have developed their method, and it may be admitted at once that it is extremely well done. To give examples: the subject of solution is discussed in a simple elementary manner in an early chapter of part i., in which the meaning of the term, determination of solubility, and the plotting of curves is explained. The subject is taken up again at the beginning of part ii., when equilibrium between solids and liquids is discussed, and such topics as supersaturation and eutectics are considered. Again, the effect of the electric current in effecting chemical change described in part i. serves as an introduction to the theory of ionic dissociation presented in part ii. In this way there is little or no overlapping, and the subjects are systematically developed. Also, a zealous beginner who wishes to learn something more of a subject may, if he chooses, turn to part ii., and satisfy his curiosity, although unfortunately no reference is given in the text to the continuation in the advanced section. The possible disadvantage of such treatment is that it limits the scope of part ii. through want of space, and consequently restricts the range of some of the subjects which might otherwise have been expanded with advantage. This criticism may, of course, be met by the different view of the authors as to the standard of knowledge demanded for the pass degree.

Putting this point on one side, the book, we feel sure, will commend itself to teachers and students by its logical arrangement, clear descriptions, excellent illustrations (with the exception of Fig. 51), and convenient size. It may also be pointed out that, unlike some of its predecessors, it is not overloaded with facts. There are some omissions in the index. Thus "the law or rule of Le Chatelier" is twice referred to in the text, but is left out of the index, and so is "vapour pressure." Charcoal stoves (p. 121) are said to yield carbon monoxide, which is true enough, but so do coke stoves, which are much more common, at least in this country, and a frequent source of danger.

(5) Every teacher sooner or later will probably consider that his peculiar experience will afford him special advantages for producing a book on practical chemistry. Indeed, it seems a natural and proper feeling in anyone devoted to the subject. Whether the results obtained by different methods are essentially different is another question. One is inclined to think that it is the teacher rather than the book that counts in the long run. Here at least is a book produced by two teachers whose hearts are in their work, and who possess the additional advantage of being "untrammelled by examination requirements of any kind." Through their laboratory 300 boys pass weekly and are instructed by the methods described in their book. This, along with the traditions of the school, on its scientific side, are strong recommendations in themselves, and are further emphasised by a study of the character and arrangement of the exercises. The latter are clearly described and illustrated, and follow in a natural and logical sequence. The apparatus is simple and easily made and set up, and the number of quantitative operations sufficient to ensure exact manipulation. One feels that school chemistry is here dignified as a rational study rather than imposed as a compulsory acquirement of "the dirty part of physics." It is a book that may be warmly recommended for use in any well-equipped school laboratory.

OUR BOOK SHELF.

Factor-table for the First Ten Millions containing the Smallest Factor of every Number not Divisible by 2, 3, 5, or 7 between the Limits 0 and 10,017,000. By Derrick N. Lehmer. Pp. xvi+476. (Washington: Carnegie Institution, 1909.)

THE condensation of a ten-million factor-table into a single volume of fewer than 500 pages is a remarkable feat, and it is interesting to learn how it has been done. The author's manuscript was first typewritten in duplicate, and these sheets, after correction, were photographed on glass. The photographs were inspected and corrected and then transferred to zinc plates, so that no movable types were employed in the printing. It is difficult to imagine a more effective way of preventing errors after passing for the press. The result is very compact and quite legible; auxiliary tables are provided for finding the proper entries in the main table: these may, however, be dispensed with, if desired. Multiples of 2, 3, 5, 7 are omitted, so the arrangement is really that of residues prime to 210.

There is an interesting introduction, giving accounts of previous tables and the method of sifting out successive primes; it also contains a valuable list of errors in former tables. More interesting still is the account of the MS. tables by Kulik, preserved by the Vienna Royal Academy. They are in six volumes, and profess to give the smallest factors of all numbers not divisible by 2, 3, or 5 up to a hundred millions. Kulik uses a special notation, and, judging by his tenth million, his work is not very trustworthy (not nearly so good as Dase's, for example); but the existence of such an enormous calculation by one man is very remarkable. He appears to have worked at it for twenty years.

The author makes due acknowledgments for help received; one of these is of international interest. The funds for preparing the manuscript and publishing the tables were furnished by the Carnegie Institution of Washington. Such a contribution to abstract science deserves cordial recognition and gratitude; and we hope that colleges that can afford to do so will promptly buy copies of this work. For although a factor-table is not often wanted, it is in certain circumstances indispensable, and it is very convenient to have one at a reasonable distance that can be personally consulted.

G. B. M.

Didaktische Handbücher für den realistischen Unterricht an höheren Schulen. Edited by Prof. A. Höfler and Prof. F. Poske. Band vii., Didaktik des botanischen Unterrichts. By Prof. B. Landsberg. Pp. xiii+303. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 8 marks.

A CONSIDERATION of the title gives rise to the reflection, how far this series of didactic handbooks owes its inception to the German educational system controlled to a great extent by official regulations; yet the present volume affords proof that changes in teaching methods can be, and are, effected by individual efforts. The main idea, advocated by Prof. Lindenberg, of instruction based on practical observation and experiment, has already received general approval, but the proposed sequence of procedure, explicitly scheduled under three stages, does not appear to be entirely realisable or acceptable. During the first stage, that extends over two years, the governing principle, expressed briefly, is to induce the study of single organisms in their environment with regard to form and working of the different members. The collation of individuals into groups, both ecological and classificatory, is relegated to the second stage, when it is proposed that a course of anatomy and physiology, as also an introductory survey of cryptogamic life, should be taken.

The chief aims during the advanced stage are to amplify the earlier courses of anatomy and physiology, to expound the theory of development and other working hypotheses, to correlate botany with other sciences, and to indicate the nature of biological investigation. It is manifest that from the elementary stage, when the author considers it necessary to offer a word of warning lest impatience on the part of the teacher should discourage the youthful inquirer, to the summit of the advanced course is an exceedingly long journey, too long to be traversable during school life. However, if the scheme is not workable in its entirety, various sections are practicable, and one can confidently bring the volume to the notice of teachers.

It will be found that the book is not overweighted with philosophic discussion, and that the greater part of it is devoted to illustrative examples and hints for various substages of the course. The precise paragraphing of the subject-matter under chapter contents affords a ready means of reference and a useful bibliography is appended.

Treherne's Nature Series.—(1) *British Butterflies and Moths.* Arranged by W. F. Kirby. Pp. vii+26+xii plates.
(2) *Animals: Wild and Tame.* Arranged by W. F. Kirby. Pp. ii+22+xii plates.
(4) *Minerals.* Arranged by W. F. Kirby. Pp. ii+24+xii plates.
(London: A. Treherne and Co., Ltd., n.d.) Price 8*d.* net each.

The Nature-lover's Handbook. By Richard Kearton and others. Pp. viii+265. (London, New York, Toronto, and Melbourne: Cassell and Co., Ltd., 1911.) Price 2*s.* 6*d.* net.

The fox is "a destructive animal in hen-roosts, but still common in Britain, being preserved for the fashionable sport of fox-hunting"; and, again, the female of the black arches moth "is furnished with a very sharp projecting ovipositor, an organ not usually very conspicuous in moths." Such are the main items in the notices of two species in a couple of the volumes in Treherne's Nature Series; and it will be perfectly manifest that the reader who wants the first (which, by the way, is not true for Britain as a whole) can have no possible use for the second. Again, in the volume on minerals, we find, to take one example only, under the heading of cerusite, a statement to the effect that carbonate of lead is common in most parts of the world, but nothing to show that cerusite and lead carbonate are one and the same. If little is to be said in favour of the text of these volumes, in the case of the one on animals it is difficult to give much praise to the illustrations. The case is, however, quite different with the volume on butterflies and moths, in which the coloured plates are really excellent; and, in a somewhat modified degree, commendation may be bestowed on those in the mineral volume. The low price of these "booklets" renders them accessible to all, and if they serve to awaken an interest in natural history, their issue is no doubt justified.

"The Nature-lover's Handbook" is on an altogether different platform from that of the other volumes, and cannot fail to be useful to the young student, giving, as it does, interesting notes on the animals and plants specially noticeable in each month, followed by lists of birds, butterflies and moths, and wild flowers, with the respective "station," or season of appearance of each species, in our islands. The only alteration we can suggest is that the species in the lists should be arranged alphabetically, as they are now difficult to find; and that if it is necessary to use names like "barn swallow," the dominant term should come first. R. L.

Introduction to Chemistry. By William Ostwald. Authorised translation by W. T. Hall and R. S. Williams. Pp. ix+368. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1911.) Price 6*s.* 6*d.* net.

In this volume the contents of Prof. Ostwald's "Schule der Chemie" are reproduced in narrative form, in place of the conversational method previously adopted. From the point of view of the average reader the change is a great advantage, and the book is now written in such a form as to be readily available for use in the teaching of classes of elementary students. As might be expected, much attention is directed to physical and physico-chemical properties; it is quite refreshing in an elementary book to find crystals classified according to their axes of symmetry, in contrast with the emphasis which is usually laid exclusively upon the planes of symmetry.

The most surprising fault of a book, which is in nearly every respect an admirable introduction to the study of chemistry, is found in its treatment of equivalents, atomic weights and molecular weights. After a discussion of the laws of simple, multiple, and reciprocal proportions, Dalton's atomic theory is introduced, but is followed by a table of "Combining Weights of the Most Important Elements," which represent, not the equivalents—which alone can be deduced from this theory—but the modern system of atomic weights, as firmly based by Cannizzaro upon Avogadro's hypothesis. This hypothesis is not mentioned by name, either in the text or in the index, and the latter contains no reference to gas-densities or vapour-densities; these important matters are smuggled into a chapter on carbon, and the theory which is really the basis of all determinations of atomic weights is merely used to provide a few exercises on the combining volumes of gases. A pupil who had the curiosity to inquire why the atomic or "combining" weight of oxygen relatively to hydrogen is taken as sixteen, and not as eight, would find it very difficult, if not impossible, to find a satisfactory answer in the book now under review.

This is, however, the only serious fault that has been noticed in a volume that in other respects displays the admirable quality of lucid exposition, which is characteristic of the author. The translation has been so well done that the book gives the impression of having been written first in English and then translated into German. T. M. L.

Milk Testing, a Simple, Practical Handbook for Dairy Farmers, Estate Agents, Creamery Managers, Milk Distributors, and Consumers. By C. W. Walker-Tisdale. Revised edition. Pp. 86. (London: *Dairy World* Office, 98 Fetter Lane, 1911.) Price 1*s.* net.

This useful little book has so commended itself to those for whom it was intended that it is now for the second time revised and enlarged. The new matter includes such recent developments of the dairy industry as the testing of sour milk and the description of portable appliances for use by travelling inspectors. It is a happy circumstance that Mr. Walker-Tisdale, who is himself the manager and a director of a large milk company, should thus place his experience at the disposal of other dairy managers, and it is equally fortunate that the British dairy manager and farmer, so far from abusing the monopoly he possesses (for there is practically no importation of milk from abroad) should show himself so ready to apply chemical tests in order satisfactorily to establish the purity of his milk.

The "Stomatograph."

THE recent controversy regarding the causes which had depreciated the yield of Egypt's cotton crop, terminating in the Egyptian Government's Cotton Commission of 1910, showed very clearly how little accurate knowledge of the physiology of the cotton plant was available, more especially in regard to field conditions. This ignorance was most striking in respect to the water relationships, which—Egypt being dependent on the Nile for its water—are very largely within human control.

One point of interest in this respect is the action of the stomata, especially since I showed that growth is completely arrested by direct sun, from the first emergence of the seedling until late in the summer, the heavy water loss involved by the high sun temperature (160° C. in May to August) and the low day humidity being the limiting factor.

Investigation of plant physiology in the field, however, usually requires special and automatic apparatus, and no suitable appliances were available for investigation of the stomata. After several trials I succeeded in constructing a self-recording form of Mr. Francis Darwin's "porometer," which will work without appreciable errors under any variation of wind, sun, temperature, or barometric pressure, in rain or in dust-storms.

Briefly described, the apparatus consists of an electrical air-pump expelling 3 c.c. of air at each stroke under a constant pressure of 1 millimetre of mercury. The outflow tube is closed by a definite area of leaf, so that the air in escaping has to pass through the leaf tissues. The resistance to this escape depends almost entirely on the aperture of the stomata, of which there are some seventy on the upper leaf surface and two hundred on the lower in adult leaves of Egyptian cotton. The rate of escape is a direct measure of the porosity of the leaf, as in the "porometer." A relay circuit is operated when one stroke of the pump has been completed, and this telegraphs the signal to an electromagnet carrying a pen on its armature; this pen writes on a spiral drum which revolves once every hour.

The complete appliance is very convenient in use, being composed of a box like a microscope case, which is placed on the ground under the plant to be examined; from this box issues the air-tube leading to the leaf and the telegraph wire to the recorder. The number of adjustments which have to be made in the field is thus reduced to a minimum, which is no unimportant consideration under the field conditions obtaining during an Egyptian summer.

The trace of five consecutive days recorded from the same leaf without adjustment shows the stomata slowly closing as the hottest part of the day approaches, then closing when the sun goes behind the trees at 1.40 p.m., and remaining closed all night, opening slowly after sunrise, more rapidly when the direct sun strikes the leaf about 7 a.m., attaining a maximum at 9 a.m., and thenceforward closing steadily, in spite of the brilliant illumination, since the soil around the roots is being dried up by the heavy transpiration.

A side-issue from such records as this, which promises to give further unexpected results, deals with the effect of such stomatal closure on assimilation of CO_2. I have already mentioned that the stem of an Egyptian cotton plant does not grow in sunshine, and it appears that the growth of the root is also checked; it now seems not unlikely that photosynthesis may also be arrested or reduced after a certain hour of the day through stomatal closure, this closure being dependent on the development of the root system and on the water content of the soil.

The beneficial effects of Egyptian sunshine seem to be rather indirect. W. LAWRENCE BALLS.

Ghezireh House, Cairo, July 10.

Photograph of Multiple Lightning Flash.

I BEG to enclose a copy of a remarkable flash of lightning which I took some years ago in Uruguay, South America, and which, so far as I know, has never been published—with my knowledge or permission, at any rate.

This copy is an enlargement from a small negative about $1\frac{1}{2}$ inches square, and shows the curious curl-like form in some of the streaks. One noteworthy point about this photograph is that I "snapshotted" it. I had wasted many plates in the usual way, and obtained nothing of any value, but noticed that before every big flash there was a slight flicker in the clouds where the flash came from; I waited for this, let the shutter go just as I saw the flicker, and obtained the enclosed result.

Uruguay is noted for its severe thunderstorms, and animals, fences, trees, and houses are constantly struck. Some years before this photo was taken a powder-house was blown up by lightning not far from where this flash occurred, and in the sand a few miles off

I found a fulgurite—a glass tube about $2\frac{1}{2}$ inches in diameter made by the lightning striking and fusing the sand. These fulgurites are mentioned by Darwin in "The Cruise of the *Beagle*"; he found some near Monte Video. also in Uruguay. A. E. WALBY.

67 Lansdowne Street, Hove, Brighton, July 27.

The Rearing of Sea Urchins.

I HAVE read with much interest in NATURE of July 27 a short letter from Prof. Stanley Gardiner in which he communicates the fact that a hybrid of the species *Echinus esculentus* and *E. miliaris* was successfully reared from the egg through all the larval period until after the completion of metamorphosis in the zoological laboratory at Cambridge. It may interest your readers to learn that by means of salt-water aquaria established last year in the zoological laboratory of the Imperial College of Science in

London we have reared very considerable numbers of *E. miliaris* from the egg through the metamorphosis. The eggs were fertilised in the beginning of April, and when I left London in the middle of June there were many young Echini creeping about. The details of the methods adopted will be described in a paper shortly to appear in *The Quarterly Journal of Microscopical Science*. Last year we reared the eggs of the Serpulid *Pomatoceros* until the larvæ had attained the adult condition and had formed tubes, which were attached to the sides of the vessel in which they were.

FLIGHT, NATURAL AND ARTIFICIAL.[1]

In the words of the introduction, "The object of this report is to place at the disposal of the members of the society some of the information now available regarding the physical characteristics, powers of flight, &c., of birds. It must be clearly understood that, owing to the great difficulty experienced in collecting the details of weights, wing area, &c., the report is of a temporary nature only, and does not profess to give the fullest possible information regarding the subject dealt with. The details given, however, have been taken from the best available sources, and it is hoped that the report as a whole will be found a useful introduction to the study of bird flight." It will be seen that original observation and experiment did not fall within the scope of the committee, but, subject to this and the other limitations mentioned above, the results of their labours cannot fail to be of value.

The first section deals with the classification of birds from (*a*) the ornithological and (*b*) the aëronautical point of view. Under (*a*) table i. gives a classification after Finn into twelve main groups, further subdivided into families. The aëronautical classification presents difficulties. In table iii., column 17, are given the values of $S^{\frac{1}{2}}/W^{\frac{1}{3}}$, S being the surface and W the weight, together with other particulars for a large number of birds.

Section ii. is devoted to a description of the principal sorts of flight and of various manœuvres, such as turning in the air. Under the first head are mentioned gliding flight, flapping flight, and soaring flight, of which, however, the first does not differ essentially from the third. Instructive photographs after Marey and Milla are reproduced. Soaring has been the subject of much discussion at various times, no small part of it being hopelessly confused by misunderstanding of mechanical principles. Even in the present section paragraph 12 is not above reproach. The comparison of soaring with the normal performance of a sailing ship is certainly misleading.

When a bird maintains or increases his elevation without working his wings, the explanation is to be sought in a special movement of the air. It cannot be too much emphasised that for this purpose a uniform horizontal wind is of no avail. The larger soaring birds, such as condors and pelicans, probably find their support on ascending currents. Such currents must exist, though we on the ground perceive little of them. Even though the wind be strictly horizontal in the space where the bird is flying, advantage may be taken of variation with height or with time. As a matter of fact, the wind, near the ground at any rate, is always more or less gusty.

Travellers at sea have frequent opportunity of making interesting observations. In these latitudes one may see gulls following the ship and taking advantage of upward currents deflected from the sails or hull. From other parts of the world the albatross is often reported to follow the ship, maintaining his position for minutes or hours together without flapping of wings. Since in this case the distance from the ship may be considerable, one must appeal to upward currents deflected from the waves or to the other specialities of wind already mentioned. But is it certain that a flapping of the wings could not escape attentive observation? One would have supposed so; but the evidence is not free from ambiguity. Following upon a lecture upon the mechanical principles of flight, given in 1900,[1] a correspondent sent me an instantaneous photograph of an albatross flying "very near indeed" to the ship. In the picture the wings appear elevated as if near the top of a stroke, but to the observers at the time "the wings were fully extended in a line with the body." In answer to further inquiries my correspondent wrote: "*Without question* none of the many passengers who were watching the albatross (which was *exceptionally* near the side of the ship) saw the slightest movement of the wings when I took my snap-shot. To all appearance they were fully extended and immovable—certainly 10 to 12 feet from tip to tip." Here, indeed, is a question worthy of further attention from travellers in the southern seas.

Section iii. of the present report deals with weight, wing area, &c. The heaviest bird in the table is the Californian vulture, weighing 13·6 kilog. (30 lb.). The bird carrying the greatest weight per sq. m. is the whooper swan (21·3 kilog. per sq. m.). In section iv. we find observations and calculations regarding the velocity of birds, the power expended, &c. It appears that the maximum speed in ordinary flight does not much exceed 50 miles per hour, and that no bird moving near the earth's surface attains the enormous speed with which flying creatures are sometimes credited. These speeds are, of course, relative to the air. At considerable heights migrating birds may easily experience winds of like amount, so that 100 miles per hour, or more, relative to the ground may well be admissible.

The opinion is expressed that the power required for flapping flight has been much exaggerated. This may be true as regards regular horizontal flight, but it remains a fact that the power exerted by some birds, *e.g.* pigeons, in rising nearly vertically is very great. The question was discussed by Penaud in 1876. "In the ascent the total work developed by the bird is divided into two parts, the one fixed, that is, the work of elevation; the other variable and increasing with the time, that is, the work dispensed in finding a support in the air."

"It is thus to the interest of the bird to rise as quickly as possible, which it generally does, even when under no sense of fear. Their velocity of direct ascent is always several yards per second." And, further: "Thus, and apart from all theory, it is certain that birds are capable of developing momentarily a force corresponding at least: for the peacock, to 1 horse-power for every 66 lb., and for the pigeon and ring-dove, 57 lb."; and, as before mentioned, the work of elevation is not the whole.

In these days there is a natural tendency to overlook the work of the early pioneers. In principle not much has been added to the conclusions of Wenham and Penaud, and the latter constructed actual flying-machines. What was wanted to make flight practical was the advent of the light motor, as developed for the motor-car. When this became available, the skill and courage of such men as the brothers Wright soon led to successful human flight. Further progress is assured, but how far it will go would require a bold man to prophesy.

SOME SCIENTIFIC CENTRES.

No. XVI.—Prof. Weismann's Zoological Institute at Freiburg-im-Breisgau.

MOST students of zoology arrive at some period or other of their Wanderjahre at Freiburg, that quaint and beautiful old town on the edge of the Black Forest. To some the chief interest will lie in the Münster, in the university buildings, old and new, and in the numerous statues and fountains that are scattered through the town; yet the majority of the students will not consider the visit satisfactorily ended if they omit to call at that institute in Katherinenstrasse, which Prof. August Weismann has made famous.

The institute itself stands in a small garden close beside the Chemical and Physiological Institutes, and is built in the shape of an L, with the laboratory windows facing north. It stands gable on to the street, and its exterior presents no striking features, so that by anyone going there for the first time it could easily be passed unnoticed, as it was by the writer on his first visit. The interior, however, presents quite a different appearance: everything necessary for research is there, and the work-benches are splendidly equipped with gas and water and the necessary electric plugs and switches.

In addition to the senior and junior laboratories, rooms are set aside for the students at different stages in their course. There are special rooms for diagrams, apparatus, &c., and in the basement a large tank room. The lecture theatre, from which a small tramway runs to the museum, is large, has plenty of wall space for diagrams, and is fitted with a large Zeiss epidiascope. Finally, there is a fine suite of rooms for the members of the staff, a large and representative museum, and an extensive library, and, further, through the kindness of Prof. Weismann, his private library is placed at the disposal of those engaged in research.

A typical day's work may be of more interest than a mere detailed description of the buildings. In summer by 8 a.m., and in winter by 9 a.m., the senior students are at work. The morning's work usually starts with a short discussion. it may be on some points that have arisen in someone's "Arbeit," but very often the discussions are on any subject under the sun but zoology. As a rule this discussion soon finishes, and each student seats himself at his bench to collect the knotty points in his research for the professor's consideration, or to get some passage in a book or journal ready to lay before the professor as soon as he appears in order to get his own interpretation confirmed or utterly quashed.

Sometimes the morning's discussion is disturbed when near its height by the whisper, "Der Chef," which is always followed by a general and hurried scamper to get ready for the morning's visit. This whisper of "Der Chef" has been used on more than one occasion as a means of getting out of a tight place in an argument.

Prof. Weismann begins his day by visiting each student, going over the interesting points in his work, comparing them with other results, or by a series of questions getting the student on to the right track. During the remainder of the day the laboratories are in charge of the senior assistant, and students may either spend all their time there, or attend one or more of the courses of lectures delivered at the institute, either by Prof. Weismann on some general subject, or by one or other of the assistants on some special subject.

Photograph] [*G. v. Guaita.*

Prof. August Weismann in his Study.

On one afternoon weekly there is the seminar, which is attended by the professors, the other members of the staff, and the senior students. Some time previously recent books or articles from the scientific journals are distributed to the students and members of the staff, and at the seminar each student must criticise the book or paper given to him. As soon as the criticism is finished, the other students and the members of the staff give their opinions, and then Prof. Weismann sums up the discussion. The work in the seminar is not restricted to recent literature, nor to works published in German. Frequently a student is requested to give a review of the present state of knowledge in some biological problem, or to give a summary of the results achieved in some particular group.

The day's work is arranged and carried out in such a way as to give the student opportunity of observing, forming opinions of his own, and gaining confidence in his own judgment. There also the student is taught to get at the root of things, and, without knowing it, gradually copies the example and is imbued with the earnestness of the director.

The general routine differs very little from that followed in most German universities, and yet year after year every Arbeitsplatz in the institute is occupied, and that by a very cosmopolitan group of zoologists and of zoologists in the making.

Why is it that students from all quarters flock there? It is certainly not due to the equipment, for many of the newer zoological institutes in Germany are more lavishly equipped; nor is it due to the fact that the institute is situated in a very pleasant town. On the contrary, it is due to the reputation, but still more to the personality of the director.

Prof. Weismann's research has covered a wide field, and the resulting articles are all marked by a thoroughness and a mastery of detail which shows that he, at any rate, has just that power, often lacking in German men of science, of not allowing the details, while giving them their full value, to obscure the main issue.

Of his original investigations, that on the origin of the germ-cells in the Hydrozoa is specially interesting, as it led him from the facts there observed to formulate his greatest doctrine—the continuity of the germ-plasm, and to found thereon a theory of heredity. This doctrine had a much wider significance than was at first thought. If it be accepted, the only conclusion possible is that all variations—by this is meant inherited variations—must be congenital, and that as the direct result of this there can be no transmission of acquired characters, that is to say, of such characters as are acquired during the lifetime of the individual. Needless to say, the publication of this doctrine caused an enormous sensation everywhere, but particularly so among men of science and breeders. In spite of all the jibes and sneers hurled at it, its effect on the natural sciences has been deep and permanent, and, however much modified, however much tampered with, it forms the one firm basis of all modern views of heredity.

His thorough knowledge of both animal and vegetable cytology helped him to place his theory of heredity on a surer basis, one might well venture to say on a firmer foundation of fact than was possible for most of his predecessors and many of his contemporaries.

In the development of Darwinism Prof. Weismann has taken a leading part, not only in gaining for it in Germany an almost universal acceptance, but also in explaining its real meaning to the world at large and in freeing it from such traces of Lamarckism as still existed.

Moreover, a style which is beautiful and at the same time lucid, a persuasiveness which is equalled by few, and a capacity for following a hypothesis to its logical end, has made Prof. Weismann one of the foremost, if not the foremost, exponent of all that is best in Darwinism and in the teaching of Wallace.

His views have exercised on evolution a far-reaching influence, for they have been the direct cause, and this must be peculiarly gratifying to Prof. Weismann, of much of the recent research undertaken in this subject.

But a record brilliant as his has been is not sufficient to fill the institute to overflowing, or to rouse such enthusiasm and affection for the director as is seen there. This is purely due to the personality of Prof. Weismann, to his geniality, and to the kindness with which he guides the faltering steps, especially of strangers within his gates. In fact, his Gemüthlichkeit soon overcomes the diffidence of his students, and at the same time rouses in them a regard and affection which it is given to few teachers to gain.

No student can work through a course in zoology at Freiburg without being influenced by the enthusiasm, the earnestness, and the profound thoroughness he finds there, and gaining and retaining a feeling of the deepest admiration for that veteran in science, the director of the institute, Prof. Weismann.

No better tribute can be paid to Prof. Weismann than the affection in which he is held by his former students, to whom the phrase, "Der Chef," calls up so many pleasant memories, and no better proof of this exists than the longing with which they look back to the time spent within his halls.

W. D. H.

PREHISTORIC SOUTH AFRICA.[1]

MR. J. P. JOHNSON continues to make good use of the opportunities his mining practice gives him for the careful study of South African geology and archæology. The latest addition to his series of short books is, like its predecessors, valuable from its record of carefully observed facts and instructive illustrations. The subjects included range from the period of the Zimbabwe ruins back to the oldest of the stone implements, and perhaps even older. Occasional remarks show that Mr. Johnson had been a diligent collector of stone implements in the south of England, so that he went to South Africa as a trained observer. He has found in the rich implement-bearing gravels there abundant scope for his energies. He classifies the South African implements into three groups—Eolithic and two divisions of Palæolithic. No Neolithic implements have as yet been found. He identifies as Eolithic a series of implements collected from a gravel at Leijfontein, in the Campbell Rand. He compares them with the eoliths of Kent, which he accepts as probably of artificial origin, though he admits that this conclusion is still open to doubt.

He gives two pages of sketches of these eoliths, and though they resemble some of the characteristic Kent types, the illustrations are inadequate for any independent opinion as to their relations with the English "eoliths."

The Palæolithic implements are divided into two groups—the Acheulic, which are generally of the type which he has called amygdaliths, and the Solutric, which are generally scrapers. He regards the implements which he refers to the Solutric type as of later date than the Acheulic. Some authorities, however, hold that both belong to the same period. Mr. Johnson regards them as of different dates from the evidence of their distribution. The Acheulic implements must, he thinks, be the earlier, as they are found in older deposits, and none of the Solutric sites have yielded any of the typical Acheulic forms. He has collected Acheulic implements from seven or more feet below the surface, and found some in gravel that has been cemented to a hard conglomerate. Many of the Acheulic implements must be of considerable antiquity. They are abundantly distributed over the plateau around the Victoria Falls, and Colonel Fielden, who collected many there, is of the opinion that they were deposited before the erosion of the

[1] "The Prehistoric Period in South Africa." By J. P. Johnson. Pp. iv+89. (London: Longmans, Green, and Co., 1910.) Price 10s.

great Zambezi gorge. Mr. Johnson, however, agrees with Mr. Codrington that these implement-bearing gravels are later than the gorge, and were washed to their present position from slightly higher ground.

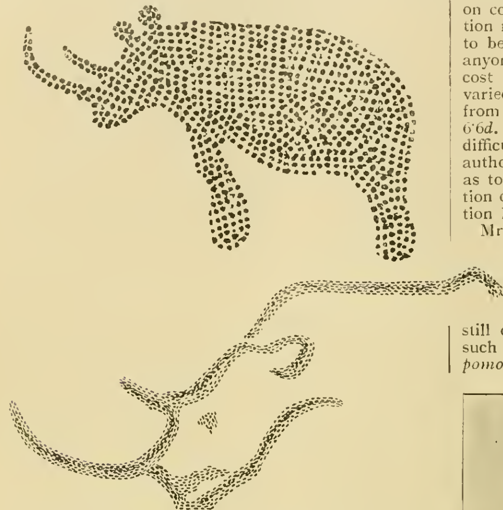

Figure of rhinoceros coarsely pecked in full, and of head of rhinoceros pecked in outline, Wolmaransstad. From "The Prehistoric Period in South Africa."

They are of a considerable, though not of the enormous antiquity, demanded by the other hypothesis.

The author adds many new examples of the rock drawings to those issued in his previous works, including some formed by pecking rock surfaces. Some of these drawings he regards as made by men of the Solutric period; and, as the men of Solutré, though skilled artists, did not use the rock-pecking process, Mr. Johnson concludes that the European and South African makers of Solutric implements were derived by separate migrations from a common eastern ancestor.

Mr. Johnson accepts the view that the Zimbabwe was made by a Bantu people. He records (p. 80) an interesting tradition in the northern Transvaal of a race of miners who were not Kaffirs, and whom he suggests were Arabs; but as these miners had guns they belonged to comparatively modern times.

J. W. G.

THE ADVISORY WORK OF AN AGRICULTURAL COLLEGE.[1]

WHEN county councils make grants to agricultural colleges they expect to get in return for their money a certain amount of instruction for students at the college and for farmers at market-day lectures, and a good deal of advisory work for rate-paying agriculturists. The volume before us represents the output of the Wye College staff in advisory work during the year 1910.

In view of the great importance of milk production in Surrey, and to a smaller extent in the suburban districts of Kent, it is natural to find a large part of the farm report taken up by the preliminary results of an inquiry into the cost of milk production. On no aspect of farming have we less information than on costs of production, and on none is more information needed at the present time, when economies have to be introduced at every turn. It will not astonish anyone acquainted with farmers to learn that the cost of food required to produce a gallon of milk varied from 3·8*d.* to 10·5*d.* The usual variation was from 5*d.* to 8*d.*, the average on fifty-nine farms being 6·6*d.* An inquiry of this nature is beset with many difficulties and pitfalls, and it would be well for the authors to obtain advice from an expert statistician as to the methods to be employed and the interpretation of the results; a more useful subject for investigation has rarely been attacked by dairy workers.

Mr. Theobald's report on economic zoology covers 130 pages, and is, as usual, well illustrated. Among new fruit-tree pests are noted the pale brindled beauty (*Phigalia pilosaria*, Hb.) and the light emerald moth (*Metrocampa margaritaria*, Linn.). Many of the old pests still continue to baffle all the efforts of the grower, such as the apple blossom weevil (*Anthonomus pomorum*, Linn.) and the raspberry beetle (*Byturus*

FIG. 1.—Female March Moths. The lower moth laying on her egg-band beneath one of the Lackey moth (×4). From the Journal of the South-Eastern Agricultural College.

tomentosus, Fab.), but there is put forward for consideration an interesting statement from "an old book" to the effect that woolly aphis may be cured by planting a nasturtium against the infested tree. But the two

[1] The Journal of the South-Eastern Agricultural College, Wye, Kent. No. 19. Pp. 426. (London and Ashford: Headley Bros., 1910.) Price 7*s.* 6*d.* (Residents in Kent and Surrey, 3*s.* 6*d.*)

problems Mr. Theobald considers of most pressing importance are the bionomics of nematodes and the study of Strongylidæ. Nematodes are responsible for considerable losses to the hop-grower, the market-gardener, the strawberry-grower, and the farmer; they have long been known to damage cereal crops, and are now recognised as potato pests. The Strongylidæ are serious parasites of sheep and other animals, yet nothing is known of the life-history of the commonest form.

We reproduce a very good photograph of a female March moth (*Anisopteryx aescularia*, Schiff.) laying her "egg band" on a twig.

The report from the Analytical Laboratory deals with the more interesting of the 377 samples sent in for analysis.

In the report from the Botanical Department, Mr. S. T. Parkinson describes some interesting experiments that will be new to many people in this country. It will be remembered that, in 1909, Prof. Molisch, of Prague, published a paper in which he advocated that perennial plants, while still in their resting stage, should be dipped in hot water prior to forcing. In the resting period he distinguishes between the "unfreiwillig" and the "freiwillig" rest; the former, being inherent in the nature of the plant, cannot be altered; the latter, being dependent on the external circumstances, can be shortened. By steeping the plant in hot water at the proper time the "freiwillig" period is therefore cut out, and its cells spring into activity, thus it has such a start over the untreated plants that it comes to maturity well before they do.

Fig. 2.—Photograph of "Dipped" (D) and Cont l (C) plants of Spirea. "Dipped" November 25; photographed December 13. From the Journal of the South-Eastern Agricultural College.

Without committing himself to this particular hypothesis, Mr. Parkinson has carried out numerous experiments, and finds that an exposure of about twelve hours to a temperature of 95° F., or, in the case of soft plants, such as seakale, to 85° F., just after the period of "deepest rest," *i.e.* the end of November or beginning of December, led to very rapid growth. Numerous photographs are given, one of which is reproduced in Fig. 2. Further studies of this interesting problem will be awaited with interest.

Experiments are recorded by Mr. Garrad on the growth of tobacco for nicotine extraction. Nicotine makes an excellent wash for fruit-trees and hops, but its price (12*s.* per lb.) is too high. Mr. Garrad shows that he produced it at 6*s.* per lb., which, if it turned out a normal cost of production, would make a profitable industry. Mr. Garrad's Indian experience has stood him in good stead, and a continuation of the work would be very useful.

Mr. E. S. Salmon's report makes very sad reading. It seems but a few years ago since he announced that a gooseberry disease had appeared in Ireland and must inevitably spread to this country, with alarming results, unless certain precautions were adopted. Unfortunately his words fell on deaf ears, and it is a matter of history that no steps were taken to exclude the disease; trouble that had not yet appeared could not rouse the authorities to action. When the disease finally came over its seriousness was at first denied, and now that many hundred acres are affected and the disease is rapidly spreading, a plan of campaign has been organised in some, *but not in all,* districts. Thus Kent is efficiently inspected by trained inspectors, while Surrey and Sussex are not.

If the serious losses now being incurred could teach all concerned a few elementary facts about plant diseases, the lesson would still be worth having, however dearly bought, but we seem to be in for equal or greater losses from a potato disease known as the Wart Disease or Black Scab. The disease is here and is spreading, yet nothing adequate is being done. It is not surprising that the Pests Committee of the Central and Associated Chambers of Agriculture should, in a communication to the Board of Agriculture, "earnestly recall your attention to the last paragraph of their report, dated December 1st, 1908, in which they suggested that the Board should appoint an advisory committee of experts to assist the Board in dealing with plant diseases generally, as recommended by the Departmental Committee on the Fruit Industry."

A JUNGLE FOLK.[1]

THE Veddas of Ceylon have long been regarded as one of the most interesting of the varieties of mankind, and one way and another a good deal has been written about them in various journals and books, but the information was usually scrappy and not always trustworthy. An exception must, however, be made to the careful work of John Bailey in 1863, and the sympathetic investigations of Hugh Nevill, whose valuable notes are to be found in a scarce journal, *The Taprobanian.* In "Ancient Ceylon" (1909), Mr. H. Parker gives a useful summary of our knowledge of the Veddas, together with the results of his own observations on the village Veddas. For the physical anthropology we are mainly indebted to Virchow (1881), who studied the craniology of the Veddas, and to the magnificent memoir, "Die Weddas von Ceylon," by the cousins Sarsin; this monograph deals also with their material culture, but the account of Vedda sociology is much less satisfactory. It was evident to ethnologists that the sociology and religion of the Veddas needed to be studied carefully by modern methods of sociological field research, as these people undoubtedly are little-modified representatives of a very ancient human stock, and there was a danger, owing to the very small number of the wilder bands and their gradual

[1] "The Veddas." By Dr. C. G. Seligmann and Brenda Z. Seligmann. With a chapter by Dr. C. S. Myers and an appendix by A. Mendis Gunasekara. Pp. xx+463+map. (Cambridge: The University Press, 1911.) Price 15*s.* net.

adoption of a more civilised mode of life, that their customs and beliefs might become obsolete. On being approached on the subject, the Ceylon Government, with their customary public spirit, voted a liberal grant for this purpose, and Dr. C. G. Seligmann was selected to undertake the research. He was accompanied by Mrs. Seligmann, and to her in no small measure must be credited the success of the expedition. The Veddas are a shy and intensely jealous people, but the presence of a woman in the party led to very friendly relations being established, and Mrs. Seligmann proved herself to be a first-class investigator in the field. Their results are now published as one of the Cambridge Archæological and Ethnological Series of the Cambridge University Press.

FIG. 1.—Kirikoraha ceremony. The shaman tracking the sambar (Henebedda). From "The Veddas."

Mr. Parker is inclined to believe that the forebears of the present few hunting Veddas were more civilised, and that the existing condition is a reversion to the forest life of their remote forefathers; the Seligmanns, however, regard the hunting Veddas as direct survivals of the primitive Veddas, and the traditions of a higher state of culture as mainly due to confusion between the Veddas and Kandayans of mixed Vedda descent, who until recently called themselves Veddas, or were known as such to their neighbours. A brief account is given of the various Vedda communities; the Danigala Veddas are the show "wild Veddas" described by so many travellers; although really well-off, they pose as poor, morose, wild men of the jungle—they are, in fact, professional savages.

The Vedda system of relationship is a late form of the kind known as classificatory; the working basis is the marriage of the children of brother and sister, but not of two brothers or sisters. Before marriage a man pays at least as much regard to his future father-in-law as to his own father, but after marriage the association between father-in-law and son-in-law becomes very intimate. The social system is an exogamic clan organisation with female descent. Two clans are regarded as socially superior to the others, and their members do not marry into the inferior clans. The Veddas greatly prefer living in rock-shelters to huts, but they shift their home two or three times a year as the season demands. Most of the caves shelter several families, but each family keeps strictly within its own limits. There are no puberty ceremonies for either sex, except among certain Veddas who have been much influenced by Tamils or Sinhalese. The Veddas marry young, and are strictly monogamous. A rigid sexual morality prevails, but at present, among the more sophisticated groups, an unmarried girl is allowed considerable liberty with regard to the youth allotted to her. The country is divided into hunting lands for the different groups, within which each individual has the exclusive hunting rights of a particular area or areas; when dying, a man generally gives his land to his sons, and not to his sons-in-law, but no landed property passes without the consent of the grown men of the group. Trespass is almost unknown. The religion of the Veddas is essentially a cult of the dead; with this is associated the cult of spirits, *yaku*, of certain long-dead Veddas who may be regarded as legendary heroes. The chapters dealing with the magico-religious practices and beliefs are of great interest and importance. The ceremonial dances are described and illustrated with great detail; the majority are pantomimic, and are performed with the object of becoming possessed by a *yaku*; the Seligmanns believe that there is no considerable element of pretence in the performance of the shaman.

Dr. C. S. Myers has a chapter on music, based on thirty-four phonographic records. In the Vedda music we seem to meet with the very beginnings of melody-music; there is no other people in whose music the gradual construction of music on such simple lines can be discerned. A number of Vedda songs have been transliterated and translated by Mr. A. M. Gunasekara, and Mr. Parker has done the same for the invocations. The senses of the Veddas were also tested. Enough has been said to show that this book

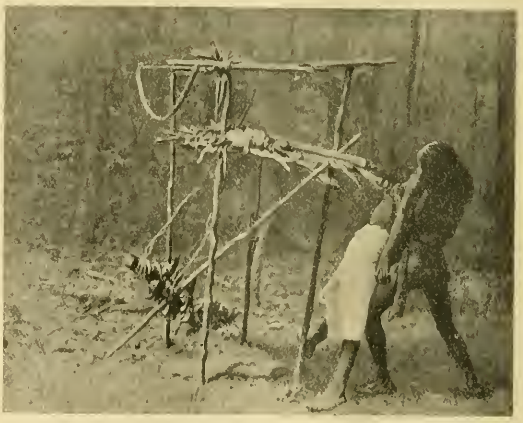

FIG. 2.—Bambura Yaka ceremony. The boar is at length killed; the possessed shaman collapsing into the arms of a supporter (Sitala Wanniya). From "The Veddas."

is of first importance, and it may be considered as the final word on the subject, as it is improbable that we shall ever learn much more about the Veddas. The Ceylon Government is to be congratulated in having secured the services of Dr. and Mrs. Seligmann for this important research. A final word of praise is due to the number and excellence of the photographs; those illustrating various ceremonies are of exceptional interest.

A. C. HADDON.

THE COAST EROSION COMMISSION.

IN July, 1906, a Royal Commission was appointed to inquire and report as to the encroachment of the sea on the coasts of this country, and as to what means are desirable for the prevention of such damage; also as to the reclamation of tidal lands as affecting the subject of unemployment. Two years later the duties of the Commission were extended to an inquiry as to whether it is desirable to make an experiment in afforestation as a means of increasing employment during periods of depression.

The Commission consisted of thirteen members, representing landowners, experts in coast defence works, geologists, lawyers, the Board of Trade and other Government departments. The Hon Ivor Guest was appointed chairman. The first report, containing the minutes of evidence heard in the earlier part of the inquiry, was issued in 1907; the second report on the subject of afforestation in January, 1909; that now issued being the final report containing the findings of the Commission.[1]

The witnesses who appeared before the Commission represented all branches of the subject, including representatives of the Board of Trade, local authorities and their officers having charge of the sea coast in England, Ireland, and Scotland, owners of land abutting on the coast, engineers having expert knowledge of sea defence works, and geologists. Committees of the Commissioners made inspections of various parts of the coasts where erosion was going on, and where reclamations had been made; and also of the works of sea defence in Holland and Belgium.

As the subject of coast erosion had not been dealt with by any previous Commission, the Commissioners thought it necessary to make an ample and thorough examination of the whole subject. The report is divided into an inquiry into the physiographical and geological conditions affecting the coast-line; an estimate of the extent of erosion and accretion of land; and where artificial reclamation has been carried out on the coasts and in tidal estuaries; engineering questions as to the type of work which has been adopted for sea defences; the central and local administration of the foreshore; and whether it is desirable to promote facilities for reclaiming tidal land; and also as to whether the defence of the coast is a national duty towards which grants of public funds ought to be made.

The inquiries of the Commission extended over five years, and the resulting report gives a very clear and able digest of the large amount of evidence taken. It deals with the subject in an exhaustive and comprehensive manner, and contains an able account of the technical considerations which should govern the design of works of defence. The finding of the Commissioners appears to be a fair exposition of the evidence brought before them, and it deals in an even-handed way with the rights of the owners of land abutting on the coast, on one hand, and of the State, as representing the other tax-paying members of the community, on the other.

The recommendations of the Commissioners are practically unanimous. There are reservations as to some of the subjects dealt with, the most important relating to the subject of the obligation of the State to protect the sea coasts.

The findings of the Commissioners may be summarised as follows:—

That there is a considerable amount of erosion and consequent loss of land taking place on certain parts of the coast; on the other hand, land is being reclaimed from the sea. Taking the last thirty-five years, it was shown by the evidence of the Ordnance Department that 6640 acres have been lost, while 48,000 acres have been gained by reclaiming tidal lands. This reclaimed land is due principally to the accretion of material brought down in suspension by the rivers. The amount and rate of erosion along the coast is governed by the nature and form of the coast. The natural protection of the coast is afforded by accumulations of sand and shingle derived almost entirely from the material eroded from the cliffs. The amount of beach material therefore depends on the amount of erosion going on, and the quantity is limited, and is not inexhaustible.

The material eroded travels along the coast in definite directions, due to the action of the tides, the wind and the waves. Its travel may be arrested by projecting headlands and river mouths.

Much damage to the coast has been incurred by the removal of this beach material in some places for road-making and constructional purposes.

The evidence shows that if works of protection are carried out with due regard to the local peculiarities of the district to be dealt with, and on sound engineering lines, erosion of the coast may be prevented. The fact also is disclosed that a very large amount of money has been wasted on groynes, sea-walls, and other defence works, owing to a want of knowledge of the conditions prevailing in the neighbourhood where the works were carried out; also that works designed solely with regard to the protection of a particular line of coast may lead to increased erosion on the coast to the leeward side, owing to the stoppage of the travel of the beach material. If the land to be protected is ordinary agricultural land, the cost of protection may be greater than the value of the land to be protected.

The Commissioners advise that the whole care of the coast should be placed under the administration of the Board of Trade, who should be constituted the central authority of the United Kingdom for the purpose of sea defence. That the Board should be invested with power to enable it to control the removal of materials from the shore, making it illegal to remove any sand, shingle, or stone without their previous consent being obtained; the approving of works of construction on the shore; the supervision of existing local authorities concerned with sea defences, and, where required, the creation of new authorities for the purposes of supervision of the coast to employ a staff of scientific experts to secure systematic observation of the movement of beach material and for watching the coast in order to prevent removal of such material where doing this would be injurious; also to sanction the borrowing of money by local authorities for defence works, and to determine the period over which repayment should be made. At present this duty rests with the Local Government Board, which only allow a period of ten years for groynes and twenty years for more solid works. This limit appears

[1] Third and Final Report of the Royal Commission on Coast Erosion. The Reclamation of Tidal Lands and Afforestation. (London: Published by his Majesty's Stationery Office, 1911.) Price 3s.

to the Commissioners to operate detrimentally in the case of local authorities.

With regard to the alleged obligation of the Crown to defend the coasts from the inroad of the sea, the Commissioners, with one exception, consider that the evidence laid before them does not warrant this conclusion, and that there is not any settled principle of the Crown or statute law to support the contention that there is a responsibility for sea defence resting primarily upon the nation at large; the fact that there is erosion in some places does not affect the nation generally, and there is not any ground for the contention that sea defence is a national service.

SEASONAL VARIATIONS OF MARINE ORGANISMS.

THE present short article has been written, not for the plankton specialist, but for readers who may have had their interest aroused by some reference in purely technical papers to seasonal variations. Aquatic organisms (vegetable and animal) may be divided into two groups, those which are fixed to the bottom or cannot leave the substratum, and those which are independent of it, and live swimming or floating in the water.

Of the latter, the pelagic organisms, some, such as fishes, swim about actively, whilst others are passive organisms, with but feeble organs of locomotion or none. They float about almost like inanimate objects, at the mercy of tides and currents, and they vary in size from microscopic flagellates up to large medusæ. These more or less passive pelagic organisms (both vegetable and animal) are what Hensen in 1887 characterised under the term plankton. The study of the plankton has advanced by leaps and bounds in the last few years, and fresh discoveries (often the results of new methods and ingeniously devised apparatus) have acted as stimuli to the work.

From being a qualitative science, planktology has become quantitative, and is becoming as exact in its methods as biometrics. Formerly the investigations were considered sufficiently intense and accurate if a net made of fine silk was pulled horizontally through the water, so that the planktonic organisms were filtered out and captured. Now, it is necessary to use other methods, to pass the water through special filters, and to centrifuge measured quantities in order to catch those exceedingly small creatures which pass quite easily through the finest silk cloth. These very small organisms are of supreme importance, for what they lack in size they make up for in numbers, and some of the most keenly discussed theories in marine biology of the last few years may have to be seriously modified when more detailed observations have been made on their occurrence.

Serial investigations have shown that the plankton varies both qualitatively and quantitatively through the different seasons. It is never absent even under an ice cover in fresh-water lakes, and just as the opening of the buds serves as an indication of spring, so the appearance of certain organisms tells of the approach of the same season in the waters. Summer and autumn are both equally well marked in the aquatic world, and this applies to the seas as well as to lakes and ponds.

Some organisms are always present, but most planktonic animals and plants appear at certain seasons, and then disappear, whilst others take their places. In fact, it is quite impossible to write an account of the plankton of any waters from a series of catches made in a period of a few weeks only. A plankton investigation must extend through at least one year, so that catches may be examined representative of all seasons. If such a research be carried out it becomes at once obvious that the plankton varies according to certain external conditions, amongst which might be enumerated, sunlight and temperature of the water, chemical constitution of the medium, and, finally, the motion of the latter, particularly as regards vertical currents.

The application of quantitative methods to the study of the marine plankton has shown that, contrary to all expectation, the colder waters of the globe are more productive than those of the tropics. Compared with temperate and Arctic seas, the open ocean of the tropics is a desert so far as the plankton is concerned, with occasional oases. In our own waters the quantity of plankton present varies enormously during the year. Catches made with a net hauled vertically under the same conditions average perhaps about 1 c.c. in volume during the early months of the year. In the short space of a week in March or April, this volume may rise to 40 c.c., or even more, and remain constant for a period of some weeks, falling eventually to about 1 or 2 c.c. again during the summer. It is of the utmost importance that the causes of these variations in the quantity of the plankton should be discovered. What determines the productivity of any particular region? Why is there an extraordinary increase in quantity during certain weeks of the spring and autumn? These are amongst the most fundamental questions in the biology of the sea.

If every year was the same so far as meteorological conditions were concerned, and the plankton variations of successive years were absolutely identical, we should never be able to do more than make speculations as to the causes of such variations. Nature, however, varies the meteorological and hydrographical conditions for us, and we find that there are also corresponding annual variations in the plankton. Thus the spring and autumn maxima of the latter may be earlier one year than another, or may extend over a longer period. It is the work of the planktologist to analyse these changes and endeavour to correlate plankton variations with hydrographical and meteorological conditions.

In the Irish Sea, for example, an attempt has been made by Prof. Herdman and others to arrive at some of the causes of the seasonal variations by taking serial plankton catches through a period of several years, the hydrographic conditions prevailing being also observed. It ought to be possible in this way to correlate certain biological and physical variations. It was found in the first years of this plankton investigation that the spring and autumn maxima were due to a large extent to an enormous increase in diatoms, an increase followed by the appearance of dinoflagellates. The copepods followed these spring dinoflagellates, and attained their greatest development in the early summer. This order of succession has held good throughout all the years of this investigation (1907–11). Whilst, however, the highest monthly averages were in April in 1907 and 1910, they occurred in May in 1908 and 1909. The two years, 1907 and 1910, resembled one another so far as meteorological conditions are concerned in having a larger amount of sunshine during the early months than was the case in 1908 and 1909; and the question arises whether this early sunshine was a determining factor in the early appearance of the vernal maximum.

It was expected that this year, 1911, would perhaps throw some light on the question, and whatever the result may be when the hydrographic and meteorological conditions are worked out, the plankton maximum has certainly been very different from that of any of the previous years.

Up to the present the cause of the vernal phyto-plankton maximum still seems to be wrapped in mystery, and the same may be said of the greater productivity of the cooler waters.

Several theories have been proposed from time to time by Brandt and others to explain the vernal maximum, and of these Nathanson's appears to be the most fundamental. This author believes that vertical currents, which aid in the circulation of food materials, are responsible for the productivity of the sea in plankton. These currents are always present at certain places, and there one can always rely on finding a rich plankton. They are also present at certain seasons in other larger areas of the sea, and in lakes, and these seasons correspond to the times of maxima.

It is most probable that this explanation is not sufficient alone, and that the sunlight, the temperature of the water, and the chemical constitution are also determining factors.

The conditions surrounding the plankton are very complex, and it will probably require many years of investigation before the predominant factors in the problem can be discovered.

The work is slow and laborious, but still it aims at the solution of one of the most important problems in the metabolism of the ocean. This is the point of view from which the planktonic work at the Port Erin Biological Station is being carried out under Herdman's direction, and similar work is being prosecuted by planktologists elsewhere. It has lately been asserted that the most important part of the food of aquatic organisms is derived from organic compounds in solution in the medium in which they are living. At the present time it is impossible to say with any certainty how far this thesis may be correct, but whether it be the case or not, the plankton still retains its importance as either the immediate or the ultimate source of those organic substances upon which all marine and fresh-water animals depend.

WM. J. DAKIN.

NOTES.

IT is announced in the July issue of *The Popular Science Monthly* that during his visit to Washington at the time of the annual meeting of the National Academy of Sciences Sir John Murray, K.C.B., F.R.S., presented a fund of 1200*l.* to the academy for the purpose of founding an Alexander Agassiz gold medal, which is to be awarded to men of science in any part of the world for original contributions to the science of oceanography.

WE regret to announce that Mr. W. I. Last, director of the Science Museum, South Kensington, died on August 7 at his residence, 11 Onslow Crescent, S.W., in his fifty-fourth year. Mr. Last was apprenticed in 1873 with Messrs. Hayward Tyler and Co., and when barely twenty years of age won the Senior Whitworth Scholarship; he held his scholarship at the works of Sir Joseph Whitworth, and at the same time he followed a course of study at the Owens College, Manchester, gaining numerous prizes during this period. In 1886 he was elected an Associate Member of the Institution of Civil Engineers, and in the following year the council awarded him a Watt medal and a Telford premium for his paper on setting out the curves of wheel teeth. In 1890, after some years spent in practical work at home and abroad, he was appointed to the post of keeper of the machinery and inventions division of the South Kensington Museum; shortly afterwards the naval division was also entrusted to his care. Recognising that objects which involved mechanical movement are most intelligible as well as most attractive, both to students and to the public, when shown in motion, he arranged numerous ways of effecting this under museum conditions. One of the best methods which he devised and introduced for this purpose was the supply of compressed air for working the objects by their own driving mechanism. The plan of sectioning objects to show the working parts of machines and details of construction was carried out by Mr. Last with much success. The collections have been very widely extended under his supervision. Mr. Last received his appointment as director of the whole Science Museum in 1904. The excellence of his work on the collections was the subject of comment in connection with the recent inquiry as to the museum.

THE death at Nice is announced, at the age of seventy years, of Dr. Louis C. De Coppet, distinguished by his researches on the solubilities of salts and the lowering of the freezing point of water by the presence of salts in solution.

WE are informed by the National Association for the Prevention of Consumption that it has been decided by the Rome authorities to postpone the International Congress on Tuberculosis, which was to have been held in Rome on September 24–30, to next April.

THE London County Council, on the recommendation of the Local Government Records and Museums Committee, has resolved that the whole of the objects of London interest collected by the Council from time to time, including the boat of the Roman period discovered on the site of the new County Hall, be offered on permanent loan to the trustees of the London Museum. The museum will be accommodated in the State apartments of Kensington Palace, which was placed by the King at the disposal of trustees for the exhibition of the collections. The accommodation at Kensington Palace is understood to be of a temporary nature, the intention being eventually to house the objects in a building worthy of London.

IT is announced in *The Times* that an experiment in the direction of utilising aëroplanes in the postal service of the country is likely to be undertaken shortly by the General Post Office. The proposal is for a regular aërial service for a limited period between London and Windsor. Arrangements have been made with a number of large firms for the fixing in their establishments of special "aërial" letter-boxes, in which letters intended for the aërial service must be posted. Daily clearances will be made by postmen, and the collections will be dispatched to the central clearing house. Here the letters will be placed in sealed bags and conveyed by motor-van to the aërodrome at Hendon, where the bags will be securely fixed to the machines. The airmen will then start on the journey to Windsor, covering the distance of 21 miles in, it is estimated, half an hour. At Windsor the aëroplane staff will be responsible for the conveyance from the aërodrome by road of all the letters to the town post-office, where they will be dealt with in the usual way.

THE annual autumn meeting of the Institute of Metals will be held at Newcastle-on-Tyne on September 20–22. Sir C. A. Parsons, K.C.B., F.R.S., is acting as chairman of the local committee, and Dr. J. T. Dunn as honorary secretary. The meeting will open at 10 a.m. on Wednesday, September 20, when the members will be welcomed at Armstrong College by the Lord Mayor of the city, Sir W. H. Stephenson, and the local committee, after which a series of papers will be read and discussed, Sir Gerard A. Muntz, Bart, president, being in the chair. In the afternoon members will have the opportunity of visiting shipbuilding, engineering, metallurgical, and electrical works in the neighbourhood. In the evening there will be a reception of the members and their ladies, followed by a conversazione, in the Laing Art Gallery, by invitation of the Lord Mayor. On Thursday, September 21, papers will be read and discussed at a morning session of the institute, and in the afternoon there will be further visits to works. For September 22 the Tyne Improvement Commissioners have placed a steamer at the disposal of the local committee for a voyage to the mouth of the river and back.

THE ninth annual meeting of the South African Association for the Advancement of Science was held at Bulawayo on July 3–8, under the presidency of Prof. P. D. Hahn. The meeting was attended by members from Cape Town, Johannesburg, Salisbury, &c. The sectional presidents were as follows:—Section A, Rev. Father Goetz, S.J.; Section B, A. J. C. Molyneux; Section C, F. Eyles (Rhodesia); Section D, G. Duthie. In addition to the presidential addresses, numerous papers were read before the various sections. In particular, Mr. R. N. Hall's papers dealing with the Zimbabwe ruins gave rise to considerable discussion. Papers were read before Section A on electric clocks, by Prof. H. Bohle; aviation in South Africa from a meteorological point of view, by R. T. A. Innes; atmospheric electricity observations, by Prof. W. A. D. Rudge. Many interesting excursions were arranged by the local Bulawayo committee. The Khami ruins and various Bushman haunts were visited under the guidance of Mr. R. N. Hall. A pilgrimage was made to Rhodes's lonely grave in the Matopos, and after the conclusion of the meeting several days were spent at the Victoria Falls.

IN the July issue of *The Quarterly Review* Mr. E. Clodd contributes a useful criticism of totemistic theories under the title of "Primitive Man on his Origin." While cordially welcoming Dr. Frazer's monumental treatise on totemism and exogamy, he is unable to accept his explanation of the origin of totemism from the Arunta theory of conception, mainly on the ground that it does not account for the clan totemism, which is admittedly of primary importance, and because, so far from being the most primitive, the Arunta are probably the most advanced of the Central Australian tribes. He is inclined to prefer Mr. A. Lang's solution that at the earliest period the groups were nameless; that later on they obtained soubriquets chosen from their fancied resemblance to this or that object; "no more than three things—a group animal name of unknown origin; belief in a transcendental connection between all bearers, human and bestial, of the same name; and belief in the blood superstitions—was needed to give rise to all the totemic creeds and practices, including exogamy." Needless to say, this solution involves certain special difficulties, of which Mr. Clodd is fully aware. The result of the discussion is to increase the feeling of doubt if any single solution hitherto advanced of the complex group of facts labelled as totemistic offers a reasonable explanation of them.

THE Journal of the Gypsy Lore Society continues its useful task of studying the eastern European groups of this interesting race. We have two articles of special importance, one an account of the Gypsies of Central Russia by Mr. D. F. de l'Hoste Ranking, the second of the organisation of the South German Gypsies by Mr. E. Wittich. The predatory habits of the Russian group amply account for the fear and hatred felt towards them by the rural population. On the other hand, in Germany their moral standard seems to be decidedly higher, and their tribal organisation provides for the control of social order by the trial of offences committed by members under the superintendence of their chief at an annual assemblage held in Elsass, where the proceedings are conducted in secret session. This festival, however, often ends in a general free fight between rival members of the tribe, who take this opportunity of gratifying their feelings of revenge for bloodshed or other injuries. If a reconciliation of such quarrels is effected it is done by the exchange of glasses charged with their favourite liquor. The tribal code of social morality, with its curious system of taboos, one being that a man who eats or drinks out of a vessel which a Gypsy woman has touched with her dress or stepped over becomes an outcast, will be of much interest to students of primitive usages.

IN the same issue of the Gypsy Lore Journal Mr. J. Teutsch describes a curious form of primitive lathe, revolved by a string, which is used by Gypsy spoon-makers at their settlement in Kutusch, north of Kronstadt. The bowl of the spoon is first shaped with a set of knives and scrapers. The handles are then turned in this rude lathe, the woman worker decorating them with a series of circular stripes and bands by pressing against the wood as it revolves a rag soaked in a green dye and moistened in saliva. The method furnishes some analogies to that used by the Indian makers of so-called "Benares toys," in which, by means of a similar rude lathe, pieces of lac of various colours are pressed against the toy as it is revolved, the heat produced by this friction causing the lac to become partially melted, and leading to the deposit on the wood of thin streaks of colour.

DR. DANIEL STARET communicates to the current number of *The Psychological Review* an interesting experiment upon the influence of suggestion, or unconscious imitation, on handwriting. More than a hundred persons were investigated by the following method. Each person was provided with a set of five sheets, on the first of which was written the instruction: "We desire records of your handwriting. Will you accordingly write out the words and sentences presented on the pages given you. Kindly do this without further questioning or reflection." The second sheet contained a short paragraph of typewritten material, the subject's written copy of which provided an illustration of his (or her) normal handwriting. The third sheet was of vertical, the fourth of slanting, script; the fifth contained unusually large script, all taken from American "copy-books," and written out by the subjects of the experiment. The measurements of the slope of the subjects' handwriting were subsequently made by means of a scale of variously inclined lines drawn on transparent paper, which was superimposed on the handwriting: three letters, *l*, *f*, *p*, were selected for measurement. The size of the letters was determined by measuring their horizontal width, the lengths of entire words being measured and divided by the number of letters. All the subjects who were investigated appeared to be (unconsciously) susceptible to this form of imitation, women showing a greater tendency towards imitation than men, and those persons who showed a large amount of change in slope also showing a large increase in the size of the letters. The more "vertical" writers were, of course, influenced more by the sloping than by the vertical copy; the opposite relation obtained with the more "slanting" writers.

THE composition of Indian yams, as furnished by chemical analysis, is discussed by Mr. D. Hooper in a short note published in the Journal and Proceedings, Asiatic Society of Bengal (vol. vii., No. 3). Compared with potatoes, yams contain a larger proportion of fat and a smaller proportion of carbohydrates. The alkaloid dioscorine was detected in the tubers of several species, notably *Dioscorea daemona*; it appears that cultivation tends to reduce the amount of alkaloid.

Under the title of "Album général des Cryptogames," a new and elaborate iconograph arranged by Dr. H. Coupin is being published by the Librairie générale de l'Enseignement, Paris. It is announced that the work will deal with algæ, fungi and lichens, and that every genus and most of the species will be illustrated. A beginning is made with the lowest organisms, and the first volume, containing fifteen plates, illustrates eighty-three species under thirty-seven genera representing the family Chrysomonadineæ and part of the family Dinoflagellatæ; under the genus Gymnodinium seven species are illustrated in thirteen figures. The text is limited to a brief description of the figures, habitat, generic synonyms, and a reference under each species to the literature where fuller information can be found. The price of each part is 2.50 francs, but no estimate of the number of parts is offered.

An article on the formation of anthocyanin in plants, communicated by Miss M. Wheldale to *The Journal of Genetics* (vol. i., No. 2), provides a carefully reasoned discussion of the chemical processes involved with the view of substantiating a proposed hypothesis explanatory of the mechanism underlying the phenomenon of soluble pigment formation. The arguments are based upon data derived from observations upon the general distribution of pigment, its formation, the conditions which lead to its appearance, and the enzymes detected at the time of its production. According to the hypothesis formulated, the soluble pigments of flowering plants, collectively termed anthocyanin, are oxidation products of colourless chromogens of an aromatic nature which occur in combination with sugar as glucosides; the process of formation of glucoside and water from chromogen and sugar is reversible; the chromogen can only be oxidised to anthocyanin after liberation from the glucoside, and the process is controlled by one or more oxidising enzymes.

From the report recently to hand on the work of the Edinburgh and East of Scotland Agricultural College, it appears that all the classes are overcrowded, and the lack of accommodation is now causing serious inconvenience. The fact that the number of students last season exceeded all previous records shows that useful work is being done, and is taken as an indication that, with better accommodation and with a college farm, even better work could be turned out. Bulletins are also issued by Mr. Bruce on potatoes and on grass land, demonstrating the kind of return that may be expected from applications of artificial manures.

An interesting bulletin issued by the Nyasaland Department of Agriculture shows the great progress that has been made in the development of the cotton industry. The total export of cotton from the Protectorate is valued as follows:—

		£
1903	... ...	3
1904–5	... ...	5,914
1907–8	... ...	13,999
1908–9	... ...	28,355
1910–11	... ...	52,853 (eleven months only).

According to Mr. McCall, the director, there is still the possibility of much further growth. Some of the problems connected with the extension of the crop are discussed in the bulletin.

In making provisional estimates of the yields of crops, it is customary in the United States and in Canada to express the condition in terms of a hypothetical "normal" or "standard" crop. Mr. H. D. Vigor discusses the method in a recent issue of the Journal of the Royal Statistical Society, and shows that it has no sound statistical basis, since the standard for measurement is largely constructed in the imagination of the individual reporter. The various difficulties that arise when statisticians attempt to make deductions from the results are dealt with, and it is shown that a sounder method would be to express the probable yield as a percentage of the average yield during some convenient preceding period.

We have received from Mr. J. B. Rorer, mycologist to the Board of Agriculture, Trinidad, his report for the year ended March, 1911, in which it is stated that the cause of two troublesome cacao diseases, the canker and black rot, has been successfully traced. It appears that both diseases are caused by one and the same fungus, *Phytophthora faberi*. A bacterial disease of bananas and plaintains is also described by him, and the organisms have been isolated; they are similar to *B. solanacearum*, and are provisionally being called *B. musae*. Much attention is given to the mycological problems of the West Indies in *The Agricultural News*, the official organ of the West Indian Agricultural Department. Descriptions are given in several of the recent issues of miscellaneous fungi found during the past few months, some of which have not yet been identified.

One of the most promising methods of effecting improvements in agriculture is to bring to the notice of experts and of farmers those practices that are found useful elsewhere. It does not follow that a plan must necessarily succeed in any one place because it has been found beneficial in another, but a discussion of the factors cannot fail to be fruitful. The *Bulletin de la Société d'Encouragement pour l'industrie nationale* periodically publishes very interesting accounts of the agriculture of particular countries or districts, several of which have been referred to in these columns. In the current volume a good description of Canadian agriculture has appeared, and also of the agriculture of the Saint Brieuc district of Brittany. The method is one that might usefully be adopted more widely, and has in the past been used with great advantage in this country.

Public opinion in Australia is awakening to the harm done—to put it on no higher level—by the ruthless extermination of birds which modern millinery seems to demand, and to which heedless sportsmen contribute in no small degree. The matter is now being taken up by *The Journal of Agriculture of South Australia*, and in recent issues coloured pictures of protected birds and their eggs are given, with brief notes on description, habitat, food, &c. "The killing of our wading birds each year," it is stated, "not only renders South Australia ever more prone to plagues of grasshoppers, but is most certainly a prime cause of the decline of our fish resources. . . . In a day one ibis was found responsible for the destruction of 2410 grasshoppers, or so-called locusts. Yet each season this lovely and useful bird, together with numbers of cranes, spoonbills, and egrets fall victims. . . . It is the decimation of such birds which leads to the ever-increasing multitudes of crustaceans that destroy fish-spawn and young fish hatching out." We wish our contemporary success in its crusade.

In *The Agricultural Journal of India* (vol. vi., part ii.) Mr. Keatinge continues his account of the rural economy of the Bombay Deccan, dealing now more particularly with capital. A high rate of interest prevails for several reasons: capital is scarce in the country, and there is no organisation enabling the cultivator to get into touch with the money markets of the towns; security is not always good, and the money-lender incurs some social odium. In consequence, a man raising a mortgage on good land has even in favourable circumstances to pay 9 per cent. interest, while in less favourable circumstances he may have to pay up to 24 per cent., and on personal security the rates go up to 100 per cent. There are two papers on cotton, one by Mr. G. S. Henderson on the exotic cottons in Sind, and one by Mr. P. Venkayya on the Cambodia cotton, a hardy long-stapled annual, yielding lint of a superior white colour. An interesting summary of the cotton investigations now in hand by the United Provinces Department of Agriculture is given by Messrs. H. M. Leake and A. E. Parr in part i. of the same journal; these fall under two headings, the production of an improved type or types suited to the conditions of the Provinces, and their introduction into general cultivation.

The growing importance of the Suez Canal is shown by a Parliamentary paper recently issued, which gives the return of the shipping passing through the canal for the years 1908, 1909, and 1910. The net tonnage of the past year shows an increase of nearly three million tons as compared with 1908. The gross receipts in 1910 were the largest reached. The percentage of the British vessels amounted to 62·9 as compared to those of all other nations, Germany being second with 15·5 per cent., both showing an increase over previous years, while the remaining 21·6 per cent., representing all other nations, remain practically at the same rate.

The annual report of the conservator of the River Mersey shows that since the commencement of the dredging and deepening of the bar at the mouth of the river upwards of 161 million tons of sand have been removed, the quantity for last year being $18\frac{1}{3}$ million tons. The minimum depth of water maintained in the centre of the dredged channel is 30 feet 3 inches. Dredgers are now being employed in deepening the channel off the Askew Spit, the revetment on the south side of Taylor's Bank having been completed in November last. The report also states that during 1910 nearly two million tons of silt were dredged from the channel of the Manchester Ship Canal, the whole of which would have found its way into the estuary of the Mersey had not the canal works interposed.

Four years ago a scheme of irrigation was inaugurated for supplying water for agricultural purposes in a district in Canada near Calgary. The area of the district to be irrigated covers three million acres, and involves the construction of 4500 miles of canal, of which 1500 miles have now been completed. The main canal is 17 miles in length and 120 feet wide at the water-level, and is supplied from the Bow River. Storage is provided by a reservoir 3 miles long by half a mile wide, with a depth of 40 feet. The total cost of the whole work is estimated at three million pounds. In other parts of Canada also extensive irrigation works are in progress, notably in the fruit districts of Columbia. In this district the rainfall ranges only from 9 to 10 inches as a maximum, falling to as little as 2 inches in dry seasons. Without irrigation the land in this dry district would be worthless. The area of Canada which is being opened up for fruit farming by irrigation extends over 30,000 acres.

Communication No. 122 from the physical laboratory of the University of Leyden contains a paper by Prof. Kamerlingh Onnes on the disappearance of the electrical resistance of mercury at the very low temperatures obtained when liquid helium boils under reduced pressure. The resistance of the mercury filament in the liquid state at 0° C. was 173 ohms; in the solid state at the same temperature it would, if its temperature coefficient of resistance remained constant, have a resistance of 40 ohms. At 3° absolute its resistance had sunk below 3×10^{-6} ohms, that is to say, one ten-millionth of its resistance at 0° C. The resistance of constantin (eureka) remained nearly constant over the same range of temperature. In a second paper Prof. Onnes and Mr. A. Perrier show that paramagnetic and diamagnetic substances the magnetic susceptibilities of which at ordinary temperatures vary inversely as the absolute temperature at these very low temperatures, deviate considerably from Curie's law.

In the Bulletin for 1910 of the International Association for Promoting the Study of Quaternions and Allied Systems of Mathematics, in addition to the usual list of members and the additions to the bibliography during the preceding year, there are some reviews by Prof. J. Birnie Shaw, the secretary. The most important is the critical examination of Burali-Forti and Marcolongo's books on their new notation for vector analysis. Prof. A. Macfarlane, the president, communicates a short address, followed by a paper on the unification and development of the principles of the algebra of space. Here the author gives a well-arranged argument in favour of his system of what might be called versorial analysis. He corrects Hamilton's view of the quaternion exponential, and develops what is undoubtedly a self-consistent system, in which the square of the vector is kept positive, and associative flexibility is obtained by the introduction of the imaginary. Complexities of an unexpected kind seem to spring out of his method, but as a piece of analytical reasoning it is of great interest. No illustrations are given of the practical value of the method.

A small self-contained machine for the grinding and polishing of metal specimens for microscopic examination has been brought out by Messrs. R. and J. Beck, Ltd., and the apparatus possesses certain advantages which should render it particularly useful to metallurgists. The whole machine is carried on a small iron bed-plate, and consists essentially of a small enclosed electric motor of a substantial type and the polishing spindle proper; the motor drives a counter-shaft, and from this the drive is by a range of three-speed pulleys to the polishing spindle. The polishing discs themselves are detachable from the spindle, and run in a carefully designed casing, which not only serves to catch the spent polishing materials, water, &c., but also serves as a rest to the hand of the operator, and in an emergency saves the specimen from injury if it should accidentally escape from the operator's fingers. The attachment of the polishing cloth to the discs takes the somewhat novel form of a fairly stiff steel spiral spring acting as a species of garter, and, provided that the spring is strong enough to resist the centrifugal action at high speeds, this forms a most convenient form of attachment for both cloths and papers. With the addition of a suitable rheostat for controlling the speed of the motor, the machine should prove equal to all requirements for metallurgical polishing, although the use of separate machines

—in separate rooms, if possible—for grinding and polishing, respectively, is to be advocated.

Two years ago it was shown by Ramsay and Usher that a solution of thorium nitrate, left to itself for some months, gave off a certain quantity of carbon dioxide, and that under the action of the radium emanation the thorium solution gave off this gas much more rapidly. The view was put forward that the carbon of the carbon dioxide might have been produced during a transformation of the atoms of thorium by the action of the radium emanation. In the *Comptes rendus* of the Paris Academy of Sciences for July 24 M. Herschfinkel gives a description of a repetition of these experiments. The production of a trace of carbon dioxide by the solution of thorium nitrate left to itself, and the increase of this amount under the influence of the radium emanation, were confirmed. It was, however, found that oxidation of the thorium nitrate with a solution of potassium permanganate also gave rise to the production of carbon dioxide, and this in spite of the great care taken in preparing a pure salt. The conclusion is drawn that the appearance of carbon dioxide under the conditions of this experiment cannot be taken as any evidence of the production of carbon from atomic transformation of the thorium.

An article on scientific management and efficiency in the United States Navy, by Walter B. Tardy, appears in *The Engineering Magazine* for July. Less than 3 per cent. of all the shells fired in the battle of Santiago by the American fleet hit the enemy. There is no record that a single 12-inch or 13-inch shell took effect. The ranges were less than 3000 yards. Recently the *New Hampshire* used the old *Texas* as a target, firing at ranges from 10,000 to 11,500 yards, and landed whole salvos on the *Texas* whenever she wished. The *Michigan*, an all-big-gun ship, recently made twenty-two 12-inch hits at ranges of 10,000 yards while steaming at 15 knots, the target being only 60 feet long by 30 feet high. She fired forty-eight 12-inch shells, the percentage of hits being about 45; the shots were fired at the rate of about two per minute per gun. Organisation and strict attention to details are responsible primarily for the great improvement shown. Among other matters, coaling has received considerable attention, and the rate has been improved from 30 or 40 tons per hour to 200 tons per hour for the entire coaling period; some ships have taken on and trimmed as much as 350 tons per hour for the entire coaling period, with a record of about 550 tons for the best hour.

OUR ASTRONOMICAL COLUMN.

Rediscovery of Encke's Comet, 1911*d*.—A telegram from the Kiel Centralstelle announces that Encke's comet was discovered by Dr. Gonnessiat at the Algiers Observatory on July 31. Its position at 15h. 54·5m. (Algiers M.T.) was R.A. = 7h. 27m. 54·5s., dec. = 26° 54′ 6″ N., and its brightness was estimated as being about equal to the tenth magnitude; this position lies in Gemini very little south of Castor and Pollux.

Owing to its faintness and unfavourable position, it was not expected that this famous comet would be easily detected at this return; only under the most favourable conditions has it ever become a naked-eye object. The comet is famous as being the first short-period (3·3 years) comet for which the periodicity was established, and also for its very slow but persistent acceleration, which was held to be a demonstration of the existence of a luminiferous æther. According to M. Bosler and others, its brightness varies with the sun-spot activity through the eleven-year period.

Stellar Parallaxes.—Dr. Schlesinger's discussion and summary of his parallax results obtained with the Yerkes 40-inch refractor—the seventh paper of the series—appears in No. 1, vol. xxxiv., of *The Astrophysical Journal*; only a few of the more interesting points can be noticed here. The results for four helium stars included in the programme confirms the proper-motion results in pointing to the fact that this class of stars is situated at an enormous distance from the earth, so much so that, taking averages, a fourth-magnitude helium star is probably as distant as the ninth-magnitude stars in the same region of the sky. Of these four, three give negative and one slightly positive parallaxes; no other star measured gave a negative value.

A practical point elucidated is that with such an instrument as the Yerkes telescope the number of parallaxes that may be determined per annum, with an average probable error of ±0·013″, is about the same as the number of fine nights.

Of the twenty-six stars given in the tabular summary, three, Groombridge 34, P.M. 2164, and Krüger 60, have parallaxes greater than 0·2″; the mean values for these three are 0·266″, 0·282″, and 0·252″ respectively.

During the minute examination of sources of error it was shown that measuring the plates in duplicate adds only 10 per cent. to their weights; such measurements were early discontinued. In some cases a rotating disc was employed to reduce the brightness of the parallax star, and the final probable errors show that no increased error was thereby produced.

Prominences in 1909.—Prof. Ricco's valuable summary of the Catania prominence observations for 1909 appears in No. 6, vol. xl., of the *Memorie di Astrofisica ed Astronomia* (June, p. 83). Compared with 1908, especially with the latter part of that year, the frequency and dimensions of the prominences showed an increase in 1909. Slight differences are seen in the mean latitudes, and the maximum frequencies—in 10° zones—occurred in 20°–29° N. and the 30°–39° S. latitudes. This was the only maximum in the southern hemisphere, but in the northern there was a minor maximum in the zone 50°–59° N. The mean daily frequencies were 1·84 for the northern and 1·81 for the southern hemisphere, while the respective mean heliographic latitudes were 31·9° N. and 27·5° S. On 8 per cent. of the days of observation no prominences were seen during the first half of the year, while only two days (2 per cent.) yielded no prominences during the second half.

The Algol System RT Persei.—Contribution No. 1 from the Princeton University Observatory is a monograph, by Mr. R. S. Dugan, dealing with the observations of the Algol variable RT Persei made at the Halsted Observatory with the 23-inch telescope during 1905–8. After describing and discussing the observations, Mr. Dugan concludes that there is undoubtedly a secondary eclipse, that the two stars are practically equal in size, and that the reality of the light-changes between eclipses is fully guaranteed by the probable error.

Jupiter's Faint Satellites.—Observations of the fainter satellites of Jupiter are being kept up at the Transvaal Observatory. Four good exposures were made during April and May, but on one plate only is J viii to be found. Images of J vi appear on all the plates, and it is estimated that this object is at least two magnitudes brighter than J viii. The places given as yet are not final, but, brought up to the equinox of date, they show good agreement with those given by Dr. Crommelin's ephemeris. Observations of twelve minor planets, five of which are suspected to be new, were made during the satellite observations; temporarily the new ones have been designated T_1–T_5, and their positions are given with the above in Circular No. 8 of the Transvaal Observatory.

The Brightness of Comets 1908 III. and 1910*a*.—The variations in the brightness of Morehouse's comet and in that of comet 1910*a* have been investigated in detail by M. Orlow, who publishes the results in No. 4513 of the *Astronomische Nachrichten*. Eliminating the terrestrial distance, he finds confirmation of the result that a comet's brightness varies more than is expressed by the formula $1/r^2\Delta^2$. The ratio $1/\Delta^2/r^4$ is nearer the observed results, the index of r in the case of comet 1910*a* being 4·6.

PROBLEMS IN SEISMOLOGY.

A GENERAL report of the recent meeting of the International Association of Seismology was given in NATURE of July 27, including Prof. Schuster's presidential address, which touched illuminatively upon the broad problems of the physics of the earth's crust. The following supplementary notes are intended to give a fuller account of the many subjects which were discussed by the seismologists.

Particularly interesting was the report presented by Dr. Hecker, formerly of Potsdam, now of Strassburg, on the tidal strains produced in the crust of the earth. Hecker's well-known results have been supplemented by similar work carried out at Dorpat by A. Orloff, who also gave an account of his measurements of the deformation of the earth's crust under the action of the moon. The method of both sets of experiments is to search for a lunar periodicity in the movements of sensitive horizontal pendulums. If the earth were rigid, these movements, in so far as they are due to the influence of the moon on the vertical at any locality, can be calculated. The experimental results give, however, a deflection of the vertical which is only two-thirds of the calculated value. This is explained on the assumption that the earth's crust yields to the tidal action of the moon. Hecker's and Orloff's results show, moreover, that the force acting on the pendulum is a larger fraction of the moon's force when it acts towards the east or west than when it acts towards the north or south. In other words, the earth seems to be more rigid towards forces acting east or west than towards forces acting north or south. Sir George Darwin suggested that this might be due to the effect of the earth's rotation; and the problem thus presented has been worked out with great skill by Prof. Love in his Adams prize "On some Problems of Geodynamics." He finds that Hecker's result cannot be explained in terms of the earth's rotation, and proceeds to invoke the direct gravitational influence of the tidal wave in the Atlantic Ocean upon the vertical at any neighbouring locality or the pressure effect of the same wave on the bed of the ocean. The International Association propose to follow up the inquiry by establishing new stations in suitably chosen localities, such as Paris, because of its contiguity to the ocean, and a station in the Russian Empire far removed from the Atlantic. The installation of instruments in South Africa, say at Johannesburg, and at some place on the American continent, would also provide results which, in conjunction with the others, might lead to the complete solution of the problem. In carrying out this work the Seismological Association is to be associated with the International Geodetic Association, and funds have been voted for the purpose.

It has thus been established beyond a doubt that the earth's crust yields appreciably to the tidal action of the moon. The measurement of this yielding demands the use of delicate instruments of a type familiar to seismologists, and used by them in the investigation of earthquake movements. Every large earthquake starts tremors through the earth, and these are caught and recorded at a large number of stations in many parts of the globe. Prof. Milne, working through the Seismological Committee of the British Association, was the first to show the value of such a seismological survey; and now it may safely be said that no observatory is complete without a self-recording seismograph. Within the last few years great advances have been made in the perfecting of instruments for registering movements of the ground, and among those who have increased the precision of these instruments Prof. Wiechert and Prince Galitzin are worthy of special mention. Prince Galitzin exhibited at the congress his form of vertical motion seismograph, which utilises the same method of magnetic damping which is characteristic of his horizontal pendulum. The instrument is thus made aperiodic, so that the relative motion of the ground is faithfully recorded. The record is obtained by the action on a delicate galvanometer of induced currents set up in a coil which moves with the boom of the seismograph relatively to a strong magnetic field. The galvanometer is also made aperiodic. Prince Galitzin explained his method of finding the epicentre of an earthquake from records obtained at one place on his two horizontal pendulums. The interval between the arrival of the first and second phases of the preliminary tremors gives, as Milne and Oldham showed years ago, the *distance* of the epicentre. Galitzin has now shown how we may get the *azimuth* from the first indications of the seismograms obtained with aperiodic horizontal pendulums. The ratio of these first displacements in the east-west and north-south records gives the tangent of the azimuth angle referred to the meridian. There is an ambiguity as to the direction along which the epicentre lies, whether, for example, it is N.N.E. or S.S.W.; but this ambiguity is quite removed when the vertical component is obtained. The precision of the method depends upon the fact that the instruments are damped accurately so as just to be in the aperiodic state. By a large number of examples Prince Galitzin showed that the estimation of the position of the epicentre in cases in which the method is applicable was as satisfactory as by the usual method of comparison of times from two or more stations.

The interpretation of the times of transmission of earthquake tremors to places at various distances from the epicentre is one of considerable importance in seismological studies. The curve which shows the relation between distance and time—the hodograph, as many now call it—is not yet known so accurately as one would wish, a fact which was emphasised by Prof. Reid, of Baltimore. Prof. Wiechert's ingenious discussion of inferences to be drawn from the form of this curve has led him to a theory of the constitution of the earth which differs in some respects from other similar theories. To take into account the peculiarities of the hodograph, and especially the flattening of it at mid-stations, which has already engaged the attention of Milne and Oldham, Wiechert finds it necessary to construct the earth of three layers differing in elastic properties, the central core being, in his opinion, made of nickel-iron. A special feature of Wiechert's discussion is the account he takes of the intermingling of disturbances which have travelled to the same station, the one directly, the other after one reflection at the surface of the earth. The theory is admittedly approximate, and may require correction as our knowledge of the hodograph becomes more certain; but the mathematical reasoning by which Wiechert attacks the problem will always have its value apart from the details of any conclusion to which we may be temporarily led.

These three lines of research—tides in the earth's crust, determination of epicentres from observations at one station, and inferences as to the structure and physical properties of the inner parts of the earth—probably bulked most largely in the discussions of the congress. But many other points of interest were touched upon, such, for example, as the elastic properties of rocks, for the measurement of which Dr. Oddone gave a remarkably simple experiment and calculation based on Hertz's expression for the compression of a sphere during impact. Again, in connection with the cause of the microseismic movements of the earth's surface, Prof. Schuster and Mr. Morris Airey exhibited an instrument designed to count the number of waves which beat on the shore. The increase of pressure due to the passing of a wave was transmitted by means of a hydrostatic and electric arrangement, so as to make the recording pen move always with a slight definite motion in one direction at right angles to the motion of the strip of paper on which the record was taken. After 120 minute and individually imperceptible movements were made, the pen moved back automatically to the original position. The record was therefore a series of diagonal lines the inclination of which to the motion of the paper was greater according as the waves came faster. In the records which were shown the period indicated was about six or seven seconds for each wave. This is one of the commonly recurring periods in microseisms.

The idea of measuring the intensity of an earthquake shock by the overturning of blocks is an old one, and engaged the attention of Milne and West in the early 'eighties. Omori also constructed from these indications a dynamic scale. Prince Galitzin showed how the indications might be greatly improved by providing the blocks with edges like the projecting covers of a book. When set oscillating the block executes movements the amplitudes and periods of which diminish in such a way that resonance effects are prevented. By experimenting on a movable platform, Galitzin found that the acceleration of the enforced movement was the determining factor in the overthrow of each block.

Prof. Reid, of Baltimore, described a new method of estimating the intensity of an earthquake, the fundamental proposition being that the energy associated with an earthquake was proportional to the square of the area within a given isoseismal line.

Mr. Napier Denison, of Victoria, Vancouver, gave an account of his observations of secular movements of the horizontal pendulum, and made a strong claim for Victoria as a place well fitted for seismological work.

Prof. Omori, of Tokyo, described some of the recent volcanic and seismic phenomena of Japan, the most interesting being the rise of a new hill during the eruption of Usu-san in Hokkaido, and the increasing activity of Asama Yama, a volcano in the centre of Japan which rises to a height of 8000 feet. The dull red contents of the crater have been steadily rising in level for some time, and fairly large blocks of stone have been projected from it. A station has been built on the flank of the mountain, and seismographs installed in it. The character of the tremors is markedly different according as they do or do not accompany a volcanic eruption.

In their less strenuous moments the delegates and their friends enjoyed to the full the hospitality of Manchester, more especially the Lord Mayor's reception in the Town Hall; Prof. Schuster's garden-party at Kent House, when a remarkably good photograph was taken of all attending the congress; and the closing dinner given by the University Council, when Prince Galitzin, in a humorous impromptu speech, proposed the health of Prof. John Milne, whose characteristic reply was a fitting close to a great conference.

THE MIGRATION OF A RACE.[1]

THE theory of a relationship between the numerous languages spoken in the islands of the Indo-Pacific Ocean from Madagascar and Sumatra to the Philippines, and thence far eastward to Melanesia and Polynesia, is almost universally accepted. But the connection of these languages with the Asiatic Continent, their origin, and the means by which they reached their present settlements, are still uncertain.

In the volume before us Mr. Churchill essays to trace the migration of the Polynesian people from their first home on the borders of Indonesia, through Melanesia, to Nuclear Polynesia, that is, to the region round about Samoa, Tonga, and Niue. Dealing with the languages only, he recognises two streams of voyagers who have left traces of their passage in the loan words adopted from their speech by the Melanesians with whom they came in contact; these words being most numerous in the languages of the islands along the coasts of which the Polynesians passed, and less frequent in the languages more remote from their route.

One stream of these primitive Polynesians, or Proto-Samoans, passed north of New Guinea, by way of the Admiralty, Bismarck, Solomon, and Santa Cruz Archipelagoes to Samoa. Another stream came southward through Torres Straits, by the south-eastern shores of Papua, through the New Hebrides to Fiji. In Nuclear Polynesia the two streams resumed their ancient fellowship, and thence despatched colonies to Hawaii, New Zealand, and the Far Eastern Pacific.

Later, there came upon these Proto-Samoans a swarm of kindred people whose origin and migrations Mr. Churchill regards as indefinite and obscure, and to whom he gives the name—Tongafiti—by which they are known in Samoan history. The Tongafiti are considered to have left no definite trace of a passage through Melanesia, though their presence in Nuclear Polynesia is clearly evident. The origin and migrations of the Tongafiti are not discussed in the present volume.

In his earlier chapters the author devotes some attention to the two most prominent theories yet put forth as to the settlement of the Oceanic peoples, namely, those of Dr. Macdonald and Dr. Thilenius. The former refers the island races to an immigration from Arabia, and affirms their languages to be modern representatives of a Semitic tongue (*cf.* NATURE, March 19, 1908, p. 460). The latter regards the Polynesians as entrants into the Pacific by way of the Micronesian Islands, and sees in the Melanesian Islands, and the Polynesian settlements bordering them, the meshes of a net which has caught the drift of castaways blown westward from their homes in Eastern Polynesia. In his second chapter and elsewhere in his book Mr. Churchill utterly demolishes the Semitic theory of Macdonald, mainly on the grounds of illogical and forced etymologies, and perverted definitions of words. Mr. Churchill finds difficulties and fallacies in the argument of Thilenius, chiefly with regard to the ascription of feeble navigating powers to the Polynesians, and to the unlikely survival of castaways among an anthropophagous people.

Mr. Churchill regards the Proto-Samoans as a seafaring race, who, driven by some expulsive force, set out from Indonesia in double canoes. The principal difficulty in their navigation was the victualling of their vessels, and this led to coasting voyages wherever there were coasts to follow. When supplies ran short, a food colony was established on a suitable island until a sufficient crop was raised to carry the voyagers farther on. For these food colonies there were three requisites—a sufficient water supply, an encouraging area of soil for tilth, and an autochthonous population insufficient in number, or too weak, to prevent the settlement of strangers. Mr. Churchill considers the eastward impulse to have ceased in Bismarck Archipelago and Torres Straits, so that the crop settlements tended to become, in suitable places, permanent colonies. Also, as the fleet kept to windward in the seas along which they passed, the lands which became fixed settlements (as, *e.g.* Nuguria, Liueniua, Sikayana, Aniwa, and Futuna) would be found on the windward side of the archipelago with which they are associated. The apparent exceptions, Rennel and Bellona, though leeward of the Solomons, are, however, on the weather side of the voyagers in the southern stream.

Mr. Churchill bases his evidence of this migration upon an examination of the Polynesian words contained in the languages of the Solomon and New Hebrides islands. From comparisons of the material available to him, which are given in an appendix on data and notes, and the Polynesian content therein, set forth in a series of elaborate tables, the author deduces the amount of likeness shown by the individual languages to Polynesia. His method in the comparisons is sound and accurate, and a very welcome contrast to the wild guesses of some writers on the subject. But the deficiencies and imperfections of his material are a source of serious error. For a proper estimate of Polynesian likeness the vocabularies compared should be of equal size and range of signification, else the presence or absence of certain words would unduly exaggerate or diminish the likeness. Mr. Churchill's tables show this. He gives the coefficient of likeness to Polynesian of Belaga as 100, whilst Nggela, of which Belaga is a dialect, is given only 80. So also the likeness of Nguna to Polynesian is expressed by 93, whilst that of Sesake (the same language, Sesake being a colony from Nguna) is only 76.

Mr. Churchill makes no comparisons of grammar. All the Polynesian words present in Melanesia are regarded as loans, but if this is so, it is remarkable that many of the languages have borrowed 80 or 90 per cent. of Polynesian vocables without borrowing a single grammatical form. In some cases, not pointed out by Mr. Churchill, grammatical forms which survive in Polynesian have been preserved more fully in Melanesian languages which are not on the supposed migration route.

The backward track deduced by Mr. Churchill breaks off short at Moanus (Admiralty Island) in the north, and at Motu (New Guinea) in the south, and he leaves the starting point of the Proto-Samoans in a waste of empty sea, where non-Polynesian and non-Melanesian languages occupy the whole seaboard. He states that "only a few of

[1] "The Polynesian Wanderings." Tracks of the Migration deduced from an Examination of the Proto-Samoan Content of Efaté and other Languages of Melanesia. By W. Churchill. Pp. ix+516. (Washington: Carnegie Institution, 1911.)

the vocables in Melanesia for which we have discovered Polynesian affinities are found to carry that affinity back to Indonesia." He is "ready to pronounce the decree of Divorce upon Malay and Polynesian." Other judges of Indonesian will scarcely concur in this judgment.

It is impossible in the limits of this notice to give an adequate exposition of the value of Mr. Churchill's book to the student of Oceanic linguistics and ethnology. It is not only suggestive of points for discussion, but provides also material upon which the argument may be based. There is a bibliographical appendix, two maps, and a useful index.

SIDNEY H. RAY.

SCIENTIFIC PROGRESS IN THE UNIVERSITY OF OXFORD.

THE annual report of the delegates of the University Museum, lately published, contains a very complete record of the scientific work done in the several departments of the museum during the year 1910. In the department of physiology, special attention is directed to the establishment of an advanced practical course in physiological optics, under the direction of Prof. Gotch and Dr. Burch. A considerable amount of the requisite apparatus was made in the laboratory workshop. Prof. Arthur Thomson (human anatomy) announces that instruction in physical anthropology has now been systematically organised. The report of the Linacre professor of comparative anatomy (Prof. Bourne) also shows much evidence of steady progress. The list of additions to the collection is a long one, and numerous important memoirs have been published by members of the department during the past year.

Prof. Poulton submits a lengthy and interesting account of the work done in the rooms assigned to the Hope professor of zoology. A very fine collection and library of Oriental and British entomology, chiefly Hymenoptera, was presented by Mr. G. A. James Rothney; and other important accessions were received from numerous donors, among whom were Mr. Herbert Druce, Commander J. J. Walker, Mr. J. H. Watson, Mr. S. A. Neave, Mr. W. A. Lamborn, and the Hon. Walter Rothschild. Special attention is directed to bred specimens received from Mr. A. D. Millar, of Durban, which prove that the conclusion tentatively arrived at by Mr. G. A. K. Marshall in 1902, that *Euralia mima* and *E. wahlbergi* are dimorphic forms of the same species, is in accordance with the fact. The collection of British Rhynchota, Hemiptera, and Homoptera belonging to the late Edward Saunders, and presented by the professor and Dr. G. B. Longstaff, is described as one of the most important additions ever made to the British collection in the department. Among the original memoirs published by workers in the department are Mr. H. Eltringham's important monograph on African mimetic butterflies and Mr. R. Shelford's contributions to the Genera Insectorum.

Noteworthy additions have been made to the anthropological collections contained in the Pitt-Rivers Museum. The energy of the curator, Mr. H. Balfour, who has paid three special visits to the Victoria Falls of the Zambezi, has resulted in the acquisition of a far more complete collection representing the archæology of that region than exists anywhere else. Other important accessions have come in from the Belgian Congo, British East Africa, West Africa, the Dordogne, and the Isle of Wight. In the department of experimental philosophy, Prof. Clifton reports that an extension of the laboratory is absolutely necessary, the only alternative being to restrict the number of students.

The report of the Wykeham professor of physics (Prof. Townsend) records the transference of the laboratory furniture and apparatus from the temporary quarters in the old museum to the fine new building provided by the generosity of the Drapers' Company. The new premises have been found to be excellently adapted for giving practical instruction, and also for research work. In the department of chemistry, Prof. Odling notes the starting of a new course of advanced practical organic chemistry under Dr. Chattaway, and the publication of several important memoirs dealing with researches conducted in the chemical laboratory. These include Dr. Chattaway's work on chlorine, Mr. Marsh's on the solution of haloid double salts in organic solvents and on the halogen derivatives of camphor, and also the investigations by Mr. Lambert and his pupils on the wet oxidation of metals. The report mentions that as a result of the work still in progress, it is hoped later to establish sufficient facts to warrant putting forward a modification of the present views on the subject of the corrosion of metallic iron.

A valuable consignment of rocks and fossils has been sent to the geological department from Peru, where Mr. J. A. Douglas is engaged in using the excellent opportunities for geological study now being afforded by several important railway cuttings. The expenses of the investigation are being borne by Mr. W. E. Balston, University College, and the consignment that has been already received is the first of many that may be expected as a result of Mr. Douglas's labours. Besides the usual field-work conducted by Prof. Sollas in the country about Oxford, an excursion, attended by sixteen students, was made to the Siebengebirge and the Eifel. Much work has been done by Miss Byrne and others on the rearrangement of the collections. A long series of specimens illustrating the history of the pleistocene epoch is in course of arrangement, and the work is rapidly approaching completion.

Like other heads of departments, the professor of rural economy (Prof. Somerville) finds himself somewhat embarrassed for want of room. The laboratories of botany and chemistry included in his department have been taxed to their utmost capacity to provide accommodation for the students. For the needs of the department of mineralogy, provision has been made by the allotment of a portion of the northern room of the old Radcliffe library, lately occupied by the Wykeham professor of physics. Many additions are recorded to the collections of specimens and the stock of apparatus, and some important researches have been carried on by Prof. Bowman, his pupils, and assistants.

A remarkable feature in many of the departmental reports that have now been briefly noticed, is the great and growing need of still further accommodation if the requirements of both teachers and students are to be satisfactorily met. Much has already been done; all departments alike tell the same tale of great and increasing activity in scientific work. Much still remains to do; but the document before us gives good hope for the future, for it contains abundant evidence that the ancient University of Oxford is becoming more and more alive to its responsibilities in the matter of scientific progress, as regards both teaching and research.

ADVANCES IN REPTILIAN PALÆONTOLOGY.

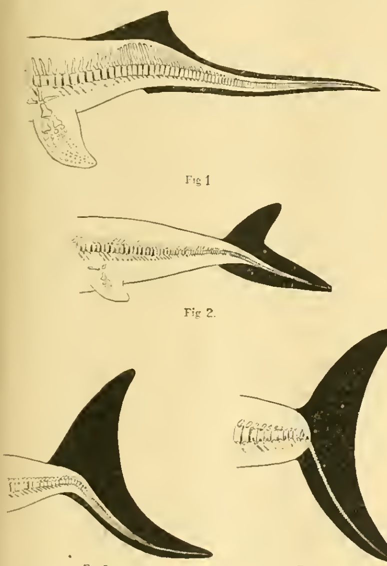
IN the July number of *The American Naturalist* Dr. O. P. Hay reopens the discussion with regard to the position of the limbs in Diplodocus and other sauropod dinosaurs, criticising the views of those who assert that these reptiles carried themselves in elephantine fashion, and maintaining his own opinion that the general pose was more after the crocodilian style. In regard to what may be called the elephant pose, it is pointed out that since a straight femur appears to have characterised the Proboscidea from the beginning, its occurrence in the modern representatives of the group may be regarded as a primitive feature, rather than an adaptation to the support of great bodily weight. At the conclusion of his arguments with regard to the pose of the sauropods, Mr. Hay expresses doubts as to whether the erect bird-like posture attributed to the carnivorous dinosaurs of the Jurassic is really true to nature. "The extraordinary development of the pubic bones of Aristosaurus, the expanded and ankylosed distal ends of which reached nearly half-way to the forelegs, seems to me to indicate that these animals, when in repose, had a prone position, resting much of the weight on the pubes, and that when running their legs straddled considerably."

In reference to the opinion of Dr. Matthew that Sauropods were too bulky to have lived on land, it is added that "the law to which he gives expression does, of course, prescribe a limit to the size an animal can attain, but who has yet determined what that limit is?"

To vol. vii., part 4, of the Annals of the S. African

Museum, Dr. Broom contributes an illustrated article on the dinosaurs of the Stormberg beds. Seven generic types, namely, Euskelesaurus, Hortalotarsus, Gyposaurus, Gryponyx, Massospondylus, Ætonyx, and Geranosaurus, are recognised, of which the third, fourth, sixth, and seventh are described for the first time. The first six are referable to the carnivorous group, but the last is characterised by the presence of a predentary bone to the mandible. This feature suggests that the horizon of the Stormberg beds from which it was obtained is of Lower Jurassic, in place of Triassic, age; and, even so, Geranosaurus will be the oldest known type with a predentary.

The angulated outer and rounded inner surface of the terminal segment of the second hind toe in Gryponyx, Massospondylus, and Ætonyx indicates that the investing horny claw had an edge adapted for combing or scraping; and it is suggested that it was employed for cleaning the skin and scales. If this be so, the dermal covering was probably unlike that of crocodiles or lizards; and it may be that the scales were long and narrow, with intervals of soft bare skin between them. Such a skin would certainly require cleansing with the claw after the reptiles had been hunting on the muddy banks of lakes.



Tail-fins of Ichthyosauria.

FIG. 1.—*Mixosaurus nordenskjoeldi.*
FIG. 2.—*Ichthyosaurus quadriscissus* (young).
FIG. 3.—*Ichthyosaurus quadriscissus* (adult).
FIG. 4.—*Ichthyosaurus trigonus posthumus.*

In the same issue Dr. C. W. Andrews describes portions of the skeleton of a plesiosaur (*Plesiosaurus capensis*) from the Uitenhage beds of Cape Colony. The species, which belongs to the group of small forms represented in the European Wealden by *P. degenhardti* and *P. valdensis*, is the first plesiosaur known from South Africa. The occurrence of a member of the group in that country is of special interest, in view of the possibility that the Sauropterygia may have taken origin from a form related to the therocephalous anomodonts of the South African Permian.

In this connection reference may be made to the identification by Mr. H. Fuchs (*Anat. Anz.*, vol. xxxviii.) of a septomaxillary bone in the skull of the peba armadillo. In a review of this discovery by Mr. F. Müller in *Naturwissenschaftliche Wochenschrift* for July 9, 1911, it is pointed out that a septomaxillary has been hitherto known in amphibians and certain reptiles, in which it forms an ossicle on the side of the nasal capsule. Recently it has been identified in certain fossil reptiles—notably the Theriocephala and Theriodontia. Among mammals, it occurs not only in the peba, but likewise in the hairy armadillo (*Dasypus villosus*), where it is represented by an undetermined bone described by Dr. Broom. It has not yet been definitely identified as a separate ossification in other mammals; but Gaup considers that it is represented by the so-called extra nasal process of the maxilla, although Fuchs considers that in the aforesaid armadillo both this process and the septomaxillary are present. Be this as it may, the identification in armadillos of an element common to amphibians, anomodonts, and certain other reptiles is a feature of prime importance in regard to the anomodont ancestry of mammals.

The description of an embryonic, or newly born, specimen of *Ichthyosaurus quadriscissus* from the Lias of Holzmaden, Württemberg, in which the outline of the body and fins is preserved, has led Dr. E. Fraas, in *Mitt. aus dem kgl. Naturalienkabinett, Stuttgart*, to give an interesting account of the evolution of the tail-fin in the ichthyosaurs. That the specimen on which the investigation was based is extremely young is rendered evident by the great relative size of the head, which is equal to one-third the entire length, whereas in the adult it is less than one-fifth. The earliest known type of tail-fin in the ichthyosaurs occurs in *Mixosaurus nordenskjoeldi* from the Muschelkalk of Spitsbergen, in which, according to Mr. H. Wiman's figure in Bull. Geol. Inst. Upsala, vol. x., 1910, it takes the form of a low falcate fin in the basal third of the tail, continued as a marginal expansion along the whole of the rest of the tail, both above and below. In the young of *I. quadriscissus* the falcate portion and the marginal fringe are increased in height so as to form a fin approximating to the heterocercal type, with the extremity of the vertebral column bent down into the lower lobe. In the adult of the same species the increase in the size of the fin and the degree of flexure of the vertebral column are intensified, thus producing an approximation to the homocercal type. A further stage is displayed by *I. trigonus posthumus*, of the Upper Jurassic Limestone of Solenhofen, in which the fin is almost completely like that of a homocercal fish, while the flexed terminal portion of the vertebral column has diminished in relative size, with a marked increase of the angle of flexure. One step more and it would have vanished. A somewhat similar grade is presented by Opthalmosaurus of the Oxford and Kimeridge Clays. It should be added that in the hind paddle of Mixosaurus the metatarsal and phalangeal bones retain an elongated contour, and do not form a mosaic-like structure. R. L.

LONG-DISTANCE RADIO-TELEGRAPHY.

A VERY interesting paper by Mr. L. W. Austin, entitled "Some Quantitative Experiments in Long-distance Radio-telegraphy," has recently been published in the Bulletin of the Bureau of Standards (Reprint No. 159). The paper describes a complete investigation of the relationship between the current in the receiving aërial and the distance between the transmitter and receiver, the observations being mainly by the shunted telephone method. Although this method is not so accurate as the direct method, it is probably the only one available for use on board ship at long distances. Some years ago Mr. J. E. Taylor and the present writer carried out similar experiments over short distances up to 60 miles, using a thermo-galvanometer directly in the aërial. Mr. Austin has greatly extended the range, and has carried on the experiments up to a distance of 1200 miles between the two stations. The results confirm the proposition put forward by Mr. Taylor and the writer that the current in the receiving aërial varies inversely with the distance except for one important particular, namely, Mr. Austin finds, with much longer distances that he has worked over, that it is necessary to take into account the absorption, and therefore his formula contains an exponential term to allow for this.

A perhaps still more important discovery mentioned in the paper is that of Dr. Louis Cohen, that if the reduction in the strength of the received current due to absorption be written e^{-Ad}, then A is inversely proportional to the square root of the wave-length within the limits of accuracy of the experiments.

Mr. Austin again checks Mr. Marconi's statement that the received signals are proportional to the height of the two antennæ, and adding to this the observation that they also vary inversely as the wave-length, he obtains a complete formula giving the received current I_K in terms of the transmitted current I_S, the heights of the two antennæ h_1h_2, the wave-length λ, and the distance *d*. The formula is

$$I_K = 4\cdot25\frac{I_S h_1 h_2}{\lambda d}e^{-\frac{\cdot0015d}{\sqrt{\lambda}}}.$$

Where the currents are in amperes and the lengths in kilometres, the two constants 4·25 and 0·0015 may depend on the conditions under which the experiments were made, and it will be of great interest if other wireless workers will check the formula against their results and see how closely it is applicable. It must not be expected that this formula will be closely confirmed by every observation. Mr. Austin's own observations show that this is not the case. In spite of the wide range of values he has dealt with, the observations do appear to group themselves round the smooth curves given by his formula.

The formula refers only to flat-topped aërials and to general day conditions. Mr. Austin remarks that the night signals are entirely irregular, being, in general, stronger than the day signals, and this he assumes is due to there being much less absorption at night, that is to say, the inverse distance law is then more nearly obeyed, even for very long distances.

It is perhaps of interest to compare Mr. Austin's formula with the measurements in the *Monarch* tests. Putting the data into Mr. Austin's formula, and taking the wave-length at 250 metres, which was approximately the case, the received current at a distance of 60 miles given by the formula is 590 microamperes, whereas it was actually only about 50 microamperes. It is evident, therefore, that the constant 4·25 is too large for this case. One reason for this may be the great difference in the type of aërial used, Mr. Austin's formula applying to a flat-topped aërial, whereas a straight aërial was used for the Holyhead-Howth experiments; another reason, the Howth aërial had a higher resistance.

The absorption coefficient, however, seems to fall in very well with the *Monarch* experiments, neglecting the short distances, which are irregular. Taking the slope of the curves for the *Monarch* crossing from Howth to Holyhead, the absorption is rather less than that given by Mr. Austin, but the slope of the curve for the *Monarch* returning from Holyhead to Howth indicates a slightly greater absorption.

A number of tables are given in the paper to facilitate the use of the formula in practice. These tables show how extremely important it is to use a long wave-length for long distances; for instance, for transmission over a distance of 2000 miles, with a wave-length of 1000 metres and two flat-topped aërials 450 feet high, 490 amperes is required in the transmitter, whereas at 6000 metres only 105 amperes is necessary. There are still, however, many obscure points in the long-distance transmission which Mr. Austin's formula does not account for; for instance, Mr. Marconi pointed out at the Royal Institution a short time back that there were two minima near sunset and sunrise in the curve representing the strength of the received signals across the Atlantic, and also two maxima. Can this be accounted for purely by variation in the absorption coefficient, and, if so, does the absorption coefficient during the minima bear the same relationship to the wave-length as that given in Mr. Austin's formula? Do the two maxima correspond to practically no absorption, or are they higher values than would be obtained if no absorption existed as if waves were concentrated, as Mr. Austin seems to consider possible?

Whether the formula turns out to be strictly right or not, it should form a good basis on which to compare different wireless systems, and it constitutes a real advance in the published knowledge of long-distance radio telegraphy.

W. DUDDELL.

EXPERIMENTS ON AËRIAL PROPELLERS.[1]

AN article in the April *Bulletin de la Société d'Encouragement* deals with some experiments on aërial propellers made by MM. Legrand and Gaudart, with the aid of a grant from the society. The greater part of the article is a discussion on the methods adopted by other experimenters for expressing their results. M. Legrand objects to the three coefficients usually adopted in expressing the results of propeller experiments, namely, "pitch," "fraction of pitch in each blade," and "percentage slip." He objects to the use of "constructional pitch" (which is usually taken as the pitch of the pressure face chords), as it is not constant for all parts of the blade in modern propellers. He also objects to the use of the pitch corresponding to no thrust, as this is not constant for all speeds; but in our opinion this latter is constant enough for all practical purposes.

M. Legrand's objection to the use of the coefficient "fraction of pitch in each blade" is that it is not definite for a given propeller; as, in modern propellers, it is not the same for all co-axial, cylindrical sections of the blades. This objection, however, is entirely overcome by using "disc area ratio," which is equivalent to "fraction of pitch," and is also absolutely definite for any given propeller. The objection advanced against the use of "percentage slip" is that the pitch not being definite, or the same for all parts of the blade, the slip is also indefinite.

Efficiency curves by Géber and Dorand are quoted, in which efficiencies at constant rotational speeds are plotted against translational speed. If, however, efficiencies at constant rotational speeds are plotted against percentage slip, and the pitch used in the reduction of the experimental results be stated—the percentage slip being equal to $100\left(\frac{\text{pitch}\times\text{revs.}-\text{translational speed}}{\text{pitch}\times\text{revs.}}\right)$—it is readily seen that the two sets of curves are equivalent and derivable from each other. Also, plotting against percentage slip has the advantage that it brings all the efficiency curves close together.

It is generally admitted that the indefiniteness of the pitch of a propeller is a disadvantage; but it seems, as yet, to be the best "coefficient" that can be used to give a general idea of the type of a given propeller. M. Legrand does not give any substitute for "pitch," and, in connection with his own experiments, differentiates between a propeller with a big pitch and one with a small pitch.

The experiments were carried out on full-size propellers, mounted on actual aëroplanes and driven by a 50 h.p. Gnome engine. The thrust was registered during the whole flight on an autographic diagram from a Richards dynamometer, working in conjunction with a flexible mounting for the propeller. An error is admitted of at least 2 per cent. of the maximum thrust in the calibration of the dynamometer. The rotational speed of the propeller was measured by means of a direct reading tachometer, and is probably correct to about 1 per cent. But the power absorbed was measured by assuming that the brake h.p. of the Gnome engine, at a given speed, did not vary during the course of a series of experiments. By this method of measuring, we should estimate the probable error on the measurement of power to be anything up to 10 per cent. The speed of translation of the machine was measured by means of an ordinary U tube, measuring the air pressure in a converging cone. This was calibrated by flying round a measured aërodrome, taking the speed with a watch. So that, taking into account the difficulty of flying exactly over the course and of reading a water-gauge on a vibrating aëroplane, the translational speed is probably not correct to closer than 3 per cent.

[1] "Études expérimentales sur les hélices propulsives Aériennes." By M. Legrand (Bulletin de la Société d'Encouragement pour l'Industrie Nationale, April).

The results given are very meagre, and are as follows :—
[he efficiencies varied between 53 per cent. and 69 per cent. [he thrust fell off in flight about 33 per cent. from the 'alue with the aeroplane anchored. The rotational speed of the engine increased in flight from 0 per cent. to 15 per ent. above the speed with the aëroplane anchored, depending on the propeller. The experiments are to be continued vith the aid of a further grant, and we may therefore xpect more complete results of tests with the addition of nore particulars of the propellers tested than are given in he present article.

It is to be hoped that the experimenters may improve the ccuracy of their apparatus, so that their results may be f real scientific value, and not merely for the purpose of ifferentiating between a good propeller and a bad one.

FRANCIS H. BRAMWELL.

PHOTOGRAPHY IN SURVEYING.

FOR the last half a century continued efforts have been made to utilise photography in the preparation of ccurate plans of country, and thereby economise some of he time expended in the detailed measurement of every eature and object. A photographic negative provides an ccurate record of the area included in it, contains much etail which measurement alone cannot give, and is always vailable for future reference. On the other hand, the mployment of photography requires certain technical knowedge, and a good judgment in the selection of stations and iews; it is best suited to regions of considerable relief, ut even then patches of ground are liable to be omitted ltogether from the views, and such omissions are not ecognised until the work is plotted; lastly, it necessiates considerable skill in the drawing office to get he best and most complete results from the field-work. 'hotogrammetry has, therefore, developed most rapidly in ountries where mountainous districts offer favourable onditions for its employment, and where the season available for field-work is limited. France, Italy, Germany, ustria, Switzerland, and Canada have all made use of his method in topographical surveys, despite its drawacks. Mr. A. O. Wheeler[1] describes in general terms the nethods which are employed in Canada under the direcon of Dr. Deville, the Surveyor-General of Dominion ands, and employed by Mr. Wheeler on Dr. Longstaff's ecent expedition in British Columbia. But the labour ivolved in utilising the information collected by the amera has always hindered its wider employment in urveying, so that we welcome a new method of automatically reproducing it on a plane surface, which is described y Prof. E. Brückner.[2]

Some years ago Dr. C. Pulfrich, of the firm of Carl eiss, of Jena, produced his stereomicrometer, by which ie coordinates of points represented on a pair of stereoraphic plates were determined, and their positions defined, that they could be plotted on a plan. In this instruient the plates are fixed, and the movements of the index ointers are measured. A further development was the ereocomparator, in which the plates are movable, and ie points to be measured are brought under fixed marks, i this case the objectives of a stereoscope. By suitable iechanical arrangements the coordinates of any point on ie picture and the stereoscopic parallax are readily deterined, thus providing the necessary information for lotting the point measured. Lieut. von Orel, of the lilitary Geographical Institute in Vienna, conceived the lea of automatically recording the data thus measured, nd the necessary modifications have been made to the ereocomparator so as to enable the data to be plotted iechanically on a sheet of paper. This instrument is illed the stereoautograph, and in it the movements of the lates and the stereoscope of the stereocomparator are ommunicated to flat rulers resting on the drawing-board, nd by their aid the positions of points are plotted on the lan. Not only is the horizontal projection of the detail fected in this way, but contour lines representing the elief can also be drawn.

Plans on a scale of 1 : 25,000 can be accurately produced in this way, and even one on the scale of 1 : 10,000 showed but slight differences from a precise measured survey of the same on this scale. The apparatus is said to be capable of producing a map sheet 35 cm. by 25 cm. of a mountainous region to the scale of 1 : 25,000 in about ten days' work, so that it promises to be of great value in reproducing the work of travellers and explorers who will take the necessary photographs. Photogrammetric methods do not apply where surveying is organised so as to utilise a *personnel* of moderate technical ability, where each individual carries out a single stage of the work only; but where skilled technical assistance is available, and each surveyor executes as complete a survey as possible of a given area, then stereophotogrammetry, simplified by Lieut. von Orel's instrument, seems to offer great possibilities, especially when conditions of work and of surface relief are also favourable.

Though primarily adapted to topographical representation, some have tried to adapt photography to large-scale (cadastral) work, and M. J. Gaultier has proposed methods for its employment. But the indoor work of the necessary precision is tedious and costly, so that in a recent paper[1] he proposes for such work an instrument which he names the "topometrographe." This is of the nature of a plane table for precise work, stoutly built and carefully levelled, on which a base-bar is clamped. This carries the pivots of two rulers set at a distance apart corresponding to the base line used. These rulers are set at any desired angle with the base-bar by means of divided circles, and their intersection locates the apex of the triangle. Very considerable accuracy is claimed for the method, which is to be based on a network of third- or fourth-order triangulation; but its effectiveness would appear to be restricted to special cases, where such elaboration in the field is compensated for by economy in the office.

BIRD-NOTES.

FROM the point of view of forest-conservation much interest attaches to Mr. F. E. L. Beal's report on the food of American woodpeckers, published as Bulletin No. 37 of the biological division of the U.S. Department of Agriculture. The report is based on the examination of the contents of a large number of stomachs of sixteen species of these birds; but since the number of specimens examined was much smaller in some cases than in others, it is quite probable that some modification of the order in which these species are tabulated according to the nature of their food may be necessary in the future. Another element of uncertainty in this respect is due to the rapidity with which the vegetable food of the cambium-eating species passes through the stomach.

As the forests of the United States, like those of other countries, have a host of insect enemies, among which wood-boring beetles are pre-eminent, any natural agency that will assist in keeping these pests in check is of the highest value. In the case of wood-boring beetles, woodpeckers occupy the first place as destroyers, and among these the two species of the three-toed genus Picoides are the most valuable. In the typical *P. americanus* no less than 94·06 per cent. of the food consists of animal matter; while as regards its insect-food, 71·05 per cent. consists of beetles and the remainder of ants. Most of these beetles are wood-borers, although a percentage consists of harmless species. Ants also are deleterious to trees, since they often take possession of the borings from which beetles have been extracted by woodpeckers, until they in turn are routed out by these birds. Woodpeckers are frequently charged with inflicting damage on sound trees; but the charge, except in the case of the American group of sapsuckers, is considered to be unfounded. As regards sapsuckers, which feed on cambium, these certainly do inflict damage, which in some cases may be serious although, on the other hand, they consume legions of ants.

The colouring of the Jack snipe forms, according to Mr. F. J. Stubbs in *The Zoologist* for July, an absolutely perfect protective adaptation. In some localities the only means by which the bird can be detected when squatting in its proper haunts is by looking for a couple of curved blades of faded grass of a brighter hue than any indigenous to the district. When detected, such supposed grass-blades are the yellow head-stripes of the snipe. If surprised on a patch of green turf or other inharmonious background, the bird will sometimes run and squat on the mud near a patch of herbage close at hand.

It is announced in the July number of *British Birds*, by Mr. A. H. Meiklejohn, that a breeding colony of fulmar petrels has established itself in Berriedale Head, Caithness, the only other nesting haunt on the mainland being Cape Wrath, Sutherland, which was first discovered to be the resort of these birds in 1901. The most southerly breeding-place in the British Isles is Barra.

Certain erratic lights observed at night on the hillsides at Villierstown ferry, Cappoquin, Ireland, during last winter, by Miss M. E. Dobbs and the local ferryman are tentatively attributed by the former, in an article published in *The Irish Naturalist* for July, to luminous owls, this opinion being based on the assertion of the aforesaid ferryman that the lights are due to birds. In a supplementary article published in the same issue, Mr. C. B. Moffat, after quoting additional testimony to the belief that birds are their source, suggests that these strange luminous emanations may be a form of *ignis fatuus*. It is true that the latter is generally a more flickering type of light, but one resembling Miss Dobbs's description is reported from the Donabate estuary, unless, indeed, the natives mistake a bird for a phantom. But Mr. Moffat goes even further than this, and suggests that the whole story of luminous owls, which, it will be remembered, was first reported by Sir Digby Pigott in a letter to *The Times* for December, 1907, may possibly turn out to be a myth. He notes, however, that an apparently similar luminosity has been attributed to bitterns and certain herons, especially an American species, but states that even this testimony is not definitely accepted by naturalists.

Among the contents of the July number of the Journal of the South African Ornithologists' Union is an article by Mr. C. F. M. Swynnerton on nests and eggs from Mount Chirinda, southern Rhodesia.

IONISATION AND CHARGED SMOKE PARTICLES.

IN the *Sitzungsberichte der k. Akad. der Wissenschaften* of Vienna, vol. 120, part i., Drs. V. F. Hess and G. v. Sensel discuss the results of a series of experiments on the ionisation of the atmosphere made by them during August and September, 1909, on an island separating the two branches of the Danube near Vienna. The observations were made from 9 a.m. to 9 p.m., and the curves for the diurnal variation show marked minima about 5 p.m., both for the positive and for the negative ions. The main object of the authors was to investigate the connection between the ionisation and the meteorological elements, but the period of observation was too short for the conclusions to be regarded as final. The principal results are briefly as follows. For low atmospheric pressure the excess of positive ionisation has double its value at ordinary or high pressures, and a similar difference exists between the values for falling and for rising barometer; the total number of ions, and the number of negative ions, decreases as the temperature increases—a result exactly opposite to that found by Simpson and Gockel: the number of ions is greater for clear than for cloudy sky, especially if the cloud is nimbus: the number of ions is less when the wind comes from the direction of the city; and it is independent of the relative humidity, a result also different from those of Simpson and Gockel, who found that the ionisation decreased as the humidity increased. The recent establishment of systematic observations of the ionisation at some of the principal observatories ought to permit of a fuller discussion of the questions treated in this paper, which will prove valuable in indicating the observations which are specially desirable.

The same number contains a discussion by Dr. K. Przibram of experiments on the charge carried by smoke particles, in the light of Cunningham's correction to Stokes' formula for the connection between the limiting velocity and the radius of the particle. Careful series of experiments on smoke of different substances indicated a definite tendency for the charge to depend on the radius of the particle, and led the author to conclude that the particles could carry charges less than the adopted value for the charge on the negative ion, or that certain factors entered into the motion of charged particles through a gas which had not yet been allowed for. In a note added after the paper had been printed, the author states that owing to a criticism by Regener, he repeated some of the experiments with the plates of his condenser closer together, when he found much less dispersion in the values for the charge. Consequently, the conclusions founded on the earlier experiments may be subject to modification.

HIGH-PRESSURE WATER-POWER WORKS.[1]

THE utilisation of high-pressure water-powers represents the latter portion of the wonderful and rapid development which has occurred in hydraulic works during the last twenty years. Such powers are necessarily situated in mountainous districts, and may be at some considerable distance from thickly populated centres where a demand for power exists. Comparatively low falls were more in use until the question of long-distance high-tension electrical transmission could be looked upon as a sound technical and commercial proposition, and this has only been satisfactorily solved within the last few years.

Hydro-electric stations do not lend themselves very readily to hard-and-fast rules. It by no means follows that what has shown itself to be satisfactory in one case will be equally satisfactory in another. Engineers of every branch are represented in work of this kind, besides surveyors, architects, miners, railroad men, and in some cases geologists and also meteorologists have to be consulted. High-pressure plants usually work out considerably cheaper than low-pressure plants for the same power, but a long transmission line may so increase the capital outlay on the former that a low-pressure station near the consumer is preferable. A very great advantage possessed by high-pressure plants over other types is the readiness with which the irregular flow of rivers may be regulated to supply a constant-power demand by means of storage reservoirs and weirs. The whole rainfall of a district may thus be utilised. Storage, however, increases the cost of a station very considerably. The greater the head of water, the more rational will a storage reservoir be, since the same quantity of accumulated water will represent a proportionately larger store of energy.

Too little attention is usually devoted to the pipe-lines and conduits carrying the water from the lake or river to the turbines. Not a few engineers consider that the pipe-line is a secondary part of a hydraulic power-plant. Pipe-lines are often built by engineers who are experts in the choice of material and in the manufacture of a pipe, but who do not understand the essentially important functions which a complete pipe-line, and especially a high-pressure pipe-line, has to fulfil. The general arrangement, the relative dimensions of different parts of the pipe-line, the methods of anchoring and placing of fixed points, are all such important factors that they can only be properly determined by the turbine builder.

The Necaxa power-station of the Mexican Light and Power Co. is supplied with water under a head of 1312 feet from a reservoir having a capacity of 1500 million cubic feet. The first part of the scheme, commenced in 1903, consisted of the construction of a large earth dam above the falls of the Necaxa River to form the storage reservoir which supplied the power-station with water for about 50,000 horse-power. The dam has a maximum height of 197 feet, length 1270 feet, and greatest breadth at the base 951 feet. An earth dam was selected as the type most suitable for a country periodically liable to earthquakes. Two feeder pipes 6 feet in diameter start from the intake tower in the lake and pass through a tunnel which emerges below the dam wall. These pipes are made of riveted plate, and pass to a receiver pipe which is under a pressure head of 177.8 feet. Six high-pressure pipes descend from the receiver to the power-house. Sluice valves are provided at the receiver to control each pipe, and air pipes are laid from behind the valves on each high-pressure pipe up the hill to a height

[1] Abstract of a paper read at the summer meeting at Zürich of the Institution of Mechanical Engineers by Mr. L. Zodel, of Zurich.

above that of the reservoir level. The six pressure lines are composed of welded pipes 30·7 inches external diameter, and have a thickness varying between 0·39 and 0·87 inch. The maximum static head is 1417 feet. The turbines are Escher, Wyss and Co.'s impulse wheels, each designed to generate 8200 horse-power at 300 revolutions per minute.

The company has greatly increased the water available by diverting the Texcapa, Tenango, Nexapa, and Xaltepuxtla Rivers into the Necaxa reservoir by means of an extensive system of tunnels through the dividing ridges. The catchment area has thus been raised to 154 square miles, and can shortly be further increased by another 77 square miles by bringing in the large Laxaxalpan stream. The present storage capacity of the entire system is about 4220 million cubic feet of water.

As a first step to enlarging the power-house, the capacity of each of the existing six turbines has been raised to 11,000 horse-power by fitting new runners and new nozzles. The velocity of the water in each of the six pipe-lines was thereby increased to the exceptionally high figure of 18 feet per second, a velocity which has not been found to be injurious in any way. Two new units of similar design and by the same makers have been installed; these are each of 16,000 horse-power, and are supplied with water through a new pipe-line system. The total capacity of the station is now 98,000 horse-power. The electrical energy is transmitted a distance of 93 miles to the city of Mexico and to other towns.

The power works of the Rio de Janeiro Tramway, Light and Power Co. are supplied from the largest artificial reservoir formed by a dam wall at present in existence. It has a total volume of 7840 million cubic feet. The length of the lake is 17 miles. The dam is of the arched concrete type. The gross maximum head at the power-house is 1015 feet. There are six impulse-wheel turbines, built by Escher, Wyss and Co., each generating 9000 horse-power at 300 revolutions per minute. The generators supply three-phase current at 6000 volts and 50 cycles, which is stepped up through transformers to a line voltage of 88,000 for transmission to Rio de Janeiro, the distance being 55 miles.

Some very difficult work had to be carried out on the pipe-line of the power-plant at Tyssedalen, near Odda in Norway. The Ringedals Lake provides an ideal natural storage reservoir at an elevation of 1426 feet above and 2·17 miles distant from the fjord at the edge of which the power-station is situated. A regulating tunnel from the Ringedals Lake discharges into the little Vetle Lake immediately below, which forms a second small regulating basin. A tunnel 11,200 feet in length passes through the mountain to the penstock chamber, from which the pipe-line leads down to the power-house. The tunnel is driven through granite for the whole of its length, and was completed in two years. The erection of the pipe-lines was work of a very difficult character. The total length is 2360 feet, and the pipes reach an angle to the horizontal of 55 degrees.

A typical high-pressure power-station in Switzerland is that of the Kraftwerk Brusio Company, which utilises the water of the Poschiavino River in the Canton Grisons on the south side of the Alpine chain. About 55,000 horse-power are developed, the greater part of which is transmitted to the industrial districts of northern Italy over a transmission line of 93 miles. The total head available is about 3280 feet, and is used in two stages. The upper lies between the Lago Bianco, on the Bernina Pass, and the Lago di Poschiavo, giving an effective head of 1970 feet for the Robbia station. The lower is between the Poschiavo Lake and the Italian frontier at Campo Cologno, where the head obtained is 1375 feet.

The River Siagne rises in the Alpes Maritimes province of south-eastern France to the north of Cannes. A power-station is situated near the village of St. Césaire, and utilises a fall of about 1142 feet of the Siagne; about 14,000 horse-power are available. The high-pressure pipe-lines of this plant have demonstrated in a most drastic manner what the consequences of incorrect design can be. The original pipe-line had to be abandoned after a few months' running on account of unsatisfactory working of the plant, and an entirely new pipe-line had to be built on totally different principles, in spite of the fact that the chief dimensions of the pipes were perfectly correct and amply sufficient for the conditions of head and discharge, and, moreover, were not altered in the second pipe-line. The principal faults were owing to the following:—(1) Too great a length of the upper portion, under low pressure, with pipes of small thickness, whereby a continual working or respirating phenomenon became apparent in this part of the pipe-line. (2) Insufficient fixing or anchoring of the pipes in the lower portion of the line, and a most curious position of the distributing pipe, in which very harmful vibration, combined with displacement of the pipes, could take place on sudden variations of water velocity or shocks in the pipe-line; this might easily lead to a burst, especially in the case of riveted pipes. (3) Unsuitable dimensions of the connecting pipes between the distributor and the turbines, with their length too great and their diameter too small, resulting in considerable accentuation of the pressure variations.

French engineers in general build pipe-lines without expansion joints; a large number of such high-pressure pipe-lines are now in continuous operation in France. This design must be characterised as irrational, especially in view of the demands made at the present day on the pipe-line of a central station with continually and rapidly changing water velocities.

THE SCIENTIFIC STUDY OF NAVAL ARCHITECTURE IN GERMANY.[1]

It may sound strange if, in the land of ships—the land that has probably done most towards the practical and scientific development of the whole domain of shipbuilding—I take upon myself to describe the aims of scientific study in Germany and the methods which it is now adopting.

Apart from small unimportant beginnings, the real nursery for scientific study in the various domains of naval architecture in Germany has been the institution now known as the Königliche Technische Hochschule zu Berlin, in Charlottenburg. Since 1904 the Königliche Technische Hochschule in Danzig has likewise taken part in this work. The naval architectural departments of both these colleges have the same end in view, namely, the training of the young men who will later in life take a successful part in the building of the mercantile and naval fleets of Germany.

In accordance with the system adopted in all the technical colleges in Germany, it is a preliminary requirement for the admission of the students to the Charlottenburg technical college, that they should have passed the matriculation examination of a Gymnasium, Realgymnasium, or Oberrealschule. As these schools comprise nine forms, it follows that candidates for admission to technical colleges must be between eighteen and nineteen years of age. Since a further qualification is a practical training of one year at a shipyard of recognised standing, the age of the candidate is increased by six months—often by a whole year. To this must be added the period of military service, which is required of every physically and mentally sound German citizen, but which, in the case of an educated man who has obtained his volunteer certificate, is restricted to one year. For those who contemplate a career in the higher ranks of the Imperial naval construction department, the period of practical work and the year of service are spent in naval establishments, that is to say, in an Imperial dockyard and on board a naval training ship respectively, before the course of study at the technical college is entered upon. It may thus be said that the course of study begins when the student is twenty-one, and that it has been preceded by a certain period of preparation in the practical work of shipbuilding or marine-engine building.

The course of instruction is arranged in the following manner:—Within the department for naval architecture a distinction is made, in the first instance, between the professions of naval architect and marine engineer. The course of instruction itself in almost all the subjects comprises lectures and tutorials or "practices," the object here kept in view being that what is taught in the former is put into practical shape in the latter. It is a general principle

[1] From a paper read before the Institution of Naval Architects on July by Prof. O. Flamm.

in the German technical colleges, that so far as possible no lectures are to be delivered without the accompanying tutorials.

In all the departments devoted to different professional branches, the course is a four-year one. At the conclusion of the second year, the preliminary examination for the degree or diploma is held, the final examination being taken at the close of the fourth year. The first two years are principally devoted to the more general studies in mathematics and natural science subjects, although a beginning is made with the introductory lectures and tutorials in the main subjects at the outset of the first term. But whereas the general subjects at first take up much more of the student's time than the special subjects, this proportion gradually alters as the course proceeds till it finally becomes reversed.

Another feature of the arrangement of the studies is that the lectures are, so far as possible, delivered during the earlier terms, while the drawing-office work gradually assumes greater importance as the course proceeds. This is intended to give the student in his last year as broad a base as possible for designing and applying what he has learnt from the lectures.

The primary object of the course of instruction during the first two years is to give the student a general grounding on the broadest possible lines in mathematics and natural science subjects, and concurrently therewith to introduce him to the elements of his special subject, so that, after passing the preliminary examination, he may devote himself in a higher degree to the direct study of his profession during the last two years.

In the course of these two years, then, the tutorials gradually take the place of the lectures, and the professional study proper is gone into in detail. The student of naval architecture is engaged in designing and working out the plans of merchant and war vessels, and in studying the arrangement and working of shipyards, while the marine engineering student is at work on marine boilers, reciprocating, turbine, and internal-combustion engines. In addition, auxiliary engines and propellers are thoroughly gone into.

Students in each branch concern themselves with the other just so far that, in their respective parts of the work on one and the same vessel, they can completely understand one another, and give due consideration to each other's requirements.

The domain of airship construction and aërial navigation, which is closely related to naval architecture, has been included in the province of the latter, and it may be of interest to mention that quite a number of the first designers and engineers who have specialised in airship construction were formerly students in the department of naval architecture.

One of the important aims of science as applied to naval architecture is directed to the keeping of the rules of the classification societies in general accordance with the latest advances in knowledge. This refers chiefly to the arrangement, scantlings, and riveting together of the structural parts of the hulls of vessels, and to the application of the laws of mechanics, statics, and dynamics. A second aim is that the rules of these societies, which are gradually gaining in authority, shall be prevented from developing into crystallised and inelastic ordinances which interfere with the scientific development of ship design.

Both for instructional purposes and for scientific research work, suitable laboratories are nowadays of the very greatest value. In all branches of engineering, there are many questions the solution of which by pure analytical methods is impossible, and which therefore can only be dealt with by practical experiment. To what excellent use in this way have not the existing testing laboratories in almost all countries been put! At the Technical College in Charlottenburg the mechanical engineering section in particular has established numerous laboratories, and they have been of the utmost value both from the educational and from the industrial point of view.

The Technical College at Charlottenburg now possesses twenty laboratories, which serve the purposes of the research work of the professors as well as those of instruction. A short time ago a project for the installation of a second laboratory for the civil engineering section for the investigation of hydraulic questions was unfortunately rejected by the Prussian House of Representatives. It is a remarkable circumstance that in the entire establishment the section for shipbuilding and engineering should be the only one which has no laboratory! It must be admitted that this is very much to be deplored, and that the course of instruction as well as the solution of engineering problems is immensely impeded thereby. It may readily be understood, therefore, that the naval architectural section is doing its best towards the early attainment of an establishment of this kind so as to close up the gap in its structure.

My endeavours are directed to the establishment of a suitable naval architecture laboratory in which experiments may be made on the action of the screw propeller, and in which the gross and net amounts of work done by the latter, *i.e.* its efficiency, may at the same time be determined. Further experiments will then be made to determine the effect on each other of several screw propellers arranged abreast, or one behind the other, and also the effect exercised on them by the rudder. We shall then know whether it is possible to design high-speed propellers of high efficiency, and our knowledge over a wide range of under-water phenomena will be available for further advances in this branch of engineering. Students should take part in all inquiries of this kind, so that the results may benefit succeeding generations of engineers and enable them to play a leading part in the scientific progress of their time.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

A REUTER message from Simla on August 3 states that Lord Crewe has accepted the scheme for a Mohammedan University at Aligarh, provided adequate financial support is forthcoming.

WE have received from the Department of Technology of the City and Guilds of London Institute the programme for the session 1911–12, containing regulations for the registration, conduct, and inspection of classes and examination of candidates in technological subjects, and for the award of teachers' certificates in manual training and domestic subjects. We notice that the names of the two examinations held at the end of the session have been changed from "ordinary grade" and "honours grade" to "grade I." and "final examination," corresponding, in a sense, to the two new examinations in science subjects instituted by the Board of Education under the names of "lower" and "higher"; but in certain subjects there are first- and second-grade examinations before the final examination can be taken. The list of subjects in which examinations are to be held in 1912 numbers seventy-nine, as compared with seventy-eight during the present year. The new subject is entitled "Heating and Lighting," and covers very fully the science and technology of these important processes. All inquiries for information in connection with the recognition of classes in technological subjects, examinations, and inspection should be addressed to the Superintendent, Department of Technology, City and Guilds of London Institute, Exhibition Road, London, S.W.

THE eighth annual report of the Education Committee of the City Council of Manchester for the year 1909–10 gives much interesting information as to the progress which is being made in the various grades of education administered by the committee. In the Municipal School of Technology the number of individual day and evening students enrolled for the session ending July 31, 1910, was 5018, as compared with 4988 for the same period in 1907–8, an increase of 30. The number of individual students enrolled in the day departments was 733, as compared with 780 for the session 1908–9. The class entries for the session were 11,071, against 10,500 for the session 1908–9. These figures do not include the class entries in respect of students in the day departments of the school. During the session, 200 students in the day departments of the school were enrolled as students of the Victoria University of Manchester in the faculty of technology, 97 with a view to qualify either for the degrees of Master and Bachelor of Technical Science, and 103 for the certificate in technology. A large amount of original work was carried out by members of the staff and the more advanced students pursuing post-graduate courses in the various departments. Much of the work has been embodied in papers read before scientific societies, and published in the scientific and technical Press. The full record affords proof that the school compares favourably in the matter of research with other institutions of a similar character. Under the regulations adopted by the committee, a considerable number of tests and commercial investigations have been carried out during the year, chiefly in the departments of engineering and chemistry.

THE new handbooks containing the arrangements for the session 1911–12 at University College, London, in the faculty of engineering, the school of architecture, and the faculty of medical sciences have now been published. The college is a university centre for preliminary and intermediate medical studies. Its faculty of medical sciences comprises the departments of physics, chemistry, botany, and zoology (the preliminary medical sciences), also the departments of anatomy, physiology, and pharmacology (the intermediate medical sciences), and the departments of hygiene and public health and of pathological chemistry (post-graduate study). Each of the departments is also equipped for more advanced work, and provides facilities for research. The faculty of engineering, including the departments of mechanical heating and ventilation, electrical, civil and municipal engineering, is intended to provide for students wishing to devote themselves to engineering a systematic training in the application of scientific principles to industrial purposes. The courses are also suited to the requirements of students who intend to enter for appointments in the Indian Public Works Department, engineering department of the General Post Office, department of the director of engineering and architectural works in the Admiralty, Patent Office, and other similar services. The departments have been recognised by the Board of Trade as providing suitable technical training for marine engineers. Facilities are provided for post-graduate and research work in all the subjects. All communications should be addressed to the Provost, University College, London.

SOCIETIES AND ACADEMIES.

EDINBURGH.

Royal Society, June 19.—Prof. Bower, F.R.S., vice-president, in the chair.—M. Jules **Cardot**: Les Mousses de l'Expédition nationale antarctique écossaise. These were collected in various localities visited, and included a number of new species and genera.—Dr. J. **Aitken**, F.R.S.: Some nuclei of cloudy condensation. Some years previously the author, when enumerating the dust particles in the air at certain regions of the West Highlands remote from centres of population, had noticed from time to time a sudden, and at first inexplicable, increase in the number of dust particles. A recent study of the phenomenon had shown that the increase was due to the sunning of the material on the foreshore of neighbouring islands and coasts. The paper discussed the probable causes of this production of dust particles, and described a number of experiments on the direct effect of sunlight upon various substances.—Dr. A. A. **Lawson**: Nuclear osmosis as a factor in the mechanism of mitosis. A study of the spore mother-cells of Disporum, Gladiolus, Yucca and Hedera, and the vegetative cells in the root tip of Allium, has revealed a series of stages in the development of the mitotic spindle which has hitherto been overlooked. They are important and critical stages concerning the fate of the nuclear membrane, and are to be found in the early prophase, preceding the organisation of the equatorial plate. Contrary to the generally accepted view, it has been found that the nuclear membrane does not break down during spindle formation, but behaves as a permeable plasmatic membrane should behave under varying osmotic conditions. The interpretation of these stages throws an entirely new light on the problem of the "mechanism of mitosis," and necessitates a revision of the accepted views of nuclear phenomena. It goes to prove that osmotic conditions are active factors in the formation of the acromatic spindle.—Dr. A. G. **M'Kendrick** and Dr. Kesava **Pai**: The rate of multiplication of micro-organisms: a mathematical study. Assuming the law that the rate of increase of fast-growing organisms is proportional to the number of organisms present and to the concentration of the food-stuff, the authors express this in the mathematical form $dy/dt = by(a-y)$. At the beginning, y is small compared with a, so that the constant ab is equal to the rate of change of log y. From the graph which gives log y in terms of time, the value of ab may be readily obtained, and from the indications of the experiments the limit a towards which y tends may be inferred. The quantity also gives by a simple calculation the period of a generation. The numbers calculated from the integrated expression were found to be in good agreement with the numbers obtained by direct measurement.

July 3.—Dr. Horne, F.R.S., vice-president, in the chair.—Prof. A. H. **Gibson**: The resistance to flow of water through pipes or passages having divergent boundaries. The rate of loss of head in water flowing steadily along various types of expanding tubes was the object of the research—such types as circular pipes with uniformly diverging boundaries, rectangular pipes with two sides parallel and the other pair uniformly diverging, trumpet-shaped pipes with the curved boundary made so that the square of the speed fell off uniformly with distance, &c. In this last-named form there was a distinct reduction in the loss of head in a given length as compared with the loss in uniformly diverging tubes. The divergence which gave greatest efficiency was from 10° to 16° in the rectangular pipes, and from 7° to 10° in the circular pipes.—Dr. W. T. **Gordon**: The structure and affinities of *Metaclepsydropsis* (*Zygopteris*) *duplex* (Williamson). This Carboniferous fern was first recorded by Williamson in 1874, when he was investigating the structure of fossil plants from Pettycur, Fife, numerous petioles of the fern being discovered among his specimens. The same species had since been obtained near Régmy, in France; but in all these cases only fragments of petioles and pinnæ were discovered. Recently, however, stems and roots have been found at Pettycur. In a silicified mass of material several pieces of stems were obtained in close association with innumerable fragments of petioles and pinnæ. Certain emergences from the stem were noted, and an examination of the petioles soon established a series showing a continuous variation from the normal petiole trace to a trace which was identical with these emergences. In this way it was proved that the stems and petioles belonged to one and the same species. The stem stele is very simple in structure. The axis consists of a circular cylinder in which the outer zone is composed of long stout tracheides, while the inner zone is formed by a mixture of long narrow tracheides and conjunctive parenchyma. The stem emits petiole and root-traces at long intervals, and occasionally bifurcates dichotomously. In the theory of the medullation of the zygopterid stele, this stem is of some importance, since it exhibits a stage closely similar to that shown in the stem of *Ankyropteris corrugata* (Williamson). Like some other members of the Zygopterideæ, *A. corrugata* has a biseriate arrangement of the primary pinnæ, while in *M. duplex* and others a quadriseriate distribution of these appendages is shown. In both the quadriseriate and biseriate divisions it is now possible to arrange the stems in a series which demonstrates the gradual medullation of the stems, and is, at the same time, compatible with the geological age of the specimens:—

	Quadriseriate division	Biseriate division	
Lower Carboniferous	(1) *Diplolabis römeri* (2) *Metaclepsydropsis duplex*	(1) No known stem	
Upper Carboniferous	(3) *Etapteris diupsilon* (*Lygopteris Grayi*)	(2) *Ankyropteris corrugata*	
Permian ...	... ...	(3) *a. Ankyropteris scandens* *b. Ankyropteris Decaisnei* *c. Ankyropteris Brongniarti*	These three probably the same species

In each division the stems with the same number, (1), (2), (3), are at first sight practically indistinguishable, but it will be seen that the medullation in the biseriate division is geologically later than in the quadriseriate.—W. G. **Robson**: Laboratory note on a simple method of finding the radius of gyration of a body. When a body is suspended symmetrically by a bifilar suspension, its moment of inertia about the vertical axis through its centre of mass can be expressed very simply in terms of the period of oscillation about that axis and the period of oscillation as a pendulum in the plane perpendicular to the bifilar.

NEW SOUTH WALES.

Linnean Society, May 31.—Mr. W. W. Froggatt, president, in the chair.—Prof. T. D. A. **Cockerell**: The bees of the Solomon Islands. Only one species of bee (*Nomada psilocera*) had been recorded from the Solomon Islands up to the end of last year. Mr. Froggatt's collection, obtained in 1909, comprised representatives of fifteen undescribed species, referable to the genera Meroglossa, Halictus, Nomia, Crocisa, Anthophora, Cœlioxys, Megachile, and Trigona. The Solomon Islands evidently possess a strong Indo-Malayan element; but Mr. Froggatt's collection brings out the fact that there is also an Australian element, the striking representative of which is Meroglossa, now for the first time recorded from outside Australia.—H. J. **Carter**: Revision of Pterohelæus (continued) and of Saragus, with descriptions of new species of Australian Tenebrionidæ. The tabulation of the described species of Pterohelæus is continued, together with descriptions of five new species, bringing the total up to eighty-two. A tabulation of the species Saragus is also given, and descriptions of five new species, increasing the total to fifty-five. Sixteen new species of other groups of the Tenebrionidæ are described, including two for which new genera are proposed.—E. **Meyrick**: Revision of Australian Tortricina (concluded). The concluding portion of the revision deals with the two families Eucosmidæ (19 genera, 149 species) and Chlidanotidæ (2 genera, 3 species). The former is largely developed throughout the northern hemisphere, but is less conspicuous in Africa and South America, whilst in Australia and New Zealand it is inferior in numbers to the Tortricidæ. The real extent of its inferiority is, however, partially disguised by the number of species of Indo-Malayan type (especially in the genus Argyroploce) which have penetrated into Queensland. The family Chlidanotidæ is a curious one, comprising at present only a few small genera of Indo-Malayan origin.

June 28.—Mr. W. W. Froggatt, president, in the chair.—Dr. T. H. **Johnston** and L. **Harrison**: Notes on some mallophagan generic names.—T. **Steel**: The fertilisation of *Pittosporum undulatum*, Andr. The previously observed occurrence of two kinds of flowers borne on separate trees is confirmed, the one kind being male and the other female. The former are characterised by the conspicuous stamens, which are aborted and inconspicuous in the latter. Occasionally ripe seed-vessels containing fertile seeds have been noticed on staminiferous trees, and the flowers from which these were derived have been traced. These flowers were found to have shortened barren stamens, the anthers being shrivelled and non-dehiscent. In no case were staminiferous flowers found on female trees.—E. C. **Grey**: Contribution to a knowledge of the chemistry of blood. No. 1. Globin sulphate and globin from ox blood. (1) 100 c.c. of ox blood yields 16·79 grams of globin sulphate, which is equivalent to 15·43 grams of globin. (2) The globin from ox blood is more basic than that from the hæmoglobin of the horse. (3) The sulphate of globin precipitated from solutions containing varying concentrations of sulphuric acid is of constant composition, containing 8·08 per cent. sulphuric acid. (4) The percentage of nitrogen found in the globin sulphate is 14·9, from which the calculated percentage of nitrogen in the globin from the blood of the ox is 16·03 per cent. (5) The globin precipitated by trichloracetic acid was found to contain 0·45 per cent. sulphur.—Dr. R. **Broom**: The affinities of Cænolestes (Marsupialia). Thomas regarded this South American form as a diprotodont, not closely allied to any of the living forms, but more nearly related to the existing marsupials of Australia than to those of America. Miss Dederer, Gregory, and Sinclair, while agreeing that Cænolestes should not be placed in the Diprotodontia, prefer to relegate it to a distinct suborder, the Paucituberculata. After reviewing the evidence, the author concludes that as Cænolestes differs from the typical polyprotodonts only in tooth-specialisation, it should not be removed from the Polyprotodontia, but merely be made the type of a distinct family, or section at most.—P. **Cameron**: A collection of parasitic Hymenoptera (chiefly bred) made by Mr. W. W. Froggatt in New South Wales, with descriptions of new genera and species. Part i. Seventeen species, referable to the families Chalcididæ, Braconidæ, Evaniidæ, and Ichneumonidæ, are described as new.

THURSDAY, AUGUST 17, 1911.

A POLYGLOT DICTIONARY OF PLANT NAMES.

A Dictionary of Plant Names. By H. L. Gerth van Wijk. Part i., pp. xxiv+710. Part ii., pp. v+711–1444. (Haarlem: Published by the Dutch Society of Sciences, 1909–1910.)

THIS is one of those books that cause wonderment and admiration—wonderment, because it will be used, we should say, by comparatively few persons, and admiration of the author, who has devoted so much of his life to the service of the few, the work having been some twenty-five years under compilation.

"It is so planned that it will enable one to find the name by which a plant is known in four modern languages, if one knows the Latin name, and also to find the Latin name, if only the name in one of these four languages is known."

The languages chosen are English, French, and German, "to which the editor naturally added Dutch names."

In the first volume, now under review, the Latin names are alphabetically arranged, followed by the names used in English-speaking countries, or used in works written in English; by the names used in French-speaking countries, or used in books in the French language, &c. The author's aim has been to include the vernacular names of wild and cultivated plants, of varieties and subvarieties, of parts of plants now or formally (formerly) used in medicine or industrially, and of flowers and fruits; also the scientific names given to parts of plants which are, or were, used in medicine, &c., &c. This, of course, is an immense task, and a task that could scarcely be accomplished in a critical manner by one person. Therefore, if we say that Mr. Gerth van Wijk has achieved only a partial success, it must not be regarded as unkind or ungrateful criticism. To be generally useful a polyglot dictionary of any subject should be compiled on methodical and discriminating principles. The casual inquirer requires assistance where the student can find his way, and the mere heaping up of names is of little service to him. By casual inquirer we mean a person who has to consult a dictionary in connection with his occupation, profession, or pleasure, and for whom it is necessary that the information offered should be presented in an easily intelligible and practical form.

Now, it may be assumed that nearly everybody of the reading community comes under this category. A selection of examples of treatment will be of more service than general criticisms. As a component of pasture herbage, and as a weed, *Achillea millefolium* is one of the commonest herbaceous plants in the temperate regions of the northern hemisphere, and it has a correspondingly large number of names. In addition to the common English names, milfoil and yarrow, about thirty other English names are cited; they are mostly, however, of quite local application. These are arranged in alphabetical order, beginning with arrowroot, and continuing with the equally unfamiliar and unused bloodwort, camil, cammick, cammock, carpenters'-grass, dead man's daisy, devil's nettle, dog daisy, and so on. Then follow the French names, about equal in number, and the German, occupying a solid column, and numbering upwards of one hundred and fifty! Passing the less numerous Dutch appellations, we come to the officinal Latin designations of parts, as *capitula achilleae, folia millefolii,* &c., and nearly one hundred German names in relation to medicinal properties, some of them repetitions from the main list.

With all this great wealth of German names there is nothing to show which are in common use, or generally accepted as book names. No doubt a very large proportion of these names are either book names or of quite local use, and many of them mere dialect variants, of interest only to the etymologist. We have not Pritzel and Jessen's "Die deutschen Volksnamen der Pflanzen" before us at present; but Mr. Gerth van Wijk seems to have copied everything. The same in English; but although we miss all reference to Holland and Britten's "Dictionary of English Plant Names," we think the author must be indebted to it. Selecting another common plant, the daisy; there are four columns of foreign names, mostly German and Dutch. The dandelion occupies another two pages, and in this way the 1444 pages are filled with names without distinction, save that those in commoner use are printed in spaced type.

Of course, an author is at liberty to make the book of his mind, and it is perhaps scarcely legitimate to suggest that he should have done something else; but if he had taken the popular names (not translated names) from the leading "floras," pharmacopœias, and publications on economic botany, he might have produced a useful work. We are told by the author that the second volume is to contain the popular names in alphabetical order, with the Latin names appended. Has he estimated, we wonder, the amount of expansion these solid columns of names will undergo when each one begins a separate line? Well, the pagination would be tripled, at least! It should be added that what the author has set himself to do he has done very well. Errors are not prominently frequent, but there are names puzzling enough, and some apparently impossible. The nomenclature of the "Index Kewensis" has been followed so far as possible for the Latin names, and the position is this: knowing the Latin name of a plant, it is easy to arrive at the lists of popular names; but supposing it is wished to find the equivalent of poppy, apart from its Latin name, in French or German, the dictionary does not help us; nor will the second volume supply this kind of information. Indeed, to attempt this now in the author's plan would extend the work beyond imagination; yet, after all, this is just the kind of information that most of us want, and turning up common names, such as daisy and poppy, in ordinary French and German dictionaries, the ordinary equivalents are found.

W. BOTTING HEMSLEY.

PROBLEMS OF WATER SUPPLY.

The Geology of Water Supply. By Horace B. Woodward, F.R.S. Pp. xii+339. (London: Edward Arnold, 1910.) Price 7s. 6d. net.

THE geology of water supply is one of those applied subjects which are extremely difficult to treat of adequately within the limits of a small volume, inasmuch as geology constitutes only one of the factors which have to be taken into consideration, and the part which it plays varies with so great uncertainty that each individual case must be dealt with practically on its merits. It may be said at once, however, that we have here an extremely useful book, one which sets forth with great clearness the main geological features to be recognised by the engineer, chemist, or physical geographer when confronted with a problem of water supply, and indicates to him the critical point where the geological doctor must be sent for. The examples quoted in illustration of general principles are naturally mostly taken from the British Isles, but there are many of great interest from other parts of the world, particularly from the United States and the British Dominions beyond the Seas.

After an introductory chapter and some general remarks on rainfall and atmospheric impurities, the author states some general geological considerations, and proceeds to describe the modes of dispersal of rain on the surface and underground, special reference being made to rivers and underground channels, swallow holes, pipes, bournes, dumb-wells, and springs. Then follows a chapter on surface sources of supply, which include storage of rain-water, supplies from springs, streams, and rivers, ponds, dew-ponds, and lakes and reservoirs. The geological interest increases in the next chapter, on underground sources of water supply—wells of all kinds—and then follow three chapters on the water-bearing strata of England, working backwards through the geological record. The succeeding chapter, on prospecting for water, applies the information already provided to the selection of sites for wells and borings, having regard to the quantity and quality of water required, the geological uncertainties underground, and, incidentally, to the belief that trustworthy aid can be obtained from various methods of water divining. This is, in our opinion, the most valuable chapter in the book; the hints as to the examination of particular districts and the diagrams illustrating local peculiarities which may be met with are extremely clear, and will form a useful warning to the non-expert of the danger of trusting too much to apparent simplicity of structure.

The next section of the book concerns itself with the water supply in polar, arid, and other regions, and in islands, where special conditions arise; a non-geological chapter refers shortly to the quality of water and the examination thereof by chemical and bacteriological analysis; and, lastly, we have a chapter of great interest on mineral waters, *i.e.* waters which contain in solution more than the 60 or 70 grains per gallon which marks the "potable" limit.

A final chapter adds to the growing body of evidence which may one day be deemed sufficient to justify the constitution of a National Water Board, which would enable "the various independent authorities dealing with the conservancy of rivers, with canals, drainage, sanitary matters, and water supply," to act to some extent in concert.

A useful glossary and bibliography and a satisfactory index are appended.

In reviewing a suggestive book of this kind it would, of course, be easy to embark upon a discussion of many things which, as the author is always careful to point out when he comes to them, are still largely matters of opinion, but space forbids more than the mere laying of emphasis upon one or two points. We note the need for further investigation of the conditions of percolation, and the solvent action of water in a permeable formation such as limestone. Where the limestone formation is exposed it would seem that, the solvent power of the percolating water being quickly lost, solution takes place chiefly along cracks or joints, which are opened out into fissures, caves or underground channels being formed where the rock material is strong, and subsidence occurring where it is weak; but where the permeable formation is overlain by an impermeable, it appears that percolation takes place with great slowness, and water obtained by boring through the upper strata is not quickly replaced from a distance. The analytical work of Mr. W. W. Fisher and Dr. J. C. Thresh in the oolites in Oxfordshire and the chalk under London is extremely significant; it suggests important conclusions in connection with, *e.g.* the lowering of the water-table under London, the outflow of water from the chalk in Kent and Hertfordshire and in other parts of England where similar structures occur.

With regard to maps showing underground contours, we agree that contours delineating the upper surface of covered water-bearing formations are valuable, and that an extension of work similar to that of Mr. W. H. Dalton is desirable. But we think that Mr. Woodward underestimates the usefulness of maps representing underground water-contours, which give much information as to the direction of flow of underground water and its variations from time to time under varying rainfall and pumping.

We note few slips, but it may be worth pointing out that the New River derives much of its supply from an intake from the Lea, and the Glencorse reservoirs largely supplement the Crawley springs in contributing water from the Pentland Hills and Edinburgh.

PARASITISM.

Survival and Reproduction: a new Biological Outlook. By H. Keinheimer. Pp. x+410. (London: J. M. Watkins, 1910.) Price 7s. 6d. net.

THE plentifully quoted pages from the writings of Darwin, Kropotkin, and others contained within the structure of this book form far more than its skeleton. Their presence justifies the statement that the work contains many luminous passages and much translucent information.

That part of the work which spatially connects the unmistakably clear words of penetrative genius and the brilliantly facetted phrases of clever men, and which is contributed by the author, is, however, of another kind: rather fluorescent than luminous, and by no means transparent.

Not that the author is without some literary deftness and incapable of pressing home a plain fact in a convincing manner. Thus, for instance, where he acknowledges his indebtedness for embodying so large a part of Geddes and Thompson's well-known work on "Sex and Evolution," explaining that it would be mere presumption on his part to attempt to do again what they have already done far better than he could do. Reading the book, it is soon clear that this is true, and, as of great relevance, a truth as well stated although otherwise evident. That it is stated well no one will deny.

The author's own meaning is presumably contained in the commentary paragraphs that follow each of these lengthy quotations. The redundancy of reiterated references to "parasitism" contained within these comments is reminiscent of a well-known dialogue between two dramatists unfortunately departed to the nether-world and there contesting their respective excellences in metrical statement. Entitled to one line with which to conclude his fellow competitor's heroic verse, one candidate secures a repeated success by the use of always the same phrase, some such simple phrase as "and I lost a little oil-can."

From these reiterated comments it would appear that parasitism is responsible for many things, chiefly perhaps for "the passing of natural selection." This is by no means surprising when the author's comprehensive concept of "parasitism" is fully grasped. The term is defined as connoting

"Every condition whereby one organism lives predaceously, stealthily, or indolently, *i.e.* retrogressively, by the work of others. In view of the dynamic interdependence of life, the epithet must also apply to all transitory phases of violation of fundamental laws of assimilation and division of labour, even the highest and most strenuous organisms occasionally being guilty of such transgressions."

To this definition there are, however, so many numbered corollaries that "parasitism" is by no means understood until wider reference is made. Briefly, let it be said that there is the whole work to refer to.

Herbert Spencer, so it would seem, has anticipated this intellectual venture in a somewhat remarkable manner. Thus the author quotes his explanation of the limits to cell-growth in terms of an increasing disparity between mass and surface, and appends the following comment: "Herbert Spencer here very lucidly, though unwittingly, states the case of pathology and parasitism, and consequent limitations."

The author deliberately stating this case, so it would seem, is by no means so clear, and as a consequence places difficulties in the way of that criticism which he foresees apparently without fearing.

"Anyone honestly wishing to challenge my views is, of course, very welcome to do so. But if criticism is to be effective, it must state categorically in what particulars I am wrongly interpreting observed facts, and must also show that my physiological position is unsound."

This statement may become more pregnant when the author has detailed these particulars, and provided a view of his physiological position.

J. S. MACDONALD.

THE DIVINING ROD.

Graf Carl v. Klinchowstroem. Bibliographie der Wünschelrute. Mit einer Einleitung von Dr. Ed. Aigner: der gegenwärtige stand der Wünschelruten-Forschung. Pp. 146. (München: Ottmar Schönhuth Nachf., 1911.)

THIS book contains a fairly complete list of the various publications in regard to the divining-rod, beginning with the work of R. P. Bernhardus, published in 1532, and ending with papers issued during the current year. This list extends over 103 pages, and the contents of each book or paper are indicated by a brief note following the title of the publication.

The list is naturally more complete in respect of German publications than of any others; there is a useful index giving the names of the various authors who are mentioned. The thanks of those who are interested in the matter are due to Graf von Klinckowstroem for the care he has taken in collecting the information and presenting it in useful form. There is also an interesting introduction by Dr. Eduard Aigner, of Munich, who endeavours to sum up impartially the present condition of matters in connection with research on the action of the divining-rod. He points out quite correctly that the attitude of those who refuse to investigate the matter at all is just as absurd as that of their opponents, who are willing to accept all the claims of the "diviners" without further investigation.

Dr. Aigner also points out that a certain percentage of failures does not necessarily prove that the "diviners" do not possess the powers they claim, for if these powers have any real existence, they may be conditioned by circumstances at present unknown to us, and one may be at times asking the "diviners" to perform experiments under impossible conditions.

An explanation of the recorded successes of "diviners" is suggested, which presupposes the power of the "diviners" to recognise the difference produced in the atmosphere by the presence of water, metals, &c. The most important argument in favour of this is based on the investigations of Dr. Kurz and Prof. Gockel (*Physikalische Zeitschrift*, x., p. 845) and of T. Wulf (*idem*, x., p. 997), in which a lessening of the gamma-radiation over water is said to be proved. This lessening is said to take place over quite insignificant water-sources.

If this view were correct, it ought, of course, to be possible to produce a physical apparatus capable of replacing the "diviner," and several articles of this kind are on the market. The reviewer has applied for permission to test some of these, but he has not so far succeeded in inducing those concerned to allow him to do so. Dr. Aigner says that successes of one form of apparatus are spoken about, but that they do not appear to have been verified by competent authority.

The reviewer is of opinion that further experiments are desirable, and that these should be directed mainly towards ascertaining whether or not the movements of the "diviner's" rod are caused by any influence outside himself. The experiments are difficult to carry out, because it is clearly fair that the conditions should be those acceptable to the "diviner"; these vary greatly, few "diviners" being entirely in agreement when asked to describe clearly the extent of their powers.

J. Wertheimer.

DIOPHANTINE ANALYSIS.

Diophantus of Alexandria: a Study in the History of Greek Algebra. By Sir T. L. Heath, K.C.B. Second edition, with a Supplement containing an Account of Fermat's Theorems and Problems connected with Diophantine Analysis and some Solutions of Diophantine Problems by Euler. Pp. vii+387. (London: Cambridge University Press, 1910.) Price 12*s.* 6*d.* net.

THIS is far from being a mere reprint of the first edition; in fact, it is in great part a new work, which, in conjunction with Tannery's critical edition of the "Arithmetica," makes Diophantus at last accessible to the ordinary reader.

The introduction, besides giving a historical account of Diophantus, the MSS. of his works, and the writers who have dealt with them, contains most interesting and valuable sections on Diophantus's notation and methods of solution. As to the first, we are astounded, as in the case of Archimedes, at the ease with which enormous numbers are computed, in spite of the cumbrous Greek notation. An instance in point is the famous cattle problem (attributed to Archimedes), which is briefly discussed on pp. 121–4. Its solution involves the Pellian equation $t^2-4729494u^2=1$, and according to Sir T. Heath's calculations, the value of one of the unknowns of the problem would be a number containing 206,545 digits. Of the methods of Diophantus not much can be said, because he uses so many ingenious devices to suit different problems; but we may note his dexterity in choosing his unknown quantity, and his curious plan of "working back" by a sort of rule of false position. A good example of the latter is v. 29 (p. 224): "To find three squares such that the sum of their squares is a square," where it will be seen that an insufficient assumption is corrected and modified in a sort of tentative way until a solution is found.

It would be unprofitable to go into any detail here on the nature of Diophantine problems in general; to appreciate them it is necessary to read Diophantus, Fermat, and Euler. By a very happy inspiration, the present volume has been made to include all the notes of Fermat upon Diophantus, and extracts from his correspondence with Frénicle and others; besides this we have solutions of seventeen Diophantine problems by Euler, which are models for those who feel inclined to work in this fascinating field. There can be little doubt that there are still numbers of arithmetical problems to be solved by Diophantine methods, and Fermat's method of reduction (*descente*) for proving the impossibility of certain indeterminate equations awaits rediscovery and development. Moreover, the theory of algebraic forms and symmetric functions ought surely to lead to new arithmetical applications of a Diophantine type. To give an example of the sort of thing we mean: Let x, y, z be three variables; we have identically

$$\Sigma x(y-z)^3=(y-z)(z-x)(x-y)(x+y+z).$$

Now put $x, y, z=\xi^3, \eta^3, \zeta^3$, and suppose that $\xi^3+\eta^3+\zeta^3=m\xi\eta\zeta$; then the previous identity leads at once to

$$A^3+B^3+C^3=mABC$$

with

$$A, B, C=\xi(\eta^3-\zeta^3),\ \eta(\zeta^3-\xi^3),\ \zeta(\xi^3-\eta^3).$$

This is a partial sample of what Fermat would call a *descente*; of course, it is now well known as the theory of residuation of points on cubic curves, but it is interesting to see how it results from an elementary algebraic identity, and there are still arithmetical problems in this connection which do not appear to have been solved.

It may interest those who are unacquainted with the subject to give one typical Diophantine problem and its solution. The problem is "To find two positive integers such that their sum is a square, and the sum of their squares a biquadrate." One solution is (4565486027761, 1061652293520), and it has been proved by Lagrange that, as Fermat "confidently asserted," this is the simplest solution. More exactly: the same problem may be put in the form, "Find a right-angled triangle such that the hypotenuse and the sum of the sides are both squares," and Fermat's assertion was that the above solution gave the smallest of such triangles.

In conclusion, it may be remarked that there is a *crux* in the Greek text which does not seem to have been finally disposed of. After putting the problem, "To find two numbers such that their sum and product are given numbers," Diophantus adds the condition, "the square of half the sum must exceed the product by a square number." ἔστι δὲ τοῦτο πλασματικόν. It would be possible to translate this, "This is artificial" (as opposed to "natural"), but there does not seem to be any point in this. On the other hand, to translate "This can be seen from a model" would give good sense, because we should only have to replace a diagram in Euclid by a corresponding arrangement of counters; unfortunately, this seems to read more into the text than is legitimate. Neither of these alternatives is proposed in the note on p. 140; the editor prefers, on the whole, Xylander's *effictum aliunde*, which is not far in sense from "artificial," in the context. The same phrase occurs in two other places, and in each case we can give a quasi-geometrical arrangement of counters to show that the condition is necessary; so far, this is in favour of the second alternative suggested above.

G. B. M.

A TEXT-BOOK ON HELIOTROPISM.

Light and the Behaviour of Organisms. By Prof. S. O. Mast. Pp. xi+410. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1911.)

THE question of the influence of light upon organisms must have appealed to the inquiring mind ever since a moth was seen to fly into a candle or a plant was observed to bend towards the sun. The closing of many flowers at night coinciding with the opening of others would have also been arresting movements to many unknown observers. But how subtle the influence of light may be has only comparatively recently been appreciated. The bending of plants towards the sun may readily be explicable on the ground of the importance of light in the preparation of the plant-food, but the hydroid zoophytes were discovered to possess the same property of bending towards the source of light, although they do not find thereby any known assistance to their maintenance. Larvæ of many diverse marine animals are also strongly attracted by light, and these, again, make no use of it so far as is known. Many animals, indeed, prefer rays of a particular region. As Lord Avebury showed years ago, the common Daphnia, if covered by a spectrum, aggregates under the green and yellow rays; ants, on the other hand, aggregate chiefly under the red and green rays, showing a special avoidance of violet and ultra-violet rays. Such varied and definite susceptibility seems quite unintelligible unless it is connected in some way with well-being, and no one has as yet shown any such correlation. The problems, then, of the meaning of the attraction or repulsion which light exerts are evidently very diverse, and the work of Mr. Mast is devoted to their analysis and consideration.

The first section contains an interesting historical summary of observations chiefly upon plants. Ray was apparently the first to suggest an explanation of the movements of plants, which he attributed to the flow of sap, being attracted to the problem by the sensitive mimosa then recently introduced from America. Early in the nineteenth century de Candolle reversed the daily periodic sleep-movements of leaves by exposing them to a new light rhythm—an interesting anticipation of F. Darwin's work. Many other points of interest are raised, including a discussion of the use of such terms as "tropism," originally the relation between the bending of a plant and the source of stimulation.

In part ii. the author sets out an account of his experiments on certain plants (Plumules of Indian corn and leaves of Tropæolum), and arrives at the conclusion that differences of light-intensity are responsible for the movements (observed by a special "light-grader"), but the method of regulating the movements is still a mystery. The section on the light-responses of unicellular plants and animals includes some original observations, as does that upon cœlenterates and various larval forms of higher animals. The general summary of this section is given on pp. 228–235, and includes a useful analysis of the work of many writers. The third part of the book is concerned with general considerations—the adaptive nature of light-responses, the phenomenon of aggregation in different intensities, and so on. This section and the last (which deals with reactions of animals to different wave-lengths) are very diffuse, and might well have been considerably shortened, as in many cases the discussions are not capable of leading to any definite solution; and if the excuse be offered that "behaviour" in its broadest sense was the subject of treatment, then surely the problem of colour-adaptation might have been mentioned. The points that emerge from this work are that there are many striking movements towards or away from the source of light which are quite unintelligible unless animal metabolism is favourably effected thereby, and we have no reason to suppose it is; and, secondly, that the way in which these orientations are effected is equally obscure. The book is written by a pupil of Jennings, who has done so much to analyse the behaviour of the lower organisms. It contains a very useful bibliography, and should prove helpful to that increasing number of experimental biologists and psychologists who are interested in the behaviour of organisms.

F. W. G.

PLEASANT PATHS OF NATURE.

The Airy Way. By George A. B. Dewar. Pp. vii+253. (London: Chatto and Windus, 1910.) Price 6*s.* net.

IN a delightfully breezy volume Mr. Dewar plays lightly on the word "airy" in its varying application, straying, by the way, into the rapid-running waters—the fishes' airy way. Following two most interesting chapters on flight and one on the watery way, the contents of the rest of the volume may be sufficiently indicated by the chapter headings dealing with the airy moor and links, the fritillaries' airy way, the airy lane and common, rooks in the airy way, and "my airiest downs"—a year's observations on the chalk. Field naturalists will be grateful to the author for his gift of conveying impressions in a few words—impressions which many may have felt, but could not perhaps express so aptly.

A few quotations from this pleasant book will serve to illustrate the pertinence of his remarks and the accuracy of his observations. Of the swift, a bird for which he has a great admiration, he says that it *is* flight, and is fitted with two scythes to cut and sweep through the air. Of the start of birds from the ground he writes:

"Hide behind a hedge or wall, and, when every pigeon beak is down, tap your stick on the ground. As you tap—whilst sound is still coming from the stone—every bird is in the air. You would as soon try to reckon the time between the hammer striking the cap and the discharge of the cartridge as reckon the time between the stick striking the stone and the discharge of the pigeon party."

And of the salmon:

"No man swims if a salmon swims. The keeping afloat, and the slow movements of a man in comparatively still water, should not be given the name we give to the swift, sure, glorious action of the salmon in the fury of storming streams. Does a man who sits in a flying machine which makes its way through the air 'fly'? If so, the swift and the merlin and eagle have an action for which we should find another name. One thing such acts have in common—progress. They have little else."

Mr. Dewar says truly that though no date in a calendar can end or begin winter, yet there are some natural events—small touches, but sure—that end one season and begin another. One of them is the nest—with the eggs—of the earliest song-thrush. "The nest may be set in a winter hedge, and a return of iron days and nights kill the work and prevent other thrushes starting on their nests for weeks to come. It does not signify. The first thrush nest found in March in the thorn or ivy, the clay dried, the eggs laid, ended winter." But he does not do the fly-catcher justice when he says it can squeak, and has besides a fretful monosyllable or so, and there is his music. It is true that the fly-catcher very rarely sings, and that many people have apparently never heard the song; but it does really sing occasionally for all that. How one wrong letter will alter the look of a sentence, and even puzzle the reader for a moment! We notice "swallow" written for "sallow" in one place, and "root" for "rook" in another.

TEXT-BOOKS OF PHYSICS.

(1) *Mechanics and Heat: a Text-book for Colleges and Technical Schools.* By W. S. Franklin and Barry Macnutt. Pp. x+409. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 7s. 6d.

(2) *A Text-book of Physics.* By H. E. Hurst and R. T. Lattey. Pp. x+638. (London: Constable and Co., Ltd., 1910.) Price 8s. 6d. net.

(1) WITHIN the last half-century much experience has been gained as to the methods which can be used most profitably in the teaching of science; nevertheless, there is still much diversity of opinion as to the best method to be used. Followers of the heuristic school maintain that a student should build up his knowledge of science by his own unaided exertions, the function of a teacher being to guide the student's mind insidiously toward the correct path. Has any teacher ever attempted to proceed severely on these lines? It may be doubted. So far as the teaching of physics is concerned, such an attempt would be so ridiculously futile that no one could have made it seriously. Ideas such as those connoted by the words "energy," "potential," "entropy," and a host of similar expressions could scarcely be derived by any student, even if he were of the type that might develop subsequently into a Kelvin or a Rayleigh. Quite apart, however, from the question of possibility, it may be argued that no student has received a satisfactory training unless he has learned to profit by the knowledge which has been accumulated by others. Dismissing, then, the claims of the heuristic system as enunciated by its most rigid adherents, the question arises, To what extent is a student necessarily dependent on personal observation, and to what extent is it profitable for him to imbibe ideas directly from his teacher? No general answer can be given to this question, since so much must depend on the personalities of both the student and the teacher; but if it be accepted that science is the study of real phenomena, it must follow that the practical work done by the student must be sufficiently extensive to give him a clear idea of the phenomena which he investigates. Not only the nature of the experiments, but the order in which they are performed, is of importance. Most of the difficulty experienced by students in becoming acquainted with the dynamical properties of solids and fluids is due to the practice of studying the laws of statics exhaustively before the laws of motion have been mastered; much of the time now spent in the experimental study of statics might be devoted with advantage to the performance of simple experiments designed to illustrate the laws of dynamics. In a systematic course of study an accurate and comprehensive knowledge of mechanical principles should be gained as early as possible, for most of the exact sciences cannot be mastered without such a knowledge.

Messrs. Franklin and Macnutt have advisedly devoted the first 269 pages of their text-book to the study of the mechanical properties of solids and fluids; such subjects as virtual work, the properties of rotating bodies (including the gyrostat), the analysis of the stresses called into play by straining an elastic substance, and the fundamental laws of hydrodynamics are dealt with in a simple but illuminating manner. A few errors may be noticed. The action of the Pitot tube cannot be deduced from the force exerted by a jet of liquid impinging normally on a plane. The velocity of stream, as measured by a Pitot tube, should be equal to $\sqrt{2gh}$, where h is the height at which the liquid stands in the tube, instead of $\sqrt{gh}$, as given on p. 260. The depression of the surface of the water escaping from the central outlet of a laboratory basin is not essentially due to rotation of the water; even when the water approaches the outlet radially its velocity must increase and its pressure must diminish. In general, however, the treatment of the subject is excellent, and the student is afforded an opportunity of becoming acquainted with many interesting phenomena connected with engineering practice, which are not generally mentioned in books devoted to the theory of mechanics.

The second part of the book is devoted to the study of heat. The first and second laws of thermodynamics are discussed fully, and the most interesting properties of solid liquids and gases are dealt with in passing. The graph given on p. 401 exhibits the rate of cooling of a teapot as compared with that of a Dewar's vacuum flask, and is interesting as showing that the rate at which the teapot loses heat is scarcely affected by radiation, being due almost entirely to convection and, to a small extent, to conduction. How many teachers, it may be wondered, have explained that a silver teapot loses heat more slowly than a porcelain one, on account of the high reflecting and consequent low radiating qualities of polished silver?

(2) Messrs. Hurst and Lattey have written this book for students preparing for the Preliminary examina-

tion in physics in the Oxford Natural Science School; the general standard adopted is somewhat lower than that required for the examinations in physics for the Intermediate B.Sc. of the University of London. The book has been carefully written, and the diagrams are well drawn and reproduced. A large assortment of questions (without answers) is given at the end of each chapter. For the rest, there is not much to distinguish this book from many others on the market. The ordinary ground is covered in a trustworthy but somewhat uninspiring manner, and very little attention has been devoted to display. One or two errors may be mentioned. Ohm's law cannot be proved by the aid of experiments conducted with the potentiometer, as stated on p. 520; the use of the potentiometer is based on the truth of Ohm's law. One of the diagrams on p. 466 indicates that when a charged body is suspended inside an insulated metal can, the distribution of the lines of force radiating externally from the can depends on the position of the body inside the can. This conclusion is well known to be inaccurate. A very bad example is set to students on p. 16, where it is stated that—

"A velocity of 20 miles per hour was gained in 15 minutes; if the acceleration had been uniform, $\frac{20}{15}=1\dot{3}$ miles per hour had been added in each minute, or $\frac{1\dot{3}}{60}=0{\cdot}02\dot{1}8\dot{3}$ miles per hour in each second."

One of the first things that should be impressed on a student of physics is that recurring decimals have absolutely no meaning with regard to physical measurements.

E. Edser.

EXPERIMENTAL PSYCHOLOGY.

Lectures on the Experimental Psychology of the Thought-Processes. By Prof. E. B. Titchener. Pp. ix+318. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1909.) Price 5*s*. 6*d*. net.

A Text-book of Psychology. By Prof. E. B. Titchener. Part II. Pp. ix+303–558. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 6*s*. net.

In these books Prof. Titchener has made two valuable additions to the list of excellent psychological text-books that already stands to his name. The first takes its place by the side of his "Lectures on Feeling and Attention" as another detailed and advanced discussion going to the very heart of general psychological theory; the second is the completion of a new "Text-book of Psychology," intended to take the place of his well-known "Outline."

The lectures on thought-processes are five in number, in which are discussed the general function of mental imagery and its relation to thought, "objective reference" as the universal characteristic of consciousness, the modern methods employed in the experimental investigation of the thought-processes (by Marbe, Binet, Watt, Ach, Messer, Bühler, &c.), and the general conclusion as to the existence of a distinct "thought-element" to which most of these investigators find themselves driven. Titchener finds this conclusion unjustified by the facts, and to be explained, partly at least, by a confusion of the psychological with the logical point of view. "Cortical set," *i.e.* a purely physiological factor, together with a residuum of mental imagery, a residuum so inappreciable that it escapes introspection, are to be looked upon as the more probable factors in the make-up of so-called "imageless thought" than any ultimate thought-element.

The first lecture contains an excellent account of the difference between modern psychological sensationalism and the older sensationalism of the associationist school. Whether the difference is so fundamental as Prof. Titchener imagines it to be is perhaps doubtful. When, *e.g.* he writes: "The experimentalists, on the other hand, aim to describe the contents of consciousness not as they mean but as they are," one may perhaps be allowed to demur. Would not such a complete abstraction of mental process from meaning make a theory of knowledge impossible? A distinction so rigorously drawn between psychology and epistemology or metaphysics really implies a denial of the existence of the latter sciences. In Lecture II. an analogy for the reference to an object implied in all thought is taken from physical organisation.

"Every constituent part of an organism points to and implies all the other parts. In the same way the ideational process which is the vehicle of conceptual meaning is involved in a network of reproductive tendencies; it points to and implies all the special ideas that fall under the concept in question."

Is it not more accurate to say that the "reference" and implication in the former case is explicable on the analogy of that in the latter, and not *vice versa*? The complete identification of "meaning" and "context" may solve many difficulties, but does it not raise still greater difficulties in doing so? Such doubts as these may arise in perusing the lecture, but Titchener does really come to close quarters and grapples with the central difficulty in a way that does much to justify his unshakable faith in psychology and its competency to include the whole field of mental life.

The later lectures are an excellent description and criticism of experimental work on thought. The conceptions of *Bewusstseinslage* and *Aufgabe* are fully explained and the exact position of the problem up-to-date made clear. In the "Notes," which fill more than 200 pages, the original authorities are extensively quoted, and many points are discussed in much greater detail. The entire book will be found of the utmost value to the advanced student.

The "Text-book of Psychology," Part II., deals with Perception Association, Memory and Imagination, Action, Emotion, and Thought, all in a clear and straightforward way. The descriptions are based upon experimentally-determined data, and give an excellent idea of the extent to which Experimental Psychology has widened and deepened the more general science. Very full references for further reading are given at the ends of the chapters. By the device of type of two different sizes the book has been made suitable both for the beginner and also for the more advanced student.

W. B.

OUR BOOK SHELF.

The Art of the Goldsmith and Jeweller: a Treatise on the Manipulation of Gold in the Various Processes of Goldsmith's Work, and the Manufacture of Personal Ornaments, &c., &c., for the Use of Students and Practical Men. By T. B. Wigley, assisted by J. H. Stansbie. Second edition, revised and enlarged. Pp. xii+264. (London: C. Griffin and Co., Ltd., 1911.) Price 7s. 6d. net.

THE work of the goldsmith and the jeweller, like that of many other craftsmen, has undergone a striking change of late years. Formerly the goldsmith was an artist making his own designs, and working them out with infinite patience and cunning, but seldom finding himself bound down to routine. He served an apprenticeship and was taught the various branches of the craft. Now that vast quantities of cheap jewellery of all sorts are manufactured, largely by the use of machinery, the workmen, even if something more than mere machine-minders, are engaged on some one special branch and learn no other. Such a system, of course, threatens the artistic side with extinction, and the establishment of technical schools and the production of such books as this one under review, revealing the mysteries of the ancient craft, become a necessity.

Mr. Wigley, with his long experience as headmaster of the Jewellers' and Silversmiths' Association Technical School, has the advantage of knowing what teachers and students require, and has written a very useful book. It is not detailed enough for students without demonstrations, but for the same reason it would not be painfully tedious to practical men, and would be by no means out of place in the workshop.

Details, however, are not lacking. Students are warned against certain pitfalls with almost meticulous care. As an instance, there may be cited the remark on p. 36, in dealing with the preparation of gold alloys:—"In adding decimal quantities together it is important to keep the decimal points under each other." On the other hand, some workshop knowledge is assumed, as on p. 70, where we are told that a lathe may be used for "turning pillars and small fittings, milling bezels, knurling edges of stud backs, sawing off joints, &c.," none of these terms being explained.

The book does not give an accurate picture of the industry as it exists to-day, as it leaves out of account most of the labour-saving machines and large-scale manufacturing methods. Moreover, the artistic side is not so persuasively presented as in Wilson's "Silver Work and Jewellery," and little space is devoted to history, but the book seems exactly adapted for those preparing for the technological examinations of the City and Guilds of London Institute, and thus it thoroughly justifies its existence.

The Adventures of James Capen Adams, Mountaineer and Grizzly Bear Hunter of California. By Theodore H. Hittell. Pp. xiii+373. (London: T. Werner Laurie, n.d.) Price 6s. net.

As we learn from the introduction, this book has a somewhat remarkable history. It first saw the light at Boston, U.S.A., so long ago as 1860, but, on account of the breaking out of the civil war, only a comparatively small number of copies appear to have been issued, and its publication was soon discontinued altogether. The present issue is an exact replica of the original, and is thus out of date in the matter of typography and illustrations; indeed, in the case of the latter this is self-apparent, as they are in a distinctly "prehistoric" style. The remarkable history of the book is, however, by no means exhausted by the above, for Mr. T. H. Hittell, who took down the narrative from the lips of J. C. Adams in the autumn of 1856, is still alive, and has acted as editor of the present issue. In saying that the book is a replica of the original, it might have been mentioned that the introduction and a postscript are new. The latter gives an account of the last days of Adams, who joined Barnum's exhibition, and appears to have died soon after 1860, if not, indeed, at the close of that year.

Such interest as the book possesses for the naturalist is to be found in the circumstance that it relates to a period when the big-game fauna of North America still retained a considerable share of its original abundance; and it is specially noteworthy to find Adams describing how he once "rounded up" a herd of prongbuck (antelope), and actually killed some half-dozen with his knife. But Adams, although he had a try at game of every kind, appears to have devoted special attention to grisly bears, which he not only killed, but captured and tamed to such degree that they were used for carrying baggage on the march. The book is thus well worthy of the attention, not only of those devoted to sport, but also of those interested in animal-taming. R. L.

A New Law of Thought and its Logical Bearings. By E. E. Constance Jones. With a preface by Prof. Stout. Pp. viii+75. (Cambridge: University Press, 1911.) Price 2s. net.

MISS JONES's object in this brief essay is to propound "a certain analysis of categorical propositions of the forms *S is P*, *S is not P*, to show that this is the only general analysis which it is possible to accept, and to indicate its bearing upon logical science." We need propositions of these forms for significant assertion, and without them no satisfactory statement can be given of the three fundamental laws of thought. The first two of these are commonly formulated as (1) *A is A*, (2) *A is not non-A*, and the third sometimes as *A is either A or non-A*. Desperate efforts have been made by logicians to give a valuable meaning to *A is A*; but if *A is A*, interpreted as *A is A*, is retained as the first fundamental law, there is no possible passage from it to *A is B*. Lotze therefore gives up (theoretically) *S is P*. *A is A* tells us no more than *A is A*, and if we begin with it, we must also end with it, if we are to be consistent. We must, then, not begin with it, but with a law of significant assertion—assertion of the forms *S is P*, *S is not P*. If we start with the principle that *every subject of predication is an identity (of denotation) in diversity (of intension)* this law and the laws of contradiction and excluded middle do furnish a real and adequate and obvious basis and starting point of "formal" logic.

Miss Jones illustrates and applies her contention in a concise but interesting way, and Prof. Stout thinks that she makes out her case.

Electricity in Locomotion: an Account of its Mechanism, its Achievements, and its Prospects. By Adam G. Whyte. Pp. vii+143. (Cambridge: University Press, 1911.) Price 1s. net.

THE author gives in a very concise form a brief history of the first tramways and railways, and proceeds to show how the development of electric tramways has taken place in spite of great opposition from the æsthetic point of view, and also from causes arising out of the Tramways Act of 1870. The various systems of electric traction are carefully considered and the advantages of each fully discussed. Further chapters deal with the trolley omnibus, accumulator, electric traction, and regenerative control. The causes of failure of the accumulator-driven vehicle are adequately considered, and also the advantages of the trolley omnibus when acting as a feeder for electric tramways.

The latter part of the book is devoted to petrol-electric vehicles and electric railways, while a chapter is included which deals with electric traction curiosities. A full description is given of the system and working of the Metropolitan District Railway, the London, Brighton, and South Coast electrified line, and the "Underground" Tube combination and the other tubes.

With regard to the petrol-electric systems, some interesting facts are given dealing with its aspect with regard to marine propulsion as advocated by Messrs. Durtnell, Mavor, and others. The advantages of the system, if successfully applied to warships and liners, would be enormous, but at present it has not got very much beyond the experimental stages, though there is hope that it may prove its worth in the near future.

Finally, the monorail systems are described, together with some other general arrangements of self-contained generating stations on wheels, &c., making, with the previous chapters, an interesting summary of the history of electric traction from its commencement to the present day.

British Ferns: a Pocket "Help" for the Collector. By F. G. Heath. Pp. x+130. (London: Sir Isaac Pitman and Sons, Ltd., 1911.) Price 2s. net.

THE author's knowledge of fern species and their habitats has been manifested in previous publications, so that one is prepared to find this real pocket-book, measuring 6½ by 3¾ inches, a trustworthy and desirable acquisition when making an excursion in quest of ferns. Forty-five species are enumerated, but varieties with one exception are omitted. The descriptions are written primarily for the amateur collector, and serviceable assistance is provided in the illustrations. The information is tabulated under the headings frond length, description, usual habitat, and localities. The list of localities, given as fully as possible, represents an arduous piece of work. Certain introductory sections are prefixed, of which the two giving definitions and general habitats are most desirable and helpful, but the others are imaginative rather than scientific; it is not necessary to go beyond the statement that every point of the germ (sporeling) is equally ready to produce roots or a stem. Disregarding the first four sections, the book provides a compact, informative guide.

Aërial Locomotion. By E. H. Harper and A. Ferguson. With an introduction by Prof. G. H. Bryan, F.R.S. Pp. xii+164. (Cambridge: University Press, 1911.) Price 1s. net.

POPULAR handbooks on aërial navigation are now issuing from the press in a constant stream, and as their number grows the reviewer naturally judges of each new arrival by comparing it with its forerunners.

The exact public for which the little book under notice is intended is difficult to determine. The book is accurate, but it is dull; it is unattractive, and is poorly arranged. We cannot imagine the book being read for amusement, as the style is difficult to follow, or for information, owing to the absence of shoulder-notes, index, sectional arrangement, and other of the common aids to study.

Clarity of expression is lacking in very many places, while the sentence on p. 60, "If the elevator is carried normally in a different position during flight, all the conditions of flight are changed," is quite incomprehensible.

As has been said, the book is accurate, but it is scarcely calculated to attain its apparent object of interesting the public in the science of aëronautics.

Nature's Pageant: The Story of the Seasons. By Margaret Cameron. Pp. iv+120. (London: Blackie and Son, Ltd., 1911.) Price 1s.

THIS little book is an attempt to teach nature-study to children of seven years of age. They are supposed to read the simply-worded story, in which plants and animals talk, and to look at the pictures. In our judgment, nature-study lessons are of little value unless they are concerned with the observation of the objects themselves; and such attempts as are here given to combine information with imagination are not the best means of cultivating interest in literature or science.

Assaying and Metallurgical Analysis. For the Use of Students, Chemists, and Assayers. By E. L. Rhead and Prof. A. H. Sexton. Second edition. Pp. x+451. (London: Longmans, Green and Co., 1911.) Price 12s. 6d. net.

THE differences between this edition and the preceding one are not important. A few new methods are included, such as the determinations of copper and of iron by titanous chloride and the volumetric estimation of nickel by cyanide, but the text generally remains unchanged, and the merits and occasional defects of the book have not been modified. It is still one of the most useful works on the subject available.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

On the α-Ray Theory of Aurora Borealis.

IN a letter to NATURE of April 13 (vol. lxxxvi., p. 213) I gave reasons for the view that at least some of the forms of aurora borealis are caused by a type of rays which, as regards absorption by matter, follow the same law as α rays from radio-active substances. In the letter I also mentioned that the diurnal distribution of aurora apparently would require a negative charge of the rays.

My arguments which lead to a negative charge was based on the assumption that the simplest orbits, like that of (*a*), ought to occur more frequently than the more complicated, like that of (*b*), both of which are theoretically possible. This assumption, which indeed might seem legitimate, is not, however, a consequence of exact mathematical calculation, for the problem of finding the relative probability of the occurrence of the various possible orbits has not yet been solved.

Further, an exact determination of the diurnal distribution of aurora is made difficult through the effect of sun—and moonlight; but, even if we take it for granted that the aurora are most frequently found on the evening side, there is, so far as our present knowledge goes, no necessity for assuming a negative charge of the cosmic rays.

Moreover, the explanation of the thin drapery form, given by Störmer,[1] requires orbits like (*b*) having turned round the magnetic axis a great angle, and if such an orbit is going to strike on the evening side a *positive* charge is necessary. These matters will be more fully discussed in a subsequent paper.

There are some other points not mentioned in my previous note which are of considerable interest. In order to explain from the radiation theory the formation of thin drapery bands, a strictly homogeneous radiation is neces-

[1] Arch. des Sci. Phys. et Nat., 1907.

sary. Now we know that the α radiation given out during one radio-active transformation is, in fact, homogeneous.

A most peculiar property of aurora is the formation of parallel bands. It seems as if the bands were mutually connected in some way. When one band leads the others will form similar equidistant curves, and it is frequently observed that if one of the bands moves, the others will undertake a similar movement.

I think these most peculiar properties will be immediately understood if we assume each band to be produced by its own homogeneous radiation, and that the homogeneous radiations corresponding to the various bands start from the same source. If so, the various groups will be subject to the same conditions, with the exception that they will be slightly differently bent by the fields of force which they have to pass through on their way to the polar regions. If, therefore, one homogeneous bundle makes itself felt as a thin luminous band along the magnetic parallel, the rays from the other groups, having started under the same initial conditions, must give rise to bands similar in form, but with a difference in position, corresponding to the difference of stiffness of the various groups.[1]

Now the existence of homogeneous groups given out from the same source is a simple consequence of the α-ray hypothesis, because a number of different radio-active compounds will be formed through the atomic disintegration and eject groups of homogeneous α radiations.

In that way the auroral drapery bands should form a kind of *magnetic spectrum* of the α rays given out by some radio-active matter present at the sun. Thus a possibility opens out of studying and identifying the radio-active substances on the sun by examining the magnetic α-ray spectrum produced by the earth's magnetic field in the form of drapery bands.

In the following table is given the "magnetic auroral spectrum" of the radium family calculated on the assumption that the earth's magnetic field is that of an elementary magnet :—

Substance	$\phi_0=16{\cdot}5°$ d. km.	S_d	$h=120$ km. β
Radium	0	24	11·5
,, F	24	15	7·2
,, emanation..	39	25	11·9
,, A	64	69	33·0
,, C	133		

ϕ_0 is the angular distance from the magnetic axis to the radium band, which is farthest north, h is the height to which the draperies are supposed to descend, d is the distance from one of the bands to that of radium, S is the distance in km. and β the angular distance between successive bands. The draperies are supposed to be seen near the zenith at the height $h=120$ km. Any attempt at identification with actual observations is hardly possible with the material at my disposal, but such identification may be possible, *e.g.* through the development of the photographic methods. I think, however, that the values found are of the right order.

Summing up, I think we may say that, so far as our present knowledge goes, the properties of auroral drapery bands, and probably other forms of aurora, are well explained by assuming that they are caused by α rays from some radio-active substances on the sun. In order that the rays shall preserve homogeneity, it is necessary that the radio-active matter is distributed in extremely thin layers, and in such a way that the radiation gets out without traversing other kinds of matter.

The arguments in favour of the α-ray hypothesis are, in short, the following :—

(1) The straight-lined structure of the draperies is explained from the small scattering of α rays.

(2) The rapidity with which the luminosity stops at the bottom edge of the band is explained from the "range" of the α rays.

(3) The maximum intensity of the luminosity is explained from the variation of ionisation along the path of the α particle.

(4) The explanation from the radiation theory of the thin drapery bands is in favour of a positive charge, while the diurnal distribution of aurora gives at present very little information in this respect.

(5) The parallel drapery bands are explained from the fact that a mixture of radio-active substances formed by atomic disintegration gives out a mixture of homogeneous groups of α rays.

(6) Calculation of the height of aurora from the relation between velocity and range found by Bragg, Kleeman, and Geiger has shown that α rays with velocities of the same order as found for ordinary radio-active substances would get down to heights varying between 70 and 300 km., which is, indeed, the interval of height most frequently found for aurora.

(7) According to Störmer's calculations, the draperies, when formed by α rays, should appear at an angular distance of about 17° from the magnetic axis, which gives very nearly the right position of the auroral zone.

(8) Radiation of the β-ray type cannot explain the structure of the draperies on account of their great scattering, and being magnetically much softer than the α rays they do not give the right position of the auroral zone

(9) The spectrum of aurora has not yet been interpreted in terms of spectra physically known. This negative result indicates that the auroral spectrum owes its peculiarities, not so much to the gases present as to the peculiar way in which the light is produced.

In my opinion the spectrum should be produced by α rays penetrating through the upper strata of the atmosphere. It might be possible for those who possess a sufficient quantity of radium to examine the spectrum produced when α rays pass through rarefied gases.

L. Vegard.

University of Christiania, May 30.

Occurrence of a Fresh-water Medusa in Indian Streams.

Dr. Annandale's interesting announcement, in Nature of August 3, of the discovery of a fresh-water Medusa in streams of the Western Ghauts, emboldens me to mention that, at the beginning of the hot season of 1879 or 1880, I saw and handled one of these beautiful little creatures in the lake at Purulia, in Chota Nagpore.

This lake, as I remember it in those years—since when I have never had an opportunity of revisiting it—was a sheet of water of no very great size, and a maximum depth of about 24 feet, said to have been formed by damming the mouth of a wide and shallow ravine so as to catch and hold the ordinary surface drainage. Its flora and fauna were just those of an ordinary Indian "tank"; in the cold season it was used as a sort of port of call by wild-duck; and in the rainy season two little islets that rose above its waters became discordant and unfragrant nurseries of night-herons and snake-birds.

I caught the Medusa—there was only one—when taking my customary morning swim, and though I afterwards kept a look-out, I never saw another.

The few friends to whom I ever mentioned the matter always very politely changed the conversation; but Dr. Annandale's discovery now leads me to think that it might be worth while to look for medusæ in the pools of the Damuda, Subanrika, and Kasi Rivers, which run through Chota Nagpore on their way to the Bay of Bengal.

Heathlands, Belvedere, Kent. A. Alcock.

Interglacial Conditions in the South of England.

Recent observations here through excavations connected with the opening up of the district have enabled me to appreciate the importance of the letter which appeared in Nature (December 15, 1910, p. 206) from Mr. Hazzledine Warren on the "Arctic Plants from the Valley Gravels of the River Lea." He speaks of the evidence as leaving "no doubt that the Pleistocene age was closed by a partial return to glacial conditions, succeeding an epoch when temperate conditions prevailed." Reserving for the moment a discussion in any detail of the evidence now to hand in the upper Valley of the Stort (an affluent of the Lea), I merely wish, with your courtesy, to say now that the physical evidence bears out Mr. Warren's contention;

for we must, I think, recognise hereabouts a younger Boulder Clay as distinct from the "Chalky Boulder Clay" of the Herts and Essex plateau, along with interglacial deposits consisting largely of the outwashings of the older Boulder Clay.

It is easy to understand that a great latitudinal range of variations of climatic conditions in these lowland regions of south Britain would be necessarily contemporaneous with the more definitely marked *altitudinal* variations of the snow-line in the Alpine regions of Britain and Europe, whether from regional subsidence or otherwise. One may venture to say that we have here a record contemporaneous perhaps with that of the "Hessle Boulder Clay" or the "Purple Boulder Clay" (Brit. Mus. "Guide to the Stone Age," p. 8), and with the "Würm" (vierte Vergletscherung) of Alpine glaciation (Credner, "Geologie," tenth edition, p. 739); also Werth, *Globus*, Band xcvi., No. 15, p. 231).

The Anti-kathodes of X-Ray Tubes.

THE special requirements to be fulfilled by materials adapted for use as anti-kathodes are somewhat exacting, and the range of such materials is therefore limited. It is, further, unfortunate that the platinum, tantalum, &c., are in general costly, and that the expense of X-ray tubes is hence, considering their life, high. In casting about for some means of avoiding this difficulty it has occurred to me that carborundum, a material now quite familiar as an abrasive, might be a suitable facing for the anti-kathode. Carborundum, being a product of the electric furnace, is exceedingly refractory; electrically it is a very bad conductor. Messrs. Helm have constructed for me a tube fitted with an anti-kathode from a square inch of carborundum grinding slip, and I have used this tube, so far as my limited laboratory means allow, with perfectly successful results. My coil is only of low power, and I have no means of making any comparative tests of a quantitative type. It seems likely, on theoretical grounds, that the emission from such a tube would be of low penetrative power, but, so far as I can judge, the tube does not seem to pass so readily into the hard condition.

My object in this letter is to bring this matter to the notice of others who are in a position to test the properties of carborundum as an anti-kathode material. If its radiation is of a low penetrative type, such a tube might have advantages in certain superficial treatments in electro-therapeutics, *e.g.* ringworm of the scalp, &c. I should be greatly interested in hearing of any experimental trial.

The Action of Carbon Dioxide on Litmus.

I WRITE to direct attention to the inaccuracy of a common statement in elementary text-books describing the action on litmus of carbon dioxide in solution.

It is generally stated that the action of carbon dioxide is to turn litmus "wine red," while the fact is that carbon dioxide dissolved in distilled water turns neutral litmus red, just like any other acid.

The cause of the wine-red colour usually obtained is the presence of alkaline bicarbonates as impurities. That this is the case can be seen by adding a drop of ammonia or of sodium carbonate solution to the carbon dioxide solution, when the colour changes, first, from red to blue, and then, after an interval which depends on the amount of alkali added, to the wine red usually associated with the action. A weak solution of lime water acts similarly, and this would seem to give the genesis of the error, as if hard waters are used to make up the solutions the wine-red colour is produced.

The point may not be of the greatest consequence, but it does not seem to be generally known, and the columns of NATURE would seem to offer the best means of disseminating, to those whom it chiefly concerns, the knowledge of another "text-book" error.

THE BUSHONGO: AN ETHNOGRAPHICAL STUDY OF THE CENTRAL CONGOLAND PEOPLES.[1]

IT is difficult to write an adequate review of this work, the result of Mr. Emil Torday's last expedition to central Congoland (1907–9), an expedition in which he was accompanied by Mr. M. W. Hilton-Simpson and a very clever painter, Mr. Norman H. Hardy. Mr. Torday has had the advantage of the collaboration of Mr. T. A. Joyce, of the British Museum and the Royal Anthropological Institute, and Mr. Joyce has been able to bring to bear on the compilation his exceptional knowledge of negro arts, implements, customs, religious beliefs, morals, laws, social life, games, songs, and folklore.

The water-colour drawings by Mr. Norman H. Hardy are, beyond all question, the best that have ever been executed so far in Negroland. They have the absolute fidelity of photographs, with at the same

FIG. 1.—A masked dancer of the Bangongo.

time an appreciation of composition and colour which makes them really works of art. Special instances to justify this praise are:—Plate 5, a masked dancer of the Bangongo (Fig. 1); plate 7, female dancers amongst the Bangongo; plate 8, a Bangongo embroideress; plate 9, a portrait of a Bangongo blacksmith; plate 11, Shika, a young girl of the Isambo tribe; plate 12, a young Bashilele man, with the profile of an ancient Egyptian (Fig. 2); and amongst the black-and-white drawings, plate 17, a study of a native engaged in the manufacture of vegetable salt (Fig. 3), together with certain interiors of houses. Three of the plates referred to are here reproduced in a reduced form.

[1] "Notes Ethnographiques sur les peuples communément appelés Bakuba, ainsi que sur les peuplades apparentées. Les Bushongo." By E. Tordey and T. A. Joyce. Annales du Musée du Congo Belge. Publiées par la Ministère des Colonies. Ethnographie. Anthropologie—Serie III: Documents Ethnographiques concernant les populations du Congo Belge. Tome II.—Fascicule I.—Coloured illustrations by Norman H. Hardy. Published by the Museum of the Belgian Congo, Brussels.

It must have been a subject of regret to Mr. Torday that Mr. Norman Hardy's health gave way, and that he was not able to remain with the rest of the party during the whole of the expedition. Otherwise, his album of absolutely truthful pictures of life and scenery in the heart of Congoland would have been even more complete than it is. Of course, the great part of the praise which critics may bestow on this splendid ethnographical work (which, I believe, is to be completed in a further volume), will be awarded to Mr. Emil Torday, who conceived the whole plan of the expedition, is exceptionally well versed in the study of the Negro, took the greater part of the photographs which so effectively illustrate this monograph on the central Congoland peoples, and has shown himself able for some ten or eleven

FIG. 2.—A young Bashilele man (with an "ancient Egyptian" profile.)

years past to penetrate remote parts of British Central Africa and of the Belgian Congo, where other Europeans would have found it dangerous and perhaps impossible to proceed, because they did not possess Mr. Torday's unique gift of discriminating sympathy with and understanding of the savage, the semi-savage, and the half-civilised negroid.

In the region more especially covered by this monograph on the Bushongo, a few great explorers, like Wissman, Wolf, von François, George Grenfell, and perhaps most notably the American missionary, Mr. S. P. Verner, have crossed Mr. Torday's paths, and owing to their writings we were not entirely ignorant of the existence of this remarkable "Bushongo" culture in central Congoland. The Bushongo—this seems a strange plural for a more or less Bantu people, but Mr. Torday is so accurate in other matters that we presume he has interpreted it correctly—were hitherto known as the Bakuba, and as such attracted markedly the attention of Grenfell and Verner. Mr. S. P. Verner, in a rather *décousu* book, which he published some years ago on his travels in Congoland, gave some very good descriptions of this aristocratic race or ruling caste, but it is possible that in his enthusiasm for them he somewhat exaggerated their physical approximation to non-Negro, Caucasian types. He made them out, apparently, to be lighter in skin-colour and more European in features than they are actually. Yet from Mr. Torday's photographs and Mr. Hardy's paintings one realises that there is some distinct infiltration of Caucasian strain in the Bushongo or Bakuba, and in such of the surrounding populations as those with whom they have mingled their blood. Livingstone noticed this more than sixty years ago in regard to the Baluba and

FIG. 3.—Native engaged in manufacture of vegetable salt.

Alunda, commenting repeatedly on their "Egyptian" profiles.

That the Bushongo brought with them at some unknown date an exotic culture into the heart of the Congo Basin, and that with their strain of Caucasian blood they further inspired the local negroes to evolve an art which in some respects is peculiar to central Congoland, cannot be open to doubt when all the facts and traditions collected by Mr. Torday are passed in review. At the present day the Bushongo speak a somewhat degraded Bantu language, much less purely Bantu than the beautiful speech of the Baluba, or than the Kongo tongue of western Congoland, or even the Bangala of the northern Congo. But in former times the speech of the ruling caste of the Bushongo was known as the Lumbila. This language ceased to be spoken about sixty years ago, but Mr. Torday was able to collect examples of it, and submit them to the writer of this review. These words of Lumbila are repeated in the work in question alongside the degraded Bantu dialect now spoken by the Bushongo. It is at once evident that the Lumbila is not a Bantu language, though it undoubtedly possesses a few borrowed words of Bantu origin. So far as I have been able to compare the fragments of this tongue with other groups of African speech, I find the only clear indications of relationship to be with certain languages of the Shari Basin, and perhaps with that vague group of Sudanese tongues to which belong the non-Bantu languages of the Upper Mubangi. Mr. Torday points out on p. 43 that the Lumbila name for river is Chari (in modern Bushongo, Nchale), which certainly recalls the widespread term for lake or river which we find in Shari, Chade, Chada (both of them terms for Lake Chad and for the River Benue).

I have pointed out in my own work on "George Green and the Congo," that this central Sudan word for a great water has penetrated far into the Congo Basin, reappearing in the name Nzadi, often applied to the western Congo, and the Portuguese Zaire. According to tradition, when the Bushongo arrived in central Congoland from their northern home they were a naked people, accustomed to eat durra corn and other millet-like grains unknown to the forest regions. Their ancient nudity would ally them more to the central Sudan and Nilotic peoples, for, strange to say, however barbarous and savage may be all the peoples of Congoland, even the Pygmies, absolute nudity in the male is almost unheard of, and is reprehended. The word Bushongo, according to Mr. Torday, means the people of the "Shongo," and "Shongo" is apparently the name for the iron throwing-knife, which was brought by the Bushongo with them in their immigration, and which only pentrates into the more northern half of Congoland. This throwing-knife in its origin is only a modification of the wooden boomerang, and in its metal form seems to have originated in the Tibesti Mountains. Indeed, there is a good deal in the work under review, as well as in the reviewer's own researches, which tends to indicate a direct southward migration into the heart of Congoland from Kanem and Tibesti; and it is probable that from this direction comes the slight Caucasian infiltration of blood, which, as the Tibesti region of the negroid Teda or Tibu peoples, was probably Caucasianised from the direction of ancient Egypt, would explain the striking outcrop of Pharaonic face outlines occurring and recurring ever and again amongst the more aristocratic types in central and southern Congoland outside the great forests.

According to a Bushongo tradition, the first chiefs of the Bushongo (who are at present settled between the Sankuru and the Kasai) were white or semi-white, but the term white is constantly applied by the negroes to races of pale-yellow or reddish skin, like the Arabs and the Fula. Mr. Torday thinks that the southward march of the Bushongo may have been part of the same series of racial convulsions as the invasion of northernmost Congoland by the Azande (Nyam-nyam). The Bangongo and Bangende tribes, nowadays so much affiliated with the Bushongo, would seem traditionally to have arisen from a mingling north of the Sankuru River between the invading Bushongo and the pre-existing Basongo-meno, and there is obviously a relationship between the Bushongo and the Bashilele, and even an infiltration of Bushongo elements (the reviewer would add) amongst the Baluba and Alunda. Perhaps even the civilisation of the old Kingdom of Kongo, founded by a legendary hunter named Kongo, may have a Bushongo origin. It is interesting to note that a totally different Bakongo people exists in the vicinity of the Bushongo territory in central Congoland, several hundred miles separated from the better-known Bakongo of the region between the Crystal Mountains and the Atlantic Ocean. The original word Kongo seems to have meant a metal spear, and consequently a hunter, and may even be related to the term Shongo, applied to the throwing-knife.

An interesting point made by Mr. Torday was the apparent establishment of the fact that when the pygmy Batwa, of the dense forests, have been established for some generations outside these forests in the open country under the protection of the Bushongo, their stature sensibly increased, so that at last their descendants were indistinguishable in physique from the other short-legged, long-armed, prognathous forest negroes of nearly normal stature.

In a succession of chapters after the first (which deals with the origin and relationships of the Bushongo) is given a full account of the elaborate government and administration of justice amongst the Bushongo and allied peoples. The long list of court functionaries reminds one of Uganda and other equatorial African kingdoms. The social life of the Bushongo, their morality (which in some respects is very high—see the admirable moral precepts set forth on pp. 85–6), their ideas of property and inheritance, commerce, sports, dances, warfare, distinctions of relationship, and forbidden degrees of affinity in marriage, their sexual life, religion, magic, funeral customs, industries, and arts, domestic animals, agriculture, building, costume, mutilation, skin decoration (tattooing), folklore, and languages are fully described and illustrated. A great deal of space is given up to the description of the really wonderful arts and industries of the Bushongo and allied peoples—their wood-carving and their beautiful woven cloths, their metal-work (very elaborate), and pottery. The linguistic information concerning the Bushongo, Bakongo, Bangongo, Bangendi, and Basongo-meno languages, will be of great interest to students of the Bantu family. This work is, in short, splendidly complete, with one exception. It is ethnological rather than anthropological, and it would have been additionally interesting if Mr. Torday had been able to include photographs of the many types of skull that he has collected, and other pictures, measurements, and descriptions, showing more clearly the physical conformation of the various peoples he has otherwise described so minutely. From the various numerous photographs and pictures one is able to deduce to some extent what is not actually described in words—namely, the physical features of these races of central Congoland; and it is interesting to note here and there a type of physiognomy occurring which is also met with on the northern Congo and in the central Sudan, namely, quite a Caucasian type of face amongst the men, with a fairly abundant growth of beard and moustache, very bushy head-hair (except where this has been removed artificially), and little of the negro but the dark skin. H. H. JOHNSTON.

THE FRENCH ANTARCTIC EXPEDITION.[1]

ONE of the problems of most far-reaching importance in the Antarctic is the nature of the southern border of the Pacific, for while we remain in complete ignorance of its structure no theory of the formation of the Pacific, the greatest geographical unit on the globe, can be more than a provisional hypothesis.

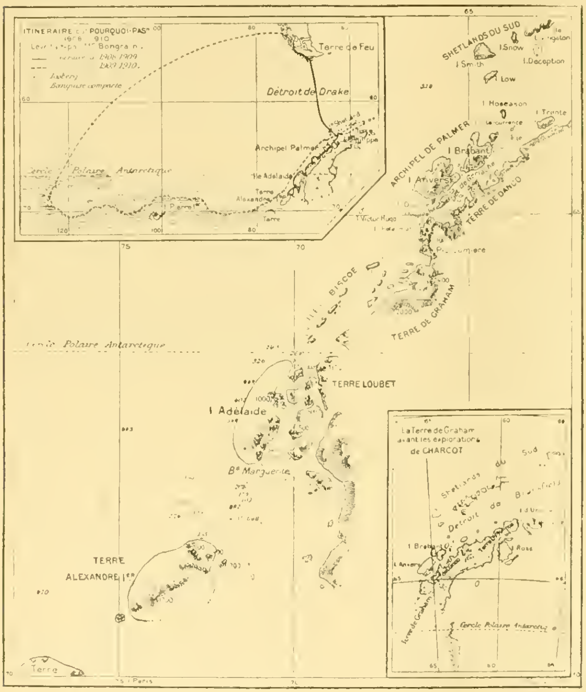
Cook's description of his view from his furthest south in the Southern Pacific suggests that he had

[1] Institut de France: Académie des Sciences. Rapports Préliminaires sur les Travaux exécutés dans l'Antarctique par la Mission commandée par M. le Dr. Charcot de 1908 à 1910. Pp. x + 104. (Paris: Gauthier-Villars, 1910).

reached the margin of an ice-clad land; but as he thought otherwise it would be rash to lay stress upon a different interpretation of the facts he described. The best clues as to the southern border of the Pacific have been obtained from Graham Land; but though the recent expeditions in that area have revealed the structure and character of the South Shetlands and of the north-western part of Graham Land, there has been no modern extension of geographical knowledge far to the south-west. The Peter I. Land of Bellingshausen, and the Adelaide Island of that stout-hearted whaler Bisco, remained the only sure evidence of the westward extension of the land.

Geographers accordingly waited with keen interest the return of Dr. Charcot's expedition, which forced its way for more than 50° westward into the unknown. A preliminary report of the results has been issued by the French Academy of Sciences, prefaced by a short summary by Prof. Joubin, of the Oceanographic Institute. Dr. Charcot describes the general course of the expedition. It left Punta Arenas, in Patagonia, on the *Pourquoi-Pas?*, on December 10, 1908. It spent the first summer in geographical and other work in Graham Land, to the west of the region so well explored by the Belgian and Swedish expeditions. It wintered on Petermann Island, one of the islands of the Palmer Archipelago, at the south-western end of Gerlache Strait. At the close of the winter it returned for stores to Deception Island, one of the South Shetlands, and was there generously supplied with coal by whalers of the "Sociedad ballenera Magellanes." The expedition thence started south-westward, and, passing Graham Land, pushed westward into the South Pacific. It passed to the north of Peter Island, and kept along the latitude of about 70° S. from 72° W. to 124° W. The end of the season and the approaching exhaustion of supplies compelled the badly damaged *Pourquoi-Pas?* to return to South America.

Dr. Charcot describes the western lands he explored as penetrated by a network of fiords filled with ice. The most important of the new lands explored is a group of islands which he calls Alexandra I. Land. Still further into the unknown he saw another land which he has left unnamed.



Course of the French Antarctic Expedition.

The results of the hydrographic, pendulum, astronomical and seismographic observations are summarised by M. Bongrain. The preliminary conclusions from the determinations of gravity at five localities differ somewhat from the theoretical results from Helmert's formula. The seismographic observations made on Deception Island are said to promise interesting results; the instruments recorded seismic storms at the winter quarters in March and September, 1909.

M. R. Godfrey contributes a report on the tidal observations, coastal hydrography, and the chemistry of the air; careful determinations of the nitrates and ammonia in the air were prepared at winter quarters. A short account of the observations on meteorology, oceanography, and atmospheric electricity is given by M. M. Rouch. The meteorological instruments were read every four hours, or more often while the ship was at sea or when more detailed records seemed desirable. The work on terrestrial magnetism and actinometry was undertaken by M. Senouque, who determined the magnetic elements at four stations—Deception, Petermann, and Jenny Islands, and Matha Bay. Dr. Gourdon describes the geological observations; he found no sedimentary rocks or fossils, but widespread igneous rocks similar to those previously recorded from the lands to the north-east. M. Jacque Liouville gives a summary of the zoological log of the expedition, which shows that a most valuable collection was made. Especial attention seems to have been devoted to parasitic zoology. The results of the dredgings during the summer voyage are described as having been very fruitful. M. Gain, the botanist, had a very limited field of work open to him on land, where he found some lichens, mosses, and the grass *Aira antarctica*; the plankton promises a rich harvest from the sea, while on shore M. Gain worked at bacteriology, and has brought back sealed preparations of fæcal matter for culture in Europe. By tying coloured badges upon some of the birds he was able to show that they not only returned to the same rookery, but to the very same part of it.

The results of most general interest were gained in the voyage into the South Pacific. The first impression is one of regret that the expedition could not follow the land in that direction, but the thick ice kept the *Pourquoi-Pas?* too far to the north. The ice conditions suggest that there is land not far to the south behind the ice-packed sea. The work in south-western Graham Land is unquestionably of great importance. Adelaide Island is much larger than its discoverer, Bisco, thought, but Graham Land, instead of extending south-westward as a continuous land, breaks up into an archipelago, or makes a sharp bend to the south-east. The lands explored clearly belong to a volcanic Andean chain, of which the coast has been penetrated by a network of fiords; but owing to the inaccessibility of the land, its composition remains less known than its distribution.

The results of the Charcot expedition suggest that Graham Land either breaks up south-westward into an archipelago, or that in the neighbourhood of Adelaide Island it curves sharply southward, corresponding to the northward curve of South America on the opposite side of Drake's Strait. Dr. Charcot's expedition, therefore, adds fresh interest to the problem of Graham Land. All interested in Antarctic research will join in Prof. Joubin's hope that the necessary funds will be provided for the full publication of these important additions to Antarctic knowledge. J. W. G.

TUBERCULOSIS AND THE MILK SUPPLY.

ON the publication of the final report of the Royal Commission on Tuberculosis the view was frequently expressed that those in authority ought, long ago, to have taken precautions against the dangers arising out of the use of milk containing tubercle bacilli. To those who have followed the matter carefully this scarcely seems to be a very rational position to assume, as, up to the publication of this report, Koch's dictum, backed by the authority of his enormous prestige, held the field. It is now recognised that Koch's pronouncement on this question was the cause of the difficulties that arose immediately after he had spoken at the London Tuberculosis Congress, and there can be little doubt that these difficulties, then foreseen, led the executive of the congress to insist so strongly on the appointment of a Royal Commission. It was evident that inspection, the use of tuberculin, the destruction of tuberculous cattle, might all be ruled out as unnecessary, if Koch's thesis that there was no danger from the presence of the tubercle bacillus was to be accepted.

Now, however, that the commissioners have reported, and in no uncertain voice, that tuberculosis, especially in the child, may be the result of infection with tubercle bacilli conveyed in the cow's milk, it is essential that the question of regulations relating to milk and meat supply should be carefully reconsidered, and that, as the commissioners put it, "Government should cause to be enforced throughout the kingdom food regulations, planned to afford better security against the infection of human beings through the medium of articles of diet derived from tuberculous animals." Also that the supply of milk from a "recognisably tuberculous cow, irrespective of the site of the disease, whether in the udder or in the internal organs, should be prohibited," as the commission has demonstrated that infection of milk may take place, not through the udder merely, but by channels through which such infection has not hitherto been followed.

This report alters entirely the whole aspect of affairs. The President of the Local Government Board is now in a very strong position as regards the tuberculosis order issued in 1909, and his own Milk Bill already drafted. Indeed, the conditions are so far changed that it is absolutely necessary that some steps should be taken at as early a date as possible to ensure the passage of legislative measures dealing with the protection and improvement of the milk supply. Hurried or "panic" legislation would, however, be unwise; a careful consideration of the whole position is necessary. On one hand are the interests of the consumer, which, in this instance, must be looked upon as of paramount importance; whilst on the other the great financial interests of the cattle breeders and dairy owners (though of secondary importance) must be considered.

In the tuberculosis order issued in 1909, but not yet brought into force, it is enacted that every person having in his possession, or under his charge, (1) any cow which has, or appears to be suffering from, tuberculosis of the udder, indurated udder, or other chronic disease of the udder, or (2) any bovine animal which is, or appears to be, emaciated from tuberculosis, shall give notice to a constable of the police force. The local authority shall then cause to be made a veterinary examination of the suspected animal, and the milk from such animal shall be kept separate and shall be boiled or sterilised. If the animal is found to be tuberculous, the local authority shall notify the owner that it is to be slaughtered. Moreover, if the owner objects, special authority must be obtained from the Board of Agriculture to slaughter.

So much for the animals themselves; and, after all, this is the point at which the question should be attacked in the first instance. It is evident, however, that until considerable advances have been made along the above lines, milk containing tubercle bacilli will still find its way into our milkshops and dairies, and regulations at least as stringent or more searching than those already in force will have to be devised in order to protect customers against milk coming from tuberculous cattle. Inspection and biological examination will, for some time, be essential, and certainly should not be neglected, as in these, probably, we have the only effective means of safeguarding the milk supply against infection from tuberculosis. It may confidently be anticipated that those in authority have already under consideration these and other points, to be attended to and included in any new measure to be brought forward.

The question of compensation is one of considerable difficulty and delicacy. How is the honest trader to be protected without at the same time making it easy for those not quite so honest to benefit at his expense? It is suggested in the tuberculosis order of 1909 that if the animal after slaughtering does not show that it was suffering from tuberculosis, full compensation as agreed shall be paid, along with a further sum of twenty shillings. If the animal is found to be suffering from tuberculosis (not being advanced tuberculosis), three-fourths of the value as agreed shall be paid, one-half of the cost of valuation being deducted. If, however, the animal is suffering from advanced tuberculosis, one-fourth of the value shall be paid, or the sum of two pounds, whichever is the greater, one-half of the cost of valuation still being deducted. It is further ordered that all suspected animals shall be isolated at once and until seen by veterinary surgeons, whilst disinfecting and cleansing shall be carried out at the expense of the owner on all premises where tuberculous animals are found.

Then, of course, the question arises, From what source shall the compensation be made? Abroad, compensation has been paid out of an insurance fund to which various authorities and individuals make contributions. The seller of the animal, the buyer, the municipality, and even the State are, in various places, put under contribution, and in a case of this kind it certainly seems reasonable that there should be some such cooperation. The farmer who sells his cattle should be prepared to pay something towards a fund that shall indemnify him for any loss that may result from the presence of tuberculosis amongst his animals. The milk dealer or butcher who runs the risk of buying a tuberculous animal, and thus of having to pay more for the food of the animal during life and of receiving a less price for the carcase after death, should be equally prepared to pay towards an insurance scheme. (Butchers' insurance associations—voluntary—have already been founded in this country.) The ratepayer, through the municipality, owes something to any scheme that protects him and his children from the dangers associated with the consumption of tuberculous milk, and even of tuberculous meat, whilst the State may well be called upon to contribute its quota towards the protection of the child, the young adult, or, in some cases, even the adults of more mature years, against the ravages of tuberculosis, one of the great factors in bringing about the diminution in the wage-earning power of the worker in the State. The whole question is no doubt now under careful consideration, and whilst it is inadvisable to press for any measures that have not been carefully considered, it must be urged that there shall be no unnecessary delay in bringing forward a Bill and putting into force a measure for the improvement of our milk supply and the protection of the consumer against infection, the reality of which has been so amply demonstrated by the Royal Commission.

SCIENTIFIC WORK IN INDIA.[1]

IN any large organisation a certain amount of subdivision is necessary to ensure economy in working, even though this may conduce to a want of connection and cooperation between the departments so formed; and when their work lies in scientific and technical fields the inevitable specialisation is likely to accentuate the evil of any such lack of cooperation, and lessen the advantages derived from the work in each. In India the Board of Scientific Advice was formed a few years ago in order that by its aid the scientific resources of the Government of India might be organised to the best advantage and their efforts concentrated on the solution of the problems which were the most urgent.

The Board held its eighteenth and nineteenth meetings in 1910, and the report for the year 1909–10 has just been published, in which contributions from the different services and departments are restricted to the scientific work coming under the various headings of the report, and do not deal with matters of departmental administration or detail. We have in consequence, within a compass of two hundred pages, a valuable summary of scientific work in India for the period under review, so far as it is covered by the departments which contribute to this report. In industrial and agricultural chemistry the work done has resulted in much knowledge gained of indigenous products and their technical applications. Reference is made to the report of a committee, appointed by the Asiatic Society of Bengal, on the adoption of a temperature of reference suitable for India, in which the temperature of 30° C. is recommended. This matter has been referred to the Royal Society for submission to the International Association of Academies in order that other countries in tropical regions may express their opinions.

The water requirements of crops have been investigated in continuation of work which has been in hand for several years, and the results are about to be published. This work and field tests at Cawnpore and Pusa have shown how great the value would be of an accurate method of determining the quantity of water which can move through soils under the influence of surface tension. Cottonseed oil was investigated in order to ascertain whether the acridity of the Indian oil could not be economically removed, and a large number of natural products were studied with a view to improving the final product. A large amount of observational work in solar physics was carried out, and advantage was taken of Halley's comet being favourably situated in April and May, 1910, to photograph the comet and its spectrum. In meteorology Mr. Field's experimental work with recording balloons resulted in more than half of the seventeen sent up in the monsoon season being recovered, but only one of those liberated in December was regained. In the present year, following that of the report, it is proposed to liberate two recording balloons weekly at Jhang in the Punjab, and to continue the search for relationships between the seasonal variations of weather in different parts of the earth, which has already produced instructive results.

In terrestrial magnetism a survey of the Andaman and Nicobar Islands is proposed as the work of the following year. Some of the geological work referred to has already appeared in the publications of the department, and an exhaustive memoir on the Triassic rocks of the Himalaya by Dr. C. Diener is about to appear. The map of the Raniganj coalfield has been revised, and much additional information relating to the underground correlation of the coal seams has been gained. Reports of coal in Sikkim were proved to be baseless, the rock being but a black carbonaceous shale greatly crushed. Advice on such matters as the suitability of building sites, irrigation dam sites, sources of suitable road metal, and the prospect of increasing a subsoil water supply by deeper boring was widely given.

In geodetic work operations were carried out in northern Baluchistan, Kashmir, and in Upper Burma on the lines of former years, but an innovation is the employment of secondary triangulation with 8-inch micrometer theodolites to fill in between the principal series instead of the third order network, which has hitherto been used. This improved grade of work will furnish permanent stations for the control of the periodic re-surveys which become increasingly necessary, and which are often required to be on larger scales than in the past. Gravity work was directed to testing the suitability of Hayford's method to the results obtained in India, and so far as work has gone his correction serves to intensify the anomalies in regions like the Indo-Gangetic plain.

In botanical survey work on the catalogue of the non-herbaceous flowering plants cultivated in the Royal Botanic Garden has been continued, the numerical index of the first 4000 plants being completed, and another 4000 being in the press. From Burma and southern India large accessions of material have been received by the Calcutta herbarium. Economic botany records a large amount of work done on the improvement of the wheat crop, not only in the field, but investigation has been carried into the mill and the bakehouse. The questions involved are of the greatest importance, and the results already obtained are of great value. Mycological studies of various plant diseases of tea in Darjeeling, of palms in Madras, of sugar in the Godaveri delta, are all instances of the value of scientific research suitably directed and coordinated.

The whole report presents a valuable survey of the application of science to many problems related

[1] Annual Report of the Board of Scientific Advice for India for the Year 1909–10. Pp. iv+210. (Calcutta: Government Printing Office, 1911.) Price R. 1 or 1s. 6d.

directly or indirectly to the inhabitants of India, and shows how much is gained by effective organisation and cooperation. We could wish that similar co-operation of scientific and technical work existed in all regions, as it already does in some, since it not only favours efficiency and economy, but also provides a useful summary of results obtained, which are often hidden in the administrative detail and statistics of an annual progress report, though they may appear subsequently in a detailed publication.

EARTHQUAKE STUDIES.

THE last two bulletins of the Imperial Earthquake Investigation Committee (vol. iv., No. 2, and vol. v., No. 1) are each from the pen of Dr. F. Omori. The second memoir deals with the eruption of Mount Usu, in Yezo. This began at the end of July, 1910, and resulted, amongst other things, in the formation of about fifty craterlets parallel to a lake shore. The highest of these was about 700 feet. As these were formed, not only did the shore of the lake rise, but there was a rapid upheaval of ground to form a new mountain. This approximately reached to the same height as that of the craterlets, when its growth suddenly ceased. A curve of barometric pressure and another of earthquake frequency in the vicinity of the mountain, but prior to its eruption, shows that premonitory shocks began when atmospheric pressure was least, and that the first volcanic explosion occurred when it was at a maximum. The frequency of volcanic after-shocks does not appear to have followed that which is usually followed by the after-shocks of a large earthquake. Dr. Omori points out that there are many instances in Japan where volcanic eruptions have been preceded by numerous earthquake shocks and "jinaris" (earth-sounds). Whenever this is the case, tromometer and seismograph observations should give warning of an approaching outburst.

Fig. 1.—The Craterlets Group opposite the New Mountain, seen from the east. The cone at the extreme left end is the "Taka-Ana," and that at the right side is the "Fuji-Yama." To the right-hand side of the figure is shown the inside, or the dislocation plane, of the "New Mountain."

The first relates to the vibrations of railway-bridge piers and trusses. The period of transverse and longitudinal vibrations of piers 82 feet in height was found to be from 0·2 to 0·4 second. As this is much shorter than that of a destructive earthquake which is from 1 to 1·5 seconds, the inference is that in a great earthquake these piers would be expected to fracture at their base.

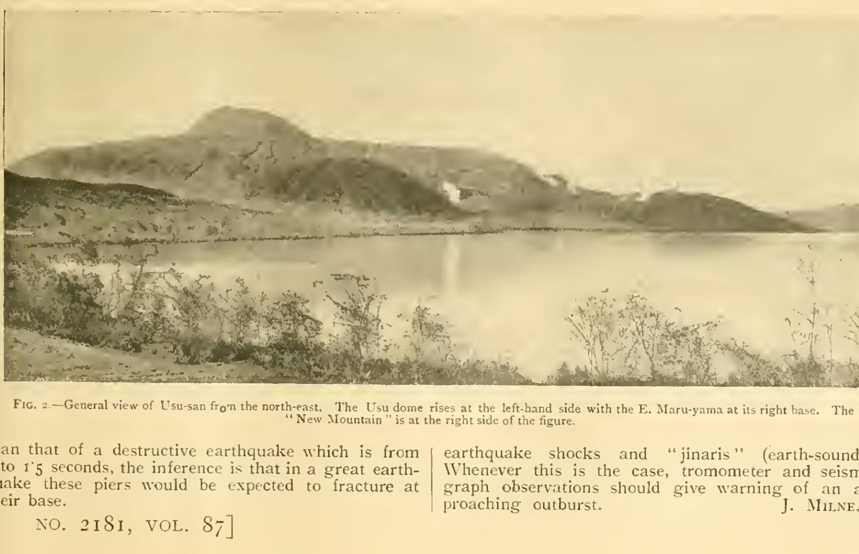


Fig. 2.—General view of Usu-san from the north-east. The Usu dome rises at the left-hand side with the E. Maru-yama at its right base. The "New Mountain" is at the right side of the figure.

J. Milne.

THE LIBRARY AND THE SPECIALIST.

THIS is the age of the specialist. There is scarcely any branch of science in a review of which it would be inappropriate to remark that "the literature of this important section of the subdivision to which we allude is already assuming enormous dimensions." The published mass of scientific research is accumulating in ever-increasing volume. The investigator, especially when the circumstances of his life are such that he lives remote from intellectual centres, is generally exposed to the danger of working either along lines inferior to those already followed by predecessors in the same field, or in a direction which has been shown to lead to barren results. During his hard-earned leisure he may have been spending his energies upon work of research, only to discover at a later stage that he has been anticipated. The philosopher will murmur, "Comme les beaux esprits se recontrent!" The man of modest temperament will say resignedly, with one of Hermite's correspondents, "Je suis prédestine, semble-t-il, à découvrir des théorèmes connus!" More ordinary mortals will exclaim, each with his own degree of vehemence: "Pereant illi qui ante nos nostra dixerunt!" In each case time has been wasted, and it may be that science has suffered.

De Morgan has somewhere said that the history of science is in the main the history of books and manuscripts. If this were true in the days of that accomplished bibliographer, to whose untiring efforts the student of the history of mathematics in the 'forties and 'fifties of last century was so profoundly indebted, it is even more so now if we consider the cosmopolitan character of the development in every department of intellectual activity. It is becoming more and more imperative that the work of investigators in any branch of science shall not be impeded by causes which, by a mere effort of cooperation, may be effectually and for all time removed. The organisation of scientific research has of late years been the text for many sermons from the leaders of opinion, and the problem of its most effective promotion is slowly and surely assuming that ultimate form which will secure the solution. We wish to direct attention to what some may consider a minor detail, but as it concerns the working specialist—and he is not always articulate—we make no apology for bringing once more to the front the relations between the libraries of the country and the investigator.

In NATURE (Feb. 15, 1906, p. 372) we referred to a paper published by Dr. Muir in the Proc. Roy. Soc. Edinburgh (Dec. 18, 1905), in which the historian of determinants indicated his reasons for the belief that "under existing circumstances mathematical research can only be pursued in Scotland with difficulty and uncertainty, and that research in mathematical *history* is practically an impossibility. . . . There can be little doubt that other subjects are in as bad a plight, and that the whole question of library aid is worth serious and prompt attention from all scentific men." In the current number of the *Quarterly Journal of Pure and Applied Mathematics*, on presenting his "Fifth List of Writings on Determinants," Dr. Muir returns to the charge, and laments that practically nothing has been done in the way of improvement, so far as London is concerned, for the last five years. He finds that the large *general* libraries—*e.g.* those of the British Museum, the Royal Society, South Kensington, University College, &c.—are "surprisingly well supplied with mathematical works and are reliably cared for." On the other hand, there is "no self-sufficient reference-library for mathematicians," and "the libraries that have a partial mathematical equipment are as far as ever from entering into cordial cooperation with one another for the purpose of providing a reasonable substitute." The library of the London Mathematical Society is "poorly housed, poorly cared for," and "has many of its serials imperfect." The library of the Mathematical Association is practically valueless, has no home of its own, and does not even possess a printed catalogue, though this blemish, we understand, is to be remedied. In all cases the main faults are redundancy and deficiency. One great failing is the imperfection and even the absence of series of mathematical periodicals. For instance, the only sets to be found in the country of recent volumes of the *Periodico di Matematico* with its supplements, of the *Journal de Mathématiques Spéciales et Elémentaires*, of the *American Mathematical Monthly, L'Intermédiaire des Mathématiciens*, and *Wiskundig Tydschrift* were after some search discovered in the hands of a private individual. As for the *Monatshefte, Rivista di Fis. Mat.*, &c., and *Math. is Phys. Lapok*, Dr. Muir had, we are inclined to think, to make a pilgrimage to the Continent to consult them for his purpose.

This is a state of affairs that is little to our credit. Surely the time has come to remove these impediments in the way of the working specialist! Until we possess a "self-sufficient" mathematical reference library it ought to be possible to do something to the point by proper cooperation between our libraries, general or otherwise. To diminish duplicates by exchange or gift, to complete imperfect sets of serials, to keep on hand an up-to-date list of serials in which they are deficient, with a list of the libraries where they may be found—this is the least that each library ought to do, and if the matter were properly organised it might be done in a few months, so far as mathematics is concerned. The longer it is delayed, the more difficult will it become to place within reach of the working specialist the mere tools of his trade. There is little doubt that in other branches of science than mathematics there will be many who will bless Dr. Muir for thus directing attention to this serious blot upon our *organisation* of scientific research. The matter appeals to all who are interested in the advancement of science. Miserably inadequate as are the funds at the disposal of the British Association for that object, we cannot help feeling that here at any rate a small grant in aid would be well spent, and would be productive of fruitful results.

FLIES AS CARRIERS OF INFECTION.[1]

THIS report contains further work on the importance of flies in the conveyance of disease parasites.

The first report, by Dr. Copeman, Mr. Howlett, and Mr. Merriman, deals with the range of flight of flies. In July last year Postwick, a small village five miles east of Norwich, experienced a plague of flies. No special conditions existed in the village for the breeding of the flies, and attention was directed to a refuse depôt about half a mile distant. The opportunity was taken to ascertain to what distance flies may travel and whether the flies in Postwick were derived from this refuse heap, and, if so, whether the flies were merely attracted to it from the surrounding country or whether they were distributed from it as a breeding centre. For this purpose flies were caught in various localities, marked by being shaken with coloured chalk powder, and liberated; subsequently some of the flies were recaptured. The experiments showed that the flies were distributed from the refuse

[1] Further Reports (No. 4) on Flies as Carriers of Infection. Reports to the Local Government Board on Public Health and Medical Subjects. (New Series, No. 53.)

heap as a breeding centre, and that they may travel as far as 1,408 yards from the place of liberation.

Mr. E. E. Austin contributes the second memorandum on the species of flies present at Postwick; the great majority consisted of the common house-fly. The part played by flies in the dispersal of the eggs of parasitic worms is the subject of the third report, by Dr. William Nicoll. Many experiments were performed, and it is shown that the ova of several worms may be conveyed by flies, the ova in some cases being ingested, in others merely sticking to the surface of the body. Those adhering to the body are generally got rid of within a short time, but when ingested they may remain for two days or more in the intestine. The habit of flies of feeding in turn on excrementitious material and on human foodstuffs obviously suggests that house-flies may play a part in the dissemination of infection of parasitic worms. Dr. Graham-Smith describes further observations on the distribution of bacterial infections by house-flies and blow-flies. It is definitely shown that both are capable of infecting fluids, such as milk and syrup, on which they feed and into which they fall. With house-flies gross infection may be produced for at least three days, and a smaller degree of infection for ten days or more. Blow-flies may carry the infection longer—up to three or four weeks.

The reports, in addition to the observations recorded, contain summaries of previous work on the subjects with which they deal, and form valuable contributions. R. T. H.

NOTES.

CONSIDERABLE progress has now been made with the arrangements in connection with the forthcoming meeting of the British Association at Portsmouth. Suitable meeting rooms have been found for nearly all the sections within about seven minutes' walk of the reception room. The programme of entertainments and excursions promises to be very attractive, and includes a naval display at Whale Island, steamer trips and coach drives in the Isle of Wight and in the South Downs, where visits will be made to Arundel Castle, Goodwood House, West Dean Park, and Parham Park. The following corresponding members and foreign representatives have announced their intention to attend the meeting:—Prof. Cleveland Abbe, U.S. Weather Bureau, Washington; Prof. Carl Barus, Brown University, Providence R.I., U.S.A.; M. A. Gobert, Brussels; Prof. A. A. Michelson, The University, Chicago, U.S.A.; Prof. W. Ostwald, Leipzig; Prof. Otto Pettersson, Stockholm; Prof. F. W. Clarke, U.S. Geological Survey, Washington; Prof. W. J. Humphreys, Mount Weather, Va.; Prof. H. Freundlich, Leipzig; Prof. Albin Haller, Paris; Prof. E. J. Cohen, Utrecht; Prof. R. Wegscheider, Vienna; Prof. Hans von Euler, Stockholm; Prof. P. Zeeman, Amsterdam; Prof. J. W. Spencer, Washington; Prof. Caullery, Paris; Dr. Johan Schmidt, Copenhagen; Dr. P. P. E. Hoek, Haarlem; Prof. H. Jungerson, Copenhagen; M. Chas. Lallemand, Paris; Dr. F. Graebner, Cologne; Prof. H. Webster, Nebraska; Dr. A. Goldenweiser, Columbia University, Missouri; M. A. van Gennep, Seine; Prof. N. Zuntz, Berlin; Prof. Behal, Paris; Prof. H. J. Hamburger, Gröningen; Prof. H. C. Cowles; and Prof. A. A. Noyes.

THE drought and excessive temperature of the present summer continues with great persistence, and if it had not been for the rains which fell generally over the country during the latter half of June, the season would have been practically rainless. The dry weather has embraced nearly the whole of England, although probably it has been most pronounced in the Midland and south-eastern districts, where the aggregate rainfall so far for the summer is only about 50 per cent. of the average. In Scotland and Ireland occasional rains have fallen, as shallow disturbances have skirted our northern and western coasts on their passage from the Atlantic. At Greenwich the aggregate rainfall since the commencement of July only amounts to 0·32 inch. The absence of cloud has resulted in an abnormal amount of sunshine, and the rays of the sun have been exceptionally fierce, and on at least three occasions this summer the black bulb thermometer at Greenwich has exceeded 161°. In the south-east of England the duration of bright sunshine for the first ten weeks of summer was 668 hours, which is 184 hours more than the average. The shade temperature has exceeded 80° at Greenwich on thirty days between July 1 and August 14, and 90° has been exceeded on five days. The shade temperature of 100° at Greenwich on August 9 is the highest authenticated reading in London since trustworthy records commenced in 1841, and is 3° higher than any previous reading at Greenwich, the previous record being 97·1° on July 15, 1881. There have in all only been three days since 1841 with the temperature above 95°; these were 96·6° on July 22, 1868; 97·1° on July 15, 1881; and 95·1° on August 18, 1893. The temperatures in other parts of London on August 9 were also a record, and the same occurred in many parts of England. A reading of 98° was recorded at Epsom and Canterbury, and at Raunds in the Midlands, 97° at Hillington, and 96° at Marlborough, Fulbeck, and Lincoln. In France and Germany the heat has also continued to be excessive. On Tuesday, August 15, there was a cooler air generally over England, and in London the highest temperature was 75°, which is the lowest day maximum for a month.

MR. C. E. ADAMS, of the Department of Lands, New Zealand, has been appointed astronomical observer at Wellington in succession to Mr. T. King, who has resigned.

MR. T. SOUTHWELL, scientific adviser to the Ceylon Company of Pearl Fishers, Ltd., and Inspector of Pearl Banks, Colombo, has been appointed (by the India Office) Deputy Director of Fisheries, Bengal.

THE council of the Royal Statistical Society of London has awarded a Guy medal in gold to Mr. G. Udny Yule "for his extraordinary services to statistical science, for his valuable contributions to the Transactions of the society, and for the special work done by him in the interests of the society."

THE geological and archæological collections made by the late Rev. E. Maule Cole, all the objects of which are connected with East Yorkshire, have been presented to the Hull Municipal Museum by Lady Philadelphia Cole.

THE appointment of Mr. F. W. Taylor, of Denver, Colorado, as Director of Agriculture in the Philippines, is expected to mark the beginning of the application of scientific methods to the cultivation of land in those islands. Mr. Taylor was professor of horticulture in the University of Nebraska from 1891 to 1893. He superintended the departments of agriculture and horticulture at the expositions at Omaha in 1898, Buffalo in 1901, and St. Louis in 1904. He has lately been occupied as an irrigation engineer.

THE council of the Institution of Civil Engineers has made the following awards in respect of students' papers read during the session 1910–11:—the "James Forrest" medal and a Miller prize to Mr. D. Hay (Birmingham), and Miller prizes to Messrs. D. A. Howell (Bristol), R. Bonner (Bristol), G. F. Walton (London), R. G. Parrott (Manchester), E. E. Farrant (London), A. C. Dean (Manchester), H. W. Coales (Birmingham), A. H. Meade (London), A. C. Swales (Leeds), and H. J. F. Gourley (Manchester).

In connection with the celebration of the tercentenary of the Authorised Version of the Bible (1611–1911), a special exhibition, illustrating the natural history of the Bible, has been arranged on the east side of the central hall in the Natural History Museum, Cromwell Road, London. Printed descriptive labels have been attached to the exhibits, which comprise all the animals, plants, minerals, and precious stones mentioned in the Bible. A guide book to the exhibition has been prepared, and is on sale, price 6*d.* (postage 2*d.*). The exhibition is open to the public free daily.

The Manchester Microscopical Society has arranged, as in previous winters, to provide through its Extension Section lectures and demonstrations of a popular character on scientific subjects. The lectures are arranged for delivery in and about Manchester. The cost, as a rule, is limited to lecturers' expenses, which in most cases do not exceed a few shillings. The work of lecturing and demonstrating is entirely voluntary and gratuitous on the part of the members of the society, but hire of slides, travelling, and out-of-pocket expenses are charged, and in some cases an additional small fee for the lecture is asked for. The list of lectures includes sixty-five subjects, most of which deal with the biological and geological sciences. Secretaries of societies desirous of including lectures on nature subjects in their syllabus may receive a copy of the lecture list on application to the honorary treasurer and secretary, Mr. R. Howarth, 90 George Street, Cheetham Hill, Manchester.

The Technical Museum in Vienna, which is nearing completion, was initiated by Austrian manufacturers, with the assistance of the State and of the city of Vienna, to commemorate the sixtieth anniversary of Emperor Francis Joseph's reign. The foundation-stone was laid on June 20, 1909, and the building, which is situated opposite the palace of Schönbrunn, covers an area of more than 20,000 square yards. The museum will demonstrate chronologically the development of industries and crafts, illustrate the technical achievements of the present day, and by periodical exhibitions stimulate and promote future progress. In other words, it is intended as an educational centre to spread a knowledge of science and technology from the point of view of national welfare. Considerable progress has been made in stocking the museum, and several large and valuable State collections have been secured already. The historical sequence in the development of pure and applied science is not yet completely shown in the exhibits available for the museum, and the authorities appeal to men of science, technologists, manufacturers, and craftsmen in all countries to assist them in procuring suitable objects for the museum. Everything pertaining to technical labour will be acceptable, principally tools, machines, apparatus, models, materials, methods of working, finished articles, as well as plans, designs, books, illustrations, and manuscripts. The names of donors will be recorded by inscription on the gifts and in a memorial book. Further particulars can be obtained from the office of the Technical Museum, Vienna, I. Ebendorferstrasse 6.

Mr. Noel Buxton, M.P., and Mr. J. H. Whitehouse, M.P., have issued a memorandum relating to the formation of an "Inshore Fisheries Parliamentary Committee," which has made certain proposals to the Board of Agriculture and Fisheries apparently with regard to the administration of the Development Fund. It is proposed that a sub-department of the Board, consisting of "Inshore Fishery Commissioners," should be established, and that this body should administer a grant of money for the purposes of local cooperative societies for purchasing boats and gear, and for insurance; credit banks; loans; the circulation of information, such as means of transport and distribution; the cultivation of shell-fish and the provision of foreshore allotments, and the policing of the territorial waters. The prosecution of scientific investigation is not suggested; and since the committee remarks that even the best of the fishery committees "are unable to prevent injury to the spawning beds," it is evident that it passes over the fishery research of the last twenty years. The objects of the memorandum are excellent, but it is quite certain that some of them cannot be carried out economically and efficiently without great familiarity with local conditions and a certain amount of scientific research; and this information, with the organisation for increasing it, already exists in the case of several of the better equipped fisheries committees. There are parts of the coasts of England and Wales where fishery research and regulation have never been adequately developed, and a good deal might be said in favour of applying the proposals of the Parliamentary Committee to these neglected inshore areas; but it is difficult to understand why all the organisation for local investigation and control, built up laboriously during the last twenty years by some of the district committees, should be ignored, and the problem of improvement of the inshore fisheries tackled again in apparently a *de novo* manner.

We learn from *The Japan Times* that the Imperial Academy of Japan has awarded a medal and testimonial to Dr. Kimura for his discovery of the term in the variation of latitude which is generally known by his name. This is the first award under a benefaction which the Academy owes to the Emperor. As at present understood, the complete expression for the variation of latitude at a station in longitude λ is

$$x \cos \lambda + y \sin \lambda + z,$$

where x and y are the rectangular components of the displacement of the pole on the earth's surface relative to its mean position. The third, or z term, which was discovered by Dr. Kimura and is the subject of the award, is annual in period and independent of the longitude of the station. Dr. Chandler therefore sought to explain it as a result of the mean parallax of the stars observed, but found on examination that not more than one quarter of its amount could be accounted for in this way. The nature of the term points to an apparent and unexplained oscillation of the centre of inertia of the earth with a semi-amplitude of 4 or 5 feet. The addition of two observing stations in the southern hemisphere, one in West Australia and the other in the Argentine, to the six international stations previously established in the northern hemisphere, has corroborated the objective reality of the phenomenon, which still presents, therefore, an extremely interesting problem in geophysics. On the occasion of the presentation to Dr. Kimura a lecture was delivered by Prof. Nagaoka, in which he recounted the circumstances in which the discovery was made. The observations made at Mizusawa, the latitude station in Japan under the charge of Dr. Kimura, were suspected of inaccuracy, but the most careful examination failed to reveal the source of error. Finally, Dr. Kimura was able to prove that the errors were not due to an instrumental or personal source, but arose from a cause affecting all the stations alike. He thus vindicated his accuracy as an observer, and discovered what appears to be a very remarkable phenomenon at the same time. The circumstances are of a piece with the whole history of our knowledge of the variation of latitude; and this is perhaps natural enough, since it is entirely a question of residual phenomena only revealed by observations of the highest order of accuracy.

In *The Athenaeum* of August 12 Prof. W. M. Ramsay reports a very interesting and important archæological discovery, which will hereafter throw much light on the religion of Asia Minor. This is the holy place of Men Askaenos at Pisidian Antioch. The site contained no temple, but only a great altar standing in an enclosure surrounded by a massive wall. The shrine has clearly remained in the state in which it was left by the Christians when they destroyed it in the fourth century. No other primæval sanctuary on a mountain top, dedicated to a known god and famous throughout Asia Minor, has ever been discovered. The sacred way with votive reliefs on the rocks, the wall of the precinct covered with votive dedications to Men Askaenos, the church built of materials collected from the shrine, the theatre of the Hellenistic or Roman period, present a combination of interesting archæological remains without parallel in this region; and the shallowness of the soil renders excavation particularly easy. It may be hoped that funds for the excavation of this unique sanctuary will soon be provided, and the work carried on by some of the scholars who have been trained by Prof. Ramsay in archæological research in Asia Minor.

The third season's investigations, conducted at Avebury by the British Association under the superintendence of Mr. H. St. George Gray, commenced in April last. The results of the work supply further corroboration of the conclusions already arrived at that the "temple" dates from the Neolithic stone period. This is shown by the discovery of two worked red-deer antlers, a finely chipped flint knife, and fragments of prehistoric pottery. This last is formed of a coarse, thick black paste containing grains of various substances introduced to bind and strengthen the ware, such as pieces of burnt bone and tiny bits of charcoal. Its chief interest lies in the fact that it is ornamented on both faces, the impressions of twisted grass, or cord, and finger-nails being clearly defined. This pottery was found about $5\frac{3}{4}$ feet below the surface. At a lower depth, but still below the Roman stratum, another form of vessel was discovered, ornamented in a herring-bone pattern, which was impressed by means of a notched implement of wood, bone, or antler, or by a shell with its natural ribbing. This pottery is identical with specimens found in the West Kennet long barrow, at Peterborough, on the Thames at Mortlake, and in General Pitt-Rivers's excavations at Handley, North Dorset. The date of the Avebury circle seems to be definitely fixed by these discoveries.

The Hittite Excavations Committee, the honorary treasurer of which is Mr. R. Mond, Coombe Bank, Sevenoaks, has issued an appeal for assistance in archæological research in certain parts of Asia Minor and northern Syria. Much information has already been collected regarding Hittite civilisation by the excavations at Boghaz Keui, the capital of the great Hittite kings in the fourteenth and thirteenth centuries B.C. Numerous clay tablets have been discovered here which will throw welcome light on the relations of the Hittite Empire with Assyria on the east and Palestine, the Ægean, and even Egypt on the west. It is now proposed that excavations shall start on the great mound at Sakje Geuzi, which lies four days' journey eastward from Adana, near Tarsus, and on an ancient route between the east and west by way of Carchemish and the Cilician Gate. Prof. J. Garstang, who will take charge of the operations, has already made some preliminary excavations on this site, and has discovered a palace with sculptured portico which promises to contain most interesting material, possibly that bilingual inscription which would solve the riddle of innumerable documents.

The Scientific American of July 22 contains an appreciative notice, accompanied by a full-page portrait, of Prof. Henry Fairfield Osborn, who, it appears, takes his second name from the Connecticut town in which he was born in 1857. In the course of the article reference is made to the strong support accorded by Mr. Osborn to the tritubercular theory of the evolution of mammalian molars, and likewise to his investigations into the phylogeny of the titanotheres of the American Tertiary.

The so-called British bird-fauna has just been augmented by another subspecies in the shape of the Alpine ring-ouzel (*Turdus torquatus alpestris*), of which, as recorded by Mr. M. J. Nicoll in *British Birds* for August, a specimen was shot at Guestling, Sussex, on May 23. This race, which ranges from central and southern Europe to the Balkans, differs from the typical form by having more white on the secondary quills, and the presence of large median patches of white on the feathers of the breast and chest, and of white streaks on the under tail-coverts. The more eastern *T. t. orientalis*, which ranges into Egypt, is intermediate in colouring between the typical and Alpine races.

No. 3 of the first volume of the Records of the Canterbury Museum, New Zealand, is devoted to a continuation of the account of the zoological results of the New Zealand Government trawling expedition of 1907, Mr. E. R. Waite dealing with the fishes, Mr. H. Suter with the molluscs, and Mr. C. Chilton with the crustaceans. In a summary of the results of the expedition Mr. Waite directs attention to their bearing on the supply of local food-fishes. One of the results is the marking out of areas suitable for trawling; and although there appears to be no evidence of commercial trawling having in consequence been undertaken on an extended scale, it seems that the favourable report as to the potentialities of the Chatham Islands for line-fishing has been effective in attracting capital to what it is hoped will prove a profitable venture.

We have received copies of six guides to the Grange Wood Museum at Croydon and its various sections, written by the hon. curator, Mr. E. A. Martin. Unfortunately, at least some of these lack that accuracy and "up-to-dateness" which are of such prime importance in publications of this nature. On the first page of the Guide to the Back-boned Animals we find, for instance, the statement that the Chordata (in its restricted sense) includes the sea-squirts and the lamprey, instead of the sea-squirts and the lancelet. In a reference on the same page to the notochord, the author assumes his readers to possess more knowledge than they are likely to have acquired. On p. 8 the statement that the constituent bones of the chelonian shell articulate by means of teeth is misleading, while on the next page readers are led to believe that chameleons are restricted to N. Africa. The classification of both birds and mammals is quite obsolete; it is stated that there are only two kinds of monotremes, Edentata is misprinted Endentata, and the *horns* of antelopes are referred to as *antlers*. In the Shell Guide Lamellibranchiata is spelt with two m's, and Spondylus is included among gastropods; and, to take one example from the Fossil

Guide, we are told that Dolichosaurus was still in existence in the Chalk, whereas it is only known from that formation.

In part ii. of the Proceedings of the Zoological Society of London, published in June, Dr. W. N. F. Woodland has published a thesis "On the Structure and Function of the Gas Glands and Retia Mirabilia associated with the Gas Bladder of some Teleostean Fishes." The structure of these bodies is well illustrated by eight coloured plates, and an ingenious hypothesis is advanced to explain the remarkable conformation of the well-known rete mirabile duplex constantly associated with the gas gland (oxygen gland). The general theory put forward to explain the actual mode of production of oxygen by the gland—a very interesting physiological problem—is, we notice, almost entirely based upon the study of stained microscopic preparations, and thus lacks the essential support only to be derived from physiological experiment. The author, however, has recently investigated the physiological aspect of the subject at Plymouth, and has supplied an account of the results obtained in a further paper to be read before Section I at the forthcoming meeting of the British Association at Portsmouth.

Prof. Hans Driesch's essay "Die Biologie als selbständige Grundwissenschaft und das System der Biologie," almost entirely rewritten, has appeared in a second edition (Leipzig: Wilhelm Engelmann, price 1.20 marks). The book is issued as "Ein Beitrag zur Logik der Naturwissenschaften," and is a clear statement of the value of the interaction of philosophy and biology.

The new volume (xliii., 1 and 2 Heft) of the *Morphologisches Jahrbuch* (Gegenbaur) contains, among other memoirs, a detailed account of the spinal cord of the dugong, by Drs. Dexler and Eger. The simple segmentation of the body of the animal and its adaptation to aquatic life are found to be reflected in the cord, which is almost uniformly segmented, and exhibits no trace of thickening in the lumbar region; there is, however, some shortening in the cervical portion. The form, size, stainability, position, pigment, tigroid substance, nuclei, and processes of the nerve cells do not present any special peculiarities. Dr. Hans Bluntschli describes an abnormal pelvis of a female Java ape (*Macacus cynomolgus*), which exhibits differences from the normal similar to those shown by a human "Naegele pelvis." Dr. K. Ogushi contributes the first instalment—the description of the skeleton—of his account of the anatomy of the Japanese three-clawed turtle (*Trionyx japanicus*).

Prof. Raymond Pearl deals in the current number of *Scientia* with biometrical ideas in biology, their significance and limitations. He points out that the real purpose of biometry is the general "quantification" of biology, that the biometrical constants (mean, standard deviation, coefficient of correlation, &c.) are constant characters of the "group" (for instance, a species) as such, and that the shape of the variation curve for the particular group of organisms is a definite character for the group. Biometry furnishes, in fact, a valuable and refined extension of the descriptive method; but it must not be applied loosely; it is necessary to use in its application as much general "biological intelligence" in regard to the significance of the problem attacked, the validity of the assumptions made, and the applicability of the methods to the particular problem as would be exercised in an investigation by any other method.

The second Heft of vol. xcviii. of the *Zeitschrift für wissenschaftliche Zoologie* comprises three memoirs. Herr Rungius gives a detailed account of the anatomy and histology of the alimentary canal, larval and adult, of the water beetle *Dytiscus marginalis*. Dr. Gustav Fritsch describes the histology of the eye of a fruit bat (Pteropus) from Sumatra. The remarkable point in the structure of the eye is the presence of finger-like processes extending from the choroid into the middle layer of the retina. The author regards these as comparable to the pecten of the eye of birds, and attributes to them a nutritive function and the *rôle* of regulating pressure in the eyeball. Herr Kapzov has investigated the intimate structure of the cuticle of insects, and finds that it has a honeycomb appearance, due partly to variations of pressure during its formation, and partly to varying activity of the hypodermis cells which secrete it.

Among the articles in the July issue of *The Popular Science Monthly* is one by Mr. A. H. Thayer on concealing coloration, the writing of which was prompted, in the first instance, by certain statements in Mr. Roosevelt's recent book on African animals. Mr. Thayer holds that it is the rule for animals to be coloured like the background which most concerns their feeding and escaping attack; but the human observer, in order to experience the concealing effect of such marking, must look at the animals from the same level as their normal enemies; in many cases he must look *up* to them from near the level of the ground. The reed and sky markings of zebra and oryx make it difficult to distinguish them, in their usual surroundings, by night as well as by day. Prof. Montgomery advocates the expansion of the usefulness of natural history museums. He holds that they should be centres for instruction in taxonomic work, which can be better undertaken there than in university laboratories. Under such an arrangement, taxonomic collections and courses may well be abolished from universities. He also enters a plea for increased opportunities for research by the staffs of museums.

The July number of *Tropical Life* is devoted to an account of the rubber exhibition recently held in London. An important feature was the excellent quality and appearance of certain samples of Castilloa, Funtumia, and Ceara rubber. Castilloa rubber from Mexico was shown in block, sheet, and crêpe forms; Funtumia and Ceara were sent from the Gold Coast as "biscuit," as well as in balls. Specimens of Castilloa from Tobago, comparing favourably with sheet Para, received general commendation.

Noteworthy among the numerous diagnoses of new plants, chiefly from tropical Africa and Asia, published in the *Kew Bulletin* (No. 6), are the descriptions of two species of Impatiens from Malaya, communicated by Sir Joseph Hooker; *Impatiens peltata* is distinguished by its peltate leaf, and *I. Vaughanii* bears characteristic sepals. Another important determination is supplied by Dr. O. Stapf of a lawn grass, locally termed blue couch, that has found favour in some coastal districts in New South Wales. The author refers it to *Digitaria didactyla*, specimens of which he has also discovered from Madagascar and Tonkin. It grows more strongly than *Cynodon dactylon*, which is generally employed for lawns in the colony, and is said to possess other advantages.

Prominence is accorded to a contribution by the eminent zoologist Prof. E. Giglio-Tos in the *Botanisches Centralblatt* (July 15), in which it is claimed that the recent experiments with reciprocal hybrids recorded by Prof. de Vries, and briefly noted in these columns (Nature, April 13), provide striking confirmation of certain laws in hybridism advanced by the author. According to one of these laws, crosses from reciprocal hybrids show a return to the characters of one of the original species, and these are the only crosses in which hybrid characters are not maintained. Another law states that when crosses are raised from a hybrid and one of the original parents, if a hybrid carrying the male character is crossed with the female parent, or *vice versa*, the hybrid characters are maintained; in the other alternatives there is a return to the characters of the parent.

It seems reasonable to affirm that primitive or natural woodlands still exist in parts of Scotland, although the question does not admit of definite proof. Interesting evidence, based upon an examination of selected observational areas, is submitted by Mr. C. P. Gordon in the Transactions of the Royal Scottish Arboricultural Society (vol. xxiv., part ii.). He discusses three types of "Urwald," *i.e.* birch, Scots pine, and oak. On the ground of inaccessibility and condition of the trees, the birch woodlands on the shores of Loch Ossian and Loch Laggan, ranging to an elevation of 2000 feet, are considered to be primitive. Antiquity is claimed for the Scots pine forming Locheil Old Forest in Inverness-shire; although the trees have flattened crowns, the quality of the wood is excellent, and surpasses that of any imported Scots pine timber. Again, the shape and development of the oaks on Lochwood Moss in Dumfriesshire suggest that this forest is primitive; epiphytic growth of the common polypody and Usnea is here a striking feature. The article also contains notes on the ground floras observed.

The example set by the United States in retaining a large tract of country as a sanctuary for wild life has been followed by several other countries, including Canada and Switzerland. Mr. J. S. M. Ward appeals in *The Builder* for August 4 that something similar should be done in England. The growth of towns and of small holdings, and the gradual conversion of England into a "Black Country," are causing the disappearance of the real wild country. Efforts should be made to save sanctuaries near our different towns, a matter which might be taken in hand as an extension of the town-planning movement. Forestry should be encouraged wherever possible; much land in private hands might become sanctuary to all practical purposes. Two or three sanctuaries already exist; Epping, though an accidental one, has been a great success in this direction, and so has the Brent Valley Bird Sanctuary of the Selborne Society. Mention should also be made of the work done by the National Trust and by the Commons and Footpaths Preservation Society. Many of the most beautiful spots in England have been saved by their joint efforts, and there are signs that these bodies intend to extend their work in the direction of the provision of sanctuaries.

The number of new seedling sugar-canes available for planters is greater at the present time than ever before, and experiments are undertaken by the West Indian Department of Agriculture to serve as a guide to planters in selecting the most promising sorts for cultivation. In order to render the investigations applicable to a wide range of conditions, the location of the different experiment stations is chosen with the view of making each station, so far as possible, representative of the cane-growing district round about it, so that, as a whole, the stations supply a complete survey of the conditions under which sugar-cane is grown in the particular island. The report of the experiments conducted in the Leeward Islands for 1909–10 is now issued as Pamphlet 67 of the West Indian Department.

The Agricultural Journal of the Union of South Africa contains each month papers of scientific and of technical interest by officers of the Department. A report is published in No. 3 of the new volume showing that cotton can be successfully raised in the Cape Province. The cultivation is attracting a good deal of local attention, and the crop is satisfactory in quality; there seems the promise that cotton-growing may become a profitable industry. In No. 4 Dr. Theiler gives an interesting and complete summary of recent work on ticks and the part they play in the propagation of diseases in cattle; the particular diseases dealt with are biliary fever in horses, caused by *Piroplasma equi*; redwater in cattle, caused by *P. bigeminum*; gall sickness, or anaplasmosis, due to *Anaplasma marginale*; fevers, caused by *Piroplasma mutans*, by Spirochætes, and the East Coast fever caused by *P. theileria*; and heartwater.

The annual report for 1909–10 of the Department of Agriculture, British East Africa, shows an encouraging growth of production and a steady influx of settlers with capital. The climate is very varied, and ranges from temperate to tropical within somewhat narrow distances; in consequence, a considerable variety of crops can be produced. Beans, coffee, maize, and millet have increased enormously in area, and in spite of the growing local demand there is a large balance for export. Rubber has likewise increased in amount, and a still further increase is foreshadowed in the future, as the plantations have not yet reached the tappable stage. Sem Sem is also a valuable and increasing crop. On the other hand, copra and wax have fallen off in value; but the decline in copra is not regarded seriously, because the cocoanut is now put to more economical uses. There is a large and growing export of hides, chiefly ox and goat, while ostrich farming, which has recently been introduced, promises to become an important industry.

MM. Claude, Ferrié, and Driencourt give in the *Revue générale des Sciences* for July 30 an account of the experiments made for the determination of longitudes by means of wireless telegraphy between Paris and Brest, a distance of about 600 kilometres, and afterwards between Paris and Bizerta, which are separated by about 1550 kilometres. Diagrams of the instruments and connections are given. In the experiments between Paris and Brest in July, 1910, comparisons by radio-telegraphic and telephonic signals gave the same degree of precision, the mean error being less than 0·01s. In the experiments with Bizerta at the end of 1910 suitable radio-telegraphic signals actuated by a clock at the Paris Observatory were received, so that coincidences could be accurately observed, and the differences between the mean comparisons of the same series were of the order of 0·01s.

In the *Revue générale des Sciences* for July 30 M. Lallemand, the director of the Levelling Service of France, discusses the most suitable form for an international air-map, and proposes a system of marks to enable the aviator to determine his position. The Permanent Committee for Aërial Navigation of the Ministry of Public Works has adopted 1 : 200,000 as the most suitable scale, each sheet containing 1° of latitude by 1° of longitude; longitudes are to be reckoned from 0° to 360° in an easterly direction from the antimeridian of Greenwich; for the ordinary numbering of the parallels of latitude a continuous numbering from the South to the North Pole is proposed with the view of avoiding the change of sign on passing the equator. For local marks a rectangle containing a dot indicating the position of the place in the map sheet, and the number of the map sheet would be painted on a house-roof or other suitable surface, and this is considered more practical than giving the name of the place. The projection employed is the same as that of the international 1 : 1,000,000 map.

ACCORDING to the *résumé* of communications made to the Société française de physique on July 7, M. M. Kernbaum has succeeded in showing that the "oxygenation" of water, which two years ago he proved could be obtained by allowing the ultra-violet rays from a mercury lamp to act on the water, can be obtained from sunlight. Since it is the ultra-violet rays which are effective, the action is most marked at high altitudes, but it is large enough to be easily detected at sea-level if the water is in presence of air.

IN a thesis submitted for doctor's degree in mathematical science at Geneva, M. Hermann Streele, of Neuchatel, dealing with the theory of mercurial compensation for pendulums, suggests a new form of pendulum in which the free surface of the mercury is near the middle of the column, the upper part resembling a barometer tube. This form, he claims, enables him to compensate theoretically both the actual changes of temperature and the error due to the want of uniformity of temperature in different parts of the pendulum chamber. He follows Herr Wanach (remembered as one of Prof. Albrecht's longitude observers) in condemning the old approximate formulæ of Lord Grimthorpe and others, but apparently fails to realise the great dependence of makers on "trial and error." He has not completed the theoretical study, as he ignores, for instance, any molecular temperature effect, and from the practical point of view he has omitted any mention of devices for keeping the atmospheric pressure nearly constant. No hint is given of any possible application of "invar" to mercurial pendulums, though its striking success in bimetallic compensation would seem to recommend a trial of this alloy for some part of the pendulum, if not for the actual stalk.

EXTENSIVE schemes of improvement of the docks of the Port of London, forming part of a more extended scheme resolved on some time ago, are now about to be carried out at a cost of four millions of pounds. It is anticipated that when these works are completed, they will be sufficient to meet the needs of the port for several years. The remainder of the proposed improvements will be deferred until the increase of trade renders them necessary. The works now to be put in hand include the construction of a new deep-water dock of sixty-five acres. It is anticipated that this will occupy five years, and the estimated cost is 2,150,000*l.* This dock will be constructed to take vessels of considerably larger size than those which now can find accommodation in the Thames, the depth being 38 feet and length of the lock 800 feet, or 250 feet longer than that of the present Albert lock. The East and West India docks are to have their approach widened to 80 feet, and depth increased to 31 feet, allowing the entrance of vessels up to 9000 tons. The South-west India dock and the London docks are to have new entrances constructed, and to be otherwise made to meet modern requirements. The water in the latter is to be increased so as to make it 4½ feet above Trinity high-water mark by means of a pumping installation.

A CLASSIFIED list of new books and new editions added to Lewis's medical and scientific circulating library, 136 Gower Street, W.C., during April, May, and June, just received from Mr. Lewis, is a useful catalogue of important works published during that period.

OUR ASTRONOMICAL COLUMN.

COMET 1911*b* (KIESS).—Observations of Kiess's comet, made by Mr. Stratton with the Newall telescope on July 22, 25, and 26, showed a head some 3′ in breadth, but without any sharply defined nucleus. Mr. Newall, in No. 4517 of the *Astronomische Nachrichten*, does not give the times of the observations, but states that the comet was visible to the naked eye.

Spectroscopic observations revealed a bright band at λ 516 in which the head was seen to be 5′ or 6′ broad, and the band could also be traced along the tail to a distance of at least 5′; bands were also seen at λλ 474, 516, and 564, and the continuous spectrum was recorded as very faint.

A note appended to the ephemeris given in No. 438 of *The Observatory* directs attention to the fact that on September 3 the earth will pass through the point traversed by the comet on August 7; a careful watch should be kept for cometic débris in the form of meteors.

BROOKS'S COMET, 1911*c*.—New elements and ephemeris for comet 1911*c* are published in No. 4517 of the *Astronomische Nachrichten* by Dr. Ebell. As the new positions, especially for the later dates, show considerable departures from those we reproduced in these columns on August 3, we give the following abstract from the ephemeris :—

Ephemeris (12h. M.T. Berlin).

1911	α (true) h. m.	δ (true) ° ′	log *r*	log Δ	mag.
Aug. 16	21 22·0	+39 33·5	0·1932	9·8632	8·5
,, 20	21 4·3	+43 6·8	0·1747	9·8324	8·3
,, 24	20 41·9	+46 43·8	0·1552	9·8033	8·0

This comet was observed by Mr. Stratton on July 25 and 26, and was found to have a bright nucleus which gave a continuous spectrum; the band at λ 516 in the spectrum could be traced faintly for about 2′ from the nucleus both towards the sun and in the opposite direction. The comet could be seen with a pair of opera glasses.

A large number of observations of position and brightness are recorded in the *Astronomische Nachrichten* (No. 4517) from Greenwich, Utrecht, Algiers, and many other observatories. At Algiers Dr. Gonnessiat found, on July 22, a 4′ or 5′ nebulosity having an eleventh-magnitude nucleus which was not central. Herr G. van Biesbroeck found that the magnitude of the comet seen with opera glasses on July 26, 27, and 29 was about 8·0.

ENCKE'S COMET, 1911*d*.—Dr. Gonnessiat's report of the rediscovery of Encke's comet appears in No. 4517 of the *Astronomische Nachrichten*, and states that the comet was a difficult object in the dawn. Perihelion passage takes place on August 19, and an ephemeris giving positions from August 24 to September 21 appears in No. 438 of *The Observatory*; for August 24 and 28 the positions are 10h. 44·5m., 5° 46′ N., and 11h. 16·1m., 1° 2′ N., respectively.

THE OBSERVATION OF METEORS.—Amateur astronomers not possessing efficient instrumental equipment cannot do better than devote their attention to the observation of meteors, about which students of cosmogony still require to learn many things.

For such observers the publication (*Observatory*, No. 438) of a letter written by the late Prof. Alex. Herschel to Mr. Denning in August, 1876, is full of interest and practical information. Those who had the pleasure of corresponding with Prof. Herschel will understand that it is impossible to describe a letter of his in detail in a confined space, but the amateur will find especially interesting the discussion of "trains." These phenomena are seldom properly described, and Prof. Herschel takes some pains to impress upon his correspondent the great importance and the almost infinite variety of the luminous phenomena attending a meteor flight.

BETA AND GAMMA RAYS IN SOLAR PHENOMENA.—From Dr. A. Brester, Jz., we have received an interesting monograph dealing with the theory that solar phenomena are produced by the solar emission of β and γ rays. Dr. Brester starts with the terrestrial aurora produced by electrical radiations, and shows that the solar phenomena may be similarly explained. The presence of helium as a prominent solar element is taken as evidence of the presence in the sun of the radio-active elements from which the β and γ rays may emanate. The monograph is published by W. P. van Stockum et Fils, The Hague.

PAPERS ON INVERTEBRATES.

IN the Records of the Indian Museum for May (vol. vi., part 2), Dr. N. Annandale describes certain curious masses dredged in the Bay of Bengal, which on examination proved to be sponges associated with gregarious molluscs of the family Vermetidæ, the latter being embedded in the former. The masses, which were in a bad state of preservation, are of two types, one consisting of shells with serrated ridges embedded in moderately hard black sponges, and the other of smoother shells associated with stony sponges, ranging in colour from red to yellow. The ridged shell is *Siliquaria muricata*, and the associated sponge *Spongorocites topsenti*. The second type comprises two molluscs, *Spiroglyphus cummingi* and *Siliquaria cochlearis*, the associated sponges being two forms of *Racodiscula sceptrellifera*, which differ from one another in colour. When fresh, the masses of the second type must have had a brilliant appearance, the sponge being red or orange, the shells pink, and the soft parts of the molluscs yellow. Both the two sponges associated with the three Vermetidæ are found elsewhere growing alone.

In two issues of the Proc. U.S. Nat. Mus. (Nos. 1823 and 1826), Mr. Paul Bartsch catalogues the recent and fossil representatives of the molluscan genera Cerithiopsis and Bittium from the west coast of America; and in No. 1820 of the same serial Messrs. Dall and Bartsch describe several new shells from Bermuda, including some of the aforesaid Cerithiopsis.

Variation in certain Jamaican species of land-snails of the genus Pleurodonte (or Pleurodonta) forms the subject of a paper by Mr. A. P. Brown in the Proceedings of the Philadelphia Academy for February, 1911. Variation in the height of the spire indicates two waves of migration into the district from the north, the first being probably represented by an extinct race from near Somerset. In analogous cases the variation in the height of the spire has been attributed to difference of atmospheric pressure according to altitude, tall-crowned forms being found high up, and *vice versâ*. But, as Mr. Brown points out, this cannot be a *vera causa*, the diurnal oscillations in pressure at a given point being in some parts of the island more than equal to variation due to altitude. Moreover, in one at least of the mountain forms, increase in spire-height is accompanied by a diminution in the size of the shell. In the author's opinion, such variations are mainly controlled by local differences in humidity.

In the same serial for March, Messrs. Pilsbry and Ferriss continue their review of the land-shells of the south-western United States, dealing in this instance with those of the Grand Canyon and northern Arizona. The molluscan fauna of the Grand Canyon consists, with one exception, of northern Arizona types; but the canyon forms an impassable barrier to Oreohelix, of which distinct species are found on its two sides.

Certain features in regard to the vertical distribution in the San Diego area of the minute translucent crustacean *Eucalanus elongatus* (a relative of the better-known *Calanus finmarchicus*) are discussed by Mr. C. O. Esterly in vol. viii., No. 1, of the Zoological Publications of the University of California. Despite considerable hourly variation in the numbers taken in plankton, it does not seem that the species performs diurnal vertical migrations; and the reason for the numerical variation is therefore still unknown. The author is led to suggest that diurnal vertical migrations may have in part a protective object in many species, seeing that Eucalanus is adapted in other ways to life in the plankton.

How much remains to be done in connection with South African earwigs is made evident by the fact, as recorded by Dr. M. Burr in vol. x., part i., of the Annals of the South African Museum, that out of nineteen species from the districts south of Rhodesia, no fewer than seven proved to be new. One of these is assigned to Apterygida, a genus, as now restricted, previously known only by *A. alpipennis* of Central Europe.

The lug-worms (Arenicolidæ) of South Africa are discussed by Dr. J. H. Ashworth in vol. xi., part i., of the same serial. The special interest of this article is the record of the rediscovery of *Arenicola loveni*, a species hitherto known solely by a specimen from Natal preserved in the Riksmuseum at Stockholm, and described by Kinberg in 1866. An examination of the internal organs of this specimen, supplemented by others recently obtained by Dr. Gilchrist at Saldanha Bay, Cape Colony, shows that the reference of the species to the typical genus is correct.

The one article in vol. iv., No. 7, of Records of the Indian Museum is devoted to the description, by Mr. E. Brunetti, of nearly fifty new Oriental flies of the group Nemocera.

To *Biologisches Centralblatt* for July 1 the Rev. Father Wasmann contributes the first part of a critical review of Escherich's "Termitenleben auf Ceylon."

In vol. xxxiii., No. 4, of Notes from the Leyden Museum Dr. R. Horst revises the characters of the genus Notopygos, typified by an amphinomid worm from St. Helena described by Grube in 1855. The special feature of the genus is the dorsal position of the vent, some distance in advance of the terminal segment. Shortly afterwards Grube referred to the same genus a Costa Rican annelid, mentioning the presence of two dorsal cirri. In 1857 Kinberg, who was apparently unacquainted with the account of this second species, diagnosed the genus as having a single cirrus, making no mention of the dorsal position of the anus. He also referred two annelids, respectively from Tahiti and Panama, to the new genus Lirione, on account of the presence of a pair of dorsal cirri. Apparently the single cirrus specimens, which were from St. Helena, did not belong to Notopygos, of which Lirione is now shown to be a synonym. The genus is now known from St. Helena, Costa Rica, Florida, Bermuda, Malaya, the Amirante Isles, and Australia.

In No. 1846 of the Proceedings of the U.S. National Museum Mr. E. Kirk discusses the relationships, classification, and genealogy of certain "Eleutherozoic Pelmatozoa," in other words, of free-living echinoderms of the cystid and crinoid groups. "With the possible exception of the Holothuroidea, we may hold," writes the author, "that such eleutherozoic echinoderms as are known to us have been derived from statozoic ancestors. . . . In the case of the eleutherozoic forms we have one newly acquired set of tendencies superimposed upon another set. These secondary tendencies, induced as they are by a form of life widely at variance with that under which the first set operated, tend to vitiate the force of many of the primary tendencies, if not indeed to nullify some of them. . . . Such being the case, one's efforts to establish relationships among these aberrant forms are apt to be unsatisfactory at best. In many cases, however, the eleutherozoic Pelmatozoa stand so near the point of inception of their several lines that the problem is not greatly complicated by the presence of altered or superimposed structures." Nevertheless, the classification and grouping adopted in the paper are admittedly artificial and arbitrary.

THE FOSSIL ELEPHANTS OF RUSSIA.[1]

ALTHOUGH a fine series of elephant remains from Tiraspol, Government of Kherson, preserved in the Geological Museum of Moscow University, forms the basis of Madam Pavlow's monograph, the author has examined several other collections, such as one from Kouialnik, near Odessa, and a second at Kief. The Tiraspol elephant has been identified with that form of the mammoth distinguished, on account of the thicker plates of its molars, as *Elephas trogontherii*, and characteristic of the horizon of the Cromer Forest-bed. Madam Pavlow finds, however, that in the Tiraspol molars the plates are still thicker, and accordingly regards them as representing a new species—*E. wüsti*, or *wuesti* as it

[1] "Les Éléphants Fossiles de la Russie." By Marie Pavlow. Pp. iii+60+3 plates. Nouveaux Mémoires de la Société Impériale des Naturalistes de Moscou, tome xvii, livraison 2. (Moscow, 1910.)

should be spelt—which is considered to connect the typical mammoth by means of *E. trogontherii* with the broad-plated *E. meridionalis* of the Val d'Arno and Forest-bed. Two molars from Tiraspol are stated to approximate respectively to those of *E. armeniacus* and *E. antiquus*, but it is scarcely likely that three more or less closely allied forms occur in one deposit. *E. trogontherii* is recorded from Nijni-Novgorod, *E. meridionalis* from Kowialnik, and the typical *primigenius* from a prehistoric station at Kievo-Kirillovskaïa. Finally, a molar from Tiraspol and a second from Bessarabia are respectively compared with those of the Siwalik *E. hysudricus* and *E. planifrons*.

The important part of Madam Pavlow's paper is, however, contained in the discussion as to the mutual relationships of the various species and races. After noting the resemblances between *hysudricus* and *meridionalis* on one hand and *antiquus* and *namadicus* (which some naturalists regard as inseparable) on the other, the author suggests that *meridionalis*, by an increase in the number and degree of compression of its molar plates, passed by means of *wüsti* and *trogontherii* into the mammoth, which died out without descendants. On the other hand, a thin-plated phase of the *meridionalis-hysudricus* group appears to have given rise to *antiquus* and *namadicus*, while the latter in turn produced the modern Indian elephant. The idea that *antiquus* was the ancestor of the living African elephant is considered improbable.

The main objection to these views appears to be the phylogenetic separation of the Indian elephant from the mammoth, the two being closely connected by the so-called *E. armeniacus*, which was probably the animal hunted by Thothmes III. in Mesopotamia. Moreover, the suggestion that *E. namadicus* (= *antiquus*) was the parent of the Indian species is unlikely on account of the peculiar form of the forehead in the extinct species. That the *meridionalis-hysudricus* line gave origin to the Indian elephant, and that the mammoth branched off from the same stock, perhaps, as Dr. Andrews has suggested, by way of *armeniacus*, is a far more probable supposition, and one that fits in with all the facts. In regard to the African elephant, there is a general tendency to connect it with *antiquus*, Dr. Andrews even going so far as to suggest ("Guide to Elephants in Brit. Mus.," p. 42) that the narrow-toothed form of the latter may have been the actual ancestor, or at all events nearly related to the ancestor, of the existing species, although in a previous passage (p. 39) he states that *antiquus* is unlikely to have given rise to descendants.

While venturing to dissent in some degree from her theoretical views, I may conclude by expressing appreciation of the value of the work of Madam Pavlow, as it is only by means of such investigations that we can hope to solve the riddle of the elephants. R. L.

WORK OF THE PHYSIKALISCH-TECHNISCHE REICHSANSTALT IN 1910.

THE subjoined notes, based upon the annual report of the above institution for last year, indicate a few of the more important researches, &c., undertaken.

One of the chief researches was the joint work carried out at the Bureau of Standards, Washington, in conjunction with representatives of the English, French, and American standardising laboratories, the most important portion of this work being the determination of the value of the E.M.F. of the Weston normal cell. This was found to be 1·0183 international volts at 20° C. within limits of 1/10,000, agreement being secured in this respect among the countries mentioned. The value given has therefore been accepted in Germany as from January 1 last.

A research on the specific heat of gases at low temperatures by the continuous-flow method has been made. In using this method, a measured quantity of energy C^2R is conducted electrically to a gas passing through a tube at a constant rate of flow. If the temperature-difference dt between inflowing and outflowing gas is known when the stationary state has been attained, as also the quantity of gas Q flowing through the calorimeter in a certain interval of time, then $\frac{1}{J}\cdot\frac{C^2R}{Qdt}$ is the specific heat of the gas provided no thermal loss takes place, J being the mechanical equivalent of heat.

In the course of the ordinary conductivity tests on copper carried out during the last few years, it has been found that with great approximation proportionality exists between temperature coefficient and electrical conductivity, *i.e.* that a very approximate formula was $\alpha_{15}.c_{15}$ = const. (α_{15} temperature coefficient, c_{15} specific resistance in ohms m/mm^2 at 15° C.). The mean value for all types of copper tested at the Reichsanstalt since 1905, for the constant, is $6{\cdot}7_6{\cdot}10^{-5}$. The same relation seems to hold —of course, with other values for the constants—for aluminium and iron. A similar relation has been found by Dellinger at the American Bureau of Standards.

The investigation into the variation of wire resistances with atmospheric humidity has been continued, and further experiments made on coils hermetically sealed in accordance with the suggestion of the Bureau of Standards. Two coils were filled with petroleum and two with paraffin oil, and sealed up, measurements being made before and after sealing. The coils filled with paraffin oil have shown good constancy, while the petroleum-filled ones have not been so constant.

A comparison has been carried out between the German standard petroleum testers and four English testers, the result being that the flash-point as given by the English instruments is, on the average, 2° C. lower than with the German instruments, the same oil being used for both.

Some comparative tests have been made on Seger cones in the electric and the ceramic furnace, the results showing that the cones collapse in the ceramic furnace at much lower temperatures than in the electric furnace of the Reichsanstalt. A definite opinion as to the reason for this difference is not pronounced.

Investigations have been instituted into the change in length of hardened steel. The twenty sets of end rods, of 10, 25, 50, and 100 mm. length, forming the basis of the experiments, were again measured in November, 1910. The lengths of the great majority of test-pieces have become constant, four years after manufacture; the changes observed in the remainder are within small limits (fractions of a micron). The results are to be published shortly.

A series of tests have been made on the energy-loss in dielectrics. An experimental condenser was built up of ten plates of solid insulating material interleaved with copper-foil sheets, the capacity being from 0·004 to 0·01 mfd. A description of the method of testing is given, and the results up to now show that over a range of frequency 0 to 2000 periods the phase-variation in the case of some substances is only to a slight extent dependent on the frequency, while in the case of others the variation is considerable. Sometimes it was also noticed that the phase-difference depended on the voltage applied.

Numerous other researches more or less important in character were undertaken during the year, but space will not permit of describing them here. Those interested will find the report of the Reichsanstalt published in the *Zeitschrift für Instrumentenkunde* for April, May, and June.

E. S. HODGSON.

RECENT PUBLICATIONS OF ECONOMIC ENTOMOLOGY.

INSECT pests of trees and crops demand constant attention on the part of the expert, and a very voluminous literature is growing up round the subject. Few laboratories are more prolific in published papers than those of the Bureau of Entomology of the United States Department of Agriculture. Among recent papers, we note one by F. M. Webster on the alfalfa weevil (*Phytonomus murinus*, Fab.), a pest introduced from Europe or North Africa some six years ago, and now spreading somewhat widely in Utah, and another paper by the same author on the lesser clover-leaf weevil (*P. nigrirostris*, Fab.), an insect introduced probably fifty years ago, but not very common even yet; it suffers from at least two parasites, a small Tachinida and a fungus, *Empusa sphaerosperma*. The broad-nosed grain weevil (*Caulophilus latinasus*, Say) is described by F. H. Chittenden, and also the long-headed flour beetle (*Latheticus oryzae*, Waterh.); both are found in stored cereal products, and may become serious pests if they succeed in establishing themselves. Two other pests infesting stored cereal products are also described, the lesser grain-borer (*Rhizopertha dominica*, Fab.), which is fairly common, and is cosmopolitan in its distribution, and the larger grain-borer (*Dinoderus truncatus*, Horn), which is more confined to tropical countries. The ravages of the codling moth (*Carpocapsa pomonella*, L.) in California are dealt with by S. W. Foster; two full broods of larvæ could be traced during the season, the first, however, being relatively small, and often overlooked. Treatment with a lead arsenate spray is recommended. The grape leaf-hopper (*Typhlocyba comes,* Say) an insect causing damage to vines in the Lake Erie Valley, is shown by F. Johnson to yield to a nicotine spray. Three pests on crops are dealt with: the timothy stem-borer (*Mordellistena ustulata*, Lec.), a pest which has recently been observed by W. J. Phillips; the sorghum midge (*Contarinia sorghicola*, Coq.), described by W. H. Dean; and the maize billbug (*Sphenophorus maidis*, Chittn.), by E. O. G. Kelly. The alfalfa caterpillar (*Eurymus eurytheme*, Boisd.) is dealt with by V. L. Wildermuth; it is very common, and does a good deal of damage in various localities. A very useful bulletin by L. O. Howard sets out various remedies against mosquitoes. The best mixture for keeping them off was found to be 1 part of oil of citronella, 1 of spirit of camphor, and ½ of oil of cedar; a few drops sprinkled on a towel and hung over the bed will keep mosquitoes away during the night. For the actual bite the most satisfactory remedy is said to be moist soap. Traps are described, and methods for the destruction of the insects over both large and small areas are set out.

Hydrocyanic acid has long been recognised as one of the most potent fumigating agents, but great practical difficulties are met with in its use, which so far have not been entirely overcome. If the concentration of the acid is too high the tree is killed, if too low some of the insects escape; further, the optimum concentration depends somewhat on the conditions. Thus there is almost an indefinite field of work for entomologists, and a stream of bulletins is issued on this subject. Among recent issues from the United States Bureau of Entomology are two by R. S. Woglum and one by C. C. McDonnell.

The work of the West Indian Department of Agriculture is published in the West Indian Bulletin, but summaries are also given in *The Agricultural News*, the fortnightly organ of the Department. In vol. xi., No. 2, of the bulletin H. A. Ballou gives a list of the insect pests prevalent during 1909–10, a corresponding list of the fungoid pests being prepared by F. W. South. This is the first occasion on which information of this nature has been collected, and it is proposed to repeat the reports each year in order to obtain some records of the increase or decrease of any given pests, and thus to determine the effectiveness of the preventive measures used for control. The value of such a plan is obvious, and it might with advantage be adopted in our own country.

Considerable interest attaches to the control of insect pests by natural parasites, and we note that in Barbados the hymenopterous parasite *Zalophothrix mirum*, Craw., was able to keep in check the black scale insect (*Saissetia nigra*, Nietn.), whilst in St. Vincent it was not so effective. Simple instructions are given in issues of *The Agricultural News* showing how planters may introduce the parasite among the insects, and thus increase its action; in No. 232, in particular, a summary of the whole subject is given. Active search for parasites of other pests is in progress by other departments; investigators were, for instance, recently sent from the United States to Panama to search for parasites of the citrus white-fly (*Aleyrodes citri*), of the cotton boll-weevil, and allied species.

A well-illustrated bulletin has recently been issued by P. L. Guppy on the life-history and control of the cacao beetle (*Steinastoma depressum*, L.), which for some years past has been a serious pest and a source of trouble to planters in Trinidad. Hitherto nothing definite seems to have been worked out in regard to its life-history, and its habits have only been superficially observed. Mr. Guppy's publication supplies much useful information on the insect.

WATER SUPPLY.[1]

THE question of water supply is in one aspect a scientific one, and in another aspect a political one. The source of all water supply is evaporation, which raises and purifies water which is taken up from the land and the sea, which after condensation is returned to us as rain, dew, snow and hoar frost, and these waters are to be found ready to our hand in springs, streams, lakes, and in the envelope of earth which is tapped by means of wells. In early days the water supply was a matter of hand to mouth. In the matter of water, at any rate, men drank water when they were thirsty—unlike the characters in Maeterlinck's "Palace of Happiness," who had, you will remember, the Luxury of Drinking when they were not Thirsty and of Eating when they were not Hungry. In the old days people, in relation to these ordinary articles of diet, acted upon the advice given in that old-world book "Sandford and Merton," and "only drank when they were dry." Yet even in the old days men in this country used water occasionally for washing, although the modern passion for baths had not developed in the dark ages. We find, however, that even in these early days there was a political aspect in water supply. The existence of springs in many cases determined the sites of cities. Many towns have been built on rivers partly because they were sources of water supply, but mostly when the rivers were navigable and afforded a highway for ships. Now, however, it is found that populations have increased to such an extent in certain localities, owing to the gregariousness of men and other political considerations, that the immediate sources have proved inadequate, and great towns in this country—like Rome in ancient days—have had to go a distance for their water supplies, and have had to construct great engineering works for the conveyance of water to the area of distribution. Water is at present collected and sold in England to a value of nearly 8,000,000*l.* annually, and when it is delivered at the house of the consumer it costs him about 2*d.* a ton.

Aqueducts, or channels by which water is conveyed along an inclined plane, were known to the Greeks, but there are no remains of those they constructed. The Roman aqueducts were amongst the most important of their great works, and the present supply of Rome is still carried by these artificial rivers, sometimes through passages cut in the hills, sometimes on arches bridging the valleys and carrying the water across the plains. One of these aqueducts is 62 miles in length. We in this country have had to go even further afield for our water sources. A large portion (56 per cent.) of the supply of Liverpool is brought from the River Vyrnwy, in North Wales, a distance of 68 miles. Leicester is 60 miles from the sources of the Derwent Valley Water Board supply; Birmingham gets its water from Radnorshire, a distance of 74 miles; and Manchester from Thirlmere, by means of pipes and aqueducts, a distance of 96 miles. Paris derives some of its water from the Champagne district through pipes and aqueducts 80 miles in length, and some from Vanne, a distance of 104 miles. There has, too, been a suggestion that London should draw its public water supplies from Wales, which would involve carrying the water about 200 miles. This scheme was first suggested by Mr. Bateman in 1867. He proposed to collect the rainfall on 204 square miles, and, by means of an aqueduct 173 miles in length, to bring 230 million gallons of water a day to London, and he estimated the cost at 11,400,023*l.* About the same time, too, there was a suggestion to carry the water of Ullswater and Hawswater, which it was said could supply 550 million gallons a day from an area of 100 square miles to the metropolis, supplying Liverpool, Leeds, Bolton, Bury, Blackburn, Huddersfield, &c., on the way. These great ideas were, of course, too large to be realised in these small times, and many of these towns have, since the suggestion was made, supplied themselves with water by means of comparatively small scale works instead of becoming parties in a national undertaking.

The difficulty of meeting the demands of such large towns is obvious, from the fact that it involves such great works and such heavy expense to secure an adequate supply.

[1] From a discourse delivered at the Royal Institution on Friday, March 17, by J. H. Balfour Browne, K.C.

To-day, the ratepayers of Birmingham are paying not only water rates, but contributing out of the ordinary rates 64,000*l.* a year to meet the heavy annual charges in connection with their Welsh scheme. Such a fact indicates that for places far from the sources of supply, and with wealth comparatively small to that of the great Midland towns, the difficulty of securing any supply for their future wants has become increasingly difficult, and may soon become impossible; and in this aspect the question of the future water supply of our populations becomes a significant political question, and because it is a matter of real importance to the health and trade of our great town populations, it has received no attention at all at the busy hands of our platform politicians. And yet, in my view, no matter is more worthy of serious consideration and attention, and none is more urgently practical, than the question of the future water supply of England. At one time England was able with its rich fields to feed its own populations, but, as trade prospered and populations increased, it was found impossible to produce food-stuffs sufficient for our people, and at present probably five-sixths of the total food of the people is imported from abroad. It is in this connection that current politics has taken in hand the problem how we are to continue to obtain these supplies from abroad; and while one school of politics thinks that the future is assured to us so long as the price of the loaf is not increased, another recognises the necessity of earning sufficient here to enable us to buy our food in other markets. But in relation to water supply we are in a worse predicament. We must depend for that on the rainfall of our own lands, and the improvident way in which our sources have been squandered in the past, the way in which the long arm of wealth has been allowed to appropriate sources which may not naturally or geographically belong to the community in question, the exhaustion of local sources, and the waste of underground water which takes place in connection with the mining operations of England, has much complicated the great question, and has made the future of Britain as to water supply both precarious and serious.

I have pointed out that the sources of supply are from springs, streams, and wells which tap the underground sources. There are in some quarters objections to rivers—full-grown rivers—as a source of supply, largely due to the fact that communities with insanitary rashness and short-sightedness have thrown their refuse and filth into streams, and made them the carriers of sewage. This matter was fully discussed recently in Parliament when the Great Yarmouth Water Company endeavoured to secure an additional supply of water to the town beyond that which it then drew from Ormesby Broad. We know, of course, that the rainfall in the Eastern counties is much less than in the west of England and Wales, and the company had been advised by most competent engineers that the most suitable source of supply was from the River Bure. The population above the proposed intake was very small, only one person to four acres, but still it could not be said that no sewage did find its way into the river. But even this insanitary indiscretion is condoned by nature, and rivers, especially rapid and turbulent streams, have a way of burning off effete matter which is put into its liquid charge. Whether this process of purification is absolutely effective or not is still a moot point, and chemists and bacteriologists are divided as to the safety in any case of drinking water which has been subject to sewage pollution. The great experiment of London has failed to convince some of these experts.

London derives the bulk of its water from the Thames. In the Thames watershed, above the Water Board's intake, there are at least 1,000,000 people and about 800,000 other animals. The London water is supplied to nearly 7,000,000 people. This is obviously a large experiment, for there are about as many people in Water London as in the two kingdoms of Norway and Sweden, about the same population as there is in widespread Canada. The water mains of London, according to the chairman of the Board, would reach from London to New York and back; and yet, notwithstanding the supply of river water, the health of London is exceptionally good. Indeed, there are some persons who seem to think that river water is really more wholesome than any other, and there is an interesting statistic produced in proof of this assertion. The death-rate of Great Yarmouth, which, as I have said, now takes its water from the Bure, is 15 per 1000; Chester, which is supplied from the Dee, 15·4 per 1000; and Greater London, which drinks water from the Lea and the Thames, has a death-rate of 13·3. But against this the death-rate of the great towns which have pure hill waters for their supplies are, in the case of Birmingham, 15·9; Manchester, 18·2; and Liverpool, 19·2. If statistics were absolutely convincing, the case for river water as against hill water would seem to be made out. But we must weigh statistics, and not allow them merely to count. It might almost as reasonably be suggested by anyone who was an opponent of municipal trading that the results were due to the fact that in the first three cases the water was supplied by companies and in the last three by corporations.

But, apart from any such questions, it is obvious that Thames and Lea water as supplied to London is far from being an unsatisfactory drinking water. But it is only fair to remember that just as in economics there is no such thing as "raw material," so in the case of our raw waters the water as delivered is in most cases a manufactured article.

It was always understood that mere sedimentation carried down a certain number of the germs which were contained in water, but the experiments of Dr. Houston and others show that millions of these germs in water artificially infected with cholera vibrios are dead at the end of a week's storage.[1]

It is in these circumstances that the Metropolitan Water Board has abandoned the idea of going to Wales for its supplementary water supply, and proposes, by a Bill in the present Parliament, to obtain power to construct a chain of reservoirs for the purpose of decanting the raw river water at Staines, and to spend 6,000,000*l.* on this great scheme which is to supply the wants of Greater London for the next thirty years—until, indeed, the population of the metropolis may be twelve millions.

But I was referring to the immense difficulty that any comparatively small town has in our days of securing a pure supply of hill water. So great is the difficulty that as I have said, the Metropolitan Water Board has properly hesitated to go to Wales, having spent 47,000,000*l.* in the acquisition of the London water companies—the enormous difficulties of a Welsh scheme seem to have been too great even for the gigantic financial resources of London. It is not, therefore, a matter for wonder that a town like Great Yarmouth has to look to some near source of supply for the further wants of the town, and, as I have said, they were advised to have recourse to the Bure. There were the usual objections to river water, and in this case it was urged that the river which drains the Broads is in summer the home of a large floating population in house-boats and other craft. It was, on the other hand, said that the same objection might be made against the Thames, for the Thames above the intakes has, in a momentary lapse into poetic diction, been called "the water park of London." But here again the health of London was in evidence, and in the case of Yarmouth power was taken to prevent any house-boat anchoring within a considerable distance of the intake.

There was another objection urged to the taking of water from the Bure for town supply. When the wind was in the north-west the waters of the German Ocean were heaped up by the spade-work of the gusts, and when that happened at the same time as a spring-tide the waters of the Bure were held or backed-up, and it was said that, owing to the mixing action which takes place between sea and river water, the waters of the river at the point of intake would be salt or brackish. It was argued that it was ridiculous to supply a river water impregnated with chloride of sodium to two towns like Yarmouth and Lowestoft. But here science came to the help of the water company. The occasions when the north-west winds and the high spring-tide synchronised were of course very rare, and it was proposed by the Bill that whenever such an event took place and when there were more than 20 grains of common salt to the gallon (that is, in 70,000 parts) in the Bure water, the company should cease to pump from

[1] Dr. Houston has found, too, that even a week's storage of raw river water is an enormous protection against the "cultured" and "uncultured" bacilli of typhoid fever, and "that less than a month's storage is an absolute protection against typhoid fever."

the river, and supply the town only from the stored water of the Ormesby Broad. Sir William Ramsay, too, invented for the occasion a little instrument. It was a small glass cell, containing two copper plates. This was to be sunk in the river, and so long as the plates were in contact with the fresh river water no electric current passed between the plates. But when salt water was substituted for fresh, and it was sufficiently salt to have 20 grains of chlorine to the gallon, an electric current passed and rang a bell. If this little apparatus was placed in the river two or three miles below the intake, there would be timely warning of the uprush of the sea water, and it was explained that it could be made not only to ring a bell but to stop the pumping-engine. This apparatus was exhibited to the Lords' Committee, and, upon salt being added to the water, the bell rang.

It may be of some use if I say something about the sources and methods of supply. There is nothing very new about water supply. Even in deep wells we have been anticipated: Joseph's Well at Cairo is 297 feet deep, and some of the wells in China have gone to a depth of 1500 feet. In modern times we have in some cases been abandoning our well supplies. At one time almost the whole supply of Liverpool was drawn from wells in the New Red Sandstone. To-day she only draws 7·36 per cent. from wells—36·42 per cent. from Rivington and 56·22 per cent. from Vyrnwy. There is a well at Passy, near Paris, 1923 feet deep, and it delivers $5\frac{1}{2}$ million gallons of water a day. In South Dakota there is a well which penetrates the earth's crust 725 feet and raises $11\frac{1}{2}$ million gallons a day. In relation to the purity of such underground supplies, many of them in this country are derived from the chalk, and it is interesting to note the precautions which nature has taken to purify such supplies. It is found that such soils as chalk breathe air and expel gases just as the human lungs do. The breathing is long-drawn and irregular, and depends mainly on the barometric pressure of the atmosphere. But that such breathing takes place can be shown by the simple experiment of closing the folding doors over a chalk well and holding a lighted candle to the bucket rope-hole, and the sensitive flare will show the indraft or outdraft as the case may be; which varies, of course in intensity according to the extent of recent barometric changes. When water has to be got from underground sources, then a well has to be sunk, adits driven, a pump established, and the water raised to the clear water-tank. In some cases, however, nature not only does the purification of our water by its chalk lungs, but does our pumping for us, as in the case of an artesian well.

But not only have we been anticipated in the matter of wells; in aqueducts we are mere imitators of our predecessors, who even understood, it is obvious, the principle of the inverted syphon, as it is called, by means of which water is carried in pipes across valleys running down hill on the one side and up hill on the other; for Lyons, in France, was supplied long ago by means of lead pipes from 12 to 18 inches in diameter, 9 miles in length, and worked under a head of 200 feet. It is true that the favourite method of engineers before the nineteenth century, when cast-iron pipes came into use, was to cross valleys by bridge aqueducts, and this, apparently on the ground that the materials of their pipes (either trunks of elm-trees hollowed out, from which our word "trunk main" has survived to us, or lead) did not lend themselves to the conveyance of large volumes of water as the ordinary aqueduct did. The favourite system of supply in this country to-day is undoubtedly by means of a gravitation system, either from natural lakes like Loch Katrine or Thirlmere, or from artificial lakes—or, as they are called, "impounding reservoirs." These reservoirs, by means of a dam formerly formed of earth, with a core of impervious puddled clay, but now more frequently of masonry, catch and impound the water which falls upon the gathering ground. Of course, it is desirable to avoid a gathering ground which consists of cultivated land or upon which there is any considerable population. The best gathering ground is one composed of impervious rocks—for porous strata steal too much water—and covered only with mountain pasture or moorland. In many cases no objection is made to the existence of sheep upon the gathering ground; but Liverpool, in the case of its Rivington works, has purchased the whole of the gathering ground, and, after destroying and pulling down many of the farms and buildings, has kept a great part of the gathering ground free from sheep and let it to a sporting tenant. The largest gathering ground in this country dealt with by water works is the Birmingham gathering ground, which will collect the water from 44,000 acres, while the Thirlmere scheme of the Manchester Corporation has only a contributory area of 11,000 acres, and the Vyrnwy works of Liverpool Corporation only 22,000 acres.

Hundreds of dams have been built in this country to collect the waters from gathering grounds in connection with water supply to towns, or water supply to canals and waterways. The wall which impounds the water at Vyrnwy is 85 feet high. The Manchester Corporation, which had to deal with a natural reservoir, constructed a dam only 50 feet in height, but the masonry embankment at Caban Coch, the reservoir of the Birmingham Corporation, is 122 feet high above the bed of the river; and some of the other dams of that great scheme, when complete, will be 128, 120, 101, and 98. These walls, of course, have behind them immense quantities of water varying from 8000 million gallons, in the case of Birmingham, down to the very small number of gallons which run down a mill goit. The tensile strain or tear of such a mass of water as that at Caban Coch is enormous, and in that case the work is strong enough to bear such a strain up to 12 tons per square foot. The Bouzay dam, near Epinal, in France, which was bad in design and faulty in construction, gave way with the pressure of $1\frac{1}{4}$ tons to the square foot.

On January 13 of this year a dam of a reservoir containing 250,000 cubic metres of water, which belonged to the Huelva Copper and Sulphur Company, Spain, owing, it is said, to a hidden spring under the masonry, gave way, and eleven people were drowned. That is near to-day, and affects us like a new wound. But even if none of us have memories which go back to 1840, tradition has told us of the bursting of the Bradfield Reservoir, which drowned the town of Sheffield, and put the country round for a distance of 12 or 14 miles under water. In that catastrophe 250 lives were lost, and property was destroyed to the extent of 327,000*l.* in value. The Holmfirth Reservoir, which had an embankment 90 feet high and 150 yards long, after heavy rains burst in 1854, and 100 people were drowned in that night, and property valued at 600,000*l.* was destroyed. In most of these cases, however, the calamity can be traced to the defective engineering skill which went to the construction, or subsequent carelessness in the maintenance. But many engineers would tell you that they have sleepless nights when one of these great cauldrons are filling with water for the first time—and people in the valleys below may well hold their breath until the stability of these great walls has been proved. In the case of the Bradfield Reservoir, the burst reservoir filled the Don Valley with a mad flood. In the town of Sheffield the water rose to the height of the roofs of low buildings. Dead cattle were carried down by the waters, and in some cases deposited on house-tops, and as in the days of Horace "fishes roosted in elms."

In the case of spring waters, these are collected where they issue from the earth from their underground recesses in protected tanks, and from these the water, which in many cases has been sufficiently filtered by nature, is conveyed to the clear-water tank, as in the case of surface water. But when, as in the case of surface water, nature does not produce a ready-made article, and the water is liable to surface pollution, then filtration is a necessity, and, as in many other cases, in this connection our ancestors were wiser than they knew. Indeed, experience is often more valuable than science, and is universally the foundation upon which all safe science is built. Sand filters have been used in Britain since about 1829. These filters are tanks from 6 to 8 feet deep. Over the floor drain pipes or channels lead to the outlet pipe, and over these we lay a layer of broken stones and gravel. These stones are laid to a depth of 2 or 3 feet, the larger stones being at the bottom of the tanks, and the smaller bearing the 2 feet of sand, which was supposed to be the filtering and purifying medium. The water is allowed to percolate downwards at a certain slow rate, and the effect is to remove mechanically certain matters in suspension. For many years our chemical experts saw little or no value in sand filtration, because in chemical analyses they found little or no difference between the filtered water and the unfiltered raw water. But it was left to bacteriologists to find the real significance of sand filtration. We know now that after use a jelly-like deposit is formed on the top of the sand, and that that film has prevented the water from getting through the filters at the ordinary vertical rate of 4 to 6 inches an hour, or about 2½ million gallons a day per acre of sand. One ingenious engineer had the jelly scraped off the surface of his filter, and the water flowed more freely certainly, but there were within a few hours urgent telephonic messages from the bacteriological department announcing the arrival of thousands of bacillus coli, and that the water supplied by that company was not fit to drink. The fact is that it is the organic slime which is formed on the top of the sand, and which the sand is only useful in supporting, that is the effective agent in filtering the water, for the organic slime destroys the micro-organisms which are in impure water. It is in this respect that our ancestors, in using their sand filters, were wiser than they knew.

While the micro-organisms which cause cholera, typhoid, and tubercle are so rapidly conveyed to us by means of water, and then exercise their fateful activities, which bring us disease and death, there are beneficent bacteria which "come to succour us who succour want," and these are applied as a bastion or a defence against our enemies by means of the at one time despised sand filter. I think it was Napoleon who said that a wise general should not fight too often with the same enemy, for the enemy was apt to learn too much from his implacable foe. We have fought often with the bacillus of cholera and typhoid, and have learned of our battles. Nothing could be more tragic in the way of instruction than what took place at Hamburg and Altona in 1892. Both Hamburg and Altona are dependent for their water supply on the Elbe, but the intake for the Hamburg supply is above the town; the intake for the Altona supply is below Hamburg, at a place below the point where the sewage of that town, with its 800,000 inhabitants, is discharged into the river. The Hamburg supply had, therefore, a great initial advantage over that of its neighbouring town. But the cholera epidemic scourged Hamburg, and the Angel of Death passed very lightly over Altona. At Hamburg the deaths from cholera amounted to 1250 in 100,000, and at Altona to only 221 per 100,000 of the population. Where the division between the two towns was only the imaginary line down the centre of a street, and the houses on one side of the street, being in Hamburg, were supplied with the above-town water, and the houses on the other side were supplied by the below-town water, the cholera visited with fatal results the houses on the Hamburg side, while those on the Altona side were free from the disease in this new Passover.

These haggard statistics are to be accounted for only by the fact that the foul sewage-polluted water of the Elbe which was supplied to Altona was carefully filtered, while the comparatively pure water taken above Hamburg for the supply of that town was not. Altona had the protection of the micro-organisms in its sand filters. Hamburg had no such protection, and suffered accordingly.

A similar experience in relation to another water-borne disease—typhoid—has been put on record by the Massachusetts Board of Health. There in twenty years, from 1856 to 1876, the death-rate from typhoid in that State was 8·6 per 10,000 of population; in the years between 1876 and 1895, when private wells had been given up and a public supply of filtered water substituted, the death-rate was only 4·1 per 10,000, and between 1896 and 1899 the death-rate went down to 2·6 per 10,000. The State Board report says:—"The death-rate from typhoid fever has generally fallen as the percentage of the population supplied with public water has risen, for the reason that the majority of the deaths from this disease have occurred among communities and portions of communities not supplied with public water."

But an examination of our own Thames water at Hampton showed there were 1644 micro-organisms in twenty drops of water, and the water, after passing through the sand filters, was found to contain only thirteen such organisms in the same number of drops. The discovery of the 1644 germs was at the time so startling that the shares of one of the water companies dropped in value; and I think these 1600 did valiant duty in the arbitration which had to determine the value of the company's undertakings when they were being transferred to the Water Board.

But notwithstanding these startling vindications of sand filters, the great town of Chicago takes its water from Lake Michigan, which receives the untreated sewage of various towns having in the aggregate a population of more than two million people, and has not thought it necessary to subject its water to any preliminary purification before distribution. That town has, however, with curious inconsistency, diverted its own sewage from the lake, but it has undertaken that sanitary improvement only in connection with the commercial undertaking of the drainage and ship canal.

We know that one of the riddles of the politico-economic platform is, "What is raw material, and what is a manufactured article?" But we have seen sufficient to see that "raw water" is quite a rare commodity, and that most of our waters are manufactured articles. Even eastern countries like China and India have long "doctored" water with alum to get rid of clay by coagulation. But in this country not only do we get rid of the turpidity of water by sedimentation, but we purge the waters of micro-organisms, including pathogenic germs, by storing in large reservoirs, as well as by filtration. Very hard waters, waters containing lime and magnesia, are treated and softened by what is called Clarke's process. Everyone knows that chalk waters fur boilers and kettles, and that the bicarbonate of lime is precipitated by boiling; but Clarke's process consists of a chemical method which expels chalk by chalk, and is an ingenious application of science to the practical purpose of softening water which lengthens the life of boilers and saves soap. But, again, water may be too soft. Hill waters are sometimes too soft to be palatable. Water at Keswick is under half a degree of hardness; Loch Katrine water, 1 degree; Thames and New River water is about 14 degrees.

But it is found that distilled water, or soft lake or river water, acts with extreme rapidity upon lead, and many cases of lead poisoning have occurred in consequence of persons drinking waters which have been in contact with the lead of which distributing pipes are, for the most part, constructed. It has been said that sand filters remove the lead; but at present it is the rule to treat, or "doctor," these very soft waters, as is done at Sheffield, where, to overcome this difficulty, from half to (rarely) three grains of powdered chalk is added to each gallon of water with excellent results. It has been found, too, that loam or clay remove by merely carrying down organic or inorganic impurities from water; and it is certain that the precipitation of lime which takes place in Clarke's process has some effect in the same direction, although, from experiments made by Dr. Percy Frankland in connection with the Cambridge Water Bill of 1910, it does not seem to be a thoroughly effective method of purification. In connection with that Bill, a suggestion was made that suspicious waters—waters drawn from wells in the chalk in close proximity to certain villages—could be made perfectly safe by the chlorination of water; and it was stated that the ozone process which has been adopted in relation to certain waters forming part of the supply to Paris is also a useful and protective process in cases where waters are liable to organic pollution, and in which the danger-signal of bacillus coli is found. These instances are sufficient to show that water, to be potable, must pass through the hands, not only of the engineer with his filter and storage, but also through the hands of the chemist and bacteriologist; in fact, water, unlike the poet, is made, not born.

There is at the present time a good deal of sporadic information as to the water supplies and resources in various localities, and mining engineers have, from their experience, some knowledge of the subsoil or underground waters, for these, of course, are the enemy with which they have to contend in their operations; but there is no general survey to determine what are the supplies and what are the water resources of this country; there is no general knowledge as to the underground water supplies. We know that in many districts these are being pumped for supply; in many where mining is going on they are, with reckless economy, being pumped to waste. But what is required is a comprehensive knowledge both of the overground and underground reserve forces for water supply, and until that is prepared any legislation with regard to water supply must be merely hand to mouth, unscientific, and futile; and this seems to have been the wise opinion of Mr. Lithiby, of the Board of Trade, who gave evidence before the Joint Select Committee on the Water Supplies Protection Bill, which sat and reported during the last session of Parliament.

The necessity for the acquisition of such knowledge is emphasised by the proceedings and report of the Royal Commission which has been inquiring and reporting upon canals and waterways since the year 1906. No one can say that the investigations of that commission have not been exhaustive, although many may think that the reservations of Lord Farrer and three other commissioners seem to show that their labours will prove absolutely futile. But the commission has gone further, and proposes to improve the waterways of England, and great new or improved canals are to connect the Midlands and South Staffordshire with the estuaries of the Thames, the Humber, the Mersey, and the Severn. These four routes, which are, after all, only to be large barge canals, suited for barges of, in one scheme, 100 tons burden, and in another of 300 tons burden, are, in the report, referred to as the "cross," and if this gigantic scheme is carried out at an expense, according to Sir John Wolfe Barry's estimate, of, for the small scheme, 13,393,483*l*., or for the large scheme of 24,513,823*l*., certainly England would be financially crucified. But criticism of that imaginative proposal forms no part of my present purpose. It is only interesting to me to note that after the commission had adumbrated this idea, and ascertained approximately the cost of constructing the "cross," which, as I have said, would be a cross greater than England could bear, they bethought themselves how they were to get water for their canals—in the deplorable absence of the Alps—and they instructed an engineer to survey and inquire and to give them an estimate of the cost of getting the water. I have no doubt he did his work as well as he could. He found ready to his hand the admirable statistics as to rainfall which are collected by Dr. Mills, but complains, rightly enough, that "other questions connected with the national water supplies appear to receive less attention." Of course, it is quite an exception to find anywhere river gaugings, and the engineer in question says:—"This inquiry has shown the necessity, if such problems as those which the following reports attempt to solve are to be thoroughly investigated in future, of some public authority being charged with the duty of recording the flow of rivers, and of the proportion of the rainfall available or run-off in catchment basins overlying different geological strata in various parts of the country."

But this claim to water for canals, which, according to the reporter, would involve an expenditure of 1,194,000*l*., without including the cost of obtaining the power or the cost of water compensation, and is, of course, in addition to the sums estimated for construction by Sir John Wolfe Barry, raises again in an acute form the whole question of our national supplies, and points to the absolute necessity now of some systematic dealing with this great question. The nation is being forestalled by municipalities, and here is a suggestion that a Canal Board should lay a gigantic hand upon some of our sources of supply. The time for dealing with the matter is *now*; but, as in other cases, it is quite likely that the matter will be postponed until it is "too late."

SELF-LUMINOUS NIGHT HAZE.[1]

THERE is one phase of the night skies which does not seem to have received much or any attention. It is the occasional presence of self-luminous haze. This matter does not seem to be similar to the luminous night clouds, "die leuchtenden Nachtwolken," which were observed by O. Jesse and others some twenty-five or thirty years ago, and were found to be clouds at such great altitudes above the earth's surface (upwards of 50 miles high) that they received the sunlight long after or before the ordinary clouds. The observations of O. Jesse were printed in the *Astronomische Nachrichten*, Bd. 121, pp. 73, 111; Bd. 130, p. 425; Bd. 133, p. 131; Bd. 140, p. 161. In *Astronomische Nachrichten*, Bd. 140 (No. 3347), he gives a long list of altitudes, determined by photography, which range from 81 km. to 87 km. The mean value given by the observations from 1885 to 1891 was 82 km. (52 miles). These clouds were seen in the northern hemisphere only near the time of the summer solstice. In the southern hemisphere they were seen at the opposite season. From his papers it is clear that these sunlit clouds were in no way related to the present subject, and I only mention them to forestall any suggestion that they were similar to the ones seen by me.

The objects to be described here were apparently at the altitude of the ordinary higher clouds. They have been seen in all parts of the sky and at all hours of the night. In a paper on the aurora[2] I have previously directed attention to the frequent luminous condition of the sky at night. This feature long ago impressed itself upon me. Indeed, anyone who has spent much time under the open sky hunting comets, &c., will have been forcibly impressed with this peculiarity. In most cases this illumination has been due, evidently, to a diffusion of the general star light, perhaps by moisture in the air. This latter condition is present as a whitening of the sky, which gives it a "milky" appearance. At other times the sky is more or less feebly luminous; but the luminosity is different from the other condition, and is evidently not due to a diffusion of star light. In reality, the sky seems to be self-luminous. Sometimes the whole sky has this appearance, and at other times a large portion only. At times the illumination is so great that the face of an ordinary watch can be read with no other light than that of the sky. It is indeed seldom that the sky is rich and dark. In any determination of the total amount of the light of the sky the results must be uncertain, because of the great changes that so often take place in the amount of the illumination. The self-luminous condition frequently occurs when no ordinary indications of an aurora are present. It is, nevertheless, doubtless of an auroral nature, for Prof. Campbell has shown that the spectrum of the aurora is essentially always present on a clear dark night (*Astrophysical Journal*, 2, August, 1895, p. 162).

I have given an account[3] of the remarkable pulsating clouds of light that are seen here occasionally, which usually, but not always, have an easterly motion—generally south-east. They are mostly confined to the northern half of the heavens. There is another phenomenon that has been visible on a number of nights of last year, and also in the present year, of which I have seen no record. This consists, usually, of long strips of diffused luminous haze. I believe that this is really ordinary haze which for some reason becomes self-luminous. It is not confined to any particular region of the sky nor to any hour of the night. It always has a slow drifting motion among the stars. This motion is comparable with that of the ordinary hazy, streaky clouds that are often seen in the daytime. They are usually straight and diffused, and as much as 50° or more in length and 3° or 4° or more in width. In some cases they are as bright, or nearly as bright, as the average portions of the Milky Way—that is, they are decidedly noticeable when one's attention is directed to them. They apparently are about as transparent as ordinary haze. Sometimes, when seen near the horizon,

[1] From a paper read before the American Philosophical Society on April 21, by Prof. E. E. Barnard.

[2] *Astrophysical Journal*, 31, April, 1910.

[3] *Astrophysical Journal*, 31, April, 1910, p. 210, &c.

where they may be quite broad, they have strongly suggested the "dawn" or glow that precedes a bright moonrise. Their luminosity is uniformly steady.

The reason I refer to this matter as haze, and the reason I think it is only ordinary haze made self-luminous, is because on one occasion I watched a mass of it in the north-western sky which was slowly drifting northerly in the region of the great "dipper" of Ursa Major as daylight came on. These hazy luminous strips had been visible all the latter part of the night—new strips coming and going slowly, sometimes several being seen at once. As daylight killed them out I noticed, when the light had increased sufficiently, that there were strips of ordinary haze exactly the same in form and motion, and occupying the same region of the sky. I am sure they were the same masses that had appeared luminous on the night sky. My impression, therefore, is that these hazy luminous strips were only the ordinary haze which had for some reason become self-luminous. I am specially certain that these masses are not luminous as a result of any great altitude which might bring them within reach of the sun's light, for they were frequently seen in such positions that the sun's rays could never reach them. The sun or moon, therefore, had nothing to do with their illumination. It is also needless to say that they are not related to the pulsating auroral clouds which I have previously mentioned.

I have not noticed this luminous haze in former years, though it may have been present; and did it not seem unreasonable, one might suspect some relation between this condition of the atmosphere and the possible passage of the earth through a portion of the tail of Halley's comet on May 19, 1910.

It seems to me that these objects should be observed and a record made of the times of their visibility and their motion, &c. It would be valuable to have records of them from different stations to see if their luminosity is due to some general condition of the earth's atmosphere at the time. It is not probable that this luminosity is in any way due to local conditions. In the records here given, it is possible that on one or two occasions an aurora was also present, but I have tried to confine the accounts to what I have called, and believe to be, self-luminous haze. They were not seen previous to June 7, 1910.

[Prof. Barnard then gave details of observations made on various dates from June 7, 1910, to March 2, 1911.]

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

An advanced course of instruction on "The Systematic Design and Manufacture of Dynamo-electric Machinery" will be given at the City and Guilds (Engineering) College, South Kensington, during the forthcoming session, under the general supervision of Prof. T. Mather, F.R.S., professor of electrical engineering at the college. The course is to prepare men to take up positions as designers in electrical works. It will deal with present-day problems in design, construction, and testing, in a thoroughly practical manner. An experienced designer and draughtsman, specially engaged for the purpose, will devote his whole time to the drawing-office work in connection with the course. The course is intended for post-graduate and other duly qualified students, the number of which will be strictly limited. Application for admission to the whole course, or parts thereof, should be made by letter to the Dean, City and Guilds (Engineering) College, Exhibition Road, London, S.W.

The President of the Board of Education has appointed a departmental committee to inquire and report—(*a*) Whether it would be inconsistent with due regard to educational and hygienic considerations that the *minimum* standard of playground accommodation for new public elementary schools prescribed in the Building Regulations of the Board of Education—viz. 30 feet per head of accommodation should be modified or adjusted according to the size, design, or situation of schools, the proximity of recreation grounds or open spaces, the density of population, the cost of land, or otherwise. (*b*) How far it is possible or desirable to define more precisely the standard of playground accommodation which the Board of Education will require under the Code of Regulations for Public Elementary Schools in the case of existing schools or to regulate the practice of the Board of Education in dealing with cases in which the playground accommodation is considered to be insufficient. The committee will consist of Mr. L. A. Selby-Bigge, C.B., principal assistant-secretary of the Elementary Education Branch of the Board of Education (chairman); Sir George Newman, chief medical officer of the Board of Education; Mr. J. C. Iles, H.M.I., divisional inspector for the North-western Division; Mr. F. H. B. Dale, H.M.I., divisional inspector for the Metropolitan Division; Mr. A. B. McLachlan, of the Local Government Board; with Mr. L. J. Morison as secretary.

The latest report of the U.S. Commissioner of Education gives some interesting statistics of the so-called land-grant colleges, established under the provisions of the Act of Congress of July 2, 1862, and receiving aid from the Federal Government from funds provided by Acts of Congress of 1890 and 1907. Each State received from the U.S. Treasury during the year ended June 30, 1910, the sum of 8000*l.* for the benefit of these land-grant colleges—commonly called agricultural and mechanical colleges—making a total of 400,000*l.*, exclusive of the sums paid for experiment-station purposes, expended by the Federal Government in aid of these colleges. There are sixty-eight of these institutions, sixteen of which are separate institutions for the coloured race. These colleges are in a period of rapid growth, shown by a marked increase in the number of instructors and students and the value of their property and income. The total number of instructors during the year in all departments of the sixty-eight colleges was 6665, of which 742 were women. The total number of students enrolled for the year was 80,646, an increase of 9·6 per cent. over the preceding year. The total value of the property held for the benefit of these colleges amounts to 23,568,600*l.*, an increase for the year of 910,000*l.* The total income from all sources, excluding the grants for experiment stations, was for the year about 4,180,000*l.*, an increase of some 459,000*l.* during the year.

The "Directory for Higher Education, 1911–12," issued by the Education Committee of the Staffordshire County Council, contains the regulations of the committee and details of schemes in operation throughout the county. Very complete provision is made for technological instruction, and among the subjects catered for the following may be mentioned:—Instruction in mining is provided by means of lecturers, whose whole time is devoted to the work, and their assistants. For this purpose the county is divided into two portions, comprising the North Staffordshire coalfields and the South Staffordshire coalfields respectively. Theoretical and practical classes in metallurgy and iron and steel manufacture are conducted in accordance with the regulations of the Board of Education and the City and Guilds of London Institute. Instruction is also provided in pottery and porcelain manufacture, boot and shoe manufacture, silk manufacture, and in wrought-iron work. In order to enable teachers in elementary and secondary schools to impart instruction in various branches of technical and manual training, the committee provides special classes at convenient centres. In localities where suitable instruction is provided already, classes in approved subjects are recognised by the committee, and with the object of encouraging the attendance of teachers at such classes, grants towards their railway fares are made. The work of the committee in rural districts falls under three heads: instruction directly supplied in special subjects, viz. agriculture, horticulture, hygiene, domestic subjects, and wood-carving and drawing; evening schools taught by local teachers, and earning a grant from the Board of Education; and experimental and demonstration plots.

The Charity Commission has given notice that it proposes to make an order establishing a scheme for the future regulation of the People's Palace in East London. The scheme sets forth that with reference to the administration of the East London College, in connection with the Palace, by the Council, the charity and its endowments shall be administered by a body of governors fifteen in number. Of these the master and clerk of the Drapers' Company shall be two, the Drapers' Company shall nominate six, the Central Governing Body two, the County Council one, and four shall be coopted members. So long as university education is carried on by the Council in the present college premises, the governing body shall grant the use of them at a rent of 1*l.* per year. The scheme goes on to state that the Drapers' Company shall pay to the governing body the sum of 7000*l.* per annum. The company may, however, discontinue such payment on giving notice and, at the expiration of five years, paying for the purpose of the scheme the sum of 30,000*l.* If at the date whereon the payment of 30,000*l.* becomes due university education is being carried on in the present college premises, the money shall be applicable for the future maintenance of the East London College as may be directed by the Board of Education. So long as university education is carried on and the annual payment from the Drapers' Company is received, the amount is to be paid for the purposes of the East London College, and the scheme determines that the part of the endowment of the charity which is held for educational purposes consists of the present college premises, so long as university education is carried on there, the sum of 7000*l.* per annum so long as it is paid by the Drapers' Company or the 30,000*l.* to be paid by the company in the event of the discontinuance of the annual payment. The educational endowment is to be administered under the title of the East London College as a separate educational foundation for the promotion of university education.

WE learn from *The Pioneer Mail* that new buildings of the Poona Agricultural College were opened by Sir George Clarke, the Governor of Bombay, on July 18. The college at present consists of two large buildings, and another is in course of construction. In the main building all work except that relating to chemistry and physics will be done, the smaller one adjoining being devoted solely to these latter subjects. The complete course at the college lasts three years and includes practical farming, general chemistry, botany, agricultural engineering, veterinary science, agricultural climatology, entomology, and so on. During the course of his address Sir George Clarke said there is only one fault in the Bombay Agricultural Department: it is far too small, in comparison with the needs of cultivators and the vast magnitude of the task which it has undertaken. "If I were an Indian politician," he continued, "I should worry Government, in season and out of season, to spend more money upon the improvement of agriculture and the acquisition and spread of knowledge. We require much more research work because the problems of India are her own, and careful investigations carried on in other countries may be valueless in our special conditions. We want more demonstration farms where cultivators can receive an object-lesson by which the advantages of improved methods can be brought home to their minds. I should like to see many more lecturers employed in going about among villages to instil new ideas and to awaken interest. I think we should also establish rural schools where the elements of practical agriculture could be taught in the vernacular. The demands upon the Government are now so many and so insistent that we cannot do all we wish. If the nature and vast importance of agricultural work were more widely known, I am certain that our many wealthy and generous philanthropists would come forward to help. There can be no better proof of patriotism and no better way of promoting prosperity than the increase and development of the production of the land, which lies within our power if adequate means were available."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society.—Prof. J. H. **Poynting**: Small longitudinal material waves accompanying light waves. (Received July 26.)

All experiments on the pressure of light agree in showing that there is a flow of momentum along the beam. This flow is manifested as a force on matter wherever there is a change of medium. When the light is absorbed, the momentum is absorbed by matter. When the beam is shifted parallel to itself there is a torque on the matter effecting the shift. The momentum would therefore appear to be carried by the matter, and not merely by the æther. Though there is an obvious difficulty in accepting this view when the density of the matter is so small as it is in interplanetary space, it appears to be worth while to follow out the consequences of the supposition that the force equivalent to the rate of flow of momentum across a plane perpendicular to a beam of light acts upon the matter bounded by the plane. This rate of flow per square centimetre is equal to the energy density or energy per cubic centimetre in the beam. Of course, in experiments, only the average of the rate of flow during many seconds and the average energy per cubic centimetre in a length of beam of millions of miles is actually measured. But on the electromagnetic theory of light, which suggested the experiments and gives the right value for the pressure, this pressure is equal to the energy density at every point of a single wave.

Let us suppose that we have a train of plane polarised electromagnetic waves of sine form, the magnetic intensity being given by

$$H = H_1 \sin \frac{2\pi}{\lambda}(x - vt),$$

where H_1 is the amplitude of H. The electromagnetic energy per unit volume is $\mu H_1^2/8\pi$, and

$$\frac{\text{Energy in longitudinal waves}}{\text{Electromagnetic energy}} = \frac{\mu H_1^2}{32\pi\rho v^2} = \frac{1}{S}\frac{\mu H_1^2}{S\pi} \Big/ \frac{\rho v^2}{2}$$

which is one-eighth of the electromagnetic energy divided by the energy which the matter would have if it were moving with the velocity of light in that matter.

This shows how infinitesimal is the fraction of the energy of the beam which is located in these waves of compression of the material.

The fraction is proportional to the intensity of the beam.

As an example, take a beam of the intensity of full sunlight just outside the earth's atmosphere, in which the energy flow is about $1{\cdot}4 \times 10^6$ ergs/sec. The energy density $\mu H_1^2/S\pi$ is therefore $1{\cdot}4 \times 10^6 \div v$. Put $v = 3 \times 10^{10}/n$, where n is the refractive index. The fraction is

$$\frac{1}{4} \cdot \frac{1{\cdot}4 \times 10^6}{27 \times 10^{30}} \frac{n^3}{\rho}, \text{ or about } 1{\cdot}25 \times 10^{-26} n^3/\rho.$$

At the surface of the sun it would be about 40,000 times as much; say $5 \times 10^{-22} n^3/\rho$.

It is interesting to note that if a beam of light is incident on any reflecting or absorbing surface, and if the pressure of light is periodic with the waves, it must give rise to ordinary elastic waves in the material of frequency double that of the light waves.

EDINBURGH.

Royal Society, July 14.—Sir William Turner, K.C.B., president, in the chair.—Prof. F. A. **Forel**: Refractions at the surface of a lake, mirages, and *fata morgana*. In discussing mirages and refraction effects over the surface of a lake, one must distinguish between refractions in air over warm water and refractions in air over cold. In the former, with the warm layers below, the curve of refraction is concave upward; in the latter it is convex; and the horizon is, respectively, elevated above and depressed below its normal position. On a summer day, as the temperature of the air changes from being lower to being higher than the temperature of the water, there appears a phenomenon called by the Italian men of science the *fata morgana*. It has the appearance of a series of rectangles, as if some great cliff or the quays of an enormous city extended along the opposite side of the lake. The higher line of this striated zone coincides with the horizon of the refraction over cold water, and the lower line is continuous with the horizon of the refraction over warm water. The *fata morgana* is the fusion of the two types of refractions as the one succeeds the other.—J. Y. **Buchanan**: Experimental researches on the specific gravity and displacement of some saline solutions.

Paris.

Academy of Sciences, July 31.—M. le Général Bassot in the chair.—R. **Radau**: The tables of the moon, based on Delaunay's theory. The solar perturbations of Delaunay, with some additional corrections suggested by Andoyer, may be considered as sufficiently exact from the point of view of practical astronomy, but there is still a lack of agreement with the observed figures as tabulated by Hansen. Means are suggested for further reducing the differences between the observation and calculation.—P. **Villard**: A self-recording electrometer with carbon filaments. A U-shaped carbon lamp filament, carrying a small cylindrical mirror made of a short piece of glass capillary tube silvered inside, forms the moving part of the electrometer. The sensibility of the instrument can be readily modified so as to be suitable either for use in an observatory or in a balloon.—Lecoq **de Boisbaudran** and A. **de Gramont**: The spectrum of gluanum and its bands in different sources of light. The wave lengths of the principal components of three bands (green, blue, and indigo) are given. The general similarity with the corresponding aluminium bands is pointed out.—Édouard **Heckel**: The genus Spermolepis of New Caledonia and its relations with the genus Schizocalyx.—M. **Javelle**: The Wolf comet (1911*a*). Observations made at Nice with the 76 cm. equatorial. Data are given for July 15, 20, 21, 22, 26, 27, 28, and 29. The comet appeared as a feeble nebulosity, about 10 inches in extent, and with a nucleus below the 14th magnitude.—M. **Esmiol**: Observation of the Brooks comet (1911*c*) made at the observatory of Marseilles with the Eichens equatorial of 26 cm. aperture. Data given for July 22. The comet appeared as a round nebulosity, 0·2′ in diameter, with a nucleus of about the 12th magnitude.—M. **Borrelly**: Observations of the Brooks comet (1911*c*) made at the observatory at Marseilles with the comet-finder. Data given for July 22 and 23.—A. **Korn**: An important class of asymmetrical nuclei in the theory of integral equations.—May Sybil **Leslie**: The molecular weight of the thorium emanation. An application of the apparatus used by Debierne (effusion through a small orifice) for the determination of the molecular weight of the radium emanation to the thorium emanation. The results show that the molecular weight of the thorium emanation is in the neighbourhood of 200.—Edm. **van Aubel**: Hall's phenomenon and the transversal thermomagnetic effect in graphite. Graphite shows Hall's phenomenon in the opposite sense to antimony, or in the same sense as pure bismuth, like the other varieties of carbon.—L. **Dunoyer**: Researches on the fluorescence of the vapours of the alkaline metals.—William **Duane**: The mass of the gaseous ions. Under the experimental conditions described in the paper, all the results obtained were opposed to the hypothesis of the existence of positive ions.—J. **Danysz**: The β rays of the radium group. The β rays from the radium emanation have yielded a magnetic spectrum of seven homogeneous bundles, the velocities of which have been exactly determined.—Eugène **Cornec**: The cryoscopic study of some mineral acids and some phenols. The method used consists in neutralising the acid or phenol gradually by a strong base and determining the freezing point for each mixture; the neutral point is indicated by an angular point on the curve.—H. **Pelabon**: The metallography of the selenium-antimony systems. The results obtained confirm the conclusions drawn in an earlier paper from a study of the fusibility curves.—M. **Jouguet**: Indifferent points.—F. **Bodroux** and F. **Taboury**: The action of bromine in presence of aluminium-bromide on cyclohexanol and cyclohexanone.—F. **Bodroux**: The action of anisaldehyde and piperonylaldehyde upon the sodium derivative of benzyl cyanide.—A. **Barillé**: The action of soda water upon lead, tin, and antimony. The causes of poisoning by chemical alteration. More lead and tin are dissolved by soda water from an alloy of tin and lead than from either of the pure metals, and this is true even for an alloy containing only 0·5 per cent. of lead. The author concludes that all the metallic parts of a soda-water siphon ought to be protected by enamel or similar means from contact with the liquid.—Marcel **Badouin**: Study of the action on the brain of the annular deformation of the skull of the Gallo-Roman period.—Maurice **Arthus** and **Bolesława-Stawska**: Poisons and antipoisons. A criticism of the results of experiments by C. J. Martin and T. Cherry, on the interaction of a toxin and antitoxin *in vitro*. The authors' experiments with mixtures of cobra-venom and its antiserum lead to the conclusion that the neutralisation of the venom by the antivenom is practically instantaneous, and rather resembles the neutralisation of an acid by a base than a diastatic action. The same conclusion was arrived at when working with the venom of *Lachesis lanceolatus* and of *Crotalus terrificus* and their corresponding antivenoms.—M. **Mazé**: Researches on the formation of nitrous acid in the plant and animal cell.—Gabriel **Bertrand** and Arthur **Compton**: The influence of the reaction of the medium on the activity of cellase. A new distinction from emulsine.—E. **Voisenet**: A ferment causing bitterness in wine, a dehydrating agent for glycerol. An account of the isolation of a bacillus, capable of transforming glycerol into acrolein.—C. **Levaditi** and S. **Muttermilch**: The diagnosis of sleeping sickness by the examination of the attaching properties of the serum.—Jules **Welsch**: A depression of the Lower Eocene north of Blaye in Cosnac (Charente-Inférieure).

THURSDAY, AUGUST 24, 1911.

TWO WORKS ON WIRELESS TELEGRAPHY.

(1) *Précis de Télégraphie sans Fil. Complément de l'Ouvrage: les Oscillations Electromagnétiques et la Télégraphie sans Fil.* By Prof. J. Zenneck, Translated from the German by P. Blanchin, G. Guérard and E. Picot. Pp. x + 385. (Paris: Gauthier-Villars, 1911.) Price 12 francs.

(2) *A Handbook of Wireless Telegraphy: its Theory and Practice. For the Use of Electrical Engineers, Students, and Operators.* By Dr. J. Erskine-Murray. Third edition, revised and enlarged. Pp. xvi + 386. (London: Crosby, Lockwood and Son, 1911.) Price 10*s.* 6*d.* net.

(1) THE literature of wireless telegraphy grows apace, both in new books and new editions. This at least is a proof that the art is in a progressive condition. The book by Dr. J. Zenneck before us is a French translation, under the title "Précis de Télégraphie sans Fil," of a work by him which appeared in Germany two years ago, called "Leitfaden der Drahtlosen Telegraphie."

It is, as the author tells us, intended as a condensation and supplement of his larger treatise on "Electrical Oscillations and Wireless Telegraphy," published in 1905. In the present work mathematical discussions have been almost completely avoided, and the reader is referred to other sources for the systematic proofs of the few formulæ given. The book appeals therefore to the general reader or practical worker who wishes for a non-mathematical but scientific discussion of phenomena. The numerous excellent diagrams, curves, arrangements of circuits, and illustrations of apparatus are sufficient to convey to the careful reader a large amount of solid information on the subject. One good feature is that there is no attempt to describe various "systems" of wireless telegraphy by different inventors; but the separate elements which make up the arrangements generally used are scientifically discussed. Beginning with the analysis of the phenomena of oscillations in a condenser circuit and the measurement of the quantities concerned, we have successive chapters on the transformation of oscillations, resonance curves, antennæ, radiators, detectors, receiver circuits, and directive telegraphy.

The treatment for the most part follows orthodox lines as adopted in other standard treatises on the subject, and is characterised by a German thoroughness of treatment, though marked by an occasional tendency to claim for Germany rather more than is historically warrantable. Thus, for instance, the electric hot-wire thermometer figured on p. 66 is attributed to Riess, whereas Sir William Snow Harris first described it in the Philosophical Transactions of the Royal Society in England in 1827, long before Riess. In the same manner, Prof. F. Braun is given credit on p. 161 for the modern coupled transmitter, whether single coil or double coil, which is called "l'émitteur couplé ou émitteur de Braun," although the recent judgment of Mr. Justice Parker in the British High Court of Justice has declared that the modern tuned coupled transmitter first described by Marconi, whether used with a two coil or with an autotransformer, was not anticipated by the inventions of Braun. The double transformation transmitter, the arrangement of which is figured on p. 173, is the invention of this reviewer, whose name, however, is not mentioned in connection with it. The chapters on resonance curves and on antennæ are very good, but that on transmitters might have been improved by a little more attention to the description and theory of impact dischargers, which are of considerable importance.

In discussing the action of directive antennæ, Dr. Zenneck advances a theory—which is not, however, supported in this book by mathematical proof—that the explanation of the greater range of a bent antenna in the direction opposite to that in which the free end points is to be explained by the different shape of the wave surface on the two sides, so that the wave obtains a greater reach one way than the other, just as a rifle when fired carries further if elevated than if depressed. Another explanation has been given by the writer, based on an opinion expressed by Sir J. Larmor, that the bent antenna can be regarded as a combination of closed and open antennæ. This theory receives experimental support from the work of Bellini and Tosi on directive antennæ. One of the most interesting as well as practical questions in connection with long-distance wireless telegraphy is that of the atmospheric absorption and the influence of daylight in reducing the range of transmission for certain wave lengths. This is generally attributed to ionisation of the atmosphere produced by ultra-violet solar light. This solar radiation is, however, so rapidly absorbed by the atmosphere that the chief effect can only be produced at high altitudes. The theory that it is due to the direct action of ultra-violet light on the sending antenna is not supported by any experimental evidence. The hypothesis that it is due to ionisation of the air receives some confirmation from a certain variation of radiotelegraphic range with variations in atmospheric electricity. It is well known to radiotelegraphists that occasionally atmospheric conditions exist in which quite extraordinary and unusual distances are covered by day as well as by night, and that curious differences exist in the facility with which electric waves of large wave length are propagated in different directions.

We cannot say yet that the phenomenon has received adequate explanation, but materials are being slowly gathered which may in time point to an explanation. The same may be said of the abnormal manner in which electromagnetic waves of long wave length travel round the curvature of the earth. Marconi has succeeded in sending and detecting radiotelegraphic waves at a distance of 6000 miles, or a quarter of the way round the earth. The subject of this abnormal diffraction has been discussed mathematically by Poincaré and by Nicholson, but the complexity introduced by the purely atmospheric and surface absorption of the wave makes it almost impossible to check the mathematical theory which has been given.

(2) The second book before us for review is a third edition of Dr. Erskine-Murray's well-known "Handbook of Wireless Telegraphy." The present edition contains a considerable amount of new matter, but the explanations given of fundamental effects, such as the creation of Hertzian waves, are somewhat too brief to be very useful. The student is not much assisted merely by reproducing on a double page Hertz's well-known diagrams of the electric radiation of a dumbbell oscillator accompanied only by an extract from Hertz's own book, and without further elucidation of the difficulties involved. Rather too much space is occupied in some parts by extracts from original papers, whereas the essentially new information could be concentrated and difficulties removed by a more independent authorship.

After the usual introductory chapters dealing with early history, three chapters follow on detectors for electric waves, considerable space being given to the theory of magnetic detectors and descriptions of forms which have not been much used for radiotelegraphy, whilst the contact or rectifying detectors are very briefly treated. With regard to Fleming's glow-lamp detector, the erroneous remark is made that Dr. de Forest "improved this detector." As a matter of fact, his improvements did not enable it to operate better than in its original form. Chapters viii., ix., x., xi., and xiii. are devoted to descriptions of the Marconi, Lodge-Muirhead, Fessenden, Hozier-Brown, de Forest, and Telefunken "systems" of wireless telegraphy. All of them, however, involve essentially the same system, viz. the spark method, and differ only in the details of the apparatus used. A chapter, which is, however, interesting, is given to methods and apparatus which have never reached the practically efficient stage, such as the "world wave telegraphy" described in chapter xviii., in which Tesla's somewhat tentative experiments are discussed. There is no evidence that any useful telegraphic work has been carried out by these methods.

In the chapter on theories of transmission, a large amount of information is collected on the influence of atmospheric states on radiotelegraphic transmission. Facts are being accumulated which seem to connect variations in received signals over long distances with changes in atmospheric electricity. Much work has yet to be done before a satisfactory theory can be evolved, and it is therefore perhaps premature to attempt to construct such theories in text-books issued now. For one thing, we need much more information than we now possess as to the variation in atmospheric conductivity at high elevations, which may some day perhaps be provided by the use of dirigibles or aëroplanes.

Dr. Murray's book concludes with a useful chapter on high-frequency electric measurements and appendices containing many valuable practical tables, curves, and memoranda. The book is well printed and fully illustrated, and certainly one to be included in any radiotelegraphic library. J. A. F.

THE SCIENCE OF SHIPBUILDING.

The Design and Construction of Ships. By Prof. J. H. Biles. Vol. ii., Stability, Resistance, Propulsion, and Oscillations of Ships. Pp. x+428. (London: C. Griffin and Co., Ltd., 1911.) Price 25*s*. net.

THIS second volume was originally intended to complete the work, but the author found his materials growing rapidly and wisely decided to develop more fully in a third volume his treatment of ship-designing. Like the first volume—reviewed in NATURE, February 18, 1909—the second is complete in itself. It will be of much value as a text-book for advanced students of naval architecture, and as a book of reference for men engaged on the practical details of ship-design. The contents are arranged in four sections; in which the stability, resistance, propulsion, and oscillations of ships are discussed. Under each head is presented an excellent *résumé* of the accepted theory of the subjects treated; in association with valuable data, drawn from recent practice, illustrating the characteristics of various types of ships. A mass of information which was previously widely scattered in various publications has thus been concentrated, including published results of the latest experimental research work.

In dealing with the geometric theory of stability the author has naturally followed the lines laid down by M. Charles Dupin in his memoir entitled "Stabilité des Corps Flottants" (published in 1814), one of the series of "Applications de Géometrie" presented to the Institute of France. Dupin for all practical purposes exhausted the subject, although certain corrections and extensions of his generalisations have since been made by other investigators, more especially as the result of determinations by calculation and experiment of the stability of actual ships made during the last forty years. Prof. Biles describes the methods of calculation, as well as the ingenious integrating instruments (devised by Amsler and others) by means of which arithmetic labour has been greatly reduced. Typical examples are given of curves of stability constructed for many classes of ships, and for different conditions of lading; and the whole section has been arranged in a manner which will enable advanced students to master present knowledge of the subject, while draughtsmen and others who are engaged in the work of calculations of stability will find help and guidance.

From the middle of the eighteenth century mathematicians and experimentalists have been attempting general solutions of the problems of water-resistance to the motion of ships, but with moderate success, and with small practical influence on ship-design, until the late William Froude, little more than forty years ago, introduced the system of experiments on models. Froude demonstrated the law of comparison between ships and models moving at "corresponding speeds," and showed how to make the necessary correction for frictional resistance when passing from models to ships. Model experiments are now universally regarded as necessary to successful steamship design, when precedents have to be surpassed or greater speeds obtained. They can be applied both to the determination of the ship-forms most suitable under the conditions of a given problem, and to the selection of the most efficient propellers.

The first experimental tank, designed and built by Froude, was placed at Torquay, near his residence. It was comparatively modest in size and equipment, and was not intended to be permanent; but it continued at work for many years, first under the direction of the founder, and then under that of his son (Mr. R. E. Froude, F.R.S.), and yielded remarkable results, greatly to the benefit of the designs of ships of the Royal Navy. About twenty-seven years ago the Admiralty decided to construct at Haslar (near Portsmouth) a larger and better equipped experimental tank, to the designs of Mr. R. E. Froude, who has happily continued ever since in charge of its operations, and has greatly developed the system. This Admiralty tank has been the pattern adopted for tanks subsequently established in this country by a few leading firms of shipbuilders, and for many tanks established abroad. France, Germany, Russia, Italy, the United States, and Japan have followed the lead; and the latest, largest, and best equipped of the series is that which has been added to the National Physical Laboratory by the generosity of Mr. Yarrow. The primary purpose of that tank is the conduct of systematic experimental research, and great results may confidently be anticipated from its operations. Previous tanks have necessarily been chiefly devoted to experiments on models representing ships which are to be built, and pure research work has had to yield to more pressing requirements. At the same time, it is but fair to recognise the fact that many very valuable results of a general character, influencing the selection of the most suitable ship forms and propellers, have been published already. Mr. R. E. Froude (with the sanction of the Admiralty) has been the principal contributor; but Mr. Taylor, the superintendent of the United States tank, Colonel Rota of the Italian Navy, Prof. Sadler of Michigan University, and others have added to available information. Prof. Biles has summarised and analysed the results of tank experiments in the present volume, and has undertaken the labour of presenting the facts in a condensed and practical form; he has thus rendered a service to all who are interested in the subject.

Closely connected with the resistance experienced by ships in motion is the subject of propulsion, which is treated in the third section of this book in an adequate and practical fashion. Model experiments on propellers have been, and are of great value, but they require to be supplemented by trials on full scale. The author has brought together available data and indicated the need for further information. He states the conditions which chiefly govern the efficiency of screw propellers, and gives details of the methods of designing them. Progressive speed trials of actual ships are described and recommended, and there is universal agreement that such trials are essential to success in the practical application of model experiments. Numerous examples are given of the results obtained from experiments both on ships and models.

The subject of the oscillations of ships in still water and among waves furnished the opportunity for a second great contribution by the elder Froude to the science of naval architecture. His work in this direction really constituted a new departure in ship-design. Much has been learned from experiments both with ships and models since Froude indicated the way, and a great deal has been done towards endowing ships with greater steadiness and limiting their oscillations. This result has been due in part to a better understanding of the problem and partly to the use of bilge keels, moving weights, internal water tanks, and other special arrangements the action of which tends to limit the range of oscillation of ships in a sea way. These arrangements are discussed by Prof. Biles, and the effects produced by their use are illustrated by results observed on board ships when in actual service at sea.

Although this book is primarily intended for the use of students of naval architecture, it will be seen from the foregoing summary of its contents that it deserves a wider circulation. It should, in fact, have an interest not merely for students and naval architects, but be welcomed by mathematicians and others, to whom the subjects treated and the experimental results recorded should offer many attractions. W. H. W.

JURASSIC AND CRETACEOUS STRATIGRAPHY.

Traité de Géologie. By Prof. Emile Haug. Vol. ii., Les Périodes géologiques, fasc. 2. Pp. 929–1396. (Paris: A. Colin, n.d.) Price 10 francs.

THE Jurassic and Cretaceous systems were for long the most popular among British geologists, and the former will always be of special interest as the principles of historical geology were established by William Smith from work on the Jurassic rocks of the south-west of England. The second part of the second volume of Prof. Haug's "Traité de Géologie" is devoted to these two systems, and we are glad to note that he retains the Rhætic in the Jurassic. The work is of great value as a summary of a wide range of recent research, and its excellent photographs illustrating many well-known Continental localities are of unusual artistic merit. The book is a useful complement to the great treatise of de Lapparent, with its invaluable tabular correlations. Prof. Haug gives short, readable summaries of the stratigraphical classification and geographical distribution of the formations, and deals especially fully with the bathymetric conditions of their disposition. Lists of characteristic fossils are given, and he wisely gives only generic names. Exception may be taken to some of his palæontological conclusions, such as the affinity of Tetracidaris to Archæocidaris.

The amount of space devoted to different areas is very uneven. In spite of the historic importance of the English Mesozoic rocks, they receive very scant attention. Thus the list of literature on the Jurassic contains 361 titles, of which only eighteen, including eight by Mr. Buckman and two by Prof. Pavlov, deal with the British Jurassic. He apparently considers that British Jurassic geology has not been kept up to date, and remarks that it is difficult to determine the precise equivalents of the Dorsetshire Kimeridge and Portland beds; he is disposed to adopt the view that the division between Kimeridgian and Portlandian should be drawn through the middle of the Kimeridge clay. The brief reference to the English rocks leaves more space for the account of their Continental representatives, of which a summary of recent work is of most value to British geologists.

The classification of the Cretaceous system adopted by Prof. Haug shows that there is no prospect of agreement as to the nomenclature. He subdivides this system into three groups, the Eocretaceous, all of which he regards as Neocomian; the Mesocretaceous, for the period of the great Cretaceous transgression during the Albian, Cenomanian, and Turonian; and the Neocretaceous, for the upper divisions, all of which he calls Senonian.

Prof. Haug, on the authority of Prof. Cayeux, accepts (p. 1161) the depth of the chalk sea as not more than 150 fathoms. Mr. Jukes-Browne, on the other hand, has recently reasserted the view that parts of the chalk are truly deep-sea deposits. M. Cayeux's low estimate is inadmissible for some zones of the English chalk.

One of the most instructive features of this treatise is its indications as to the progress of opinion on the principles and problems of stratigraphy, which are especially well illustrated by the Mesozoic rocks. Prof. Haug decides in favour of the existence in Jurassic times of well-defined climatic zones. The influence of climate on the distribution of the Jurassic fauna was recognised by Marcou in 1860, and Neumayr in 1883 defined five climatic zones approximately parallel to those of the present day. Several authorities have, however, denied their existence, and Prof. Haug shows that some of the arguments upon which Neumayr based his zones, can no longer be maintained. It would have been very surprising if thirty years' further palæontological research had not modified the known range of some of the fossils. Thus the genera Phylloceras and Lytoceras are less characteristic of the equatorial zone than Neumayr thought, and the distribution of those genera proves to be controlled rather by depth than by climate. There has also been a greater interchange between the faunas of the boreal zone and the north temperate zone in western Europe than was known to Neumayr. Nevertheless, Prof. Haug concludes that the existing evidence confirms the existence of the Jurassic climatic zones, though he retains only the boreal and equatorial zones of Neumayr. The fuller evidence now available enables him to recognise in Upper Jurassic times several well-defined zoological provinces.

The nature of earth movements is a problem of which Prof. Haug's solution greatly affects his views. He adopts a law that subsidence in one locality is compensated by simultaneous elevation in another. Hence transgressions of the sea upon the land are not universal, for while the sea is advancing in some places it is retreating elsewhere. This law is in direct conflict with the principles of Prof. Suess, and though there is no general discussion of the question in the present volume, attention is prominently directed to various instances where the evidence is consistent with Prof. Haug's law. Prof. Haug has prepared a series of maps of the distribution of land and water at various geological dates; their most novel and useful feature is the importance attached to the bathymetric conditions under which the beds were deposited. They, however, show an extreme acceptance of the view so characteristic of much French geology that beds were laid down in existing geosynclinals, and their occurrence in long, narrow bands is due to original distribution and not subsequent denudation. The maps of the world constructed on this principle do not look convincing. Thus Prof. Haug's map of the Jurassic world (p. 1113) represents by far the larger part as land with the seas in the Lower Jurassic limited, except in Europe, to narrow bands. Hence, according to Prof. Haug, instead of the oceans having been permanent throughout geologic time, there were periods with no oceans at all. The same map, moreover, considerably exaggerates the area in western Australia submerged by the middle Jurassic transgressions. Where the ocean waters were stored during the dry intervals is not explained, and the evidence available as to the Jurassic climates renders any such vast excess of land most improbable. Prof. Haug is to be congratulated on the value of this work, of which perhaps the chief drawback is the omission of economic geology.

J. W. G.

PRACTICAL DIETETICS.

Food and Feeding in Health and Disease: a Manual of Practical Dietetics. By Dr. C. Watson. Pp. xvi+638. (Edinburgh and London: Oliver and Boyd, 1910.) Price 10s. 6d. net.

THE subject of food and diets has rightly attracted considerable attention of late. When dealing with a community of individuals—soldiers and sailors, jails, Poor-Law institutions, &c.—fed by the State or by a local authority, it is obvious that a knowledge of the food values, nutritive and calorific, of the articles of diet, may conduce to considerable economy. On the other hand, a mere knowledge of the chemical composition of the food materials is by no means all the information required, for although the requisite chemical elements may be present in the right quantity the material may not be properly assimilated. Thus gelatin is nearly related to protein in elementary chemical composition, but it can only partially replace the latter. The manner in which the material is prepared and served, *i.e.* the art of cookery, also plays a part in nutrition, for a "tasty" dish acts secondarily by increasing appetite and the flow of saliva and gastric juice.

In disease and convalescence it is essential for the well-being of the patient that both the kind and the quantity of his diet should be regulated.

In the present work the whole subject of food and feeding is exhaustively dealt with, both in health and in disease. Starting with the classification of foods, their absorption and digestion, the important question of the daily amount of food required in health is dealt with. The opinion is expressed that Chittenden's dietary, in which the protein content is only one-half to one-third that contained in the ordinary standard dietary, will maintain the body in a satisfactory state of health, and that an ordinary dietary does give some excess which is injurious to health. At the same time, it is recognised that further observations are required before we can accept Chittenden's results as giving a standard for universal application.

Milk and milk products and eggs are next considered, and then animal foods and their composition. The information given is both varied and voluminous; for example, the influence of different breeds of cows on milk production is considered, and the usual Scotch method of cutting up an ox is illustrated. Full tables are given of the composition, constituents, and nutritive values of all foods—flesh, farinaceous, fruit, vegetable, and mineral. The condiments and alcohol are also considered. As regards that vexed question, the use of alcohol, the author expresses the opinion, with which we fully concur, that

"while the use of alcohol in the treatment of disease is now very restricted, there is no question as to its undoubted value in the treatment of certain diseases, more especially in their critical stages. . . . We must recognise that alcohol is a very valuable therapeutic agent in the treatment of some diseased conditions."

The dietetic treatment of disease is treated very fully and completely. Alternative views are stated with fairness and in a broad-minded manner. Not the least valuable parts of the book are the complete cookery recipes which are included; in this respect the work becomes one of very real practical worth and supplies a decided want. For them the author expresses much indebtedness to his wife.

We have read the book with great interest, and can recommend it as a complete and practical epitome for the student of dietetics, and one which should be of much value to every practising physician.

R. T. H.

FOREST MANAGEMENT.

Schlich's Manual of Forestry. By Sir Wm. Schlich, K.C.I.E., F.R.S. Vol. iii., Forest Management. Fourth edition, revised. Pp. x+403. (London: Bradbury, Agnew and Co., Ltd., 1911.) Price 9*s*. net.

THE fourth edition of the third volume of the above "Manual of Forestry" contains somewhat more matter than its predecessor. The volume is divided into four parts, in which the various departments of forest management are dealt with. A strong feature of the new and revised edition is the number of practical examples given to illustrate the use and application of the various formulæ.

Part i. deals with forest mensuration. A concise description of the various measuring instruments is given and also the procedure generally followed and the formulæ used in calculating the volume of single trees and whole woods. Determination of age and increment are also dealt with. This subject is treated of first, as it naturally forms the foundation of forest management and leads up to what follows in the succeeding parts.

Part ii.—forest valuation—is devoted to the consideration of forest capital and the returns yielded therefrom. The author has been very successful in his method of presenting and explaining this difficult and intricate subject to the reader. He starts by analysing the forest value into its several components, such as the forest soil, the growing stock, the forest as a whole, and the rental derivable from the soil or the forest as a whole. In order to deal with this subject fundamentally the author gives a preliminary chapter divided into four sections. Section 1 shows how the value of property is determined; section 2 shows how the rate of interest applicable to the forest industry may be fixed; section 3 contains the formulæ necessary for calculating with compound interest; and section 4 contains an explanation of the methods of estimating receipts and expenses. With these preliminary matters made plain, he proceeds in the next four chapters (occupying twenty-six pages) to deal with valuation of forest soil, growing stock, whole woods or forests, and the determination of the rental of forests. Chapter vi., which concludes this part, treats of the methods of calculating the financial results of forestry. This subject is usually dealt with separately under the heading "Forest Statistics," but it has been here condensed in a perfectly efficient manner into about sixteen pages as a logical appendage to forest valuation.

Part iii.—the foundations of forest management—likewise contains six chapters. A very interesting introduction is prefixed which sets forth the aims and objects of systematic forest management and forest working plans. The succeeding five chapters deal respectively with increment, rotation, normal age, classes, normal growing stock, and normal yield, while in the final chapter the relation between increment, growing stock, and yield is discussed.

Part iv. explains the preparation of forest working plans. This is the direct sequel and outcome of the previous part. In preparing his working plans the forester aims at bringing every part of his woods and forests into a state as near theoretical perfection as possible. His endeavour is to regulate and bring into a normal condition the increment, rotation, age-classes, growing stock, yield, &c. This necessitates an experienced survey and a very critical knowledge of the forest and its environment. The references in this part to pages and chapters of the previous volumes of the manual indicate in themselves that the forester must be thoroughly acquainted with the fundamentals of sylviculture before he can attempt to construct a rational working plan which is possibly the most important, and at the same time difficult, thing to do in the whole art of forestry, but, as has been indicated, the author has so clearly and thoroughly explained the fundamentals that the intricacies of the working plan may be easily understood. At the end of the book are given appendices containing many useful tables, such as tables for measurement, compound interest, and yield, working-plan schedules, and an index.

The author is to be congratulated upon the production of this volume, which can be warmly recommended to all students of forestry, foresters, and forest owners. Its value at present is great, and it will become greater in direct proportion to the spread of scientific forestry training and the extended afforestation of suitable lands in this country.

A. W. B.

THE MECHANICS OF THE SOCIAL BODY.

Mécanique Sociale. By Prof. Sp. C. Haret. Pp. iv+256. (Paris: Gauthier-Villars; Bucarest: Ch. Göbl, 1910.) Price 5 francs.

THIS volume represents an attempt by Prof. Haret to apply the laws and methods of mechanics to the study of sociology. The condition of an individual at any point of time, he argues, may be conceived as indicated (at least, in its principal aspects) by the magnitudes of three different factors—his economic possessions, his intellectual state, and his moral state. Supposing these three quantities to be measurable, the condition of the given individual at the given time can be represented by the coordinates of a point P, with reference to three rectangular axes OX, OY, OZ, which define his position in the "social space." If these coordinates do not change, the individual is in a state of "social rest"; when they vary, he is in a state of "social movement." Any cause which may produce or vary a social movement is termed a "social force," and any such force may be represented by a vector in the social space. Two individuals are said to possess the same "social mass" when the same social force, applied for the same time, produces the same movement. With such definitions, it is argued, all the ordinary laws of statics and dynamics apply.

That the idea is a novel one, possessing some attractiveness, we are willing to concede. The scheme of coordinates chosen also emphasises the fact, occasionally forgotten in some statistical investigations, that economic, moral, and intellectual changes are not (to use the common phrase) on the same plane, and index-numbers which measure changes in such diverse quantities should not be averaged together. But that the laws of mechanics apply to a system of material points representing, in the way described, the condition of a given population, does not seem to be proved.

The very difficulty that would surely occur to almost any reader at the commencement is ignored, and this, it seems to the reviewer, is the source of all subsequent difficulties. The three axes chosen do not represent quantities of the same kind or dimensions, but quantities quite different in kind. The mere representation of movement in the "social space," the magnitudes and directions of velocities and accelerations, will all depend on the three arbitrary scales chosen. Forces parallel to the three axes do not differ merely in direction but in kind: we cannot speak of forces which are equal in magnitude but different in direction until the three scales are defined. That the ratio of the masses of two individuals is not the same for all forces is admitted: for a given force in one direction the acceleration produced in A may be greater than that produced in B; for a force in another direction the contrary may be the case. The "economic," "moral," and "intellectual masses" of the individual are, in fact, like "economic," "moral," and "intellectual forces," totally different things. Prof. Haret proposes to evade the difficulty by regarding the forces as varying instead of the masses, but this is surely inadmissible. If A and B move, say, with the same accelerations when subjected to the same economic force, but with different accelerations when subjected to the same moral force, it is impossible to say that one and the same force is, in the latter case, different for the two individuals merely in order to avoid admitting that their "masses" are different.

It is with regret that the reviewer finds himself unable to accept the author's thesis, for undeniably it possesses a certain picturesque suggestiveness. Economic forces, for example, are often of a more or less periodic character, and seem to be accompanied by moral forces which are also periodic. If these got a quarter of a period out of phase with each other, the social body would start revolving round its intellectual axis . . . What would happen? G. U. Y.

THE GUM-TREES OF AUSTRALIA.

A Critical Revision of the Genus Eucalyptus. By J. H. Maiden. Vol ii., part i.–part xi., of the complete work. Pp. iv+59+iv plates. Vol. ii., part ii–part xii of the complete work. Pp. iii+61–100+iv plates. Published by authority of the Government of the State of New South Wales. (Sydney: W. A. Gullick, Government Printer, 1910.) Price 2s. 6d. each part.

THE first part of this comprehensive work was issued in 1903, and it is wholly devoted to the description and illustration of *Eucalyptus pilularis*. Parts two and three appeared in the same year, each dealing with only one species, *E. obliqua* and *E. calycogona* respectively. When reviewing those early parts, each of which contains four plates of figures, we ventured to suggest that Mr. Maiden had commenced with a fullness of detail that might imperil the completion of the work, considering that the genus comprises many more than a hundred species. Two species, *E. incrassata* and *E. foecunda*, are described in the fourth part (1904), and illustrated by no fewer than twelve plates. At this rate the probabilities of completion seemed to be exceedingly remote, and the author apparently realised the fact, for succeeding parts have included successively a greater number of species; parts one and two of the second volume containing ten species each, illustrated by four plates.

It is almost superfluous to mention that the genus Eucalyptus is the most important commercially in the vegetation of Australia, and its elucidation is correspondingly desirable. Some of the species are very abundant and widely dispersed, whilst others are very rare and local, and consequently liable to extinction.

At least two other botanists—Bentham and Mueller—have dealt with the whole genus before Maiden took up the work, and Mueller also possessed field knowledge. But one generation of botanists by no means mastered all the details of classification of this difficult genus. Mr. Maiden has the advantage of the results of the investigations of his predecessors, and he has fully availed himself of it, even to the extent of visiting Europe to study the types of the species described by the earlier botanists. The value of his classification can only be estimated after the practical use of it in the determination of new material. The figures in the parts under review are mostly of leaves attached to a small piece of the axis, detached inflorescences, and mature seed-vessels, the originals of all the figures being carefully recorded.

It may be mentioned, however, that the same author's "Forest Flora of New South Wales," so far as issued, contains figures of thirty-eight species of Eucalyptus, figures of larger branches, in flower and fruit, thus supplementing those of the "Revision." Of the latter, fifty-six plates have been published, illustrating fifty-nine species. Details of the economic value and the popular names are fully given only in the forest flora. The usefulness of Mr. Maiden's important work must remain comparatively limited until its completion; therefore any acceleration in its publication would be welcome. But it is to be feared that the author's arduous duties as director of the Sydney Botanic Garden and State botanist leave him little time for original research. Since the foregoing was written we have heard from the author that he had been laid up for two months and was only slowly recovering from a severe surgical operation.

W. Botting Hemsley.

AIRMEN AND AVIATION.

The Aeroplane, Past, Present, and Future. By C. Grahame-White and Harry Harper. Pp. xv+319. (London: T. Werner Laurie, 1911.) Price 15*s.* net.

THIS is one of those books which may be classed as ephemeral—that is to say, it is written for to-day and only for to-day; to-morrow it will be obsolete. The title is misleading, for throughout the book there is no general description of the machine or explanation of the principles of its actions. It is a curious circumstance that, although purporting to be written by a well-known aviator and a journalist who has specialised in the subject, yet out of the fourteen chapters which the book contains no fewer than ten of them are put down to the authorship of other writers.

The three anonymous chapters on "Flights and Records," "The World's Airmen," and "Aeroplane Fatalities" are but amplified lists such as may have been culled from the daily papers, and are already becoming somewhat out-of-date. A short chapter on "The Fascination of Flying" is presumably by Mr. Grahame-White, and gives a pleasant sketch of reminiscences.

Of the other chapters, that by Colonel Capper on "The Aeroplane in Warfare" is probably quite the most important; but this, of course, cannot be more than a series of suggestions. Although not new, it may be of interest to note that Colonel Capper firmly believes that the systematic use of aeroplanes "may revolutionise the tactics of the battlefield," but he wisely adds that in order to obtain such important results "no haphazard aggregation of individual machines and pilots, on the outbreak of war, can be relied on."

Mr. Howard T. Wright's chapter on "The Power Unit of Aeroplanes" records in simple language many interesting facts concerning engines and propellers. Mr. Henry Farman writes on "The Constructional Future of Aeroplanes," in which he says: "Personally, judging from what I know of the possibilities of the situation, I estimate that the maximum speed which will be reached during the year 1911 will be 150 kilometres an hour." We have not arrived at this yet, but there is time. Mr. Roger Wallace summarises some points on "Aerial Law." The chapter on "Sporting and Commercial Possibilities of the Aeroplane," by Louis Blériot, is somewhat disappointing, as is the "Future of Flying," by Louis Paulhan.

While the book is readable and interesting, it tells us little that is new or really instructive. Throughout it gives one the idea of having been rapidly put together and hurriedly produced, without careful planning or proper supervision. There is a profusion of excellent illustrations from photographs; in fact, there seem almost too many, since some of them, such as that of "Captain Dickson describing an aerial reconnoitring trip," might well have been omitted.

OUR BOOK SHELF.

La Haute-Loire et le Haut-Vivarais. Guide du Touriste, du Naturaliste, et de l'Archéologue. By Marcellin Boule. Pp. viii+366. (Paris: Masson et Cie., 1911.) Price 4.50 francs.

In our own islands we have few guide-books precisely of the type of those edited by M. Boule. Praeger's guide to County Down comes first to mind, a book in which scientific considerations associate themselves with the choice of summer quarters and hotels. M. Boule has had the help of specialists in the description of the flora, commerce, archæology, and inhabitants of the picturesque region of which he treats; but the routes by road or footpath are known to him as a geologist, and he rightly loves the contrasts of "les froides et tristes planèzes vellaves" and the "chaudes et riantes vallées vivaraises." He points out the perfectly preserved craters of the chain of the Velay, piled above a fissure sixty kilometres in length, which broke through an upland of old granite, and the fantastic relics of earlier eruptions, like those on which St. Michel d'Aiguilhe and the high castle of Polignac stand. The country is certainly one for lovers of the unusual and the remote. Roman traditions remained in the municipal government of Le Puy down into the fourteenth century (p. 115), and the struggle of the commonwealth against the prince-bishops, who were supported by the kings of France, was as stubborn as the basaltic theatre in which the tragedy was played.

Le Puy, one of the most romantic towns in Europe, forms the natural centre for the district; but M. Boule guides us into the gorges of the Allier, where the railway forms in places the only foothold, and eastward across the broad volcanic upland, set with columnar "orgues," until we reach at Le Cheylard the rivers running to the Rhone. The upland itself has something fascinating, something not quite realised among the *burrons* of Auvergne. Fay-le-frnid, in the grey light of a summer dawn, seems remote enough from the pulse of France all round it. The author, aided by well-chosen views, shows us how the volcanic masses have controlled the higher features of the landscapes, and how the Loire stream-system has cut through the lava-flows, while, on the side of the Allier, lavas of the same age have descended into a pre-existing waterway (p. 326). Full justice is done to the phonolitic mass of the Mézenc, explored by Faujas de Saint-Fond in the middle of the eighteenth century (p. 294). We miss the name of this great investigator from the bibliography on p. 14, although Scrope's work in 1827 is mentioned. The users of this guide will become such good geologists that they will surely like to turn the pages of Saint-Fond's admirable folio. It may be hoped that M. Boule will send many lovers of unspoiled country to the strange and broken slopes of the Cevennes. "J'ai composé ce guide," he writes, "avec un rare plaisir." He has transferred this pleasure to the reader.

G. A. J. C.

The Pronunciation of English by Foreigners: a Course of Lectures to the Students of Norham Hall on the Physiology of Speech. By Dr. Geo. J. Burch, F.R.S. Pp. x+110. (Oxford: Alden and Co., Ltd.; London: Simpkin, Marshall and Co., Ltd., 1911.) Price 3*s*. net.

THIS is a delightful book. Works on phonetics are usually dry and uninteresting except to those who are willing to face the technical difficulties of the subject. But Dr. Burch, who is well known in other departments of science, invests the discussion with both wit and humour, while, here and there, he gives an amusing anecdote which is always appropriate and telling. He deals with the difficulties experienced by foreigners in catching the correct pronunciation of some of the sounds of the English language. The book is founded on lectures delivered at Norham Hall, Oxford, to foreign women students, and during the past ten years or so Dr. Burch has kept records of the chief difficulties in the pronunciation of 1305 persons of many different nationalities. He gives an excellent, although a short, account of the general mechanism of speech, and minutely describes the movements necessary for the articulation of the speech sounds of consonants, diphthongs, and vowels. There are also excellent remarks on the breathing apparatus.

It would seem that individuals of different nationalities have different methods of using their nervous and muscular mechanisms for articulate speech, so that if one wishes to reproduce the sound in any given language, one must learn how to train the articulating mechanism so as to obtain the required result. Dr. Burch gives minute directions, and it would seem that his system of teaching the correct tones of English to foreigners has had conspicuous success.

"During these ten years I have been greatly struck by the excellent pronunciation of the majority of those attending these courses. If I could speak those languages with which I am familiar with as good an accent as mine is spoken by them, I should have every reason to be proud. But this excellence has made a severer critic of me." (P. 59.)

Excellent, however, as the description of the movements of the tongue and other organs may be to guide the student in reproducing a given sound, an appeal to the ear is all-important, and those are fortunate who have had the instruction communicated by Dr. Burch's own living voice. We feel sure that if anyone takes up this little book he will not find it dry and wearisome, as its title might indicate. It is full of interesting information supplied by one who is an experienced and versatile teacher.

JOHN G. MCKENDRICK.

Praxis der Linsenoptik in einfachen Versuchen zur Erläuterung und Prüfung optischer Instrumente. By Dr. W. Volkmann. Pp. vii+176. (Berlin: Gebrüder Borntraeger, 1910.) Price 3.50 marks.

THIS little book is one of a series composing a "Bibliothek für naturwissenschaftliche Praxis," in which the object of each volume is to provide an introduction to some branch of practical science by means of simple experiments which can be carried out with inexpensive and easily constructed apparatus. The optical equipment here described consists of some half-dozen lenses of different focal lengths, a number of simple wooden stands, some clips and lens-carriers, diaphragms, and screen, with a spirit lamp and strip of gas-mantle to serve as light source. Even with these simple means it is, of course, easy to arrange an interesting and instructive series of experiments to illustrate the properties of lenses and the formation and defects of optical images. With a pinhole and some fine gauze, one can go further, and study effects due to the fact that light is a wave motion. With but little increased expenditure the range of such experiments could readily be extended; but the apparatus described is sufficient to enable practical acquaintance to be made with nearly all the main defects of optical instruments: spherical aberration, astigmatism, coma, distortion, and chromatic aberration can all be examined, and even the theory of resolving power can be studied. The book concludes with chapters on the photographic lens, the magnifying glass, the microscope, and the telescope, in which application is made of the experimental knowledge acquired to the examination of the characteristics of a well-designed optical instrument.

To follow out the course of experiments here suggested would no doubt be for an intelligent lad an excellent introduction to the study of optics, and, though the book is not designed for school use, the German schoolmaster might find in it useful hints in experimental science teaching. For the English reader, however, it has no special interest; it shows no exceptional ingenuity in the devising of experiments, and, from its aim, novelty is not to be expected, nor, perhaps, desired.

Rhododendrons and Azaleas. By Wm. Watson. Pp. xi+116. "Present-day Gardening" Series, edited by R. Hooper Pearson. (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 1*s*. 6*d*. net.

THERE are certain prevailing ideas with regard to the constitution and requirements of rhododendrons which are only partially correct that have tended to restrict their cultivation. Thus the necessity for peat in the soil is an exploded assumption, although the presence of lime must be recognised as an effectual bar to success. Then again the tenderness of many attractive species is only too obvious, but it is fortunately possible to obtain hybrids of a more hardy character. Further, it may be mentioned that no good popular book on rhododendrons is extant; therefore the present work is eminently desirable, and the publishers are fortunate in securing the services of an author who is an ardent enthusiast, and is also thoroughly conversant with the different classes of rhododendrons and their special features. The classification in itself is tolerably complex. Botanists recognise a single genus which includes the true evergreen rhododendrons, a small group of Indian azaleas, also evergreen—comprising *R. indicum* and its allies—and deciduous azaleas or swamp honeysuckles of North America. The true rhododendron species are best developed in China, while Himalayan species, owing their prominence to Sir Joseph Hooker, are a favourite but tender group, and the North American contingent are valuable on account of their more hardy nature. The explanation of the various hybrids is difficult, and calls for the special knowledge possessed by the author. Famous collections, cultural directions, and a list of species make up the contents of a volume which every gardener—save perhaps the dweller on limestone—should purchase and study.

The Practical Flower Garden. By Helena R. Ely. Pp. xiii+304. (New York: The Macmillan Co., London; Macmillan and Co., Ltd., 1911.) Price 8*s.* 6*d.* net.

IF the descriptions of experience and garden stock presented by Mrs. H. R. Ely may be accepted as a trustworthy exposition of garden practice in the eastern States of North America, we are justified in assuming that there is very little difference between the methods pursued and the plants cultivated on the two sides of the Atlantic. We had anticipated that there would be at any rate very marked differences in the trees and shrubs; also that certain herbaceous plants would be better suited to the more extreme conditions prevailing in the States, whereas with few exceptions, such as Boltonia and Baptisia, all the border perennials mentioned in the author's lists are offered in any British horticulturist's catalogue; of the climbers or vines, *Dolichos japonicus* and *Vitis labrusca* are rarely grown in English gardens.

The reader who is searching for useful hints is likely to be rewarded by a perusal of the advice regarding fertilisers and plant remedies, although the pronounced commendation of a fertiliser of unknown composition passing under the name of Bon Arbor is tantalising if not savouring of quackery. It should also be noted that the author, like every good horticulturist, has a favourite specific, which in her case is bone-meal, especially for Delphiniums. Advice is offered on the subjects of colour-schemes and the making of lawns, but a more original note is struck in the account of a garden prepared for the growth—not cultivation—of indigenous plants. It may be conjectured that Mrs. Ely does not claim to be a botanist, as certain inexactitudes are apparent, although the only flagrant mistake is in the misuse of the term "annual."

A Short History of Ethics: Greek and Modern. By R. A. P. Rogers. Pp. xxii+303. (London: Macmillan and Co., Ltd., 1911.) Price 3*s.* 6*d.* net.

A USEFUL historical survey, chiefly descriptive but partly critical. The author's primary object is to give a short and accurate description of the leading Greek ethical systems and of those systems which represent the best type of modern philosophic ethics, from Hobbes to the end of the nineteenth century; secondarily, to show, by criticism and comparison, the connecting links between systems and the movements of thought by which new systems arise. Some familiar names are omitted, where the type of thought has already been illustrated by other thinkers; *e.g.* Reid is represented by Butler, and the French empiricists by Hume. Such recent systems as those of Wundt, Paulsen, Nietzsche, and the pragmatists are also omitted. The systems most lengthily considered are those of Plato, Aristotle, Epicurus, the Stoics, Hobbes, Butler, Hume, Kant, the German idealists culminating in Hegel, and the English utilitarians through Bentham, Mill, Spencer, and Sidgwick to T. H. Green, whose doctrine specially commands the author's admiration.

The book is well written, in commendably judicial tone throughout. It makes a modest claim—calling itself short and elementary—but those students who thoroughly master it will have obtained an excellent and more than elementary introduction to the subject.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Forest of Auchnacarry.

THE letter in NATURE of June 1 would come as a shock to foresters throughout the world. It states that the Scotch pines at Auchnacarry are perhaps the largest and finest fragment that is left to us of the primæval Caledonian forest. In area about 1500 acres, the forest contains trees 200 to 300 years old of huge size, up to 6 feet in diameter. The scenery of the forest is of great beauty, and, save for a few isolated clumps, is all that we know to remain of the great forest of Scotch pine that once spread over all suitable ground in central Scotland. The writer also remarks that nothing is left so noble, so extensive, so worthy of preservation as this doomed forest of Lochiel's at Auchnacarry.

The photograph is striking. It is difficult to believe that forest such as this was once in the place of desolate and dreary bogland such as the Moor of Rannoch. But it was no farther back than Napoleon's time that the great forest of Rannoch was cut down and turned into the dreary waste of to-day!

Surely there is here a strong case—the strongest possible case—for the Development Commissioners! We read that they have 500,000*l.* yearly for five years, and this year an extra vote of 400,000*l.* in addition; and that a portion of their funds is to be devoted to forestry "by the purchase and planting of land."

The distant view is sometimes the clearest. To the man at a distance it is as clear as daylight that, whatever may be done for minor objects, this forest of Auchnacarry, this unique national monument, should be acquired for the country at any cost.

Italy has done much since it became a nation, but it has, perhaps unavoidably, neglected much. The most patriotic Italian will at once admit that Italy has neglected its forestry. Japan does more forestry in a week than Italy in many years! Yet Italy has nationalised the remains of its Apennine forests at Camaldole and Vallombrosa. Here are giant silver-firs not to be surpassed by any on this globe. And these most beautiful forests remain as national monuments ever pointing the way towards national regeneration, the restoration of the dreary and ruined Apennines to the beauty, the fertility, and the value of past days.

Spain is preserving the remnants of its ancient forests; Portugal is guarding them jealously. Is British forestry to sink to the level of Chinese? Surely, cost what it may, this remnant of the primæval Caledonian forest should be nationalised and preserved.

There is one important point to remember. The Italians, the Spaniards, and the Portuguese can replant and restore their national forests whenever they are strong enough as nations to do it. But these northern forests in Scotland and Sweden, near the limits of tree growth, can be restored only with extreme difficulty, if at all, when once they are destroyed. They seem to be the product of conditions that have passed away, or perhaps of geological time. Witness the Moor of Rannoch and many forests in northern Sweden. When once they have passed into bog and the great draining action of the trees has been removed, their restoration to forests seems nearly impossible at any practical expenditure. With forest near its climatic limits, this is the case in other lands and other climes.

Kenilworth, near Cape Town, July 20.

The Drought and the Birds.

As a rule, water has been left in my garden for the wild birds, and they have taken full advantage of the opportunity for bathing and drinking.

On Monday, however, a hen blackbird rather surprised me. The hose was working in a shady spot. Her ladyship came near, with great caution, to drink some of the drops from the grass. Having quenched her thirst, she got under the sprinkler for a shower bath. Being disturbed she flew away, but came back for a second bath, and later for a third.

This morning she returned, apparently for another bath, waited a considerable time, but as no water was forthcoming flew away.

To me this is quite a novelty; possibly other readers have had similar experience. CHARLIE WOODS.

"Vectis," 2 Wellmeadow Road, Lewisham, S.E., August 16.

A HANDBOOK OF BURMA.[1]

WITH the conspicuous exception of Japan, scarcely a country has been more written about, in proportion to the extent to which it has been visited, than Burma; yet we are in agreement with the publishers of this book, that there is room for one of the character prepared by Sir George Scott. The etherealised visions of Fielding are fascinating reading, but give a very inadequate impression of the reality, and the ordinary book of travel is unsatisfying and inaccurate; yet between these and ponderous tomes, of which the weight and bulk make them unportable and repellent to all but the serious student, we have had no book which would give the visitor to Burma an idea of the history, administration, and sociology of the Burmese and other races, or of the aspect and productions of the country itself.

In his preface, Sir George Scott disarms criticism. After stating that the sections of Mr. Oates on the fauna, of Captain Gage on the flora, of Mr. Bruce on the forests, of Mr. Richard on means of transport, and of Mr. Mariano on music could only be excelled by those who might have larger space allowed them, he goes on to say that it is certain that the book can be greatly improved, and expresses a hope that his critics and the public will write to show how this can be done, rather than indulge in mere carping and fault-finding. Yet it is hardly possible to suggest improvements without indicating faults, and in reading through the book there seems to us to be three conspicuous faults or possible improvements, according to the point of view.

First, we must regret that the course adopted for the flora, fauna, and other special subjects was not followed in the case of the geology; secondly, we suggest the provision of a more satisfactory map of Burma than the very poor little effort which the publishers have provided; and, thirdly, the omission of the word commercial on the cover of the book. The title-page describes the work merely as a "handbook of practical information"; on the cover this becomes "practical commercial and political information," but there can be little commercial value in statements based on statistics of no later year than 1905, and the deficiency in the case of Burma is especially striking, for the petroleum industry has been so revolutionised in the last three or four years that the description on p. 240 represents a condition of things which has passed away, and in the section devoted to agriculture no mention is made of the ground-nut, which, within the last few years, has risen to importance as a crop in upper Burma and an article of export from Rangoon.

A Sawbwa paying Call. From "Burma: a Handbook of Practical Information."

For the rest we must perforce agree with the author that the book can be improved, for nothing human is perfect, but with this reservation we confess that the margin for improvement seems very small. It is not merely the best book in existence on Burma, but as nearly an ideal book as is conceivable for the purpose it is intended to fulfil. For the traveller or the intending resident, who wishes to have an intelligent appreciation of what he will see and come in contact with,

[1] "Burma: a Handbook of Practical Information." By Sir J. George Scott, K.C.I.E. New and Revised Edition. Pp. x+520. (London: Alexander Moring, Ltd., 1911.) Price 10s. 6d. net.

it will be an admirable companion, and even the resident of many years' standing cannot fail to find explanation of much that he has not understood before, and have his attention directed to many things which he had previously failed to notice.

PLAGUE IN ENGLAND.[1]

THE recent appearance of plague in East Suffolk forms the subject of some valuable reports and papers recently issued by the medical department of the Local Government Board. The reports are divided into three sections, each of which deals with the plague from different aspects. The first section contains the late Dr. Bulstrode's "report upon the occurrence, in the autumn of 1910, of four deaths at Freston, near Ipswich, from a rapidly fatal and infectious malady diagnosed as pneumonic plague, and upon the prevalence of plague in rodents in Suffolk and Essex." It also includes his report upon two localised outbreaks of disease in East Suffolk in 1909–10 and 1906–7, which may have been instances of bubonic and pneumonic plague respectively." The second section records the results of an inquiry by Drs. Martin and Roland, in the months of November and December, 1910, into rat plague in East Anglia, with special reference to the fleas infesting rodents; and the third section gives a report by Drs. Petrie and Macalister "upon the examination of rats collected in Suffolk and Essex for plague-infection between January 16 and February 14, 1911."

The information in the volume, though not sufficient to fix the exact origin of the Freston outbreak, cr the avenues by which the other two outbreaks spread, is nevertheless very complete so far as the facts could be traced. The great loss which the medical department of the Local Government Board has sustained by the death of Dr. Bulstrode is impressed upon one when perusing his able report on the investigations which he made on the plague. Like all his former work, it is characterised by care, thoroughness, and good judgment.

It appears that between September 16 and September 29 there occurred in a four-roomed cottage in Freston three deaths. Daughter, mother, and father in a family of six succumbed to an obscure lung affection after a few days' illness. In a cottage a quarter of a mile away there also died on September 29 a woman with the same symptoms. She had nursed the mother, and had evidently caught the infection from her. The main features of the illness were the obscurity of the lung symptoms, the dark-stained expectoration, the high temperature, the great prostration, and the rapidly fatal issue in about three days without any corresponding serious physical signs to account for it. In three out of the four cases vomiting and purging were present. The anomalous character of the symptoms, the nature of which puzzled the medical men attending the cases, led to a bacteriological examination being made by Dr. Heath, the honorary bacteriologist to the Ipswich and East Suffolk Hospital, who found in the specimens and cultures a bacillus corresponding in its reaction and appearance with those of the plague bacillus. The illness was then recognised as pneumonic plague, which is well known for its infectivity and fatality.

No direct evidence could be obtained as to the manner in which the daughter, a child of seven years of age, who was first attacked, had become infected, but the inquiry as to the source of infection led to the important discovery that an epizootic affecting rats and hares was prevailing in the district. Bacteriological examination of a number of rats, hares, a cat, and a ferret showed them to be plague-infected, and accordingly afforded opportunities for human infection. There was evidence also that the epizootic among rats extended so far back as 1906. In that year a large number of dead rats had been observed at Shottley and its neighbourhood, about four miles distant from Freston. It was here that a sudden and fatal illness had occurred in December, 1906, in a poor family, and had extended to those who nursed the sick. Eight persons were attacked with what appeared at the time to be a virulent form of influenza, and six of these died after three to four days' illness.

Another outbreak of a puzzling character occurred in December, 1909, and January, 1910, at Frimley, on the north bank of the Orwell, and almost opposite Shottley. It was in a two-roomed cottage occupied by a family of seven in poor circumstances. The whole of the family was successively attacked by an illness unfamiliar to the medical men, and in some cases associated with glandular enlargements. Four of the family died and three recovered. One of the family went to stay with a friend for a few days, and subsequently the child of the friend was fatally attacked with similar symptoms. Dr. Bulstrode concludes from his investigation of the Frimley outbreak that, "although there are, from lack of full information, many lacunæ in the story, the balance of evidence certainly seems in favour of a view that the malady was bubonic and septicæmic plague."

It is an instructive story, and shows that in England as in other countries plague can be overlooked both in human beings and in the lower animals. It is evident that the infection of plague has existed in this part of the country for the past four years, introduced probably by infected rats in grain ships arriving from infected ports.

Drs. Petrie and Macalister's work is valuable in demonstrating that out of 6071 rats examined from the districts immediately surrounding those proved to be infected, all were of the *Mus decumanus* variety, and none were found to be infected with plague. It is to be hoped that the Government will continue this good work in the autumn and in the coming years, for it by no means follows that the rat plague-infections which, as has been shown by Drs. Martin and Roland, occur in pockets, have been all discovered, even with this large number of examinations.

The investigations of Drs. Martin and Roland have demonstrated some interesting facts relative to the rat-flea population. It appears that the rat-flea of India, *Xenopsylla cheopis,* could not be found on any of the rats examined; that more than 50 per cent. of the rat-fleas in East Suffolk consisted of the *Ctenophthalmus agyrtes*, which evidently does not bite men, and that the remainder of the rat-flea population is composed of *Ceratophyllus fasciatus*, which bites man, but not so readily as does *Xenopsylla cheopis.* These facts are cheering so far as they go, as it is estimated that on an average there is less than half a man-biting flea for a rat. It would be reassuring if it were proved that the flea was the only method by which human plague spreads, and if the history of the three outbreaks pointed in that direction. Unfortunately, two of them appear to have been of the pneumonic variety, and the third septicæmic and bubonic in character. The evidence so far scarcely lends itself to the view that the comparative freedom of the rat from man-biting fleas will secure safety from plague in England. Dr. Newsholme recognises the dangers from this aspect of the question, and the warning given by him and the late Dr. Bulstrode as to the necessity for vigilance is timely and none too strong. The

[1] Reports and Papers on Suspected Cases of Human Plague in East Suffolk and on an Epizootic of Plague in Rodents. Reports to the Local Government Board on Public Health and Medical Subjects. New Series, No. 52. (1911.)

optimism which leads to the relaxation of sustained effort in dealing with a plague epizootic is most dangerous.

The one important fact is that the plague-infection has gained a lodgment in this country after an absence of nearly 250 years, and the only safe course to be pursued is to prevent the rat-infection from becoming endemic. Nothing is to be gathered from the fact that only a few human cases have occurred in four years in a sparsely populated locality. This is the ordinary behaviour of plague in new localities in this pandemic. Because no human epidemic happens quickly the impression is produced that the country is immune. In London in the seventeenth century there were in seventy years only four severe epidemics, and for fifteen years before the great plague of London in 1665 there was only on an average fourteen plague deaths per year in the metropolis. It is well not to place too much reliance on the different conditions existing in the seventeenth century and now. In the former period the general sanitary conditions were undoubtedly much worse than they are at present, but we have the very poor, and more of them, still with us in our slums, and they still live in an overcrowded state, with none too much light or sanitation in their houses.

W. J. SIMPSON.

THE NUTRITIVE VALUE OF BREAD.[1]

DR. HAMILL has presented an admirable report, free in every way from prejudice, which will long serve as an authoritative statement on the somewhat vexed question of the nutritive value of bread. The account summarises the scientific and technical information at present available, and clearly indicates the complexity of the problem. Previous writers on this subject, when not biassed by commercial considerations, have as a rule dealt with the question from a restricted point of view, but this report in no way suffers in this respect.

The first section deals with the classes of wheat flour, and Dr. Hamill is careful to define the technical terms used, which are usually grossly misused by popular writers on the subject. The contention that nutritive flour cannot be made in roller mills is once for all disposed of, and the advocates of the stone mill are reminded that the hard foreign wheats with brittle skins, such as form the great bulk of the wheat grown in western America, cannot be satisfactorily milled between stones. A very much greater degree of separation can be obtained in the more complicated process of roller milling, and there is no reason for a return to stone mills even if this were possible economically. With regard to colour, patent grade flours, which are the whitest, have better baking qualities than households, and therefore command a higher price—the report, however, overlooks the fact that the colour of bread depends more on the "strength" of the flour used than on its colour in the dry state.

The second section, which is supplemented by much valuable tabular matter, summarises all that is known as to the nutritive value deduced from chemical analysis of various milling products and bread made from them. Much of the experimental work quoted has been done by the United States Department of Agriculture. It is to be hoped that now that this question has received so much notice in this country, the Local Government Board will itself initiate experimental work on some of the lines indicated by Dr. Hamill; indeed, the report contains analyses of various milling products made by Dr. Monier-Williams in the Local Government Board laboratories. Valuable as these are, it is now necessary to go somewhat deeper into the matter than the simple determination of elemental composition.

In a valuable section headed physiological considerations, it is shown that many of the opinions so confidently expressed in public by such bodies as the Bread Reform League are certainly untenable, whilst upon other points our knowledge is still too uncertain to enable a definite statement to be made. Highly erroneous is the notion that high-grade white patent flour is practically devoid of nitrogenous constituents—actually the very opposite is the case, and, other things being equal, a diet which consists wholly of bread would possess greater advantages in this respect when made from strong wheats. The degree to which bread is acted upon by the digestive juices, and the extent to which the products of digestion are absorbed and assimilated, are problems requiring further investigation, and although much has already been done this only serves to indicate the complexity of the subject and to show how many factors must be taken into account. The evidence available is given in full in the report.

Much has been written about the digestibility of bran. Results are quoted which indicate that the presence of branny particles, even when very finely divided, affects the digestibility of bread. It was found by Goodfellow, for example, that when milk is taken with wholemeal bread 3 per cent. less milk was digested than when the milk was taken alone. It is probable for this reason that the large class of wholemeal breads, sold to the public at an enhanced price, are inferior to white bread excepting when they are taken for definite medicinal reasons.

Regarding the whole question from a common-sense point of view, it is a fact that the differences in nutritive value between various grades of flour made from the same wheat are insignificant when compared with the differences between flours made from different wheats. So long as Britain derives its flour from all over the world this last question is the paramount one. The big millers are so skilful in blending wheats that the flour supply of the large towns is practically uniform in quality throughout the year.

The questions of germ and mineral requirements are fully discussed, and it is admitted that the knowledge of the latter point is still very imperfect. Here, however, Dr. Hamill ventures to draw a conclusion which will be disputed by many, namely, that to ensure as large a supply of minerals as possible it is advisable to substitute very finely ground entire wheat bread for a portion of the white bread in the diet of growing children.

He qualifies this subsequently by admitting that when bread is supplemented by other foods, such as are present in an ordinary mixed diet, the advantage which one kind of bread may possess over another becomes negligible. Many children whose food consists largely of bread do not get enough of it, and are underfed in respect of all the essential nutritive substances. It is better in such cases to increase the amount of bread taken rather than to substitute another form of bread, and still better to supplement the bread by other materials such as milk, which contains a substantial quantity of the nutritive materials lacking in bread. The effect of bread on the teeth is fully discussed: the differences between different kinds of bread in this respect would appear to be negligible. This again is a direct contradiction of recent assertions.

The preparation and properties of the so-called standard flour and bread are described at some length,

[1] Dr. J. M. Hamill's Report to the Local Government Board on the Nutritive Value of Bread made from Different Varieties of Wheat Flour. Pp. 53. (Published by H.M. Stationery Office.) [Cd. 5831.] Price 3*d*.

and it is made quite clear that standardisation of flour is impossible. Analyses made by Dr. Monier-Williams are quoted to show that the differences in protein and mineral matter between the standard flours and the household flours obtained from the same wheat are very small. These analyses should serve once for all to disprove the absurd claims made for standard bread by the Bread Reform League and other food reformers. According to Dr. Hamill, "entire" wheat flours do, however, possess additional constituents due to the presence of branny particles and germ which appear to have a value of their own in nutrition. Whilst the evidence on this point is as yet of the slenderest, it is sufficiently sponsored not to be lightly dismissed, and further experimental work is urgently needed.

Sufficient has been said to show that the report gives a very faithful summary of the present position of the subject, and it should remain authoritative until new experimental facts cause an extension of our knowledge of the obscure points. It is at all events clear that our bread supply is the best available, and that legislative action is not required.

THE INTERNATIONAL COMMITTEE OF WEIGHTS AND MEASURES.[1]

THE most interesting part of the account lately published of the proceedings of the International Committee of Weights and Measures at their recent meeting at Sèvres is the information given respecting the work of the International Bureau of Weights and Measures during the last two years. Among the researches conducted at the Bureau may be mentioned an investigation of the suitability of vitreous quartz (fused silica) for metrological purposes, which was undertaken at the instance of Sir David Gill. Although the specimens experimented upon admitted of being ground and polished with facility, it was found quite impossible to engrave on them lines of permanent shape and sufficiently fine to serve as the defining marks of standards of length. Similar negative results had been obtained at the National Physical Laboratory by Dr. Kaye, who has, however, devised a method of obtaining perfectly satisfactory defining lines by depositing a layer of platinum on the silica and engraving the lines on the platinum.

The high price of platinum has led to investigations being made with the view of finding a suitable substitute for this metal in the construction of standard weights. Tantalum, which resists all the strong mineral acids except hydrofluoric acid, has been found to satisfy the necessary requirements of permanence and hardness, and it is suggested that a series of standard weights of 100 grammes made of this metal should be established for use in chemical research. Their cost would probably not be more than one-third that of iridio-platinum standards.

Dr. Stratton, of the United States Bureau of Standards, who is a member of the International Committee, communicated the results of investigations on the spectrum of neon. These tend to show that the yellow radiation of neon of wave-length 5852 tenth metres is much superior to the red radiation of cadmium as a unit for interferential measurements. Neon is also much more convenient to employ, as it does not require preliminary heating to a high temperature; it has a longer life, is less subject to accidents, is more brilliant, and requires much less attention on the part of the observer. Dr. Stratton proposes to make use of this radiation in a new determination of the length of the metre.

[1] Comité International des Poids et Mesures. Procès Verbaux des Séances. Deuxième série, tome vi. Session de 1911. Pp. vii+247. (Paris: Gauthier-Villars, 1911.)

The president of the International Committee, Dr. Foerster, invited particular attention to the important question of end measures of length. It was decided to address a circular letter to the various bureaus of standards requesting information as to their practice in regard to these standards, and describing certain patterns which the International Bureau regard as suitable for general adoption in the interests of uniformity. The patterns include three types of standards, viz., cylindrical plug gauges for measuring small thicknesses, end bars of 12 mm. diameter with spherical caps, for greater lengths, and plane-parallel blocks or plates for either the greater or smaller dimensions. The method of comparing end measures which was first employed by Airy some sixty years ago in connection with the reconstruction of the Imperial Standard Yard, has recently been tried at the Bureau, and has been found to give very satisfactory results. The verification of a series of gauges with plane ends, made by the Swedish firm Johansson, has demonstrated the extraordinary degree of accuracy which can be attained in the construction of gauges of this form.

There are several important appendices to the Procès Verbaux. The first, by Drs. Benoît and Guillaume, is an account of recent experiments with invar measuring wires. The growing popularity of these wires for geodetic operations, and the consequent demand for their verification and re-verification, have necessitated an immense number of comparisons at the Bureau, and the experience thus obtained has admitted of definite conclusions being arrived at as to how far the lengths of these wires under standard conditions can be regarded as permanent. The investigations show that in general the wires, when manipulated with the care usual in geodetic work, retain their original lengths well within one part in a million. Where greater deviations were found to occur they could in general be accounted for either by the small graduated scales at the ends of the wire having become in the course of use slightly displaced from their true tangential directions, or else by the wire having been used in regions bordering on the tropics, where it would be exposed to quite abnormal temperatures.

In the second appendix Dr. Guillaume describes a comparator designed by him for rapidly testing both line measures and end measures. The instrument, which was destined for use in the Chinese weights and measures service, in which both the metric and the native systems are recognised, was constructed to admit of measurements in both these systems to a degree of accuracy of nearly 0·01 millimetre. A simplified form of this comparator, intended for use in testing metric measures only, has also been designed by Dr. Guillaume, and promises to be a convenient apparatus for making rapid comparisons with a fairly high degree of accuracy. A measuring machine suitable for use in manufactories for checking workshop standards or for general purposes is also described by Dr. Guillaume (appendix 3).

The flexure of the 4-metre geodetic standard at the Bureau has been determined. This measure, which is made of invar, has a section of the **H**-form, the outside dimensions of which are about 4 centimetres. The results of the observations on this bar exhibited remarkable agreement with the calculated values based on the Euler-Bernoulli theory of the deflection of elastic beams (appendix 4).

The fifth appendix deals with the recent progress of the metric system of weights and measures. On January 1 last Bulgaria joined the Metric Convention, raising the number of contracting States to twenty-five. The metric carat of 200 milligrams has, up to the present, received express legal sanction in nine

European States, as well as in Japan; while in Germany, with the tacit consent of the Government, it has been adopted by the industries concerned. In eight or nine other countries the use of the metric carat is permissible, but other carats are not prohibited. Early in 1908 some of the principal diamond merchants in the United Kingdom were approached by the Board of Trade with the view of ascertaining whether the trade were prepared to adopt the metric carat. The replies received were mainly unfavourable to this project. It would be interesting to learn whether the fact that the metric carat is now generally recognised abroad has had any effect in modifying the views of the trade in this country on the subject.

Tome xv. of the Travaux et Mémoires of the Bureau is being rapidly prepared for the press. It will contain an account of the investigations by MM. Benoit, Fabry, and Perot on the determination of the metre in terms of wave-lengths of light, and an article by Dr. Guillaume on the recent progress of the metric system. If space permits, a memoir on end measures of length will also be included.

AUSTRALIAN ZOOLOGY.[1]

It is a somewhat humiliating reflection for British zoologists that such an important and prosperous part of the British Empire as the Australian Commonwealth should have to depend so largely upon German enterprise for the investigation of the native fauna. It is, of course, true that a vast amount of good work has been done by naturalists resident in Australia, and by British scientific expeditions, and as regards the vertebrates, we perhaps already have a fairly complete knowledge of the Australian fauna.

So far as the invertebrates are concerned, however, the work seems to be little more than begun. The Australian Museum at Sydney has published in the "Records" and "Memoirs" numerous important contributions to our knowledge of special groups, and also the results of various collecting expeditions, which deal with more extensive sections of the invertebrate fauna. We remember also that the late Sir Frederick McCoy published several volumes of a prodromus of the Australian fauna, in which many invertebrates were excellently figured, but the series came to an untimely end. The late Mr. Bracebridge Wilson, again, made extensive collections of marine invertebrates in the neighbourhood of Port Phillip, but a portion only of these has ever been properly investigated. Individual workers, whose names are well known in the scientific world, have made most valuable contributions to our knowledge of special groups, such as the Sponges, Hydrozoa, Polyzoa, Earthworms, Land Planarians, Mollusca, Crustacea, Onychophora, Insecta, and Arachnida. One might almost say, however, that although a good many mouthfuls have been taken (especially in the plummiest parts), Australian zoologists have not as yet developed a sufficiently keen appetite to make any very serious combined attack upon the invertebrate pudding as a whole. This is by no means altogether their fault, for it is useless for men of science to devote their lives to laborious investigations—and those of a kind which brings but little credit except amongst a narrow circle of specialists—if there is not sufficient financial support forthcoming to publish the results in a satisfactory manner, to say nothing of paying the investigators. Even the greatest enthusiasm is soon damped for want of appreciation.

It is here that our German colleagues, with their usual thoroughness, are again leading the way. The Hamburg expedition to South-West Australia in 1905 must have reaped a rich harvest, and the results are now being given to the scientific world in a series of handsome and copiously illustrated volumes which do great credit to authors and publishers alike, and far excel any attempts which have been made for many years past to deal with the Australian fauna. The third volume is now in progress, and we have before us Lieferungen vi.–x. In these parts Dr. Carl Graf Attems deals with the Myriapods (excluding Scolopendridæ); Prof. Kieffer describes the Serphidæ and Evaniidæ; Ester Lager the Phyllopods; and Dr. Hentschel continues his account of the Tetraxonid Sponges. We notice that all the illustrations in these parts are text-figures, evidently reproduced by some photographic process, and the results obtained appear to be on the whole quite satisfactory. They are doubtless comparatively inexpensive, but from the artistic point of view they cannot be considered as equal to good lithographic work. This is more especially evident in the case of the sponge spicules.

It is, of course, quite impossible to notice such a work as this in any detail. We may say, however, that the volumes will be absolutely indispensable to future investigators of the Australian fauna, and we venture to hope that they will serve as a stimulus to the numerous British naturalists in Australia to continue their own excellent work in the same systematic and thorough manner.

[1] "Die Fauna Südwest-Australiens. Ergebnisse der Hamburger südwest-australischen Forschungsreise 1905." Herausgegeben von Prof. W. Michaelsen und Dr. K. Hartmeyer. Band iii., Lieferung 6–10; Lief. 6, "Myriapoda exkl. Scolopendridæ," von Dr. Carl G. Attems; Lief. 7, "Serphidæ und Evaniidæ," von Prof. J. J. Kieffer; Lief. 8, "Actiniaria," von E. Lager; Lief. 9, "Phyllopoda," von Dr. E. Wolf; Lief. 10, "Tetraxonida," 2 Teil, von Dr. E. Hentschel. Pp. 147–393. (Jena: Gustav Fischer, 1911.) Price 18 marks.

PROF. W. SPRING.

As already announced, Prof. W. Spring, professor of chemistry in the University of Liège, died on July 17, in his sixty-third year; by his death Belgium has lost one of her foremost men of science, and physical chemistry has been deprived of an eminent investigator.

From the point of view of British chemists and metallurgists, the work of Spring has been to some extent hidden by being published almost entirely in the proceedings of the Royal Belgian Academy, so that only the more striking results of his work have become generally known. Thus Spring's name is principally associated with his work on the effect of high pressures upon chemical combination and upon the welding of particles of metals and alloys. The progress of our knowledge of physical chemistry generally, and that of metals particularly, has made us very familiar with the idea and the phenomena of diffusion in solid bodies, even at temperatures far below their fusion-point, but the researches of Spring were among the earliest to give actual data on such phenomena. Thus Spring showed in 1894 that carefully surfaced pieces of copper and zinc placed in contact in vacuo became welded together, and that at the interface a layer of yellow alloy was formed. It was not until 1896 that the late Sir William Roberts-Austen published his own classic work on the interdiffusion of solid lead and gold. Spring's work on the effect of pressure in bringing about chemical reactions between finely-powdered bodies also tended to demonstrate the molecular mobility of solids.

Perhaps the best-known work of Spring was that in which he showed what he believed to be the formation of actual alloys by the action of high-pressures upon mixtures of the pure metals in powder form. His experiments were very striking, and showed clearly that by compressing metallic powders, solid blocks of metal could be produced, and he showed further that this was accomplished without any fusion of the metal under pressure. The fact that the resulting masses were true alloys he sought to demonstrate by showing that, if the metallic powders were correctly proportioned, the resulting metal showed the low melting-points of fusible alloys and eutectics. Unfortunately the aid of the microscope was not called in for the study of these "alloys," and, indeed, the greater portion of Spring's researches were carried out before the modern methods of metallography were available, but it has since been shown that the compressed masses of solid metal produced by Spring consisted of the practically unaltered particles of the original powder, simply welded together under the action of the pressure, but without the formation of those structural constituents of the corresponding true alloys. The low melting-points of such mixtures must be attributed to local action at the boundaries of the constituents and the rapid diffusion following the appearance of liquid metal at these points. Although, therefore, Spring's original conclusions were not entirely confirmed by subsequent research, his work has borne much fruit; his demonstration of the possibility of extruding bismuth in the form of thin wire shed new light on the whole question of brittleness and plasticity, and has largely contributed to the development of the modern processes of extruding metals and alloys for industrial purposes.

Spring's activities were not confined to the physical chemistry of metals, however, but extended to researches on the colour of sky and water and on colloidal solutions—to mention only a few of the other sides of his work. It is even claimed for Spring by his friends that in his researches on turbid media he anticipated the "ultra-microscope" in principle to such an extent that the apparatus he describes differs from that now in use only in regard to the power of the microscope employed.

The sum-total of the late Prof. Spring's researches constitute a monument of a life of intense scientific activity, and it may be hoped that these researches may now be gathered together so as to make them more readily accessible, and thus to secure for them the full recognition which they deserve.

NOTES.

THE German Emperor has conferred upon Sir William Ramsay, K.C.B., F.R.S., president-elect of the British Association, the order "Pour le Mérite."

WE notice with regret the announcement of the death, on August 18, at eighty years of age, of Mr. S. H. Burbury, F.R.S., distinguished by his work in mathematical physics, especially in the theories of electricity and magnetism and the kinetic theory of gases.

A REUTER message from St. Petersburg states that the Minister of the Interior has prohibited for the year 1911 the trade in marmots along the Eastern Chinese Railway, and also the forwarding of marmot skins, flesh, and fat by rail. This measure has been taken as a precaution against pneumonic plague.

THE divisions of vertebrate and invertebrate palæontology and palæobotany in the U.S. National Museum have been combined, we learn from *Science*, into a new division of palæontology, with Dr. R. S. Bassler as curator in charge, Mr. J. W. Gidley as assistant curator of fossil mammals, and Mr. C. W. Gilmore as assistant curator of fossil reptiles.

IT is officially announced that the Governor of British Guiana has reported the adoption, as from August 1, of maritime time, which is standard time four hours slow on Greenwich time. The same standard time has been adopted in the island of Granada, as from July 1, the effect being to put back the local time of that colony by seven minutes.

IT is surprising at the present day, when the system of time-reckoning by reference to standard meridians is being adopted throughout the civilised world, that the city of Canterbury seems determined to maintain its own local time. The Dean and Chapter, in mediæval spirit, refuse to recognise any such "modern innovation" as Greenwich time, and have recently distributed cards intimating that the time observed in Canterbury Cathedral is 4½ minutes ahead of Greenwich time. The post-office and railway clocks are kept to Greenwich time, and the others anywhere between that and the cathedral clock. The resulting confusion has induced Mr. A. Lander, of 17 High Street, Canterbury, scientific instrument maker, and secretary of the East Kent Natural History Society, to make an electric clock which is kept to standard time by means of the wireless time signal from the Eiffel Tower. The first of the three time signals is received on Môrse tape travelling at the rate of half an inch per second, and the half-minute contacts of the electric clock are also recorded on the same tape, so that the rate of the clock can be accurately determined. The second signal is utilised to correct the pendulum of the master clock, and the third signal is again received on the tape to show that the clock is exactly correct. This master clock works a number of clocks and instruments on Mr. Lander's premises, such as a rain-gauge, sunshine recorder, barograph, and also a large dial in the shop window, and drops a time-ball exactly at each standard hour.

THE twenty-second annual general meeting of the members of the Institution of Mining Engineers will be held at Cardiff on Wednesday, September 13, under the presidency of Dr. J. B. Simpson. The following papers will be read, or taken as read:—the reduction, control, and collection of coal-dust in mines, S. Mavor; a rope-driven coal-cutter, W. Maurice. A number of papers which have already appeared in the Transactions of the institution will also be open for discussion.

THE death has occurred, in his seventy-second year, of Dr. J. P. Schweitzer, who was connected with the University of Missouri from 1872 to 1906 as professor first of chemistry and later of agricultural chemistry. He was a native of Berlin, and after studying at Göttingen was for a time assistant to Heinrich Rose at Berlin. He went to America in 1865, and held posts at the polytechnic institute of Philadelphia and the Columbia School of Mines before receiving his Missouri appointment.

A REMARKABLE crystal of aquamarine was described by Dr. G. F. Kunz before the New York Academy of Sciences on April 3. It was discovered by a miner on March 28, 1910, in a pegmatite vein at Marambaya, near Arassuahy, on the Jequitinhonha River, in Minas Geraes, Brazil. Its colour was greenish-blue, its form a slightly irregular hexagonal prism terminated at both ends by flat basal planes, its length 48·5 cm. and width from 40 to 42 cm., and its weight 110·5 kg., and its transparency was so perfect that it could be seen through from end to end. It is estimated that 200,000 carats of aquamarines of various sizes could be cut from it.

MR. J. ALLAN THOMSON, who has been appointed palæontologist to the Geological Survey of New Zealand, was the first New Zealand Rhodes scholar at Oxford, where he was also Burdett-Coutts scholar. He received his university training in geology and palæontology both in New Zealand and at Oxford, but for the last five years or so his work has been mainly in the direction of petrology. The New Zealand Geological Survey possesses more than one hundred thousand fossils from various horizons, but little appears to have been done hitherto to describe them or to make them available for study. It is hoped that now the survey has appointed a palæontologist on its staff the specimens will be properly described and arranged.

AT the 1909 meeting of the International Mathematical Congress, held at Rome, the subject of mathematical teaching was brought forward, and upon the initiative of Prof. D. E. Smith, U.S.A., it was decided to form an International Commission on the Teaching of Mathematics, this commission to report to the next triennial meeting of the congress, which will be held at Cambridge (England) in 1912. The commission will meet at Milan on September 18–20 of this year to take stock of the work done so far. As regards the United Kingdom, the work of collecting and issuing reports has been taken up by the Board of Education, which has appointed as delegates Sir George Greenhill, Prof. E. W. Hobson, and Mr. C. Godfrey. A number of reports have already been issued (Wyman, price 3*d.* each), and when the international series is complete it will form the most valuable collection of material at present available for the use of teachers of mathematics. The central committee consists of Prof. F. Klein (Göttingen), Sir G. Greenhill (London), and M. H. Fehr (Geneva).

IT is announced in *Science* that the Nantucket Maria Mitchell Association offers an astronomical fellowship of 200*l.* to a woman, for the year beginning June 15, 1912. The year will be divided into two periods. June 15 to December 15 will be spent on Nantucket, where the observatory is equipped with a five-inch Alvan Clark telescope, and this period will be occupied in observation, research, or study, and in lectures or instruction. February 1 to June 15, 1913, will be spent at one of the larger observatories, and the time occupied in original research and study. Every fourth year the fellowship will be available during the entire year for study at one of the larger observatories in Europe or America. The fellowship will be awarded annually, but in order that the work at Nantucket may be combined advantageously with the work at the selected observatory, the preference will be given to the same candidate for three successive years. A competitive examination will not be held. The candidate must present evidence of qualifications, giving an account of previous educational opportunities and training, and of plans for future work, as well as examples of work already accomplished. Application for the year beginning June 15, 1912, should be made, before March 1, 1912, to Mrs. Charles S. Hinchman, 3635 Chestnut Street, Philadelphia, Pa., from whom full particulars can be obtained.

THE long drought has been brought to a termination, and the excessive temperature which has continued with such persistence over England has given place to more normal conditions. The anticyclone which has so long been centred over our islands and their immediate neighbourhood has given way to shallow cyclonic disturbances which have arrived over us from the Atlantic. At Greenwich there was no rain from August 2 to August 18, and the aggregate fall from July 1 to August 18 was 0·32 inch, which fell on four days. Copious rains have, however, now fallen over London, and on three successive evenings, August 19, 20, and 21, sharp thunderstorms were experienced. On August 22 the highest temperature in London was 68°, which is the lowest maximum reading since July 2, a period of more than seven weeks. The disturbances which occasioned the recent thunderstorms over England were moving away to the eastward of our islands, and an anticyclone, centred in the Atlantic, was extending to our area. This change in the general conditions is likely to occasion a return of the fine weather with a gradual increase of temperature, although it is improbable that the temperature will be so high as that recently experienced. The summary of the weather for the week ending August 19 issued by the Meteorological Office shows that the mean temperature for the period was from 6° to 7° in excess of the normal over the entire kingdom, except in the north and east of Scotland and in the north-east of England; the excess of temperature, however, was not so great as in the preceding week.

MR. D. E. HUTCHINS, Chief Conservator of Forests, British East Africa, after ten years' forest service in India, twenty-three in South Africa, and four in Equatorial Africa, has now retired on pension. It fell to his lot both in South Africa and in Equatorial Africa to demarcate and arrest the further destruction of large areas of the beautiful extra-tropical forest that extends with but little change from the extreme south of Africa along the eastern highlands to the equator. As the latitude decreases the altitude increases. The forest that occurs at sea-level in the Knysna district of the Cape, at 3000, 4000, and 5000 feet in Natal and the Transvaal, is seen at an elevation of 7000 to 10,000 feet under the equator. The distribution of this forest is governed by the topography and rainfall of the highlands. There are wide gaps in its extension along the highlands. As one goes north, it changes somewhat in species, though but little in character. It is seen at its best on the equatorial highlands in what is now British and German East Africa. Here the trees grow with greater vigour than in the south, and the forest is enriched by the addition of a very valuable timber, the pencil cedar of Abyssinia (*Juniperus procera*). The preservation of this forest is of national importance to Africa, especially to extra-tropical Africa, the White Man's heritage; for it is a forest resembling that of the Nilgiri Shola forest of India, a forest with a dense couvert and slow-growing—the ideal water-holding forest. As a fact, it is a forest from which streams of water flow on every side, perennial streams that feed the rivers when they are most wanted. The future of this forest is assured in South Africa, the bad forestry of Natal having happily come to an end with Union. The Germans are preserving it carefully in German East Africa, no forest of this class having been alienated since 1900. But in British East Africa there hangs out a danger signal! The Colonial Office will have to see that its forest policy there is duly upheld. There is a danger that settlement, so right and necessary, in a new country may be pushed too far, to the ruin of the most valuable public assets of the country—its water and timber. Settlement is obviously the first requisite; but settlement must not be allowed to touch an acre of highland forest in a country where the forest area is only 1½ per cent. of the total area, and that is the position in British East Africa.

A SPECIAL "tuberculosis" number of the Bulletin of the Johns Hopkins Hospital has been issued (vol. xxii., No. 245). The principal article is on stereoscopic X-ray examination of the chest, with special reference to the diagnosis of pulmonary tuberculosis, by Drs. Dunham, Boardman, and Wolman. It is illustrated with three excellent stereoscopic views of the condition present in three cases of pulmonary tuberculosis.

Writing from Chinanfu, Shantung, China, Mr. Alfred Tingle refers to a statement made in a note in Nature (June 8, p. 493) that "rice in China takes the place of wheat with us as the chief source of starchy food," and points out that in Shantung rice is little used, other cereals being substituted, and that the diet is a liberal one. The statement, of course, was only a general one; and obviously in a country so huge as China, with climates varying from tropical to almost Arctic, the diet in different districts must be equally variable.

In a paper on the chemical differentiation of species, Miss Muriel Wheldale suggests that the presence of particular chemical compounds in plants may be of value either in the differentiation of, or in accentuating resemblances between, orders, families, genera, or even species. Thus the glucoside "aucubine" was first isolated from *Aucuba japonica* (Cornaceæ), and subsequently from seven species of Garrya, another genus of the Cornaceæ. It is also stated to be present in various species of Plantago (Plantaginaceæ). It would be interesting to discover if there are other connecting links between these two groups. Some of the purins are known only in the genus Thea (*Bio-Chemical Journal*, v., 1911, No. 10, p. 445).

In his report on the Giza Zoological Gardens for 1910 Captain Stanley Flower states that the number of visitors continues to show a gratifying increase, and that the number of animals, other than fishes, in the collection is larger than in any previous year, comprising at the annual stock-taking 1464 specimens, referable to 391 species. Among the more important additions were a rhinoceros and a Blue Nile elephant.

In *The Field* of August 12 Mr. R. I. Pocock illustrates the different ways in which the Indian and the African elephant use the tip of their trunks. In the former, some small object, such as a handful of bran, is held by the tip of the trunk being bent on itself, so that the object is squeezed between the tip and the lower surface of the trunk, whereas in the latter the object is held between the two lips of the trunk-tip, much after the fashion in which fruit is placed in a cornucopiæ.

The recorder of Section D (Zoology) of the British Association sends us the following provisional programme of the section for the forthcoming meeting at Portsmouth:—Presidential address, Prof. D'Arcy W. Thompson. *Discussions:* On the origin of the Mammalia, Prof. G. Elliot Smith, Dr. C. W. Andrews, Prof. A. Keith, and Dr. Marett Tims; on Wallace's line, C. Tate Regan and Guy Marshall; on the systematic position of the cyclostomes, Dr. Woodland, Prof. Dendy, and E. S. Goodrich; on the nutrition of marine organisms, Dr. Dakin, Prof. Herdman, Prof. Gamble, and Prof. V. H. Blackman. *Lectures* (with illustrations): Mr. F. Enock, on fairy flies; Dr. C. W. Andrews, on the extinct reptiles of the Oxford Clay of Peterborough. *Papers:* Recent advances in sex problems, G. Smith; some points in the anatomy of Squilla, Dr. Woodland; new species of Balanus collected by the *Siboga* in the Malay Archipelago, Dr. P. P. C. Hoek; a new epizoic hydroid on a copepod (n.g.+n.sp.) parasitic on *Scopelus glacialis*, Prof. H. Jungersen; note on the manus of a young Indian elephant, Prof. R. J. Anderson; some points in the manus and pes of Primates, Prof. R. J. Anderson; on the effect of Sacculina on the fat metabolism of its host, G. C. Robson; notes on a trypanosome found in a sheep tick, and its probable connection with the disease known as louping-ill, Major C. F. Bishop, R.A.; on the dorsal vibratile organ of the rockling (Motella), Dr. J. Stuart Thomson; momentum in evolution, Prof. Dendy; Polytrema and its allies, Prof. S. J. Hickson; the life-history and metamorphosis of Murænoids, Dr. J. Schmidt (Copenhagen); le cycle animal des glandes génitales de l'*Echinocardium cordatum*, Prof. Caullery (Paris); the hypostome and antennæ in a reconstructed trilobite (Calymene), Prof. Malcolm Laurie; (1) the vernal-plumage changes in the adolescent blackbird (*Turdus merula*) and their correlation with sexual maturity; (2) case of a remarkable egg of *Falco tinnunculus* laid in remarkable circumstances, Prof. C. J. Patten; (1) the lantern of Aristotle as an organ of locomotion; (2) solaster development, Dr. James F. Gemmell.

Messrs. Friedlander, of Berlin, have conferred an inestimable benefit on zoologists and palæontologists by the issue of a second edition of the "Zoologischer Adressbuch" (International Zoologist's Directory), which contains the names and addresses, so far as they could be ascertained, of all living persons specially interested in zoology, anatomy, physiology, and animal palæontology throughout the world, together with taxidermists and natural history dealers. The previous edition was published by the German Zoological Society in 1895, to which a supplement appeared in 1901. The present volume comprises 1109 pages, of which 88 are devoted to the index of names. As in the American "International Scientist's Directory," the names of the persons referred to are entered under the heading of their respective countries, but in place of the names being arranged in alphabetical order, they are classified according to the place of residence. Whether this is an improvement or the reverse we do not propose to discuss; but, whatever may be the general opinion on this point, the index renders it perfectly easy to find the individual addresses. Taking the British Isles as a sample of the whole, we find, so far as we are acquainted with them, both the names and the addresses entered with what is really marvellous accuracy. The names of a few deceased naturalists, such as the late T. Southwell and C. J. Cornish, are retained on the lists, while a few living naturalists, *e.g.* Mr. Hugh Gladstone, are omitted; and we notice some confusion between the officials of the Victoria and Albert Museum and those of the Science Museum. Errors of this nature are, however, practically unavoidable, and the publishers are to be heartily congratulated on the manner in which they have carried out an arduous task. As the expense in producing the work must have been very heavy, it is to be hoped that they will receive liberal support from that section of the public interested in natural history.

In the current issue of *Scientia* M. J. Costantin directs attention to some of the recent phases of the culture of orchids. He points out that 600 hybrids have been produced in the genus Cypripedium alone, many of which do not resemble their parents but look like new species, and are indefinitely fertile, and so can be crossed with each other. Observations are added on the association with orchids of a mycorhiza, three species of which have been recorded; one of these is found in the roots of Cypripedium, Cattleya, and Lælia, another in Phalænopsis and Vanda, and the third in Odontoglossum. The inoculation of an orchid with a species of mycorhiza other than that usual to it leads to one of three results: either the plant dies, the fungus dies, or they become accommodated to each other; but in this case a plant of unusual form is produced. The author suggests that these facts indicate that the environment may be responsible for the appearance of new characters.

PROF. EMIL ROHDE (in *Zeitschr. f. wiss. Zool.*, Bd. xcviii., 1 Heft) shows that chromatin diminution occurs in various tissues other than the germ cells. In the blood cells of various vertebrates the nuclei undergo a maturation process similar to that exhibited in oogenesis, portions of chromatin being cast out of the nucleus and out of the cell. In the red blood cells of mammals this process goes on to such an extent that the whole nucleus is lost. The nuclei of other tissue cells, especially those of the central nervous system of vertebrates, exhibit diminution of chromatin which the author compares with that observed in spermatogenesis. The nuclei of the nerve cells in karyokinetic division give off spherical masses of chromatin, which later lie between the resting nuclei. In other cases the nucleus breaks up into several small daughter nuclei, which Prof. Rohde compares with the division of the sperm mother cell into spermatozoa. The fact that diminution of chromatin takes place in so many different tissues and animals (those investigated range from Mustelus to man) indicates that it has a general significance; the author regards it as a characteristic of adult, that is, of maturing and dividing cells in general. Other memoirs in the same journal deal with the innervation and sense organs of the wings of butterflies and the nephridial funnels of earthworms.

To *The Journal of Economic Biology* for July Dr. H. B. Fantham contributes an important article on coccidiosis in game-birds and poultry. Owing, it is suggested, to the great increase of motor traffic, and the consequent pollution of the air in many parts of the country, white diarrhœa and other forms of coccidiosis, which chiefly affect young birds, appear to be on the increase, and there is, accordingly, urgent reasons that every available means should be taken for keeping them in check. The two important objects which should be kept in view are, first, the taking of such precautions as will tend to prevent the pollution of air and soil by coccidian oöcysts, and, secondly, to endeavour to raise the vitality of young birds, and thus enable them the better to resist the onset of the disease. In the case of domesticated poultry, cleanliness is a matter of the first importance, both as regards the young birds themselves and their surroundings; and it is probable that if such preventive measures were properly enforced and carried out, coccidiosis would eventually disappear. The author gives a full and detailed account of the structure and life-history of the parasite of coccidiosis and of its effects on the intestinal tract of its victims, but these are too long and too technical for quotation, even in brief abstract, on this occasion. *Eymeria avium*, or *Coccidium avium*, as it was formerly called, is a minute animal parasite belonging to that section of the Protozoa known as the Sporozoa, on account of the production of resistant spores. Although in some cases the whole intestinal tract of the bird may be riddled by the parasite, the duodenum and the paired cæca, or blind guts (especially long in grouse), are the parts chiefly attacked. The life-cycle of the parasite is complicated by the fact that there are two distinct phases of development, namely, an asexual phase, known as schizogony, during which there is a multiplication of the parasites by fission in the lining of the intestine of the infected bird, and subsequently a sexual phase, in which resistant cysts and spores adapted for life outside the body are produced in myriads. It is by these spores, which are swallowed by fresh birds with their food and drink, that the disease is spread.

THE difficulty of obtaining trustworthy data, at any rate in India, to prove or disprove the influence of forests on atmospheric and soil moisture is reasonably argued in an article appearing in *The Indian Forester* (July). Not the least interesting portion is the transcript of a note on the subject submitted to the Indian Government by Dr. Walker, the Director-General of Observatories. It reflects great credit upon the Government of India that, in spite of opinions mainly adverse, they assent to the initiation of a few experiments in selected localities for the purpose of tabulating information with respect to local differences in rainfall, temperature, and humidity inside and outside forest areas, as also to differences in level of the underground water table and extent of floods that might be referable to the proximity of forest areas.

AN account of the Percy Sladen Memorial Expedition (1910–11) to the Orange River through Little Namaqualand, contributed by Prof. H. H. W. Pearson, is appearing as a series of articles in *The Gardener's Chronicle*. In the current number (August 19) the author touches on the existence of a flora with a strongly marked Cape affinity occurring on the Khamiesberg range, while the low country shows entirely different vegetative formations, in which succulents predominate. The Khamiesberg is one vegetative island, while another is found on the Huilla plateau in South Angola, and possibly similar floras will be discovered on the unexplored peaks in German South-West Africa. If these islands show the remnants of a flora once continuous, whence, it is asked, and by what route, came the ancestors of the plants occupying the lowlands. The illustrations represent some of the more striking succulents, such as *Mesembryanthem digitiforme* and *Augea capensis*.

OWING to the receipt of numerous specimens of inflorescences from the graft hybrid, *Laburnum Adami*, sent to Kew Gardens for identification, Mr. W. J. Bean contributes a short article on the subject to *The Kew Bulletin* (No. 6), in which he explains how this particular novelty arose as a chance development from a graft of the dwarf purple broom, *Cytisus purpureus*, on the common laburnum. From the graft there arose a shoot which produced the intermediate type of purplish-yellow flower. Subsequently portions of trees propagated from the shoot reverted to the parent types, so that a single tree may bear at the same time the purplish flowers of the presumed hybrid, yellow flowers of the laburnum, and purple flowers of the broom. Two further examples of graft hybrids, *Crataego-mespilus Dardari* and *Crataego-mespilus Asnieresii*, are also described. They both arose on the same tree, a medlar grafted on a stock of common hawthorn, as branches showing composite characters. *Crataego-mespilus Dardari* has shown a tendency to break up into three forms, representative of the type *Asnieresii*, pure medlar, and itself. The different forms are illustrated from a photograph of three sprays gathered last June from a specimen of *Crataego-mespilus Dardari* growing in Kew Gardens.

IN the August number of *Petermann's Mitteilungen* Prof. Maurer describes a conventional projection for conveniently representing the lines of magnetic declination. For their study Mercator's projection is unsuitable, however well adapted it may be to the requirements of the navigator, since the areas in the neighbourhood of the poles are not represented, and the zones in higher latitudes are greatly distorted. In his projection the polar regions are well shown, the central point of the map being in $\phi = 0°$, $\lambda = 90°$ E. South America is considerably distorted from being unfavourably placed, but other continents suffer less.

THE Journal of the Meteorological Society of Japan for June contains original articles, with brief abstracts in English, (1) on the construction of protected rain-gauges, by Mr. J. Sato. The author gives the history of the works of some of the principal writers on this subject, and describes a gauge devised by himself, which is a modification of one adopted by the late Dr. Billwiller in the Swiss Meteorological Service. (2) An analysis by Mr. H. Maruoka of the Osaka seismogram at the time of the severe earthquake felt in Mexico on June 7. The time of its commencement in Osaka was 9h. 17m. 48s. (135th meridian); its total duration was 2h. 34m. 31s. in the E.-W. component, and 2h. 31m. 23s. in the other component. (3) Discussion of rainfall observations at Osaka for the years 1883–1910, by Mr. K. Yamada. The results of this valuable investigation are not given in English.

THE experiments of Profs. Boltwood and Strutt, and of Dr. Eve, on the amounts of uranium and radium present in radio-active minerals, have led to the conclusion that the ratio of the amounts of the two present is a constant independent of the nature of the mineral so long as its age was considerable. A long series of measurements made in Madame Curie's laboratory by Miss Ellen Gleditsch seem now to cast doubt on the constancy of the ratio. The methods used by Miss Gleditsch appear to offer little ground for criticism, and her results show a variation of the ratio of radium to uranium from $1{\cdot}8\times10^{-7}$ tu $3{\cdot}7\times10^{-7}$ for the twenty-one minerals examined. These differences she is disposed to attribute to the existence of the long-period ionium and possibly another long-period element between the parent uranium and radium, but does not exclude the further possibility of the "constants" of radio-activity being influenced by external circumstances more than we at present believe.

THE sensation produced on the retina by a source of light of short duration has for the last three-quarters of a century been taken as proportional to the product of the intensity of the source into its duration. The early experiments of Talbot and of Swan, and the later ones of Bloch and of Charpentier, provided ample justification for the law so far as it related to sources of considerable intensity. In the *Journal de Physique* for July, MM. A. Blondel and J. Rey point out that for weak sources the intensities of which are not much greater than the lowest perceptible the statement cannot be true, or there would be no lower limit to perception. On this ground they argue that the sensation should be proportional to the product of the *excess* of the intensity of the source over the minimum just perceptible into the duration of the source, and this conclusion they have verified by means of the measurements made by seventeen observers by two independent methods of observation.

WE learn from *The Engineer* for August 11 that the new Italian Dreadnought *Conte di Cavour* was successfully launched at Spezia on August 10. Admiral Mirabello's crusade against lack of homogeneousness is beginning to produce its fruits; it is not likely that Italy will add to its armoured cruisers, as opinion has turned in favour of Dreadnoughts, of which four were designed by General Masdea. The *Conte di Cavour* is the second example of these. She will have a displacement of 21,500 tons, and her turbine machinery, of 24,500 horse-power, is designed for a speed of 22 knots. There will be twenty water-tube boilers of the Blechynden type. The normal coal and petroleum capacity will be 1000 tons. The armament will comprise thirteen guns of 305 mm., twenty guns of 120 mm., and thirteen guns of 76 mm. There will be three submarine torpedo tubes, two lateral and one stern.

A COPY of the "Reports and Transactions," for the year ending September 30, 1910, of the East Kent Scientific and Natural History Society has been received. Among much other interesting information contained in the report, some facts about salt rains, contributed by Mr. W. H. Hammond, may be mentioned. On December 14, 1910, a very heavy gale from the south-east with a deluge of rain in the night occurred; on the following day all the windows which faced south-east had quite a frosted appearance when dry. Some of the substance scraped off and dissolved in distilled water was proved to consist of common salt. At Milton Chapel some years ago, in the 'eighties, on one occasion a north-east window was coated with salt after a gale, and on the *Dane John* about the same time a salt gale was experienced; it made the young leaves look as if they had been scorched by fire. Mr. Hammond states that in 1871, when a student at the Royal Agricultural College, Cirencester, Prof. Church told his class that the rain which came in a gale one day from the direction of the Bristol Channel was loaded with salt; this must have travelled about sixty miles. The report also contains observations of the "nailbournes" in the Elham Valley, Petham, and Drillingore in the Alkham Valley, Dover. Useful meteorological statistics and notes for the year 1910 from various observing stations throughout east Kent are also included, as well as natural history notes and reports of lectures and addresses.

OUR ASTRONOMICAL COLUMN.

THE COMETS 1911*b* AND 1911*c*.—Numerous observations of the comets discovered by Kiess and Brooks, respectively, are now being recorded, but they contain nothing that is strikingly new; the Kiess comet is now invisible in these northern latitudes.

In No. 4517 of the *Astronomische Nachrichten* Prof. Pickering reports that a photograph of the spectrum of comet 1911*b*, secured with the 8-inch Draper telescope on July 7, shows the bands at λλ 3883 and 4737 as bright, and of nearly equal strength; the latter was much the brighter in the case of Daniel's comet, 1907*d*.

Apparent path of comet 1911*c* August 24–September 13, 1911.

From Mr. F. C. Leonard, of Berlamont, Mich., U.S.A., we have received a lengthy report of observations of both comets made during July. Kiess's comet developed appendages on both the preceding and following sides, and on July 26 a long streamer was seen to extend for some distance in a direction perpendicular to the axis.

Brooks's comet, observed on July 25, 26, 27, and 29 presented the mottled appearance of a condensed nebulous cluster, and was 3′ or 3·5′ in diameter.

The following is a continuation of the ephemeris published by Dr. Ebell in No. 4517 of the *Astronomische Nachrichten*, and on the accompanying chart the apparent path of the comet among the stars is approximately shown; the new elements, upon which these positions depend, give October 27 as the time of perihelion passage:—

Ephemeris (12h. M.T. Berlin).

1911	α (true) h. m.	δ (true) ° ′	log r	log Δ	mag.
Aug. 24	20 41·9	+46 43·8	0·1552	9·8033	8·0

It will be noted that on August 26 the comet will pass very near to ω Cygni (magnitude 4·9), and on September 10 within a few minutes of ξ Draconis (magnitude 3·9).

THE NEW CANALS ON MARS.—It will be remembered by readers of these columns that, during the last opposition of Mars, Prof. Lowell claimed to have discovered conspicuous canals which reference to the large accumulation of earlier observations showed to be new; they were not to be found on any of the earlier drawings.

Telegraphing to the Kiel Centralstelle, Prof. Lowell now states that these two new features near Syrtis are still visible. The importance of establishing the novelty and permanence of such conspicuous "canali" as these appear to be cannot be overrated.

A QUICKLY MOVING COMET-LIKE OBJECT.—Dr. Franz reports the observation at Breslau on July 22 of a rapidly moving nebulous object, which may have been a comet very near to the earth. At 13h. 4m. (M.E.T.), the position of this object was $\alpha = 4$h. 15·0m., $\delta = +20° 36'$ (1855·0), and during an interval of six minutes the R.A. altered by about 3m., while the declination remained the same. This nebulous-looking body was of about the sixth magnitude and about 6′ in diameter, not unlike the Kiess comet which had been observed just before.

The observers at Kiel searched unsuccessfully on July 23 for an object answering to the conditions named by Dr. Franz, and Dr. Graff was equally unsuccessful at Bergedorf on July 24; both he and Dr. Franz were clouded out on July 23 (*Astronomische Nachrichten*, No. 4517).

OBSERVATIONS OF NOVA LACERTÆ.—A number of magnitude and position observations of Nova Lacertæ appear in No. 4509 of the *Astronomische Nachrichten*. Prof. Eginitis shows that the colour of the star changed from red to bluish-white during the period January to March, its magnitude meanwhile decreasing from 7·9 to 8·9. M. Luizet shows that this change of colour was very rapid during the first six weeks, and then the colour became nearly constant. Herr Jost's observations of magnitude show very small oscillations up to the end of February, and then a nearly constant diminution until the beginning of May.

At the Simeis Observatory Prof. Beljawsky made an elaborate investigation of the nova's magnitude as shown on various photographs taken through different coloured screens. The results, together with the measures of position, are given and discussed in No. 41 (vol. iv., No. 5) of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo*.

PROMINENCES OBSERVED ON APRIL 28.—In view of the total eclipse of the sun on April 28 last, Prof. Riccò made special arrangements for the visual and photographic observations of prominences at Rome and Catania, and now publishes the results in No. 4, vol. xl., of the *Memorie di Astrofisica ed Astronomia*. There was a large prominence in position-angle 48° (N. through E.), and lesser ones at 36°–42°, 163°–168° (given as 192°–198° on the figure accompanying the article), and 294°–300°.

A STAR WITH CONSIDERABLE PROPER MOTION.—Mr. Baldwin reports, in No. 4513 of the *Astronomische Nachrichten*, that the observations made at Melbourne Observatory show the star C.P.D. −70°447 to have a large proper motion amounting to −0·0711s. in R.A. and +1·214″ in declination. The position of the star, for 1900·0, is 5h. 45m. 41·036s., −70° 12′ 50·91″, and it was observed at Melbourne in 1892 and 1907.

AN ASTRONOMICAL SURVEY OF SOME PEMBROKESHIRE CIRCLES.

THE Rev. W. Done Bushell first directed the attention of the members of the Cambrian Archæological Association five years ago to some monuments in Pembrokeshire as illustrative of Sir Norman Lockyer's findings elsewhere, and a well-illustrated paper of fifty-two pages, published in the journal of that association, shows that, so far as Wales is concerned, the archæologists wish to give this "new thing" a hearing.

The author confines himself to ten groups of monuments on the southern slopes of the Prescelly Hills, covering a tract of land seven miles from east to west. As during the last five years he has made repeated visits to the district, he has gathered almost heartrending evidence of the progressive destruction of ancient monuments. "There were at Eithbed until very recently three circles, and probably three cromlechs also were associated with them. They are now no more. The largest was destroyed, we know not when or how" (pp. 17, 18). "We find this circle duly given in the earlier edition of the 25-inch Ordnance Map; it is entirely absent from the later edition issued in 1908." The author was able to trace its outline. "It has an average diameter of no less than 150 feet." "Two other circles . . . have both of them been wilfully destroyed," one in 1905 and the other in 1909. "These circles, with the accompanying cromlechs, must have formed a very noble and important group before they were thus demolished." The author, fortunately, had photographed some of the monuments before they were destroyed. Last year he recognised some of the temple materials in an "ugly house which stands close by, a veritable monument of shame" (pp. 19, 20). All archæologists will, of course, deplore such vandalism; but the significance of the loss is well expressed in the author's remark:—"We may add that the existence of three circles in immediate contiguity suggests, as in the case of the Hurlers and elsewhere, adjustments rendered necessary by precession" (p. 22).

At Cil-y-maen-llwyd, in the same district, an observer about the year 1738 saw "a circle of mighty stones very much like Stonehenge in Wiltshire, or rather like the Rollrych Stones in Oxfordshire" (p. 38). There remains just one of the mighty eighty stones.

Of the existing remnants of temples second to few in Britain, the author has secured most useful angular measures. He acknowledges the assistance of his son, Mr. Warin F. Bushell, and of Lieut.-Colonel Tupman, in preparing the plans given. A useful declination table for lat. 52° by the latter is given as an appendix. The paper is an admirable illustration of what may be done with little trouble in every district towards recording the testimony of the stones, the speediest and most effective method of outwitting the vandals. Photographs are good, plans are better, but measures are indispensable.

Given trustworthy data, we can put up with any deductions. Some of the author's opinions are tolerable only on such ground. Because of the difficulty in these latitudes of observing any celestial bodies right on the horizon, he is inclined to think that the alignments had only a ceremonial use. Early man, he thinks, "did not require the aid of an astronomer" (p. 44). "Nor would so many observation-circles have been required had their prime object been, as has been suggested (Lockyer, 'Stonehenge,' p. 17), the determination of the seasons. England has many churches, but only one Greenwich" (pp. 45, 46). Yet in a passage cited the author speaks of "adjustments rendered necessary by precession." Such, however, are some opinions which the author puts forth as "alternatives to any premature acceptance of Sir Norman Lockyer's interesting theory, at least in its entirety" (p. 44). Nothing like a proved alternative is offered, nor is it shown that the data supplied require any alternatives. Such a happy observation as that cromlechs generally are oriented so as to command the most extensive view obtainable is not universally true to the facts, and could not have been always "a primary consideration with the cromlech-builders" (p. 20). The exceptions prove what the primary consideration was, as at St. Lythans' fine cromlech, which is definitely oriented to the equinox in the opposite direction to the extensive view. JOHN GRIFFITH.

RECENT ENGLISH AGRICULTURAL PUBLICATIONS.[1]

SCIENTIFIC work in agriculture in this country is published exclusively in the Journal of Agricultural Science, but there are certain papers published in the technical journals which possess considerable scientific interest. These alone will be dealt with in the present article.

The Board of Agriculture publishes each month the Journal of the Board of Agriculture, which can only be described as an unqualified success. There are usually three or four signed articles, primarily of technical importance, but often of scientific value as well, followed by a number of short articles or notes summarising work done on a particular subject, or directing attention to important work being done elsewhere.

The progress of the sugar beet industry in Norfolk is described by Mr. W. E. Sawyer. Last year's trials showed beyond doubt that sugar beet could be produced in sufficient quantity, and of the necessary good quality, for the purposes of a factory. This year it is sought to ascertain whether the crop will pay as well as other crops, and in organising the work advantage is being taken of last year's experience. Generally speaking, it has been demonstrated that sugar beet can be produced in most parts of England, but we now require experiments on the large commercial scale to ascertain whether or not the industry will be profitable.

Dr. Goodwin writes on molasses and sugar foods for live stock. Molasses, whether from beet or from cane sugar factories, contains about 30 to 35 per cent. of sucrose and 25 to 30 per cent. of dextrose and other sugars. There are also present some nitrogenous compounds, betaine, amino-acids, &c., and also some ash constituents, but the great value of molasses as a food consists in its sugars. Unfortunately there are certain drawbacks to its use: it is very sticky and difficult to handle, and is said to be liable to theft. To overcome these difficulties the practice has arisen of adding some absorbent material to the molasses and making a mixture that could be dried, powdered, and handled easily. The absorbents are of the most varied kinds; cocoanut meal, hay, spent hops, bran, sugar-cane pith, and peat have all been used, and not a few extravagant claims have been put forward by the patentees about the beneficial effects of the absorbent. Dr. Goodwin examines certain of these claims, and shows by actual digestibility trials with sheep that only a small proportion of the added cellulose is digested in some cases.

The relation of weeds to crops is discussed by Miss Brenchley. Over a limited area, where the climatic conditions showed no great variation, *i.e.*, between Harpenden and Bedford, there was a clear connection traceable between the weeds and the nature of the soil, but none between the weeds and crop, with a few readily explained exceptions. The so-called "seeds" crops, clover, and rye grass, &c., effectually keep down certain weeds, no doubt because they so densely cover the ground; other weeds will only grow in the thin patches of cereal crops, and in other open situations.

It has long been an agricultural practice to grow certain crops simply with the intention of ploughing them into the ground, and thus adding organic matter to the soil to be converted into humus. Mr. Hall describes experiments made at Rothamsted on the relative effects of mustard, rape, crimson clover, and vetches: as was expected, the leguminosæ gave the largest increase in subsequent crops. At Woburn a different result was obtained, it being found that mustard gave better results than the leguminous tares.

[1] The Journal of the Board of Agriculture; The Journal of the Royal Agricultural Society.

Dr. Lander, in an interesting note, shows that small amounts of prussic acid, such as might be generated from a linseed cake in which the glucoside-splitting enzyme had not been destroyed, are not necessarily harmful to stock. In view of the widespread occurrence of cyanogenetic enzymes, it is highly desirable that authoritative information should be at hand as to the effect of continuous small doses of hydrocyanic acid on animals.

The Journal of the Royal Agricultural Society is published once a year only, and its appearance is always an event in the agricultural world. In the current number there is a paper by Dr. Russell, giving a connected account of the work he and his colleagues have been doing on the production of plant food in the soil, and bringing together a number of agricultural practices, previously unexplained, that fall into line with the recent work with which he is associated.

Mr. W. W. Skeat contributes an interesting account of the origin of some old agricultural words, directing special attention to the "Dictionary of English Plant-names," by Britten and Holland, and the "English Dialect Dictionary." Sir John McFadyean deals with the very important question of tuberculosis in cattle. The idea still finds credence that the offspring of tuberculous cattle will necessarily develop tuberculosis: experiments, on the other hand, have shown that if the calves are at once removed from their dams and kept free from infection they do not become tuberculous. Nor does Sir John admit that they show any special tendency to tuberculosis. All breeds of cattle are liable to tuberculosis, but no families exhibit any special liability not shown generally by their particular breed.

State aid to agriculture in Canada is authoritatively described by Mr. E. H. Godfrey, of the Canadian Agricultural Department. Mr. Godfrey has the enormous advantage of knowing English institutions, and his article will, therefore, be found of great interest to all engaged in agricultural administrative work in this country. In addition, there are the usual reports from the consulting botanist, chemist, and zoologist; Prof. Biffen reports a case where the somewhat rare hoary cress (*Lepidium draba*) obtained a footing on arable land, and spread to such an extent as to become a nuisance; while Dr. Voelcker reports the effect of zinc and other salts on crop growth in pots.

MEDICAL RESEARCH IN INDIA.

THE scientific memoirs by officers of the Medical and Sanitary Departments of the Government of India,[1] issued from time to time, contain matter and researches of the utmost importance and value.

Memoir 43 deals with the relation of tetanus to the hypodermic or intramuscular injection of quinine. For some forms of malaria injection of quinine is by far the most efficient treatment, but every now and then is followed by the dreaded tetanus or lockjaw, even when every possible care has been taken to ensure the sterility of the fluid and of the syringe used to inject it.

Tetanus is caused by a bacillus which occasionally is present in dust and earth, and may be introduced into a wound, and so give rise to "traumatic tetanus." It is a curious fact that tetanus spores free from other organisms and free from any adherent toxin may be injected into an animal without harm, and may remain latent at the site of inoculation for months. If, however, the spores have adherent toxin upon them, or if at the same time a little weak lactic acid is injected, the organism grows and multiplies and sets up tetanus. Apparently some agent must be present which weakens the resistance of the tissues before the tetanus bacillus can develop. Sir D. Semple, the author of this memoir, finds that quinine injected into the tissues produces necrosis or death of the tissue at the site of injection, and that pure washed tetanus spores

[1] No. 43: "The Relation of Tetanus to the Hypodermic or Intramuscular Injection of Quinine." By Lieut.-Col. Sir D. Semple, Kt. Pp. v+61. Price 1*s.* 2*d.*

No. 44: "The Preparation of a Safe and Efficient Antirabic Vaccine." By Lieut.-Col. Sir D. Semple, Kt. Pp. v+32. Price 9*d.*

No. 45: "Epidemic Dropsy in Calcutta." Being the First Report of an Inquiry carried out by Major G. D. W. Greig. Pp. ii+47+map+vi charts. Price 2*s.* (Calcutta: Government Printing Office, 1911.)

when mixed with quinine and injected invariably set up tetanus. Even when the quinine is injected into a site remote from the site of injection of the washed tetanus spores, tetanus may ensue. Sir D. Semple, therefore, suggests that tetanus following quinine injection when every precaution has been taken, may result from the fact that the individual has tetanus spores lying latent in some situation, introduced by some previous wound, and that on the injection of the quinine these latent spores become active. Tetanus spores were searched for in solutions of quinine, but were never found. Tetanus infection is also sometimes present in the bowel in healthy individuals. A small dose of tetanus antitoxin given at the same time as the quinine injection will effectually prevent the development of tetanus. Sir D. Semple also deals with the preparation of a safe and efficient antirabic vaccine in Memoir No. 44. He finds that rabies virus is killed by a 1 per cent. solution of carbolic acid in twenty-four hours at a temperature of 37° C., but still forms a safe and efficient antirabic vaccine, and he suggests that this method may be employed for the prophylactic treatment of persons bitten by rabid animals.

Epidemic dropsy in Calcutta is the subject of Memoir No. 45, by Major Greig. This disease, which occurs also in other parts of India, is much like ship beri-beri. The patients suffer from dropsy and neuritis of the lower limbs, shortness of breath, and weak heart. The general conclusion is that the disease is caused by a "one-sidedness" in diet, due to the use of "polished" rice and wheaten flour deficient in essential constituents. By the "polishing" of rice, the pericarp and seed-coat containing phosphorus compounds, and the fat and aleurone layers, are removed, leaving the inner endosperm, which contains little else than starch. Epidemic dropsy, however, occurs in severe outbreaks at particular periods, and it is necessary to correlate the food hypothesis with this fact. Major Greig states that, so far as his researches at present go, there is a remarkably close relationship between the price of food grains and the prevalence of epidemic dropsy. We shall await with interest the further report which is promised us on this subject. R. T. H.

MARINE BIOLOGY.

FOUR *Publications de Circonstance* have just been issued by the International Council for the Exploration of the Sea. Mr. Sven Palitzsch gives a very interesting account of investigations into the concentration of hydrogen ions in sea water, carried out on board the Danish investigation ship *Thor* during 1910. Of known methods of determination, the electrical method is the most accurate, but it is unsuitable for use on board a ship in a rough sea. The author has developed a colorimetric method, making use of standard solutions of known hydrogen-ion concentration, and comparing these with the water sample, using either phenolphthalein or naphtholphthalein as indicators. The standard solutions were sodium borate containing hydrochloric acid. The value of the determination of the concentration of hydrogen ions in sea water in comparison with the older methods of determining the "alkalinity" are discussed, and it is shown that the former factor is that which is of the most importance in relation to biological processes. The paper is a good example of the way in which the methods of marine biology can be supplemented by those of pure physical chemistry. The results may be quoted here: expressed as gram-equivalents of hydrogen-ions, the concentration varies from $10^{-7.95}$ to $10^{-8.35}$ per litre of sea water.

Two papers in the same series, by Mr. H. J. Buchanan-Wollaston, deal with the construction of a plankton net for making vertical hauls in a rough sea. It is well known that the difference between theory and practice is very great in such cases, and that plankton hauls which are called "vertical" are not, as a rule, truly so. The author suggests a net which "fishes" as it descends into the sea. It is lowered on a slack line, and whether or not the ship drifts during the operation, the apparatus descends vertically since it falls by its own weight. At the bottom, or at the required depth, the net is closed in the same way as the well-known Nansen net is "throttled," and it is hauled in the closed condition. The filtration coefficient of the net must now be determined—this is the factor expressing what fraction of the vertical column of water equal in section to the area of the mouth of the net does actually pass through the pores of the latter. Its calculation is so difficult, and the results so uncertain, that it has not been attempted except by the Kiel planktologists, by whom the method was originally devised. For such an inverted action of net as Mr. Wollaston suggests, however, the filtration coefficient can be approximated to with much greater accuracy than was hitherto possible. Mr. Wollaston's suggestions are decidedly novel, and since no attempt has been made since Hensen's time to improve the vertical quantitative plankton net, they constitute a real advance in methods.

The remaining *Publication de Circonstance* deals with the spawning and statistics of various species of gadoid fishes of the North Sea, and is written by Dr. P. P. C. Hoek. At the same time, the council has issued the fifth volume of the *Bulletin Statistique*. In spite of the international cooperation of the Governments of the principal European fishing countries for the purposes of fishery investigation, no uniform system of statistical collection of returns of fish landed has yet been developed. The council has therefore published a statistical statement of the fisheries of the various countries in which the returns have been converted and expressed in common units. The present instalment, edited by Dr. H. M. Kyle, deals with the fisheries of the year 1908, and the total value of the fish landed in the different countries during that year was about 18,000,000*l*. Of this total the North Sea contributed about one half, and Great Britain about 11,000,000*l*.

RURAL EDUCATION.

THE Board of Agriculture and the Board of Education have issued two reports by the Rural Education Conference dealing with rural education.

The "Report on a Suggested Type of Agricultural School" states the conclusions of a committee of the conference on the question "as to whether there is any place in the system of rural education, either generally, or in particular counties in view of special local conditions, for schools giving to boys leaving elementary schools a three years' course from the age of twelve or thirteen in the theory and practice of agriculture, together with continued general education."

The committee has considered separately the case of boys who intend to get their living as farm labourers and of boys who intend to become farmers or small occupiers. For the former, owing to the desirability of getting such boys into practical work on the farm as soon as possible, and to the expense and loss of time involved, they consider that there is no demand or place for schools of the type suggested.

A different view is taken of the case of those who intend to become farmers. The committee considers that this class of boys require something beyond the ordinary elementary school, and that they "should not leave school without acquiring a good knowledge of the theory and practice of agriculture (so far as it can be taught in school), together with good general instruction."

In districts where no facilities already exist (*e.g.* rural secondary schools), the report recommends the "trial by way of experiment" of one or two new types of school.

One they suggest might be termed a "Higher Grade Rural School," and worked on somewhat similar lines to the French École Primaire Supérieure. Practical agriculture would not be taught, but the curriculum would include practical gardening, nature-study, mensuration and surveying, and rural economy. The pupils would visit farms occasionally and receive some teaching in manual work incidental to farming.

The other type is described as a "Centralised Rural Continuation Day School," where boys actually engaged in farm work might be brought in several sets for one or two days per week and receive instruction in elementary science and rural economy.

The report on the "Qualification of Teachers of Rural Subjects" deals with the question of the "lack of teachers properly qualified to give instruction in rural subjects in elementary schools and the means which should be taken to raise the standard of efficiency in these subjects."

It appears that attempts hitherto made by the Board of Education to give teachers a special training in rural subjects have not been successful, and the only real progress made in this direction has been due to the efforts of local education authorities in providing special courses for the teachers in their rural schools. The report recognises that there is no inducement for teachers to qualify themselves for rural schools. The rate of pay is lower and chance of promotion less than in town schools, so that young teachers naturally object to become earmarked for country schools.

The chief recommendations of the committee are:—the extension of the training-college course so that teachers would be able to specialise in rural subjects during the third year; the provision by county local authorities of classes and courses in rural science; the encouragement of rural teachers by making their pay more nearly equal to that of the town teacher; the inclusion of rural subjects in the curriculum of secondary schools attended by intending rural teachers; and increased grants by the Treasury to the local education authorities.

Summaries of the evidence received is given in the appendices contained in both reports. J. J. G.

ESKIMO MUSIC.[1]

In 1888 Franz Boas published nineteen melodies of the central Eskimo in his well-known work on this people. In 1899 and 1900 R. Stein obtained thirty-nine songs from the Eskimo of Smith Sound, on the land west of the extreme north of Greenland. Between 1903 and 1906 William Thalbitzer collected a far greater number of melodies from North-West and East Greenland. It is good to hear that from some twenty-five of his many phonographic records permanent matrices in bronze were made, and that these are now deposited in the phonogram archives of the Danish Folklore Collection at Copenhagen.

Possessed of such extensive material first- and second-hand, Herren Thuren and Thalbitzer have endeavoured to review "the whole musical system of the Eskimo." Herr Thuren is responsible for the work of transcribing the phonographic records. This he appears to have been able to do with all the care that such an operation demands. For instance, "as in most cases an A (435 wave-lengths) was blown into the phonograph before the beginning of the melody, we were able in writing this off to set the phonograph to the speed used when the tunes were played, and thus frequently knew the absolute pitch." It is, however, a pity that equal care was not bestowed on the English dress in which this valuable monograph appears. Herr Thalbitzer is the collector of the music; a great number of melodies which were not sung into the phonograph were noted down by him "directly on the spot, the singer repeating his song for me several times whilst I used my violin to help in fixing the notes."

Unfortunately, the music of the western Greenlanders is much contaminated by European influence. In South-West Greenland "it is the European music which interests the Greenlander, and not rarely we hear Danish street melodies, to which the Greenlanders themselves put the words." The melodies, however, are always altered by adoption, and it is often difficult to determine whether these melodies are transformed European tunes or have been composed by Eskimo who have had some knowledge of European songs. In North-West Greenland European influence is less, and here "we might certainly talk of the pentatonic scale." The authors of this monograph believe that this choice of pentatonic intervals is due to the recent acquaintance of the Eskimo of North-West Greenland with European music, and that "their earlier, individual choice of intervals" is that "still found in East Greenland."

The North Greenlanders' songs resemble in several respects those of the Smith Sound Eskimo. On the other hand, the East Greenlanders differ from the latter in "that the melodic recitatives of the Smith Sound Eskimo are interwoven with or end in more complete melodic periods, whilst the East Greenlanders carry the recitative throughout the whole melody when the recitative is at all used. The very prominent East Greenland motifs constructed on the first, fourth, and fifth are not found at all among the Smith Sound Eskimo. Lastly, even the joining of the strophes to form a melody is different for the two tribes." Herr Thuren divides the East Greenland music into the following groups:—(i) recitative melodies; (ii) melodies based on the scale CFG (15) or CFGA (17); (iii) melodies based on the scale FAC (15), or F(G)AC (27), or F(G)ACD (20); (iv) melodies not included in the above (9). The arabic numbers enclosed in brackets give the number of songs belonging to these groups and subgroups.

The writers direct attention to a curious feature of East Greenland music, the tendency for the melody to rise instead of to fall at its close. They find that just those divergencies from our own diatonic scale which occur there have been noted among the Indians of British Columbia. They also lay stress on the complexity and accuracy of the rhythms characterising East Greenland music. "The more we study the songs of the East Greenlanders, the more we become convinced that not even the smallest rhythmic feature is due to chance. The same complicated accentuation, the same extremely fine subdivision of the melody come again when the periods are repeated."

These extracts are sufficient to demonstrate the importance of the study of primitive music, alike for comparative æsthetics and for ethnology.

THE KNEE-JERK.

A RECENTLY issued number of *The Quarterly Journal of Experimental Physiology* (vol. iv., No. 1, p. 67) is notable in containing a paper by Dr. W. A. Jolly, of Edinburgh, which finally settles a long-disputed question as to whether or not the knee-jerk is a reflex action. Everyone knows that when the tendon just below the knee-cap is tapped smartly, the leg is suddenly jerked forward, and the importance of this phenomenon arises mainly from the fact that its presence, absence, exaggeration, or diminution is a valuable diagnostic sign in certain nervous diseases. A reflex action demands the journey of a nervous impulse from the point struck up to the spinal cord, and down again from the spinal cord to the muscles of the thigh, and the statement has been generally credited that the time interval between the tap and the jerk is so short that it is impossible for this to occur. It was therefore held that the jerk was the direct result of stimulating the muscle itself. Nevertheless, the knee-jerk increases and decreases under the same conditions as those which increase and decrease actions which are undoubtedly reflex.

Various elaborate explanations, the best known of which is that of Sir William Gowers, have therefore had to be invented to reconcile these two statements. Such explanations are no longer necessary, now that we know that nerve impulses are in man propagated at the rate of 120 metres per second, and not at the rate of 30 metres per second, as was formerly supposed.

Dr. Jolly has made careful time-measurements, and shown that in the knee-jerk there is sufficient time for the nerve-impulse to travel to the spinal cord and back again, but that the time occupied in the cord itself is only about half that which is necessary in the case of ordinary co-ordinated reflex actions, such as the withdrawal of the feet when the soles are tickled. This is explicable on the assumption that, in the case of the knee-jerk and other similar tendon reflexes which do not involve the cooperation of several muscles, the number of nerve cells traversed in the cord is less. The increased rapidity of a tendon reflex is useful, for a sudden strain on a ligament would rupture some of its fibres or lead to injury of the joint surfaces if too great a time intervened before the muscles could contract to save the joint.

We should like to add a word of congratulation to Prof. Schäfer, the editor of the journal in which this paper appears, on the continued excellence of the new physiological periodical, which has now entered on the fourth year of its existence.

AFFORESTATION IN SCOTLAND.

When a board or council is constituted for promoting afforestation, it is evidently essential that the body should be invested with considerable freedom of action, because many of the schemes will present special problems requiring special consideration and localised knowledge. The council of the Scottish Arboricultural Society has published as a separate volume (xxv.) of their Transactions a report, compiled with great care and labour by Lord Lovat and Captain Stirling of Keir and other experienced authorities, providing a specimen example of a scheme that illustrates very definitely the complex factors that arise for consideration.

The concrete example presented is situated in the Highland district of Glenmore, Inverness-shire, and has been selected for various reasons, but chiefly because it contains wintering land of sheep farms and deer forests, and is also well suited for the creation of small holdings. Economic considerations, especially avoidance of an increased local rate, occupy a prominent place in the proposition, and it becomes obvious that the scheme of afforestation, to be financially sound, must fit in with farming and sporting conditions. The nature of the staff, and particularly the requirements of the foresters, is a second matter. The sylvicultural problems comprise a working plan, stocking of the ground, and utilisation of existing woodland produce. The afforestable land is computed at 15,000 acres, of which about two-thirds falls within deer forests and the remainder is sheep ground; according to the proposed scheme, 450 acres would be planted annually for fifteen years, and thereafter 300 acres per annum.

The tenor of the conclusions is to indicate that under a well-framed scheme large areas of land can be afforested without injury to existing interests; further, that afforestation should eventually pay its way, besides providing a great deal of permanent and periodic employment. Suggestions are also offered with regard to the nature of a proposed Central Forest Authority for Scotland, different systems of land tenure under afforestation, and the conditions of agreement between landowner and State.

PLANKTON STUDIES ON THE WEST COAST OF SCOTLAND AND IN THE IRISH SEA.

The areas in which plankton studies have been carried on during recent years in European seas, under the official international scheme of investigation, have not included the west coast of Great Britain. With the view of filling, at least in part, this lacuna in our knowledge of the plankton of the British area, Prof. Herdman has, during the years 1907 to 1910, made numerous vertical and surface hauls from his yacht during July off the west coast of Scotland, and during August and September in the Irish Sea. The material collected has been examined, and the results are presented in an interesting account by Prof. Herdman and Mr. William Riddell.[1]

In the Irish Sea the phyto-plankton reaches a maximum in April or early May, the sea swarming with diatoms (chiefly Chætoceras, Thalassiosira, and Lauderia); then the phyto-plankton gradually dies away, and is replaced by the zoo-plankton (copepods, Oikopleura, &c.), which is characteristic of the summer months. In September and October diatoms (chiefly Rhizosolenia, Chætoceras, and Lauderia) again appear in profusion, constituting an autumnal phyto-plankton maximum, usually not so marked in bulk or duration as that in the spring. This in its turn dies away, giving place to the scanty winter zoo-plankton—the minimum plankton of the year—which persists until the reappearance of diatoms in the spring. There is thus in the Irish Sea a clear periodicity in the plankton and marked differences in the nature of the plankton of the different seasons.

Examination of the gatherings made off the west coast of Scotland shows that localities not very far apart differ considerably in the nature of their plankton at the same time of the year. For instance, a vertical haul taken in the Hebridean Sea, off Canna, is a typical fine phyto-plankton, consisting chiefly of diatoms of the genus Chætoceras, whereas a vertical haul, at the same time of the year, at the entrance to Loch Fyne shows a typical coarse zoo-plankton containing large numbers of copepods. This is in marked contrast to the conditions in the Irish Sea, where a zoo-plankton and a phyto-plankton do not occur simultaneously a few miles apart. A list of the Scottish stations is given, with some particulars of the nature of the catch at each, and a detailed analysis in twenty-six cases. The evidence shows that, off the north-west coast of Scotland, at one time of the year (July), in several successive seasons, the plankton was of different types in different localities, but maintained a fairly constant character in each.

A comparison of the Scottish records with those from the Irish Sea shows that, in species present and in their abundance, the Loch Ranza plankton in July is much more nearly similar to the September than to the April phyto-plankton of the Irish Sea. But the phyto-plankton gatherings made north of Mull show resemblances to the vernal rather than to the autumnal phyto-plankton of the Irish Sea. There are three possible explanations of the differences observed between the summer plankton of the Hebrides and of the Irish Sea:—(1) the great vernal maximum, which dies away in May and June in the Irish Sea, passes off more slowly further north, and is found lingering, in some parts of the Hebrides, until the end of July, or even longer; (2) in some of the deep northern channels the diatoms, which elsewhere constitute the vernal maximum, persist in comparative abundance throughout the greater part of the year; (3) the diatoms of the July phyto-plankton may have invaded the Hebridean Sea from the North Atlantic at some period subsequent to the vernal maximum. The authors are inclined, on the evidence available, to regard the first of these suggested explanations as the most likely, but point out that further periodic observations are necessary before the matter can be decided definitely.

The authors discuss briefly the classification of diatoms into oceanic and neritic species, and give a provisional list of the two categories. A consideration of the phyto- and zoo-plankton shows that the west coast of Scotland is divisible into three well-marked areas, not merely geographically, but by reason of the distribution of its summer plankton:—(1) the Clyde sea-area to the south of, and inside, Cantyre, characterised by zoo-plankton, the species of which are, in the main, oceanic; (2) the area around and to the north of Mull, extending from Cantyre to the south of Skye, which contains in July a well-marked phyto-plankton, mainly neritic in character; (3) to the north of Skye, where a zoo-plankton again appears, which contains some oceanic species.

The plankton distribution of the west coast of Scotland may be explained in terms of hydrographic movements if it be supposed that Atlantic water gains access more freely in summer to the Clyde sea-area and to the region north-east of Skye than to the large intervening area of the west coast, that is, that an oceanic current reaches the Clyde area and another flows in round the north of Skye, while little or no such current invades the area north and south and around Mull. The authors conclude by pointing out that further observations are required in order to determine how far this explanation holds good, and also to gain fuller knowledge of the changes in the plankton. These changes are bound up with many problems of a fundamental and far-reaching nature connected with the nutrition of marine organisms, and an intimate knowledge of the changes in the plankton is essential to an understanding of the movements of the shoals of migratory fishes.

THE PRUNING OF TREES IN TOWNS.

The services of Prof. Bayley Balfour, F.R.S., have been obtained by H.M. Office of Works to inquire into the justness or otherwise of complaints made in regard to the treatment of the young trees in the Mall. His report, which has just been issued from the Stationery Office (Cd. 5823, price $2\frac{1}{2}d.$), must be gratifying to those who have charge of the trees, for he finds nothing to justify adverse criticism of the pruning. On the contrary, he was impressed by the evidence of sound practical knowledge and

[1] Trans. Biol Soc., Liverpool, vol. xxv., pp. 60–113, 11 figures.

scientific principle shown in their treatment. It was high time that someone in a position of authority should have been called on to lay down the principles that govern, or should govern, the pruning of trees in public thoroughfares. The outcry periodically made in the daily Press is usually marked by want of knowledge and unfairness. As a matter of fact, there is no work more thankless in nature than the management of street trees. In London and other great urban areas the planter's choice is restricted to a few species (of which the plane is the chief and best) which experience has proved will thrive, but which, as regards size, are quite unsuited to the spaces usually available for them. In the Mall this difficulty does not arise, for the space is ample. The object there is to control the growth of the trees that have been planted so that the foundations of a stately avenue may be laid.

Perhaps the most valuable portion of Prof. Balfour's report is that in which he shows that nature herself is always pruning. That is an aspect of the case which never strikes the lay critic. Yet the smothering out of weakly and overcrowded growths is continually going on. Correct pruning anticipates nature's end, and substitutes the prompt action of the knife for that of slow decay. If one compares the branch-system of a fully grown plane with that of a young specimen, and notes how few of the numerous branches of the latter survive, we see how drastic nature's pruning is. In such a place as the Mall it is essential that the trees should possess a certain uniformity and balanced proportions. The means to secure this end have been admirably chosen, and there the matter may be allowed to remain. But we may recommend Prof. Balfour's report to those who desire to gain some insight into the fundamental laws of tree growth with which the pruner's art should be in unison.

AN EXHIBITION OF BIBLICAL NATURAL HISTORY.

AS a supplement to the literary and historical Biblical exhibition which has been arranged at Bloomsbury for the tercentenary of the Authorised Version, an exhibition of the animals, plants, and minerals mentioned in the Bible has been arranged in one of the bays of the Central Hall of the Natural History Museum, South Kensington. The animals and minerals, respectively, have been selected, arranged, and labelled by Mr. R. Lydekker, F.R.S., and Dr. G. F. Herbert Smith, under the general supervision of the keepers of zoology and mineralogy; the plants have been dealt with by Dr. A. B. Rendle, F.R.S., the keeper of botany. The interesting guide-book to the collection is in great part a reprint of the exhibited labels, which were mainly based on the careful work of the late Canon Tristram. The minerals, which Tristram did not consider, are dealt with in a scholarly essay by the director, Dr. L. Fletcher, F.R.S., who explains how modern interpretations of the ancient names of Biblical minerals have been deduced.

The collection, and the guide to it, will be of special interest to those to whom Bible plants and animals are rich in picturesque associations; but it is, of course, part of a liberal education to know that the "unicorn" was probably the extinct wild ox or aurochs, "behemoth" the hippopotamus, the "coney" the hyrax, and the "leviathan" of Job the crocodile. Some of the corrections are curious; thus the "ferret" of Lev. xi. 30 was probably a gecko, and the "mole" of the same verse a chamæleon, and the "chamæleon" of the same verse a monitor, and the "spider in king's palaces" a gecko. An up-to-date suggestion is noticed, though not accepted—that the "badger" of Exod. xxvi. 14 was the okapi. We do not see any reference to the "fiery serpent," though the museum used to have a specimen of *Filaria medinensis*, the guinea-worm, with a label indicating that *it* was probably that reptile.

What must strike the reader most, especially perhaps when he comes to the botanical part, is the large proportion of misses that the translators made. And if we might venture on a criticism of a carefully executed piece of work, we would suggest that a little more might have been said in explanation of this. A paragraph or two on the backward state of natural history when the authorised translation was made three centuries ago would have been interesting. We also wonder why our leading scientific institution has not used this opportunity, which is undoubtedly one of wide popular interest, to tell us—who could do it better?—what is scientifically interesting in the fauna and flora of Palestine.

LIEBIG AND HIS INFLUENCE ON THE PROGRESS OF MODERN CHEMISTRY.[1]

A HUNDRED years ago Europe was still plunged in the misery of war. Almost every country had suffered the bitter experience of seeing the devastation caused by the passage of contending armies, the death and suffering of thousands of fighting men, and the want and desolation spread over still greater numbers of a helpless population. Amid all the wretchedness of the time, insecurity of property, dearness of food, frequent changes of governments, and every condition which would appear to be unfavourable, the study of nature steadily went on. France, still staggering from the fierce shocks of the revolutionary period, had still many distinguished men of science, Laplace, Berthollet, Lamarck, Cuvier, while the memory of Lavoisier was fresh and green, and Gay-Lussac, Dulong, Arago, and Chevreul were among the coming men. England, still engaged in the struggle with Napoleon, possessed Humphry Davy, Rumford, and Dalton, and Herschel among the astronomers. Henry Cavendish was still living, though an old man, and Priestley was but lately dead. In Germany, Goethe might be counted among the votaries of science, and Prussia had sent forth Humboldt to survey the world, while in Italy, Volta was busy in the study of electricity, and Avogadro, little noticed by the world, was meditating on the properties of gases and preparing for the enunciation of the great principle which is now associated with his name, though it took the chemical world half a century to recognise it. One other name must not be forgotten, and that is Berzelius, the Swede, then young, and preparing, by his eager activity in research, for that great position of almost undisputed authority in the chemical world, which he filled for nearly forty years.

To understand the influence which any one man appears to have had in his day and generation, it is necessary to bear in mind the condition of the world into which he was born, as well as the quality of his genius. The one reacts on the other. In endeavouring, therefore, to estimate the nature and extent of the services rendered to science, and to the world in general by Liebig, it is necessary to get a clear view of the state of knowledge in chemistry at the time when he appeared on the scene.

Born in Darmstadt, on May 12, 1803, where his father was a colour manufacturer, he passed through an unsuccessful school career at the local gymnasium, and, at the age of sixteen, was apprenticed to an apothecary. It soon became evident, however, that he was as little fitted to become a pill-maker as he was to be a Greek scholar, and he ultimately persuaded his father to allow him to go to the then newly-founded University of Bonn, whence he followed Kastner, the professor of chemistry, to Erlangen. But Liebig soon became convinced that he could not study chemistry effectively in Germany, and after taking his degree at Erlangen, at the age of nineteen, he proceeded to Paris. There, after many difficulties, he ultimately obtained the privilege of working in Gay-Lussac's laboratory, where he remained about two years. In 1824, on the recommendation of Humboldt, he was appointed extraordinary professor of chemistry at Giessen, being then only twenty-one years of age. He became ordinary professor two years later, and remained at Giessen until called to Munich, in 1852. There he died on April 18, 1873.

Such was the main course of Liebig's career; but to draw a picture of the man from descriptions of his personal characteristics is not easy. In early youth he became familiar with the poet Platen, who noted in his diary "the friendly earnestness in his regular features, great brown eyes, with dark shady eyebrows, which attracted one instantly."

Those brown eyes, shining with earnestness, remain in the portraits which have come down to us, and as a

[1] Lecture delivered at Oxford on August 23, at the Fifteenth Summer Meeting, by Sir William A. Tilden, F.R.S.

family feature, reappear in the faces of some of his children. Ardent, eager, enthusiastic in the pursuit of experiment, his remarkable power of exact observation stood him in good stead. Kindly and tender with children, there were times when eagerness in research or controversy led to exhibitions of impatience, but the steadfast character of the man is illustrated by the persistence of his lifelong intimacy with Friedrich Wöhler. This intimacy resulted in a correspondence which extended over more than forty years, and had consequences in the lives of both men, which were full of importance for the progress of chemical science. To this reference must be made further on.

We may now endeavour to sketch, in outline, the state of knowledge and theory when Liebig entered on his career.

The modern use of the term element, which had been introduced by Robert Boyle in the seventeenth century, was by this time universally adopted, and to the metals on the list had been added such important substances as oxygen, hydrogen, nitrogen, and chlorine. To use the words of Davy, in one of his researches on chlorine, "Neither oxygen, chlorine nor fluorine are asserted to be elements; it is only asserted that they have not been decomposed." And that is the sense in which the term has, in modern times, always been used. The process of burning or combustion was, of course, now always explained by Lavoisier's doctrine, according to which a body in burning combines with the oxygen of the air, and forms one or more chemical compounds with it. At the time that Liebig went to Giessen, in 1824, Sir Humphry Davy was still living, but his scientific career was practically closed, and Berzelius was the predominant authority in matters of theory. Gay-Lussac, in Paris, had made important discoveries relating to the proportions in which gases enter into combination. Dalton's atomic theory, propounded in 1808, though not generally accepted, was gaining ground. Broadly, the position was this: elements were clearly distinguished from compounds, chemical combination was explained by the supposition that it was due to the close approximation of atoms of opposite kinds, and the union of atoms to form a chemical compound was attributed to the attraction caused by charges of electricity of opposite nature, which were supposed to be resident on the atoms.

But the composition and nature of "organic" compounds were practically unknown. A few such substances had been isolated, *e.g.* milk sugar and grape sugar were known as distinct substances, and were differentiated from common sugar. Alcohol, nearly pure, had been known, in the form of spirit of wine, from early times. Acetic acid was known, as well as several acids found in vegetable tissues, such as oxalic, formic, malic, tartaric, and benzoic acids. There were, however, no means of determining their composition, and although Lavoisier had devised an apparatus in which organic compounds could be burned in oxygen, and the water and carbon dioxide thus formed could be collected, the process was both cumbrous and incapable of yielding exact results.

A most interesting autobiographical sketch was discovered among Liebig's papers many years after his death, and from this we learn that in his early life "at most of the universities there was no special chair for chemistry. It was generally handed over to the professor of medicine, who taught as much as he knew of it, and that was little enough, along with toxicology, materia medica, &c." But the total neglect of experiment was the source of much mischief, and the persistence of the degenerate deductive method led to neglect of the careful observation of nature. The lectures of Prof. Kastner Liebig describes as without order, illogical, and they resembled the jumble of knowledge which he carried about in his own head. When he got to Paris all was different, and the lectures of Gay-Lussac, Thénard, and Dulong had for the young student an indescribable charm. The lecture consisted of a judicious series of demonstrations—experiments of which the connection with each other was pointed out and explained; and soon the consciousness dawned on him that all chemical phenomena, whether exhibited by the animal, vegetable, or mineral kingdoms, are connected together by fixed laws.

Liebig therefore returned from Paris to his own country with the intention of founding an institution in which students could be instructed in the art and practice of chemistry, the use of apparatus, and the methods of chemical analysis. In view of the total absence of such provision elsewhere, it is not surprising to learn that, so soon as its existence became known, students streamed into the Giessen laboratory from every civilised country. It is interesting to learn from Liebig's own words what was the method he adopted. Obviously, in order to teach a large number at one time, it is necessary to have a systematic plan, and in his case this had first to be thought out and then put to the proof, as no course existed which could be used as a model. He says, however, that "actual teaching in the laboratory, of which practised assistants took charge, was only for the beginners; the progress of my special students depended on themselves. I gave the task and supervised its carrying out. There was no actual instruction. Every morning I received from each individual a report on what he had done the previous day, as well as his views about what he was engaged on. I approved or criticised. Everyone was obliged to follow his own course. In the association and constant intercourse with each other, and by each participating in the work of all, everyone learned from the others. Twice a week in winter I gave a sort of review of the more important questions of the day. We worked from break of day till nightfall. Dissipation and amusements were not to be had at Giessen. The only complaint which was continually repeated was that of the attendant, who could not get the workers out of the laboratory in the evening when he wanted to clean it."

Such was the spirit and such the method by which a great school was created! Nor was this the only result. To the influence and example of the school at Giessen may be attributed the rapid spread of the new method of teaching chemistry. In 1824 there were no laboratories devoted to the purposes of instruction. A few of the most eminent professors of chemistry—Berzelius in Stockholm, Gay-Lussac in Paris, for example—admitted one or two students already advanced in the subject to practise in their private laboratories, but only as a great favour. In this way Mitscherlich, Rose, Wöhler, and Magnus had repaired to Berzelius in Stockholm as Liebig had gone to Paris. But in a few years the fame of what Liebig was doing in Giessen penetrated to other countries of Europe, and many of the men who had studied under his direction became teachers in other lands. Here in England no chemical laboratory for general instruction existed, and only in the medical schools were a few tests described and shown. In London the Society of Apothecaries had a laboratory which had existed since 1671; but this was not used for teaching, but as a place of manufacture of drugs for use in medicine. At Cambridge the professor of chemistry was a country clergyman, who came up once a year to give a course of lectures. At Oxford the professor of chemistry was also, later, professor of botany, and in neither university was there a laboratory for instruction, nor was chemistry a subject recognised in the curriculum for a degree. Twenty years later things began to improve. In this country the first laboratory for instruction in practical chemistry was provided by the then newly instituted Pharmaceutical Society of Great Britain at their premises in Bloomsbury Square. This was in 1844, and in the following year a new and enlarged laboratory was fitted with places for twenty-one students.[1] About this time the College of Chemistry was established in temporary quarters in George Street, Hanover Square, and soon afterwards the Birkbeck Laboratory, modelled on that of the Pharmaceutical Society, was built at University College. Many other laboratories were opened about this time. In 1848 Pélouze founded in Paris a laboratory to which some English chemists resorted. But the Giessen laboratory under Liebig's direction continued to supply the majority of the teachers who in the succeeding generation founded schools, not only in Germany, but in other countries—Hofmann, for example, at the Royal College of Chemistry, and Williamson, who was appointed at University College in 1849.

Liebig's career as a chemist and investigator was influenced in no small degree by his friendship with Wöhler. Born three years before Liebig, Friedrich Wöhler

[1] I saw this laboratory about 1857. It had the aspect which one usually associates with ideas of the alchemists. Many of the operations were connected with the use of furnaces, such as fusion, sublimation, &c., and the place was full of smoke and fumes.

studied medicine at Marburg, but subsequently pursued chemistry at Heidelberg under Leopold Gmelin. Having relinquished medicine on taking his degree, he obtained the privilege of working with Berzelius in his laboratory at Stockholm. On his return from Sweden in 1824 he was appointed teacher of chemistry in the Trade School in Berlin. Some years later he became professor in the University of Göttingen. Soon after his return from Sweden he met Liebig in Frankfort, and a close intimacy at once sprang up, which continued for more than forty years to the end of Liebig's life. Two volumes of their correspondence have been compiled by Hofmann, and the perusal of these letters, extending from 1829 to 1873, affords a view of the subjects which occupied the minds of both, as well as many of the incidents of their lives. One only we have time to notice here. Liebig paid several visits to England, and in a letter to Wöhler dated from Giessen, November 23, 1837, he tells him that he has travelled through England, Ireland, and Scotland in every direction, and has seen many surprising things, but has learned little. The absence of scientific knowledge in England he attributes to the badness of the teaching. In another letter, addressed to Berzelius nearly at the same time (November 26), he says:—"England ist nicht das Land der Wissenschaft," only there is a widespread "dilettantismus," and he complains that "die Chemiker schämen sich Chemiker zu heissen, weil die Apotheker, welche verachtet sind, diesen Namen an sich gezogen haben."

Liebig's contributions to pure chemistry, though so numerous and important, can be recalled only briefly. They may be placed under three heads, namely, first, the invention and perfecting of a method for analysing organic compounds, which in all essential features is still practised everywhere.

Secondly, the discovery of a large number of new compounds, of which even the names cannot now be mentioned for want of time, but which include chloroform and chloral and many cyanides. He also established the formula of uric acid and the nature of aldehyde.

Thirdly, we owe to Liebig the conception of the theory of compound radicals, which arose out of his researches jointly with Wöhler (1832) into the products from essential oil of bitter almonds.

In a letter to Wöhler (May 26, 1839), Liebig writes that he is occupied with the study of the phenomena of fermentation and putrefaction, and having sent an account of his views to Wöhler, another letter, dated June 3, discusses the criticism which he has received from him. In the postscript to this long and interesting letter, we find a concise statement of Liebig's hypothesis concerning the action of ferments.

Before proceeding further, it will be well to understand what is meant by fermentation. If we take a solution of sugar, and add to it a very small quantity of brewers' yeast, or, if we take grape juice without any addition, in a short time, especially in warm weather, a frothing, due to the escape of minute bubbles of gas, soon sets in, and this continues until the liquid has lost its sweet taste, and has become more or less alcoholic and intoxicating. The escaping gas is carbon dioxide, vulgarly called carbonic acid, and the liquid retains, beside alcohol as the chief product, small quantities of other things. Somewhat similar changes go on in the leavening of bread, the souring of milk, the putrefaction of meat, and apparently also in the animal body in the course of many feverish diseases. One peculiarity of the process consists in the fact that the ferment, the yeast for example, serves to bring about chemical decomposition in a relatively large, almost indefinitely large, quantity of the sugar or other substance in solution.

Liebig's explanation of these changes was based on purely mechanical ideas as to the motions of the hypothetical particles or atoms. He imagined the atoms of a substance which causes fermentation or putrefaction to be in a state of unceasing vibratory motion, and that this state of agitation was communicated to the molecules of the sugar, causing them to undergo an internal rearrangement, and to break down into simpler structures of a more stable nature, in the case of alcoholic fermentation of sugar, in fact, into alcohol and carbon dioxide.

Liebig made the mistake of ignoring, as nearly all chemists and biologists of that time ignored, the constitution of the ferment. In 1859 and following years, Pasteur, the great French chemist, demonstrated the essentially vitalistic character of the phenomenon, and showed that the destruction of the sugar was an effect concomitant with the growth and multiplication of the cells of a minute organism, visible under the microscope. A special form and character of organism is concerned in each type of fermentation.

The organised character of yeast had been proved many years before by the observations of Kützing, Cagniard Latour, and Schwann. Nevertheless, the views of Liebig prevailed for some time. In the English version of his famous letters on chemistry, in the fourth edition, which appeared in 1859, there is a chapter headed "Theory which ascribes fermentation to fungi refuted." As a matter of fact, it was about this time established.

Liebig was ultimately convinced of the organic nature of yeast, but he still contended for his theory of molecular destruction by communicated agitation, as furnishing the explanation of the physiological act which comes about within the cells of the yeast. An important step was taken much later, when, in 1897, it was shown by Buchner that something can be dissolved out of yeast which, independently of the cells, is capable of resolving sugar into alcohol and carbon dioxide. Thereupon, it seemed to some that Liebig's views might be resuscitated. But the changes which occur are now known to be very complicated, involving, in the first place, a process, not of destruction, but of building up molecules of a more complex nature, before they are broken down into the final products of fermentation. Liebig's theory, therefore, disappears from the scene.

Before 1840 it may be stated as almost literally true that physiology in the modern sense of the term did not exist, and certainly there was but a small basis for chemical physiology. The chemical production of urea independently of animal life, by Wöhler, in 1828, was a fact of which the deep significance appeared only much later. The studies in organic chemistry, into which Liebig had plunged alone, or in conjunction with his friend, necessarily attracted his attention to problems connected with the phenomena of animal and vegetable life. His visit to England, in 1837, was largely occupied with observation of the methods of agriculture then prevalent, and during the succeeding years we find in the catalogue of his scientific papers, many signs of his activity in pursuit of questions connected with the application of chemistry to agriculture, the growth and nutrition of plants, the formation of fat in the animal body, the composition and classification of foods, the source of animal heat, and the chemical processes connected with respiration and digestion. It is not possible for us to enter freely into the discussion of all these great subjects, but we must glance at Liebig's views in regard to two of them, not because those views have retained their predominance, but because of the stimulus they gave to inquiry and the encouragement he gave by precept and example to the fundamental principle on which the greater part of modern science is built, namely, the constant appeal to nature, not only by observation, but by systematic experiment.

In Liebig's time all biological processes were supposed to be controlled by what was called "vital force," that is, something which is not mechanical force, nor heat, light, electricity, nor chemical affinity. We are still a long way from knowing what life is, but to show how far some physiologists have travelled in the opposite direction, I will make a very short quotation from a recent book. Concerning the use of the word "metabolism," which is a comprehensive word covering all chemical changes which go on in the body during life, the writer directs attention to its implication "that all the phenomena of life are, at bottom, chemical reactions. When a muscle twitches no less than when a gland secretes, it is not too much to say that when we are moved to tears or laughter, it is chemical reactions that are the underlying causes to which ultimate analysis must lead us." I quote this as an extreme view.

Let us turn first to Liebig's classification of foodstuffs. It is necessary to account for the maintenance of the animal functions, the growth and repair of the body, the maintenance of its temperature.

Liebig attributed, as we believe correctly, the heat produced in the body to the process of burning, which goes on in the tissues in consequence of the absorption of atmospheric oxygen. Liebig was also right in his assertion that animals do not necessarily derive fat from their food, but the animal body is a laboratory, in which fat may be manufactured from carbohydrates, such as sugar and starch. The substance burned in the body is material derived from the food, but it has long been known that the substance thus burned does not consist exclusively of sugar, starch, and fat, which Liebig called *respiratory* foods.

The other constituents of food, now included under the general term protein, which contain nitrogen, and are more or less like white of egg in properties, he called *plastic* foods. These were supposed to produce new tissue, or repair waste, and to be the source of muscular energy or power to do work.

It is now known that the case is by no means so simple, and, in fact, this classification now possesses only historical interest. The whole question when considered in the light of modern knowledge is, in fact, a mass of difficulties, and very far from being clear of serious controversy. Liebig's name is associated in the public mind almost exclusively with the extract of meat, which he prepared for the first time in connection with his studies of food. This is to do him less than justice. Liebig never proposed it for use as a substitute for meat, because it contains only a part of the constituents of flesh. It appears that his idea, in the first instance, was to turn to account the flesh, which would otherwise be wasted, of animals which in Australia and South America were then bred solely for the sake of their wool and fat. Extract of meat is to be regarded as a valuable stimulant to be consumed together with bread or other vegetable food.

Let us now turn to the investigations into the operations and theories of agriculture with which Liebig's name should be for ever associated. Whence do plants get their carbon and nitrogen, which, together with hydrogen and oxygen and water, form the material of their tissues? What is the use of the mineral substances found in the ash left on burning vegetable matter? Why are different soils adapted to different crops, and what is it that gives fertility to a soil?

The state of knowledge on such subjects is indicated roughly by the summary which had been provided by the lectures of Sir Humphry Davy in 1813. During the subsequent twenty-five years very little had been done in the way of experiment, but it would be only fair to mention the name of the great French agricultural chemist Boussingault as one of the pioneers a little in advance of Liebig in the study of such questions. Briefly, the position was somewhat as follows: it was known that plants decompose the carbonic acid of the air, using the carbon and letting the oxygen go free, but it was commonly supposed that the brown or black substance in the soil, which is usually called *humus*, and is the result of the decay of preceding vegetable growth, was the chief source of the carbon in growing vegetables. Liebig pointed out that this was impossible, because it failed to show from what source the original plants from the decay of which humus was formed derived their carbon. Liebig was the first to study carefully the mineral constituents of plants and to recognise the importance of certain substances, especially potash and phosphates. The services which Liebig rendered to the world in connection with plant physiology and agriculture are, however, less to be recognised in the shape of positive contributions to knowledge than in the example set and in the influence of that example in stimulating systematic investigation of agricultural questions. By 1840 Liebig was one of the most famous chemists in the world, and the effect of his inquiries is shown in the activity which became manifest almost immediately after the communication of his first report to the British Association at the Glasgow meeting in 1840. In Germany the Government instituted a large number of Versuchs Stationen in different parts of the country, and in 1843 the systematic experiments were started at Rothamsted which must for ever place the names of Lawes and Gilbert among the benefactors of the world.

But here I must pause to remind myself and my hearers that the subject of my lecture is Liebig and his influence on the progress of modern chemistry. He died in 1873; but the period of his greatest activity in science lies further back by thirty years. Since either period vast changes have been brought about by chemical discovery, which, be it always remembered, is based on experimental work in the laboratory. That is the reflection which supplies the explanation of Liebig's great influence on the progress of science. That influence was fully recognised by the generation of chemists now passing away, or almost gone, and it seems to be a duty to preserve as long as possible a memory so rich in past benefits and so full of suggestion for future use.

Liebig made many discoveries in chemistry; but his great and permanent service to the world was not in the isolation and study of individual compounds or series of compounds, nor in the conception of theories of chemical action, nor even in views which he promulgated concerning the operations of agriculture, the composition of food, the processes of digestion, or the source of animal heat. His great service consisted in showing how chemistry should be studied and how it should be taught, in setting the example of submitting all questions to the light obtained by direct experimental study of nature, and in thus affirming and illustrating the principle that what is called pure science is of greater permanent value than what is called applied science; a knowledge of the laws of nature is more useful than many inventions.

In the Giessen laboratory were trained a considerable number of chemists, many of whom became the teachers of the next generation. From these teachers and their pupils, guided by the same principles as those of the Giessen school, came discoveries of first-rate importance. If Hofmann, a student of Liebig's, had not been attracted to the study of aniline, an inconsiderable constituent of coal tar, if his pupil, Perkin, had not been led to a further study of its transformations, we should have had to wait a long time for the coal-tar dyes and the industries connected therewith. If a host of workers trained in Liebig's laboratory, and others emulating their example, had not cultivated the study of all sorts of carbon compounds, often unimportant in themselves, we should not have seen the numerous applications of chemistry to medicine—the saccharin, aspirin, antipyrin, sulphonal, &c.—nor the artificial perfumes, such as those of violet and lilac, which are now made independently of the original source in the flowers. Without the foundation work I have mentioned we could not now have the beginnings of the true physiology based on the study of chemical and physical processes and reactions, nor the possibility of following the changes brought about by all sorts of ferments, on the combined results of which we may hope to have a complete development of a scientific system of medicine and the treatment of disease.

But there is one other direction of Liebig's activity to which I have not alluded. Discoveries in the study of nature are of little value unless they can be communicated to that part of the world which can and will make use of them. Up to the end of the eighteenth century there were no means of publication except, on one hand, through the transactions of the half-dozen academies, and these were the only scientific periodicals, or, on the other, by the special treatises prepared by investigators for the purpose of making known their own discoveries or opinions. Thus we have the famous works of Robert Boyle on the Spring of the Air, and the Sceptical Chemist, Scheele's works on Air and Fire, Priestley's Experiments and Observations on different kinds of Air, Dalton's New Chemical Philosophy, and many others. The publication of such books was often accomplished only after years of preparation. In 1832 Liebig founded the *Annalen* which have ever since borne his name. Out of Trommsdorff's old *Annalen der Pharmacie* Liebig created a journal which has been for eighty years one of the chief repositories of the best products of the laboratories of the German Empire. Into this journal were poured the results of Liebig's and Wöhler's several or joint researches. At the time of Liebig's death, in 1873, 165 volumes of the *Annalen* had appeared, and there has been an equal number since that date.

I need do no more than mention the titles of the "Handwörterbuch" which Liebig, with the cooperation of his friends Poggendorff and Wöhler, produced between 1836 and 1856, the "Handbuch der Chemie" in 1843, and the famous "Letters on Chemistry," which were originally published as newspaper articles in the *Augsburger Allgemeine Zeitung* with the object of bringing within the ken of the general public some of the more important consequences of the advance of knowledge in connection with the affairs of everyday life.

Again, up to 1847, Berzelius had for many years prepared annually a "Jahresbericht über die Fortschritte der physischen Wissenschaften," but near the end of his life this laborious undertaking was no longer possible for him, and Liebig, in association with Hermann Kopp, the physical chemist, commenced the "Jahresbericht," which, so far as chemistry and the allied sciences is concerned, continues to this day. It is no longer so important as formerly, having fallen behind in date, but for certainly forty years it was indispensable to every practising chemist who was directly or indirectly interested in the progress of the science.

Since the days of seventy or eighty years ago, when Liebig set these enterprises in motion, the number of periodical publications devoted to recording advances in chemistry has greatly increased, and a number of journals now appear at regular intervals of a month, a fortnight, or even a week, which have become necessary in consequence of the specialisation which is characteristic of our time. We have therefore journals of inorganic chemistry, physical chemistry, applied chemistry, and some limited even to one topic, such as electrolysis or radium. Liebig's ***Annalen***, however, continues to hold an honoured place in every chemical library.

Since Liebig's day we have advanced in many directions very far. Not only has the atomic theory given us by Dalton long since become the mainstay of the chemist, but we confidently assume, on good evidence, that we know the order in which these small bodies stand in a molecule of sugar, for example, and the relation of this order to the visible forms of the crystals in which such substances are often presented. We know, too, the relative masses of these minute bodies—the atomic weights, so called—and it is certain that these weights are directly connected with the properties of the bodies the atoms compose. There is also a relation among the atomic weights, which is broadly summed up in what is known as the periodic law, from the study of which most chemists are convinced that the so-called elements were evolved out of something of a simpler order, possibly one or two primal matters to which the term element would more properly belong. Nor is this all. Everyone has heard of radium, but few of the public, I suppose, know its history. Henri Becquerel, so late as 1897, observed that compounds of the metal uranium emit something which passes through many bodies opaque to ordinary light, and which renders the air around it conductive of electricity. Following up this observation, Madame Curie discovered radium. Radium is a metal in many respects like others previously known, but differing from them in the extraordinary power of throwing off electrically charged particles with enormous velocity, together with a remarkable gaseous emanation. According to the generally received view, which we owe to Prof. Rutherford, we are face to face with a process which is the reverse of that by which we may suppose the ordinary elements, or some of them, to have been formed. The decay of matter is thus indicated, and, though the process affects only minute quantities of stuff in the earth, it is sufficient to provide food for reflection to the geologist who wants to account for the rate of cooling of the earth and to the cosmogonist who can imagine the operation proceeding elsewhere on a far larger scale. There is temptation enough here to the speculative mind. Everything is now supposed to be expressible in terms of electricity, concerning the nature of which no one knows anything. Chemical action is attributed to exchanges of electric units, and matter of all kinds is supposed to be made up of the same. In the midst of all this confusion the clear duty of the chemist, at any rate, is to follow the practice inculcated by Liebig and stick to experiment, observation, and careful inductive reasoning.

One word in conclusion. The creation of a school of thought, such as that of which the chemical school at Giessen was the centre, requires originality as well as learning in the teacher, intelligence in the taught, and a sympathetic relation between professors and students. These are more important than buildings and appliances. But much influence is exercised by the environment; that is, by the attitude of the public. Appreciation of learning and interest in the results of research have long been provided more freely in Germany than in England. Though we cannot now admit, without qualification, the reproach of Liebig, already quoted, it is still true to some extent that what the public in England wants is invention rather than discovery; the applications of knowledge before the knowledge itself.

Some people will doubt, perhaps, whether we are so much behind Germany, "learned, indefatigable, deep-thinking Germany," as Carlyle called her. We have an immense amount of popularisation of the results of science, but it is to be feared that much of this is too easy, shallow, and misleading.

I think the difference between the two peoples is to be partly acounted for by the attitude of the Governments in the two countries. In England it is the custom to leave the investigation of many important subjects, like agriculture, to the chance of private benefaction or voluntary effort. In England, again, it is only in comparatively recent times that assistance out of public funds has been given to the universities. This attitude of the Government has an immense influence in directing popular views of institutions, of things, of men. That which the masses find placed in positions of advantage by the powers set over them are naturally held in higher esteem than those which are always kept in the background or in a position of evident inferiority. In Germany the university chairs are occupied by the greatest specialists in every department, and these are men who are honoured at Court, consulted by Ministers, and trusted by manufacturers. But, after all, when we have exhausted the enumeration of all the adventitious influences at work in both countries, it seems as though there were some elements in the mental constitution of the different peoples which leads them to handle the same subject of inquiry in different ways. It has been so in the study of chemistry.

At the beginning of the nineteenth century, with the aid of the principles bequeathed by Lavoisier, the facts which had been established by Priestley and Cavendish, the discoveries of Humphry Davy, and the atomic theory of Dalton, France and England were engaged in laying the foundations of the new science. At that time Germany had no chemists. Liebig himself bears witness, in his autobiography, that in his youth "it was a very wretched time for chemistry in Germany." During the latter half of the century there arose in nearly every German university a famous school of chemistry, and in practically all cases it has been a school for the cultivation of so-called "organic chemistry," in which department German chemists have achieved the most brilliant successes. Nothing can be more important than Kekulé's theory of the aromatic compounds. Nothing can be finer than the synthetical work of von Baeyer and Emil Fischer in connection with indigo, the sugars, and the proteins, or albuminoid substances, the chief basis of the animal tissues. But it cannot be maintained that they have been equally distinguished for the discovery of broad general principles. German triumphs have been more frequently the result of that patient attention to detail which seems characteristic of the German mind.

Take, by way of illustration, the problems which at the present time loom largest before the chemical world. There are first the relations among the atomic weights, discovered by Newlands, an Englishman, and worked out by Mendeléeff, a Russian; next, the arrangement of atoms in space, or stereo-chemistry, to which the clue was furnished by Le Bel, a Frenchman, and van 't Hoff, a Dutchman; next, the process of electrolysis and the constitution of salts in solution, of which by far the most important theory, the theory of free ions, was supplied by Arrhenius, a Swede. Again, there is radio-activity with all its consequences, the isolation of radium by Madame Curie, and the greater part of its wonderful history, worked out by Rutherford and Ramsay, both British chemists. To those great fields of inquiry Germany has, doubtless, made contributions, but she did not discover them.

My own impressions are strengthened by a passage which I will venture to quote from a modern work, "The History of European Thought in the Nineteenth Century," by Dr. Theodore Merz, himself a German, though domiciled in England. He says (vol. i., p. 300): "The largest number of works, perfect in form and substance, classical for all time, belongs probably to France; the greatest bulk of scientific work probably to Germany; but of the new ideas which during this century have fructified science, the larger share belongs probably to England."

After all, German chemistry can always point with just pride to the great teacher of us all, Justus von Liebig.

EXCAVATIONS AT MEROË IN ETHIOPIA.[1]

THE ruins of the Meroë were noticed so long ago as 1772 by the famous traveller James Bruce; but his identification was not generally accepted, and it was not until three years ago that Prof. Sayce, in the course of an official inspection on behalf of the Sudan Government, recognised that unquestionably they were the remains of Meroë, and invited Prof. Garstang, then at work in Egypt, to undertake the excavation.

The Government of the Sudan encouraged the work by facilities and assistance, including the construction of a railway siding, the provision of water tanks, and materials. In this way the wants of 500 or 600 workmen were provided for. The camp became a stopping place for certain trains, which brought provisions, and it marks the site of a new station which will shortly be available to visitors. Practically nothing of the ancient city was visible above the soil when the party arrived upon the scene—no ruined buildings or connected walls, only mounds of débris and a few carved stones here and there—for the well-known pyramids of Meroë that mark the spot lie back several miles in the solitude of the desert.

The gates of the city opened, as it were, one by one before the ordered and methodical attack of the excavator's trained Arab workmen. Great temples, royal palaces, and public buildings emerged gradually from the sands; the city walls and gates and quays stood once more in their places; colossal statues, altars, and public monuments disclosed their whereabouts; the tombs yielded up their secrets; and numbers of small, artistic remains were trapped in the busy sieves.

[1] From the Guide to the tenth annual exhibition of antiquities discovered at Meroë, and the second interim report upon the excavations, by Prof. J. Garstang.

In addition to the visible results, archæology has received some new and important contributions, for, until this work was undertaken, nothing was known of the subject of the Ethiopian civilisation from the specialist's point of view, and this fact naturally doubled the difficulties of an excavation of this kind. For this reason, primarily, the first experiments (season 1909–10) were made in the tombs and isolated knolls, as being the most accessible sources of information as to the character of ordinary Meroitic objects.

The tombs, being of unknown type and securely cemented down, for some time baffled the workmen, but at last there came to light some thousands of vases—found, in some instances, as many as thirty or forty in a single tomb chamber. They were all of a style new and peculiar, without any noticeable trace of Egyptian influence. In the tombs furthest to the north vases of a special and rare kind were recovered made of thin pottery, decorated with paintings in colours (the subjects being animals, trees, or natural features), or with designs stamped upon the clay. Similar vases in more perfect state were found in 1911 among some ruined buildings in the west of the city area.

FIG. 1.—View in the Temple of Amon. Place of sacrifice in the foreground, the high altar beyond.

In addition to pottery vessels there were in the tombs a variety of objects not merely funerary in character.

In obedience to primitive instinct, the dead was laid to sleep on his bed in his subterranean chamber surrounded by the things which would be to him the most useful upon his awakening. The soldier had his weapons (sword, lance, dagger, &c., all of iron); the huntsman his bow and arrows—even his hounds were sometimes sacrificed with him. The women had equally their beads and their jewels. In a few cases the frame of a decayed wooden bed might be traced; and in every tomb the vases and dishes seemed to have contained drinks and food. It is probable that originally one of the doors was left so that it might be opened for the regular renewal of the offerings.

While this experiment was in progress, the position of the great temple of Amon was determined, and the task of uncovering it was begun. The entrance proved to be a pylon in the Egyptian style, and the central aisle leads through a series of columned halls to the sanctuaries, at a distance of 130 yards, beyond which the temple abuts on the great wall of the city. Towards this end, in the main axis, there still stood the high altar, carved in a single block of stone, decorated in relief with the figures of gods and of the king in his character of chief priest. At the foot of the altar were found the last votive offerings where they had been laid just previous to the destruction of the city.

Two small temples in the neighbourhood gave further information. One was dedicated to the Egyptian goddess Isis. In this ruin two buildings were superposed, and in the foundations of the later one (which was built, for the most part, out of the ruins of the earlier) were found two great statues of columnar form representing the king and queen of Ethiopia. The upper building did duty at a later time as a Christian church.

FIG. 2.—Deep excavation to the north of the royal enclosure.

The second temple seemed to have been dedicated to the lion god, a primitive cult of which there are a number of indications. It was situated on the east side of the town towards the desert, a fact which recalls to mind that travellers of last century speak of the great number and the ferocity of the lions in this district. Inside were found two sculptured lions in stone, one on each side of the door, and several other emblems of the same animal. Included among these was a slate plaque, carved on both sides, on the one with the design of the king in his gorgeous state robes, on the other the lion god in human form standing upright upon a man's legs. Each sculpture was also inscribed in the language and writing of Meroë; and in the inscription, thanks to the assiduous study of philologists, there can now be recognised the names of gods and personages.

The temple of the sun was discovered and uncovered at the same time. The building is surrounded by a square enclosure wall with four doorways, but the chief entrance is from the east; in this direction also there are two shrines, also constructed in stone. The outside wall of the temple is decorated with scenes of war, of triumph, and of sacrifice. A sloping way leads up from the east to the chief platform, which is entirely surrounded by a cloister. The architecture, both in the proportion of its columns and interspaces, as well as in the elegance of form and the exactness of construction, recalls the best Greek works of antiquity, and not at all the styles common upon the Nile. The sanctuary is in the middle and raised above, being approached by a number of steps in black stone. Its floors and its walls were originally covered with glazed tiles, blue and yellow, of which a number are still in position. Round the sanctuary was a kind of corridor or perambulation, exposing to view on the outside the processions and the ceremonies of the priests.

Such were the results of the first year's explorations of Meroë. There was no doubt that it was necessary to continue the excavations, and funds were provided by which the work was able to go forward during the past winter. Some of the results of this season's work are described below.

The temple of Amon was completely excavated; previously the chambers around the sanctuary alone had been cleared, but in this season's work chambers 272, 278, and 277 were found to form a part of the main building. The first two were unimportant, except that in No. 272 there was found just at the foundation-level a remarkable cameo of Greek workmanship representing a pair of galloping horses, one black and the other white; its date may be approximately fixed at 300 B.C. In the same chamber there was found a small tablet of stone decorated with low reliefs representing the king and the queen making offerings respectively to Ram-headed Amon and the goddess Isis. Below were several lines of inscriptions in Meroitic cursive character. It is unfortunate that this object (now in the museum at Khartoum) was much broken, as it is a characteristic specimen of Ethiopian art. In the chamber 277 there were evidences of a colonnade, and at its western extremity a small shrine enclosed within a screen of columns. In the main avenue, in the centre, that is to say, of chamber 270, there was found in the paved floor of the building a place specially prepared for the sacrifice of larger animals; it was about 3 metres square, surrounded by a trench and enclosing a central space about 1 metre square, in which had stood a dish of stone lined with glazed tiles. In the outer hall (No. 271) the base of an obelisk of black granite was found *in situ* just to the left hand of the entrance to chamber 270. This obelisk must have been originally about 3 or 4 metres in height above its plinth; the upper part of it, however, was broken entirely away, so that only about

FIG. 3.—Roman Bronze portrait head, probably Augustus.

half a metre of the inscribed faces remain. The inscription is in lines of Meroitic cursive script clearly engraved, and, supplemented by the numerous fragments found scattered around, constitutes one of the longest Ethiopian texts hitherto discovered. To the south of the central sanctuary 279 there was found against the main wall of the hall a stone dais approached by several steps and carved in a single piece. It is decorated around the outside with a design of bound prisoners, while upon the steps themselves are similar representations of humble captives upon which anyone mounting the dais must place his feet.

The general plan of the temple of the sun, as previously published, was confirmed. A number of subsidiary chambers were found, however, against the southern wall, and these are represented in the new plan. On this side from the west there may be seen also an ascending ramp, leading up, doubtless, to a door in the southern wall of the building. On the same side to the east there came to light a small chamber enclosed between the main wall and the colonnade. In the floor of this were numerous vases of earthenware filled with incinerated bones and charcoal, a proportion of the bones being apparently human. Just above, upon the outer face of the main wall, there are scenes representing the slaughter of young men and boys, while among the sculptures which decorate the walls (some of them now falling away from their original places) there may be recognised scenes of torture. Of special interest is a group of decorative carvings upon the west wall of the main building, supplemented by fragments, which give a contemporary picture of the whole temple as it originally stood. The wall of the inmost sanctuary may be seen rising above the colonnade which represents the cloister upon the main platform; both the inner and outer pylon are also quite distinct. Another part of the scene represents a four-columned building, apparently that of which the ruins are traceable just to the east of the enclosure wall of this temple. The sloping way leads up to this building, and a number of figures included in the decorative scheme are arranged in two groups similar to one another in which a bound captive may be seen dragged up the slope by a cord attached to his leg, while a soldier from behind encourages him to mount with the point of his spear. The representations of the king seated upon his throne and of warriors mounted on galloping horses complete these interesting scenes.

FIG. 4 —Royal jewels discovered with a board of gold.

Several other smaller buildings have been included in the season's explorations—temples, houses, baths, chambers for workers in metal, the furnaces for pottery and bricks, and all the evidences of the active life of a great city of the East. But of even greater immediate interest was the discovery and excavation of the royal city and its palaces. Following under the surface the great wall, bounding the Amon temple on the west, which all the time was the centre of these investigations, it was found that it continued with the same width of five or six yards for a length of more than 300 yards. At last, instead of turning towards the east, and thus including the temple of Amon, it turned at each corner to the west and enclosed a space of 150 yards wide. On the west side, without doubt, it touched the river in ancient times—a fact which corresponds with tradition—and here there were noticeable specially built terraces to resist the action of the water, as well as a place of disembarkation and a quay communicating with the interior.

Inside there were two prominent mounds. That to the north covered a great columned hall, with frescoes of the king and queen in scenes of ceremonial and triumph painted on its walls. In the middle there had been constructed, at a second period, a massive pedestal, as if for an equestrian statue or group, with its foundations half as high as the original columns. In front of the entrance, interred in a pocket of clean sand, there was found, on the third day of the excavations, the massive bronze head represented in the illustration. It is a wonderful specimen of Roman art, in perfect condition, and clearly work of the age of Augustus, about the time of the birth of Christ. The eyes are of alabaster, with the iris inlaid, and pupil of dark glass, while the eyelashes are in bronze. It is twice life-size. To judge from the profile, it is just possible that this head represents Germanicus (B.C. 15–A.D. 19), who during his military career was stationed at one period in Syria, and is known from the Annals of Tacitus to have made a voyage by the Nile to Aswan; but the resemblance to the Prima Porta head of Augustus makes it more probable that it represents the first emperor.

Lastly, towards the end of the season, work was concentrated upon the palaces covered by the southern mounds. In a rubbish well were found pieces of glaze-work, sistrums, ankh-signs, and vases on which were the names of several royal personages of Ethiopia, of date probably towards the sixth or seventh century B.C. Among them may be noted *Aspelut*, whose other name was *Mer-Ka-Ra*; also *Uaz-Ka-Ra* (*Hor-ma-ti-leq*) and *Mal-nefer-neq*. In another place a piece of a big scarab gave the name of the Queen Tiyi and Amenhetep III., names familiar in the eighteenth dynasty of Egypt, in the fifteenth century B.C. Finally, towards the end of the work there were found two jars of pottery full of gold-dust and nuggets, of 22½ carats, and sterling value about 1700*l*. One jar contained also some royal jewels, inscribed with the two royal names last noted, as well as money, rings, scarabs, crude amethyst, and beads of coloured glass. This, without doubt, formed part of the traditional treasure of the Ethiopians; the vases must have been stolen in ancient times from the treasury, which was found destroyed to the very last stone, and the thieves had hidden them in the place where the excavators' spades have now disclosed them.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

It is announced in *Science* that Mr. John G. Archbold has made a further gift of 8000*l*. to Syracuse University, and that Governor Dix has approved two Bills passed by the recent New York Legislature, one granting 28,000*l*. for the Oswego Normal School, and one granting 10,000*l*. for an Agricultural College, Cobleskill.

Dr. A. N. Whitehead, F.R.S., fellow of Trinity College, Cambridge, has been appointed to succeed Mr. E. Cunningham, as lecturer in the department of applied mathematics and mechanics in University College, London; and Dr. J. Sherwood New to succeed Dr. F. N. Kay Menzies as assistant and lecturer in the department of hygiene and public health.

FOLLOWING the example, set first by the London County Council, of arranging annual conferences of teachers of science for the discussion of methods of teaching and other important matters, the Director of Public Instruction for Ceylon, Mr. J. Harward, was instrumental in bringing about a second conference on science teaching in Colombo last March. We have received a report of the proceedings at this year's meetings, which were largely attended. The interest with which the proceedings were followed showed clearly that the conferences are a movement in the right direction. Four papers were read and discussed, as follows:—the teaching of elementary mechanics, by Mr. C. W. B. Arnold; the value of ugliness in electrical apparatus, by Mr. A. J. Bamford, of Colombo Observatory; the position of biology in education, by Dr. J. Pearson; and physiology in boys' schools, by Mr. E. Evans, of the Government Training College.

THE Department of Agriculture and Technical Instruction for Ireland has issued its "Programme of Experimental Science, Drawing, Manual Instruction, and Domestic Economy for Day Secondary Schools" for the session 1911–12. Among the more important alterations which have been introduced are: a course of physical and commercial geography has been substituted for that in geology in the special courses; students who have worked satisfactorily through the third-year syllabus of physics will be permitted to proceed to the fourth-year syllabus of mechanics, without having worked previously the third-year syllabus of the latter subject; students who are more than eighteen years of age on June 1 in the year in which the course is entered upon will be ineligible for grants; and grants will be payable, under certain conditions, upon the attendance of students at instruction in a fourth-year syllabus during a second year. We notice that summer courses for instruction for teachers will be continued as heretofore, but the hope is expressed that the courses will shortly have satisfied the need of qualifying teachers, and will develop into "post-graduate" courses on special subjects for those already qualified.

REFERENCE was made in the issue of NATURE for July 20 (vol. lxxxvii., p. 101) to a scheme arranged by the Royal Commissioners for the Exhibition of 1851 for the award of industrial bursaries to young men who, after a course of training in a university or approved technical college, desire to enter engineering, chemical, or other manufacturing works. The scheme is another indication of the desire of educationists to establish a link between education and industry; it is based on the assumption that college-trained men are not able, as a rule, to obtain remunerative employment in industries immediately after the completion of their college course. Its main characteristic is to lead the students to the manufacturers. In the issue of *The Times* for August 14, the writer of an article on "Commerce and the Universities," after directing attention to this scheme, gives an interesting account of the industrial fellowships inaugurated in the University of Kansas. They were initiated by Prof. Duncan in 1907. The fellowships are tenable in the chemical department by students appointed by the University, and the emoluments are provided by manufacturers. To illustrate the conditions under which the fellowships are held, those attaching to a fellowship (No. 7) established by a glass company may, says *The Times* contributor, be taken as typical. The object of the fellowship was investigation into the optical properties of glass in relation to its chemical constitution. The fellow contracted to devote the whole of his time to this investigation, with the exception of three hours a week, which he gave to teaching in the University, in return for which he was exempted from the payment of university fees. The tenure of the fellowship was for two years, and the emoluments, 300*l*. a year, were provided by the company. All discoveries made by the fellow during the tenure of the fellowship become the property of the company, subject to the payment of 10 per cent. of the net profits to the fellow; and any patents taken out by the fellow are assigned to the company. The fellow is allowed to publish any results the publication of which, in the opinion of the company, would not injure their interests. At the end of the tenure the fellow is required to present to the University a complete monograph on the work done, and, after the expiration of three years, the University is at liberty to publish the results for the use and benefit of the people.

THE executive committee of the General Council of Church Training Colleges has presented a memorandum to the President of the Board of Education dealing with the qualification and supply of teachers. The memorandum states there has been a marked and general falling off in the number of candidates for entrance into training colleges owing largely to the agitation of the last two years, which arose out of the over-supply of teachers and consequent difficulty in many cases of obtaining employment. A careful investigation leads the council to the conclusion that a pressing need of the time is the framing and publication by the Board of Education of a definite and comprehensive policy with reference to the qualification and supply of teachers. If such declaration be made, the following steps would follow in due course: (1) The definite announcement would be made that after a certain date no more (or, according to policy, a much smaller percentage of) untrained or uncertificated teachers would be appointed. Special arrangements would have to be made in the case of smaller country schools. (2) A thorough inquiry would be made into, and a careful estimate formed of, the consequent requirements of the schools throughout the country and of the existing provision to supply their needs. (3) The council feels strongly that as the revised staffing would involve increased expenditure, more care should be taken in the preliminary selection of candidates for the teaching profession, and suggests (i) that no young person should be appointed as bursar who has not shown some qualities and aptitude (apart from merely intellectual tests) for the teacher's profession; and (ii) that no bursar should be allowed to proceed to a student-teachership who has failed to prove such fitness. (4) To avoid any possible hardship to any person now engaged in teaching, existing qualifications should be recognised, subject to the requirements of efficiency, although the council is of opinion that it might be reasonable to require, or at any rate useful to encourage, untrained, uncertificated, and supplementary teachers to improve their qualifications within a certain period.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 7.—M. le Général Bassot in the chair.—Sir William **Ramsay**: The action of niton (the radium emanation) on thorium salts. Commenting on a recent paper by M. Herschfinkel on this subject, the author gives details of the method of purification of the thorium nitrate used in his experiments, with especial reference to the destruction of any organic matter which might have been present in the crude salt.—Kr. **Birkeland**: Are the rings of Saturn due to an electrical radiation from the planet? A description of the phenomena observed when a magnetised globe is placed in a strong electric field. Three photographic reproductions of the appearance of the globe under these conditions show the similarity of the luminous ring with that of Saturn. Observations by other workers are also cited in support of this view.—J. **Guillaume**: Observations of the Kiess comet (1911*b*) made with the Brunner equatorial of the Lyons Observatory. Data are given for July 15, 17, 20, and 21.—J. Ph. **Lagrula** and H. **Chrétien**: The Kiess comet (1911*b*). Its photographic aspect and its spectrum. One photograph showed a well-defined tail to the comet 1° in length. The spectrum contained cyanogen bands and the blue hydrocarbon band.—Marcel **Brillouin**: Crystalline elements and molecular orientation.—Daniel **Berthelot** and Henry **Gaudechon**: The photolysis of alcohols, acid anhydrides, ether oxides, and esters by the ultra-violet rays. Alcohols are characterised by evolution of hydrogen and formation of aldehydes. Ethers give carbon monoxide, hydrogen, and saturated hydrocarbons. Various esters were also submitted to ultra-violet light, and the gases produced are tabulated.—Amé **Pictet** and Alphonse **Gams**: The synthesis of berberine. Starting with homopiperonylamine, hydroberberine has been synthesised with homoveratryl-homopiperanylamine, and veratryl-norhydrohydrastinine as intermediate steps. Berberine has already been obtained from tetrahydroberberine, so that the synthesis is complete.—L. **Tchougaeff** and G. **Pigoulewsky**: Dithiocamphocarbonic acid.—S. **Losanitch**: The constitution of divalolactone.—E. **Caille**: A modification of the Friedel and Crafts reaction yielding α-naphthalenic ketones exclusively. The reaction is effected in carbon bisulphide at a temperature of 0° C. The yield of ketone is high, 60 per cent. to 80 per cent.; five examples of the application of the method are given.—Maurice **Arthus**: The specific characters of the antivenom serums. Anticobra serum and the poisons of the hamadryas (*Naja bungarus*) and krait (*Bungarus coeruleus*).—J. **Courmont** and A. **Rochaix**: Negative attempts at antituberculous immunisation by the intestine.—J. Kunckel **d'Herculais**: Observations on the habits of a myriopod (*Scutigera coleoptrata*). Its utility in destroying flies. The action of its poison: its supposed accidental presence in the digestive apparatus of man.—Pierre **Girard**: The preponderating *rôle* of two electrostatic factors in the osmosis of solutions of electrolytes. Normal osmotic movements.—Em. **de Martonne**: Results of the morphological analysis of the erosion levels of the Arc and Isère valleys.

August 14.—M. Armand Gautier in the chair.—J. **Boussinesq**: The spontaneous vibrations of a bar fixed at the ends and impermeable to heat, which is put in thermal equilibrium with an atmosphere at constant temperature. Simplified solutions for two problems previously studied by M. Roy and M. Annycke.—H. **Douvillé**: The geological explorations of M. Perrier de la Bathie in Madagascar.—Édouard **Heckel**: The cultural bud mutations of *Solanum maglia*, and on the first cultural results of these mutations. The first result has been the production of a violet variety. The plants show great resistance to cryptogamic diseases, and suggestions are put forward as to a means of obtaining strains of potatoes from wild plants capable of resisting disease.—A. **Calmette** and L. **Massol**: The antigenic function of the tuberculins.—M. **Verschaffel**: Observations of a double shooting star.—Armand **Denjoy**: *Analysis situs* of the plane.—Victor **Henri**: The influence of various physical conditions on the ultra-violet radiation of quartz mercury vapour lamps. Using the citrate of silver method described in a previous note for measuring the intensity of the ultra-violet radiation, the author has made determinations of the activity of a Westinghouse Cooper-Hewitt lamp under varying conditions of cooling. It was found that the ultra-violet radiation of the lamp is more intense as the temperature of the luminous tube increases. Cooling the tube with water gives only one-fourteenth of the ultra-violet radiation obtained when the lamp is in air, the watts consumed remaining the same. A study of the activity of six lamps of different makes and ages showed that for experiments in photochemistry a quartz mercury vapour lamp may be relied upon as a constant source of ultra-violet rays, the radiation being defined when the voltage, amperage, and length of the tube are known.—G. **Chesneau**: The analysis of monazite sands. Full details of the suggested method are given, accompanied with a complete analysis of a monazite sand from Madagascar.—M. **Kunz**: Feeling at a distance as a factor in the power of orientation possessed by the blind. A study of the so-called "sixth sense" of the blind. This is found to be localised on the skin, and is not exclusively an attribute of the blind. It is not connected with the sense of hearing, as is shown by the results of numerous experiments specially directed to this point.—Émile **Yung**: The insensibility to light and the blindness of the vine snail (*Helix pomatia*).

MELBOURNE.

Royal Society of Victoria, June 8.—Prof. E. W. Skeats in the chair.—A. M. **Lea**: A new Australian genus of Phoridæ, associated with termites.—F. **Chapman** and A. O. **Thiele**: A limburgite rock occurring as a volcanic plug at Balwyn, near Doncaster.

July 13.—Prof. E. W. Skeats in the chair.—Kathleen E. **Oliver**: The displacement of the optic lobes during the development of the brain of the fowl. The paper consists mainly of a series of drawings in the round of the different stages.—Helen **Kelsey**: Subdivision of the spinal canal in the lumbar region of chick embryos. In chicks of fifty-two hours' incubation the canalis centralis is bifurcated in the lumbar region. The observations extended over three years, and a large series was examined.—A. **Grouvelle**: Description de quelques nouveaux espèces de Coleoptères australiennes.—F. **Chapman**: Some Silurian species of the genus Lingula, with notes on its shell structure and a parasitic plant. Canals in the corneous laminæ were found in the fossil as in the recent *L. albida*.—J. H. **Gatliff** and C. J. **Gabriel**: Some new species of Victorian Mollusca. One new genus, Edenttellina, and eight new species, are described.—J. H. **Gatliff** and C. J. **Gabriel**: Additions to, and alterations of, the catalogue of Victorian marine Mollusca.—F. L. **Stillwell**: Notes on the geology of Broadmeadows.

CAPE TOWN.

Royal Society of South Africa, July 19.—Mr. S. S. Hough, F.R.S., president, in the chair.—J. C. **Beattie**: Terrestrial isomagnetic lines in South Africa.

CONTENTS.

THURSDAY, AUGUST 31, 1911.

THE FOUNDATIONS OF MATHEMATICS.

Principia Mathematica. By Dr. A. N. Whitehead, F.R.S., and B. Russell, F.R.S. Vol. i. Pp. xv+666. (Cambridge: University Press, 1910.) Price 25*s*. net.

THIS work contains some thousands of propositions, each, with its proof, expressed in a shorthand so concise that if they were all expanded into ordinary language, the room taken up would be ten times as large at least; space, time, and mass are not considered at all, and arithmetic is merely foreshadowed by the introduction of the symbols 0, 1, 2, and 2_r. How then, it may be asked, can the authors pretend to be writing about mathematics? The answer amounts to saying that for every branch of the tree of knowledge there is a corresponding root, and every advance in climbing seems to compel a similar advance in delving. Just as the discovery of non-Euclidean geometries led to the reconsideration of geometrical axioms, so Cantor's invention of transfinite numbers has reacted upon the theory of elementary arithmetic, and hence upon the whole of analysis and all its applications.

Besides this, there has grown up a school of mathematicians intensely interested in the logical side of their subject. Indeed, this was inevitable as soon as the primary distinction between ordinal and cardinal number was fully grasped, and the nature of the arithmetical continuum had been strictly defined. The inquirer was driven back and back to questions of order, and correspondence, and relations, and classes, until he felt bound to construct a symbolical logic fit to express the chain of deductions he found latent in the most familiar processes of arithmetic. This has led to an immense aggregation of what may be called mathematical prolegomena; and with this the first volume of the "Principia Mathematica" is almost exclusively concerned.

Thus the actual titles of its two parts are "Mathematical Logic" and "Prolegomena to Cardinal Arithmetic," and both are so elaborate that only a meagre account of them can be given in a review. The theory of deduction is based upon seven assumptions, called primitive propositions, and upon the notions of disjunction (p or q) and implication (either not-p or q). In about thirty pages the authors obtain the main results of the purely formal logic of propositions. This is followed by a very interesting section on "apparent variables," including the theory of propositions of different orders. A real advance seems to have been made here in the analysis of vicious-circle fallacies, and false generalisations, especially as they occur in mathematical reasoning. It is pointed out that such phrases as "all propositions" or "all properties of x" are strictly meaningless, and a legitimate use of such terms is based upon an axiom of reducibility (pp. 173–5) which is stated in the form: "Any function of one argument or of two is formally equivalent to a predicative function of the same argument or arguments," and its main use is at the beginning of the calculus of classes (p. 197). Whether this axiom is really simpler than the introduction of "class" as a primitive term seems debatable, but it does not matter much for practical purposes.

The next three sections deal with classes and relations, and introduce a large number of new symbols and a long series of propositions. Fortunately here, as elsewhere, each section is preceded by a summary, giving the principal theorems; and, in fact, the reader will find it helpful to go through all these summaries (after the introduction) before attacking the chapters in detail.

Coming now to the more directly mathematical part, we have first of all (p. 356) a discussion of unit classes, which illustrates the subtleties of this new calculus. Thus it is found necessary to construct a symbol for "the class of which the only member is x," as distinguished from x itself. At first this seems to be superfluous, but when we suppose x to be a class, we see that it is not. The next step is to define the cardinal number 1 as the class of all unit classes. Similarly the cardinal number 2 is defined as the class of all couples (x, y) such that (x, y) and (y, x) are equivalent; and the ordinal number 2_r as the class of ordered couples (x, y) such that (y, x) is different from (x, y). Besides these we have a symbol $\dot{2}$ for the class of all relations consisting of a single couple, including couples (x, x). Then we have a series of theorems on subclasses, relative types of classes, one-one and one-many relations, &c., leading up to the fundamental notion of similarity of classes which is the necessary basis of all arithmetic proper.

We next come to the difficult question of selections, from relations and from classes of classes respectively.

"If k is a class of classes, then μ is called a selected class of k when μ is formed by choosing one term out of each member of k."

(It would perhaps be more precise to say "a class selected from k," because μ, as a class, is not generally a member of k.) Now at first sight it looks as if a selected class could always be formed, but this is not really obvious when k is infinite, and, in fact, it has not been proved in general. If it could be, it would follow that every class can be well-ordered, and the difficulty of asserting this in general can be seen from a special case. Consider the aggregate of colours, merely as sensations of my own; how can I order them, without importing some additional foreign element, such as the time when I first became conscious of a particular one, or its analysis by a colour-box, or something of that sort? Besides this, there is the logical difficulty of making an assertion about "every" class, for one reason because assertions form a class.[1] Hence the section (p. 561) on the conditions for the existence of selections is one of special interest: its most important bearing on arithmetic is in the theory of multiplication.

The final section is on inductive relations, especially

[1] This is undeniable, because "assertions do not form a class" is itself an assertion, and only a formal, not a real contradiction of the above statement.

the ancestral relation, which, to avoid a vicious circle, is defined so as to apply to members of an infinite class. As the authors explain in a note, this section is mainly based upon Frege's work, and is used afterwards to deduce the properties of finite cardinals and the transfinite cardinal $\aleph$. Here we find the Peanesque notation in all its development, and must make up our minds to learn it thoroughly, or else to express its formulæ in an equally exact, but less unfamiliar symbolism. This leads us to the few critical remarks that we venture to offer on this admirable and elaborate work. Every communication of ideas from one mind to another is made by means of a conventional symbolism; no symbolism can be more *exact* than language, because language is, in the last resort, required to explain and define it. But it may be more *concise* than language, and this is the real virtue of the Peano notation and its derivatives. To show how easy it is to exaggerate the value of the notation as such, we may take an example from p. 16 of the present work. The authors say that "it is an obvious error, though one easy to commit," that "No A is B" is the contradictory of "every A is B," and proceed to add that the symbolism exposes the fallacy at once. Really it does nothing of the kind; truly the symbol $\sim \{(x).\phi(x)\}$, the contradictory of $(x).\phi(x)$, is different *in form* from $(x). \sim \phi(x)$, but how can we tell from looking at them that these last two symbols are not equivalent? Again, the authors profess to give a proof of the law of excluded middle; they assume it in defining the assertion symbol, for they practically say "if the proposition to which this sign is prefixed is false the book is in error," tacitly assuming (here) that all their propositions are significant. The law of excluded middle is surely axiomatic for a significant proposition, the only trouble is in being quite sure that our assertions are really significant, and in this it is reason that must guide us, not symbolism, though a proper choice of symbolism may conduce to economy of thought. As an illustration, we may refine a little on the paradox of Epimenides. Suppose a Frenchman or a German asserts "Every statement that has ever been made by an Englishman is false." This is a significant statement, and *as such* must be true or false. But suppose an Englishman says the same thing: the proposition ceases to be significant, unless he adds "except one," when it again becomes significant. Questions of this kind are not so trivial as they appear, and a really philosophical study of language might do a good deal towards making more definite the metaphysical basis of knowledge.

G. B. M.

MOVEMENT AND ESCAPEMENT.

Le Mouvement. Mesures de l'étendue et mesures du temps. By Prof. J. Andrade. Pp. vi+328. (Paris: Librairie Félix Alcan, 1911.) Price 6 francs.

SOME literary effusions—for instance, the novel with a purpose—present to the reviewer an awkward problem, namely, whether to concentrate his attention on the novel as such, or on the purpose. The present work might almost be included in some such category, inasmuch as it may be regarded from the point of view of a mathematician pure and simple, of a more or less practical mechanic, or even of an astronomer, while all the time it apparently claims to be a philosophical treatise, and as such to appeal to what may be called the general reader. In some parts of the book the philosopher is much in evidence, and in many places the absence of diagrams, and the assumption that the reader will understand determinants, vectors, or even ordinary equations of motion without explanation, would certainly repel the ordinary reader. The mathematician will find perhaps little that is novel. The suggestions of non-Euclidean space, whether that of Lobatchewsky or of Riemann, are little more than suggestions, and can only give those to whom such ideas are new the kind of shock the earlier cyclists felt on first riding a free-wheel. On the other hand, a very good historical sketch, amply provided with diagrams, is given of the development of scientific clockmaking with due respect to the great English horologists.

A brief sketch of the contents of the book will serve to indicate the scope of the author's endeavour, and it is difficult to conceive how, within the limits of such a volume, a perfectly satisfactory result could have been achieved. Perhaps only a fellow-countryman of the great French philosophers of the past would ever have attempted such a task. The first part treats of geometrical ideas of number and space, the author showing a decided preference for vectorial or polar coordinates, and for rotation as a means of translation. The finite straight line is elaborately discussed, and ordinary geometrical propositions regarded from the point of view that came into vogue about a quarter of a century ago, when Nixon's Euclid began to oust Todhunter's in some schools. Triangles and solids, plane and spherical areas, volumes, velocity, vectors, the theorems of Ampère and Stokes, moments, composition of vectors and vectorial quantities, bring us through trigonometry and statics to non-Euclidean geometry by a somewhat tortuous route.

The second part introduces force, one chapter being devoted to the notions of astronomy and celestial mechanics from Hipparchus to Newton, and another to the principles of dynamics, equilibrium, and the two fundamentals, which, in the author's view, are clock and orientation; a third dwells on the vital importance of a function of forces, on stability and conservative systems, on isolated systems, Painlevé's theorem and Laplace's invariable plane; and these are followed by simple and damped oscillations, spiral movement, elastic bodies, and fluids, and the bending of springs. The third part deals with optics more especially of the telescope, with a more special devotion to different methods of geodesy from Picard to the use of invar and the Jäderin wire, and the correction of the units of the metric system.

The fourth and last part deals with the chronometer in general, and escapements in particular, calling for continued experimental work on indicated lines, touches on chronographs and synchronisation of clocks, and gives extracts from the annual trial-numbers from the Greenwich volumes, showing the improvements makers have been able to secure in the last sixty odd years. W. W. B.

COSMICAL PHYSICS.

Researches on the Evolution of the Stellar Systems. By Prof. T. J. J. See. Vol. ii., "The Capture Theory of Cosmical Evolution, founded on Dynamical Principles and Illustrated by Phenomena Observed in the Spiral Nebulæ, the Planetary System, the Double and Multiple Stars and Clusters, and the Star-clouds of the Milky Way." Pp. viii+734. (Lynn, Mass.: T. P. Nichols and Sons; London: W. Wesley and Son, 1910.)

IT is with mingled feelings that, after reading through this immense volume of Dr. See's, the reviewer attempts to present it fairly to the readers of this journal. This book and the theory presented therein is "the culmination of continued labor extending over more than a quarter of a century." It calls therefore for a full and careful discussion. It is a great pity that the writer over and over again by loose dogmatic statements repels the critic, and that he so frequently makes claims as to the rigorousness of the methods he employs, claims which a careful examination quite fails to endorse. As an example of the former fault we choose the extraordinary statement on p. 152, which comes at the end of an account of some quite inconclusive mathematical work on the effect of a resisting medium. The italics are the author's.

"*Whatever doubt may arise as to the effect of the resisting medium in the present state of the solar system, there can be no possible doubt as to its power in our system at the epoch when the planets were formed. The observed roundness of the orbits of the planets is an everlasting witness to the presence of a resisting medium against which these bodies revolved for immeasurable ages. There is no other admissible explanation of this phenomenon, and as the resisting medium is a* vera causa, *on the secular effects of which all mathematicians are agreed, we may hold that it has as surely rounded up these orbits as if we had witnessed the transformation within the short period of human history covered by exact observations.*"

For the author's claims to mathematical rigorousness of treatment reference may be made to pp. 237, 259. The answer to these claims is twofold. On the one hand rigorous proof is from the nature of the case impossible in cosmogony. Too many uncertainties are necessarily involved in the premises for any amount of exact mathematical reasoning to lead to a rigorous proof, and even in this mathematical reasoning Dr. See is by no means perfect. It is a pity that his reply to the mathematical point raised by Mr. Brodetsky in the *Astronomische Nachrichten* (No. 4408) should be limited to the suggestion that "Mr. Brodetsky is unfortunate in writing from Cambridge." If Dr. See's views do not meet with the full attention that he desires for them (or to do them justice, that they deserve), the fault lies partly with his method of presenting them.

After these strictures we may turn to the more pleasant task of dwelling on the theory that Dr. See has built up. In his view the solar system has developed from a spiral nebula. Condensations round various nuclei have gradually developed into planets. The resistance of the medium through which these bodies have revolved about the central condensation or sun, has led to the gradual falling in and rounding of their orbits, and also to the capture by the planets of all their satellites. Thus the moon, which originally revolved outside the present orbit of Neptune, was captured by the earth while in the process of falling into the sun through the slow decrease of its orbit. The theory is supported by arguments adduced from many branches of astronomical research. Some of the material which Dr. See has brought together to support his views is of very decided interest, notably chapter ix. on the capture of comets, and chapter xxi. with its welcome extracts from the papers of Herschel. Dr. See has been very generous in the extracts he quotes from the work of other people. It is not obvious, however, why chapter xii., with its long extracts on lunar motion, should figure in this work. There is no independent criticism made of the controversies referred to, and a bare statement of the results arrived at, with references, should have amply sufficed. In some of his criticisms of other contributions to cosmogony, Dr. See is much happier than in his own constructive work. Thus some of his criticisms of Messrs. Chamberlain and Moulton on p. 106 are distinctly to the point; while independently of other workers in the same field, he has brought forward some cogent reasons against the nebular hypothesis of Laplace in its ordinary form; he also criticises some conclusions frequently drawn (though not always correctly) from the papers of Sir George Darwin.

Many points of detail offer themselves for criticism in the treatment accorded by Dr. See to all the problems discussed in his book. But we have said enough to give the general scope of the work. While not able to accept Dr. See's views as to the important part played by the resisting medium in the evolution of our system, we are prepared to find in this resisting medium a *vera causa* the effect of which has been frequently overlooked by other workers. This book is an exaggeration. It may serve to restore the true balance of forces.

It remains to be added that the book has been very well prepared for publication. It is produced in a manner that does credit to its author and publishers alike. The photographic reproductions are very good. The moon, nebulæ, and star-clouds are well represented in a series of very fine plates. It is a pity that the headings used were added to the fine photographs by Barnard. A useful summary of the whole book is added in chapter xxiv., which gives a formidable list of problems explained by the theory.

BOTANICAL MONOGRAPHS.

Das Pflanzenreich. Regni vegetabilis conspectus. Edited by A. Engler.

41. Heft. (iv. 56*a*) Garryaceæ; (iv. 220*a*) Nyssaceæ; (iv. 220*b*) Alangiaceæ; (iv. 229) Cornaceæ. By W. Wangerin. Pp. 18+20+25+110. Price 9.20 marks.

42. Heft. (iv. 147) Euphorbiaceæ-Jatropheæ. By F. Pax. Pp. 148. Price 7.40 marks.

43. Heft. (iv. 228) Umbelliferæ-Apioideæ-Bupleurum, Trinia et reliquæ Ammineæ heteroclitæ. By H. Wolff. Pp. 214. Price 10.80 marks.

46. Heft. (iv. 94) Menispermaceæ. By L. Diels. Pp. 345. Price 17.40 marks.

(Leipzig: Wilhelm Engelmann, 1910.)

THE four volumes of which the titles appear above are sufficiently diverse to indicate various general features of this elaborate series. In the first place, sufficient material for the first volume on the Euphorbiaceæ is supplied by the account of the tribe Jatropheæ, while Mr. H. Wolff includes no more than a portion of the subtribe Ammineæ in the first volume dealing with the Umbelliferæ. The termination Jatropheæ follows the official rules that tribe names shall end in -eæ, and the suffix, -ineæ, indicates that Ammineæ is a subtribe. The Menispermaceæ are amenable to treatment in a single volume, while the inclusion of four families under one cover is due to the circumstance that certain genera, formerly included in Cornaceæ—notably by Dr. Harms in the "Pflanzenfamilien"—are now severed from that family and placed in three distinct families. Of these, Garryaceæ and Alangiaceæ are both monogeneric, while Nyssaceæ comprises Nyssa, Camptotheca, and Davidia. Garrya has always been a puzzle, and even now Dr. Wangerin expresses himself somewhat dubiously as to the proposed location in the Amentales near Salicaceæ. Alangiaceæ and Nyssaceæ are referred to a relationship with the Combretaceæ in the order Myrtifloræ, the only doubtful point being the exact position of the monotypic genus Davidia. With regard to the Cornaceæ, the author has no hesitation in placing them at the very bottom of the Umbellifloræ, immediately anterior to the Caprifoliaceæ. Dr. Wangerin pays special attention to the various forms of inflorescence in the Cornaceæ, and submits an analytical key to the genera founded upon anatomical characters. The family consists of ten genera, of which Cornus is the largest with fifty species.

The tribe Jatropheæ comprises thirteen genera, including the well-known Hevea and two small new genera; Jatropha far outnumbers the other genera with 156 species, as Hevea approaches next with 17 species. Prof. F. Pax has worked out a phylogenetic arrangement of genera and species based upon a detailed study of the geographical distribution. Seven genera are wholly American, five are palæotropic, and Jatropha is tropically cosmopolitan. The chief centre of development is situated in Brazil, but other centres occur in Central America and East Africa, chiefly owing to the species of Jatropha found in those regions. Diagrams are provided to illustrate natural affinities of the genera and of different sections and subsections of the genus Jatropha.

The elucidation of the genus Bupleurum, which now extends to 100 species, is the chief feature of the Ammineæ-heteroclitæ. It is interesting to note that in a family showing such diverse fruit characters the most satisfactory characters for splitting up the genus are furnished by the leaves. The criticism of unnecessary diffuseness must be urged against the author; the extreme instance is supplied by the description of subspecies and varieties under *Bupleurum falcatum*, extending over thirteen pages.

As might be expected from a botanist of such wide experience, Prof. L. Diels has produced one of the most interesting monographs. The various sections in the general introduction of the Menispermaceæ are carefully elaborated. The family contains a very large number of lianes, not one of which climbs by means of tendrils; twining is the usual device; the extent of anomalous stem development is still a matter for investigation. The value of Miers's contributions to the classification of the family is generously emphasised, although the author finds it necessary to make a number of alterations in the constitution of the tribes. Much useful information is supplied in the notes inserted after the diagnoses of the genera. One new genus is proposed, and several new species are indicated which are scattered generally through the genera.

OUR BOOK SHELF.

The Animals and Man: an Elementary Text-book of Zoology and Human Physiology. By Prof. V. L. Kellogg. Pp. x+495. (New York: Henry Holt and Co., 1911.)

ALTHOUGH written from an American point of view, with American animals as the chief types, this well-illustrated volume may be confidently recommended to the English student on account of its lucid style, orderly arrangement, and the method of treatment of the various sections of its subjects. Based on two still more elementary text-books of zoology by Prof. Kellogg, the volume includes chapters on human structure and physiology by Miss McCracken, a fellow professor of the author at Stanford University; this lady's contribution forming eight chapters in the fourth part. The other chapters on physiology are by Prof. Kellogg.

The first six chapters are devoted to the constituent parts of animals and their respective functions; the subject being introduced by contrasting the organisation of a grasshopper—or rather a locust—with that of a snail; while in subsequent chapters a so-called sunfish (in reality a member of the perch group), a sparrow, a toad, a crayfish, and an amœba are made to serve as types of their respective classes. With part ii., containing three chapters, we have summaries of the life-histories of certain kinds of animals; mosquitoes and caterpillars, with their transformations, serving to illustrate insects, while frogs and birds are taken as examples of two vertebrate groups broadly distinguished by the great divergence in their development.

Systematic zoology and the classification and habits of animals form the subject of part iii., with eleven chapters; the author commencing his survey with the protozoa and concluding with mammals. The account of the former group is well up to date, and particular attention may be directed to the excellent description of the mode in which man becomes infected with malaria by means of mosquito bites. It is the clearest and most simple account of a complex and puzzling phenomenon which we have had occasion to read. Neither are domesticated animals left out; and in this section it may be mentioned that the author follows Prof. Keller in regarding humped cattle as descended from the bantin of the Malay countries. On pp. 270–1 Hainan is misprinted Hainau, and *cygnoides* rendered *cygmoides*, while an altogether misleading figure of a lamb is made to serve as the representative of the handsome wild sheep of Transcaspia. A brief account of fossil animals, or rather fossil vertebrates, concludes this section of the work, which is followed by the aforesaid chapters from the pen of Miss McCracken.

Chapters on the relation of micro-organisms and sanitation, on ancient and modern man, the struggle for existence, communal life, &c., conclude a very readable book on a very technical subject. R. L.

How to Enamel: being a Treatise on the Practical Enamelling of Jewellery with Hard Enamels. By H. M. Chapin. Pp. xii+70. (New York: J. Wiley and Sons; London: Chapman and Hall, Ltd., 1911.) Price 4*s.* 6*d.* net.

THIS is an unpretentious little book written by a practising enameller. It describes in plain language the simplest methods of enamelling on metals, and has the merit of avoiding all air of mystery pertaining to the craft. The writing has no claims to literary finish, and the Americanisms scattered up and down the pages will come upon an English reader with something of a shock. But the writer's gift for expressing his meaning plainly, and his practical hints as to helps and hindrances in the work, obviously the result of direct personal experience, will earn the gratitude of the reader who goes to him for instruction.

In so small a compass, of course, no more than the elements of the subject are treated, and the beginner is very properly warned that only experience can teach him his craft. By omitting some not very helpful pages on transferring photographs to enamel, room might have been found for illustrating and commenting on a few fine examples of enameller's work of former ages; or, perhaps more stimulating to craftsmen, some specimens of the handiwork of such modern masters as Lalique, Thesmar, Du Suau de la Croix, Fisher, and Dawson, would have set before the beginner something to remind him that the result of all his efforts will be worth nothing unless quickened by the breath of art.

History of Geology. By H. B. Woodward, F.R.S. Pp. vi+154. (The History of Science Series.) (London: Watts and Co., 1911.) Price 1*s.* net.

No more appropriate writer could have been found for this condensed history of geology than the author of the recently published "History of the Geological Society of London." The personal touches which abounded in that volume have of necessity been curtailed in the treatment of a wider theme; but we meet here pleasantly with Mary Anning (p. 63) and Etheldred Benett (p. 126), side by side with Humboldt and James Hall. The book is clear and interesting in all its chapters. Stratigraphy naturally assumes most importance, since it includes the succession of organisms on the earth, and this is the aspect of geology that appeals most directly to the mind of man. Perhaps there are almost too few references to the difficulty experienced by the early geologists in making headway in countries where adherence to a Jewish system of cosmogony was held to be an act of public morals. Those who begin with Mr. Woodward's present book may well pass on, guided by his fourth chapter, to the opening pages of Lyell's "Principles of Geology."

Petrology is treated less systematically, and few will agree with the statement (p. 143) that "the petrology of the Igneous rocks has the advantage of being a more exact science than that of Palæontology."

The pertinacity of Romé de l'Isle and the self-sacrificing life of Haüy receive only slight mention on p. 43. We should have liked some reference to the successful stand made by English-speaking geologists against the view that igneous rocks assumed a new facies with the passing of Mesozoic forms of life, and of the part played by Jull in this matter—since other living workers are mentioned—and in the development of the teaching of geology. The heading "Early Geological Maps" (p. 50) does not include William Smith or Macculloch, the maps of the former being described on p. 34, while Macculloch's Scotland has to wait until p. 80. "Progress in British Geology" occurs twice as a heading in chapter iii. These are small points of arrangement and are easy to correct. The portraits of geologists have been selected from good and thoroughly interesting originals. We feel that we must mention specially the early Lyell, the William Buckland expounding the tooth of a hippopotamus, and the thoughtful von Buch resting so naturally in the open air. G. A. J. C.

A Treatise on Wireless Telegraphy and Wireless Telephony. By Prof. T. Mizuno. Pp. ix+563+x+208 Figs. Written in Chinese characters. (Tokyo: The Maruzen-Kabushiki-Kaisha, 1911.) Price 4.50 yen, or 9*s.*

SEVEN years ago Prof. Toshinojo Mizuno, of the Imperial University of Kyoto, published a popular work on wireless telegraphy and telephony. At that time it was difficult to transmit messages more than two hundred miles. The present volume is in the main a theoretical consideration of the same subject, and is intended for the use of students at the university. With the exception of the numerous formulæ and equations which suggest a treatise on higher mathematics, the fact that the text is in Chinese idiographs, places this work beyond the reach of European students. The references to Maxwell and Hertz in the early chapters indicate that the author has started on good foundations. Following these, references are made to the work of many investigators in England, Germany, Italy, and other European countries.

The description of instruments, which are illustrated diagrammatically, concludes with a reference to the telephonic relay of Mr. S. Brown, which shows that the writer is well up to date in regard to modern inventions. The author says but little about his own work, or the contributions to improvements in practical wireless telegraphy made in his own country, but these exist. The whole work may be compared to a play of Shakespeare with actors in Eastern costume, but it also suggests that Japan is abreast with the abstruse researches of the West in connection with which she has made advances.

Les Machines à écrire. By J. Rousset. Pp. 177. "Encyclopédie Scientifique des Aide-Mémoire." (Paris: Gauthier-Villars and Masson et Cie., n.d.) Price 2.50 francs.

IN this little book the author dissects the typewriter of commerce, and in a series of chapters shows how in different machines each function is performed. There are fifty-eight figures. The descriptions and figures are clear, and the book should fulfil its purpose. It is a little difficult, however, to see what this purpose is, for ingenious as the mechanism of typewriters may be, it is all visible, and anyone with any sense of mechanics can see it all for himself and understand it, and, moreover, in the larger towns at any rate, there is no difficulty in finding all the better-known examples, and willing expositors in the shops in which they are sold. Still, it is well that the subject should be dealt with systematically.

Lissajous'sche Stimmgabelkurven in stereoskopischer Darstellung. By J. W. N. Le Heux. Pp. 8+18 plates [loose cards in case]. (Leipzig: Johann Ambrosius Barth, 1911.) Price 6 marks.

The author refers to the interest which Lissajous figures have in physics and mathematics, more especially when presented in their most attractive form so as to appear in stereoscopic relief. As is well known, pairs of figures otherwise identical but slightly different in phase appear when viewed in a stereoscope (or by accustomed eyes without a stereoscope) to blend together and form a single picture in three dimensions. The author discusses eighteen plates as follows, three of ratio 1 : 1, five of 1 : 2, two of 2 : 3, three of 3 : 4, two of 3 : 5, and two of 4 : 5 ratios. Some show a single line only, others give ten or more closely spaced lines. The plates are so clear that the stereoscopic effect is perfectly seen without a stereoscope.

Europe in Pictures. By H. Clive Barnard. Pp. 64. (London: A. and C. Black, 1911.) Price 1*s.* 6*d.*

The pictures in this book will serve admirably to illustrate geography lessons in schools. The text is scarcely so suitable for school purposes; it is arranged unattractively and in such a manner that the plates often have little to do with the letterpress facing them.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

A Pseudo-Aurora.

For some time I have been staying at the Kurhaus, St. Beatenberg, Switzerland, and my window commands a view of the Bernese Oberland from the Wetterhorn to the Balmhorn. The Eiger Mönch, Jungfrau, and Blümlisalp stand out most clearly above the lower mountains in front of them, of which the Faulhorn and Mesen are members. There has been a continuance of hot and dry weather for many weeks, and there have been occasional thunderstorms with both forked and sheet lightning. On the night of August 21, about ten o'clock, semicircular flashes of light shot up apparently behind the Mönch, quivered for a few seconds, and then disappeared. I counted twenty-eight in a minute. The light was sometimes intense at a central point, which was steady, and from this a quivering glow proceeded and lighted up from 15° to 20° of the horizon. The outline of the Jungfrau group could occasionally, but not always, be seen.

The appearance seemed to me very like an aurora borealis which I saw in Scotland in the 'fifties, but the centre of the light here was to the south-west of where I stood. I do not know how long the light had appeared before I saw it, but it continued to flash with great brilliancy for about twenty minutes. It then became less bright, and did not shoot so high into the sky, but extended laterally to the south for about 30° behind the Oberland chain. After half an hour more these died away, and on looking out two hours later nothing was to be seen. I am informed that a similar phenomenon was visible on the previous night, but was less brilliant. The resemblance to a true aurora was so great that I have thought it might be worth description. Lauder Brunton.

Rainless Thunderstorms.

During the long-continued drought local storms have been reported here and there, and have been described as rainless. Will you or any of your readers explain this phenomenon? I have always imagined that raindrops played a large part in the manufacture of atmospheric electricity, but I suppose that there are electrical storms in rainless countries.

A. A. M.

Hove, August 16.

The point raised in the foregoing letter is one of considerable interest in connection with the origin of the electrical phenomena of thunderstorms. The fact that thunderstorms are usually accompanied by clouds of a special character and heavy rain is common knowledge, and after Wilson's discovery of the difference in the effectiveness of the positive and negative ions as condensation nuclei it was generally assumed that condensation produced the necessary separation of the positive and negative electricity, and was an essential feature in thunderstorms. Simpson in his recent paper on the "Electricity of Rain and its Origin in Thunderstorms" makes splashing and breaking up of actual raindrops a necessary part of the mechanism of a thunderstorm.

Published accounts of rainless thunderstorms are not common, but one was contributed by Mr. E. J. Lowe to Nature for September 7, 1893. He says, "On August 9 (at Shirenewton, near Chepstow) there was no rain but more lightning than I had seen since the memorable storm of August 9, 1843. It commenced at 9 p.m., and lasted five hours. From very frequent counting there could not have been less than 10,000 flashes."

More recently, Captain A. Simpson, of the s.s. *Moravian*, described a thunderstorm near Cape Verde lighthouse, when there was no rain nor even lower clouds. "For fully an hour the sky was one blaze of lightning, and the wire ropes, mast heads, yard arms, derrick ends, &c., were lighted up." See M.O. Pilot Chart of the North Atlantic and Mediterranean, April, 1903. E. G.

Meteorological Office, South Kensington,
London, S.W., August 22.

Habits of Dogs.

Can any of your readers inform me whether it is common for dogs to eat wasps, or if it is likely to prove injurious? A young bulldog of mine ("Billy") now finds his chief amusement in catching flying wasps with his mouth, and I think he must swallow them, as they generally vanish, though occasionally I have found the corpse on the floor. It seems evident from the dog's demeanour that the sting makes some impression; he shakes his head and licks his lips energetically, and occasionally runs to a corner and rolls on his back kicking. But the next moment he is off after another. That he is not invulnerable appears further from the fact that yesterday, after treading on a wasp, he lifted a paw and limped on three legs, until I applied ammonia. There was a tender spot where the skin had been grazed between the toes; possibly the sting lit there.

The same bulldog had another curious habit. When I was on the Cornish coast he spent much of his time in rolling boulders backwards along the beach or in shallow water. His method was to embrace the stone with his powerful fore-arms and fling it towards his hind paws, licking it well over at every pause. As he generally chose the biggest stone he could well move, it was laborious work; but he was tremendously enthusiastic about it. In the garden too, if not watched, he would drag the stones from the rockery across the lawn. This pursuit has now lapsed from lack of opportunity, though he occasionally practises on a stray brick or flower-pot.

It testifies to the hardiness of the national breed that "Billy" was undamaged by a "head-on" collision with a motor-car which he had charged. I saw him knocked forward, and then struck by the wheel, but at my cry of horror he came galloping back to me as cheerful as ever. The driver had doubtless put on the brake as soon as possible, for he kindly stopped a moment later to see if the dog had been hurt. A. Everett.

Woking, August 21.

THE KACHÁRIS OF ASSAM.[1]

THIS, the last volume included in the excellent series of monographs for which we are indebted to the Government of Eastern Bengal and Assam, differs from its predecessors in that it contains less pure ethnography and more of the charming personality of the author, of whom his old friend, Mr. J. D. Anderson, contributes an appreciative memoir. Mr. Sidney Endle worked as a missionary under the Society for the Propagation of the Gospel, and as chaplain to the tea-gardens of Upper Assam, from 1864 to 1907, when, exhausted by long and devoted labour among the people he loved so well, he died in a steamer on the Brahmaputra while on his way to Europe.

The Kacháris, to use the name given to them by the Hindus, are usually known to the Bengalis as Mech, from the Sanskrit Mleccha, meaning "barbarian," but call themselves Bodo or Baro. Their Hindu name seems to be connected with that of the powerful Koch empire, which once included, roughly speaking, the present British provinces of Eastern Bengal and Assam, the name now surviving in the small native State of Koch Behar.

The people now described form part of the northern group of a once widespread race, divided from the southern group by a line closely following the Brahmaputra valley. In the southern group the strongest tribes are the Garos and the people of Hill Tippera. The separation of the northern from the southern group is complete, as is shown by the absence of common tradition and intermarriage; and their languages, though possessing much in common, differ from each other nearly as much as Italian does from Spanish. How this once united people became divided history does not tell. But Mr. Endle, with much probability, suggests that it resulted from the invasion of the Ahoms, a Shan tribe from whom Assam has acquired its name, who early in the thirteenth century entered the province from the Upper Irawaddy valley.

The Bodo Kacháris, numbering about 272,000 souls, now occupy the Kachári Duárs or passes and the districts of West Darrang and North Kamrup. In stature they are much smaller and shorter than the races of North-west India, and bear some resemblance to the Nepalese. Their physical type—square-set faces, projecting cheek-bones, almond-shaped eyes, and the almost complete absence of beard and moustache—connects them with the Mongoloid peoples. Mentally they are much inferior to their Hindu neighbours, but what they succeed in learning they retain with much tenacity. They are intensely clannish and obstinate. Owing to their comparative isolation they have acquired few of the vices of civilisation, an occasional bout of indulgence in rice-beer being one of their most obvious failings. Their standard of female chastity is much higher than that of the neighbouring tribes.

They are a prosperous people, well skilled in agriculture, growing the valuable Eri silk, out of which they weave an excellent cloth. It is curious that Col. Gurdon, the director of the Ethnographical Survey, and the author are at issue on the question whether their subdivisions are endogamous or exogamous, a matter easily solved by local inquiry. In their manners and customs they much resemble the Garos, who are described in a monograph included in this series.

In religion they are in the animistic stage, with a pantheon containing groups of household and village deities. The leading members of the former group are Bathau, the tree spirit embodied in the *Euphorbia splendens*, found in nearly every house yard, and his consort Mainao, who is, as her name implies, the guardian goddess of the rice fields.

Two appendices, one describing some of the allied tribes, the other adding three additional folk tales collected by Mr. Anderson, increase the value of the book, which, if not the work of a trained anthropologist, gives a sympathetical account of an interesting people.

Kachári Girls playing Jew's Harps (Gongina). From "The Kacháris."

[1] "The Kacháris." By the late Rev. Sidney Endle. With an Introduction by J. D. Anderson. Pp. xix+128. (London: Macmillan and Co., Ltd. 1911.) Price 8*s*. 6*d*. net.

THE PROMOTION OF AGRICULTURAL RESEARCH AND LOCAL INVESTIGATIONS.

THE Board of Agriculture and Fisheries has been in communication with the Development Commissioners with a view to the formulation of a scheme for the promotion of agricultural research and local investigations in England and Wales, and the Treasury, on the recommendaton of the commissioners, has now sanctioned the allocation of funds to be distributed by the Board in accordance with the general principles set out below. The total maximum sum which will be expended when the scheme is in full operation will be about 50,000*l.* per annum.

The scheme provides for—

(1) A system of agricultural research which will secure for each group of the problems affecting rural industry a share of attention roughly proportional to its economic importance.

(2) The concentration of the scientific work on each group at one institution or at institutions working in combination.

(3) Grants for special investigations for which provision may not otherwise be made.

(4) The grant of scholarships with a view to the increase of the number of men fully qualified to undertake agricultural research.

(5) The carrying out of investigations into problems of local importance, especially those involving the application of modern research to local practice, and the provision of scientific advice for farmers on important technical questions.

Subjects of Research.

In making arrangements for the separate investigation, so far as possible, of each group of allied subjects the commissioners and the Board have been impressed with the importance of securing continuity in work which is necessarily of considerable duration, and at the same time of providing staffs of specialists and experts who will be permanently engaged on work arising from the investigation of the same group of problems. By this means concentration and economy of effort will be better secured than it would be if a number of institutions were dealing at the same time with the same group of problems.

It is neither desirable nor possible to prevent all overlapping or duplication of work, but it is obviously necessary to proceed on a plan by which research work subsidised from public funds will not be unnecessarily duplicated. It is also desirable to arrange that each problem shall be undertaken by the institution best fitted to deal with it, and usually by the institution which has specially devoted its attention to problems of an allied nature.

It is also important to avoid the giving of undue attention to one part of the field of agricultural research, to the exclusion of other parts which are of equal scientific and economic importance.

With these considerations in view, it has been arranged that grants should be made for research in the following groups of subjects:—

(1) Plant physiology.
(2) Plant pathology and mycology.
(3) Plant breeding.
(4) Fruit growing, including the practical treatment of plant diseases.
(5) Plant nutrition and soil problems.
(6) Animal nutrition.
(7) Animal breeding.
(8) Animal pathology.
(9) Dairying.
(10) Agricultural zoology.
(11) Economics of agriculture.

Special Grants for Research.

A sum not exceeding 3000*l.* per annum will be available for assistance in respect of special investigations for which provision is not otherwise made.

Grants from this fund will be made on the recommendation of the Board's Advisory Committee on Agricultural Science, which will consider, not only whether the proposed investigation is desirable in itself, but whether it could not be better carried out at one of the special research institutions referred to above. The grants will be made from year to year, and will be for one year only in each case.

Scholarships.

In order to secure the services of a number of carefully trained men for work in connection with the scheme, the Board proposes in each of the years 1911, 1912, and 1913 to offer twelve scholarships of the value of 150*l.* per annum, tenable for three years.

It is proposed that candidates for scholarships should be selected by a special committee, representing the institutions in which the selected candidates will subsequently work. The award of twelve scholarships will be conditional on a sufficient number of thoroughly suitable candidates presenting themselves.

Local Advice and Investigations.

Grants will also be made to certain universities, university colleges, and agricultural colleges in England and Wales, for the purpose of enabling them to supply scientific advice to farmers on important technical questions, and to carry out investigations into problems of local interest, which can be more conveniently studied on the spot than at one of the research institutions.

By means of these grants it is hoped to provide an expert staff possessing both scientific and practical qualifications, the members of which will devote themselves to solving difficult local problems, and in other ways endeavour to secure the application of science to practice.

THE RECOGNITION OF PALÆOBOTANY.

IN *The Times* of August 24 a correspondent appeals for the adequate official recognition of palæobotany in Britain, and suggests that "some millionaire, anxious to be of service to his day and generation" might "do a unique and serviceable deed in endowing this neglected but important science." It is indeed strange, though true, that there is no professorship or lectureship in palæobotany in any of our universities, Cambridge alone having an ill-paid demonstratorship; and hitherto there has been no special curatorship of fossil plants even in the British Museum. This country only takes an honourable place in the promotion of the science at present because a few distinguished men of private means, and some enthusiastic students working in the midst of other duties, are devoted to it; and also because the actual occupants of the chairs of botany in Cambridge, London, and Manchester happen to make it their chief line of research.

When, however, *The Times* correspondent compares the general recognition of palæobotany in Britain and the British possessions with that which it receives in other countries, his statement is weakened by a tendency to special pleading. The distinguished professor of the Swedish State Museum, who is mentioned as "decorated with Royal Orders," is not merely a palæobotanist, but also a great geographer, the hero of several important Arctic expeditions. The United States Geological Survey may be well equipped for the study of fossil plants; but it should be added that no more important and fundamental contribution to palæobotany has emanated from America during recent years than that of the assistant curator of a university museum who pursues his researches in the intervals of many other duties. The Canadian Geological Survey may not have a palæobotanist on its permanent staff; but it does not fail to recognise the importance of fossil plants when necessity arises, and it is employing a professional palæobotanist on special service at the present time.

Finally, the statement that "our country, with all her colonies and dependencies, with their thousands of square miles of coal-bearing, fossil plant-bearing rocks, does nothing" to help the prospector, is made in forgetfulness of the exhaustive and well-illustrated "Catalogue of the Glossopteris Flora" which was published by the Trustees of the British Museum six years ago, partly with the view of helping the development of the coal-fields in India and the southern hemisphere, where the handbook is extensively used.

S. H. BURBURY, F.R.S.

By the death of Mr. Samuel Hawksley Burbury, on August 18, at eighty years of age, we have lost an ardent worker in the domain of mathematical physics who did much to elucidate the mysteries of several problems in molecular dynamics. Mr. Burbury was the son of Mr. Samuel Burbury, of Leamington, and was born at Kenilworth in May, 1831. He was educated at Shrewsbury and St. John's College, Cambridge; he was Craven University scholar, Chancellor's medallist, Browne medallist, twice Porson prizeman, and fifteenth Wrangler and second in classical tripos, 1854. He was called to the Bar at Lincoln's Inn in 1858, but his new profession did not prevent him from continuing his mathematical studies, and he thus became one of the few workers in this country who have produced original mathematical investigations while engaged in duties other than that of a mathematical teacher.

Much of Mr. Burbury's work was done in collaboration with the late Rev. H. W. Watson, F.R.S., with whom he shared the joint authorship of treatises on "The Application of Generalised Coordinates to the Dynamics of a Material System" (1879) and "The Mathematical Theory of Electricity" (1883–5), in the latter of which the authors endeavoured to place electrostatics and electromagnetism on a more formal basis than had been done by Clerk Maxwell in his original treatise. It is perhaps a pity that this book appeared at a time when experimental developments were beginning to break down many of our preconceived electrical theories, and, so far as we can gather, Watson and Burbury's treatise is not studied so much as it deserves. It affords a fairly satisfactory representation of electrical phenomena as known at the time, but, of course, every mathematical or dynamical theory of physical phenomena can only be regarded as a scheme for coordinating results of experiments in the simplest form; and with the discovery of new facts every such scheme is liable to be found inadequate when the necessity arises of superseding it by a more comprehensive scheme. It is thus probable that at the present time there is no scheme which represents our existing knowledge of electrical phenomena much better than Watson and Burbury's represented our knowledge at the time it was written.
