But, like his friend Watson, Burbury seems to have chosen as his favourite study that branch of molecular dynamics in which Boltzmann occupied a central position. Burbury and Boltzmann were certainly in constant correspondence with each other, and many of Boltzmann's papers were evidently the result of Burbury's criticisms. Perhaps Burbury's training as a barrister gave him special qualifications for playing the *rôle* of critic; at any rate, if there was a weak point in any argument Burbury would certainly find it out in a very short time. A great amount of time was spent in examining Boltzmann's "Minimum Theorem," according to which an assemblage of molecules representing on the kinetic theory a perfect gas, tends to assume the distribution commonly known as "Maxwell's Law." In the proof of this theorem the question of reversibility plays an important part, and it cannot be said that the introduction of probability considerations altogether overcame the difficulty of accounting for an irreversible phenomenon by means of a system the elements of which were subject to the equations of motion of reversible dynamics.

In his "Kinetic Theory of Gases" (1899), Burbury advanced a novel theory as to the distribution of velocities in a medium the molecules of which were too close together to satisfy the fundamental hypotheses involved in the proof of Maxwell's law. According to Burbury, the velocities of neighbouring molecules would become *correlated*, the probability factor involving, besides the usual exponential of the energy, the exponential of the vector product of the velocities of pairs of molecules. Burbury further offered, on this hypothesis, a tentative explanation of liquefaction. According to Burbury, Maxwell's law would thus become inapplicable to a dense gas. On the other hand, if applied to rare gases, it leads to the conclusion that helium and hydrogen cannot escape from the earth's atmosphere, a conclusion which the late Dr. Stoney stated was not in agreement with his observations. Thus the kinetic theory of gases affords another instance of a scheme which covered our knowledge of physical phenomena at one time but no longer does so. To overcome this difficulty we are now resuscitating kinetic theories, but employing them on a smaller scale than before—to electrons instead of molecules.

Another question which occupied Burbury, especially during recent years, was the loss of availability which occurs when two gases mix by diffusion of constant temperature. As Burbury argued, if this happens when different kinds of molecules mix by diffusion, the same thing should be true when molecules of the same kind mix by diffusion. Burbury's views on this subject were stated in *Science Progress* a few years ago. This problem again gave Burbury scope for his critical mind. It cannot be said, however, that he, or, indeed, anyone else, has succeeded in giving a reason *why* the total entropy of a litre of one gas and a litre of a second gas is equal to the entropy of the mixture when its volume is *one* litre, while if two litres of the *same* gas at the same pressure are allowed to mix, the sum of their entropies is equal to the entropy of the mixture when its volume is *two* litres. What Burbury really showed by his arguments was that the truth or otherwise of these statements can only be tested by experimental evidence.

At the present time the study of mathematical physics is rather out of fashion in this country, and it is not unusual to deprecate this study on the ground that it frequently fails to account for the results of observation. Is not this failure one of its most valuable features? Whenever a new physical phenomena is discovered, plenty of people are ready enough to invoke molecules, the æther or electrons, to account for it, and to talk about the motions of these which give rise to the observed phenomenon. The mathematical physicist comes along and says, "Very well; then let us write down the equations of motion and see if the reasoning works out correctly." He obtains a result which does not account for experimental conclusions. Which is wrong? Not the mathematician who has merely attempted to place the reasoning on an exact basis, but the *unmathematical physicist* who has endowed his ether molecules, his ether, or his electrons with properties that are incompatible with each other. In Mr. Burbury we have had a worker who never flinched from the task of following a line of argument up to its logical conclusions, however much these might run counter to orthodox views. He would drive his opponent from one stronghold to another, the controversy being conducted in the most friendly way the whole time. The contest would frequently end in a truce, both sides agreeing that there was much in Nature that we could never understand. But Burbury was rarely the first to give in. It is these passages of arms which very often enable men to appreciate each other's good qualities, and to realise the useful part which men like Burbury may play in evolving order out of chaos. G. H. BRYAN.

PROF. A. LADENBURG.

THE death occurred at Breslau, on August 15, of Dr. Albert Ladenburg, professor of chemistry in the University of Breslau. Dr. Ladenburg was born at Mannheim in 1842, and graduated as doctor of philosophy in 1863. In 1873 he accepted an invitation to take up a position as professor of chemistry and director of the laboratory at Kiel. In 1886 the honorary degree of doctor of medicine of Berne University was conferred on Dr. Ladenburg in recognition of his scientific investigations, and British and other societies, including the Pharmaceutical Society of Great Britain, also honoured him with honorary membership. He was also awarded the Hanbury gold medal for his services in the promotion of research on the chemistry of drugs. It was in 1889 that Dr. Ladenburg took up the post of professor of chemistry at Breslau, and he occupied the office with very great success.

Ladenburg's name is best known by his synthetic work on the production of homatropine. On splitting up atropine, tropic acid and tropine can be formed as derivatives; the latter Ladenburg combined with amygdalic acid to form a compound which is converted into oxy-toluyl-tropeine, or homatropine, an artificial alkaloid which, with its salts, has proved of the greatest service in ophthalmic surgery. His mathematical method of treating synthetic formulæ, and his prismatic benzene ring, place him in the first rank of chemists as a theorist; while as to his practical work, his list of communications to scientific societies and literature in this country and elsewhere includes articles on "The Valency of Nitrogen," on "Synthetic Alkaloids," on "The Relationship between Hyoscyamine and Atropine and the Conversion of the one Alkaloid into the other," on "Hyoscine," on "The Mydriatic Alkaloids occurring in Nature," on "The Synthesis of Coniine," and on "The History and Constitution of Atropine," in addition to the compilation with other collaborators of a dictionary ("Handwörterbuch der Chemie"), consisting of thirteen volumes dealing with inorganic and organic chemistry.

THE BRITISH ASSOCIATION AT PORTSMOUTH.

BY the time this issue reaches the readers of NATURE the eighty-first meeting of the British Association will have been inaugurated at Portsmouth and, given fair weather conditions, we trust it will be a useful and enjoyable gathering. Judging from the number of distinguished men of science who have expressed their intention of being present, the meeting should be of importance as regards its scientific work, as well as successful from a social point of view.

The reception-room is the large Connaught Drill Hall, which appears to be ideal for that purpose. It gives under one roof a large reception hall with post office, telephone, &c., and a comfortably furnished reading and writing room for the members. In addition to this there is also a small room set apart for the use of ladies.

In point of view of numbers, the Portsmouth meeting may not reach that of Sheffield last year, but this is accounted for partly by the absence of any special industry attached to the town, and also may, to some extent, be due to the absence of any university or university college. Most of the accommodation available is, however, booked, and those who arrive late may have difficulty in finding quarters.

The meeting rooms are a little scattered, but this was unavoidable, and notices will be displayed making the routes to be taken to the various section-rooms easy to find.

In passing, mention may be made of a convenient plan for communication between members of the association. It is a box which will be placed in the reception-room, into which notes may be dropped addressed to other members. This box will be frequently cleared, and the notes delivered on request to those to whom they are written.

The pleasures of the meeting commence to-day (Thursday), when at 2.30 a party will be taken over the dockyard and battleships. A garden-party is to be given this afternoon by Sir John and Lady Brickwood at their beautiful residence in the town. In the evening the Mayor will give a reception at the South Parade Pier, which is the property of the Corporation.

On Friday afternoon there will be a special visit to the new filtration works of the Borough of Portsmouth Water Company, and Saturday will be entirely devoted to all-day excursions, including two to the Isle of Wight, and three drives in the South Downs, starting from Chichester, to which city there will be a special train. The drives are to (1) Kingly Vale, West Dean, and Goodwood; (2) Boxgrove Priory and Arundel Castle; (3) Bignor (with the Roman remains) and Parham Park.

On Sunday the Bishop of Winchester is to preach at the Portsea parish church, and on Tuesday the Mayor will entertain the members at a garden-party. In addition, the naval authorities have organised a naval display in Stokes' Bay, consisting of an attack by torpedo-boat destroyers and submarines. Visitors should not neglect a visit to the old *Victory*, one of the most interesting "links with the past" in existence, and a full description of which, written by Mr. W. L. Wyllie, R.A., will be found in an interesting little handbook to Portsmouth which will be presented to members.

INAUGURAL ADDRESS BY PROF. SIR. WILLIAM RAMSAY, K.C.B., PH.D., LL.D., D.Sc., M.D., F.R.S., PRESIDENT.

IT is now eighty years since this Association first met at York, under the presidency of Earl Fitzwilliam. The object of the Association was then explicitly stated:—"To give a stronger impulse and a more systematic direction to scientific inquiry, to promote the intercourse of those who cultivate science in different parts of the British Empire with one another and with foreign philosophers, to obtain a more general attention to the objects of science and a removal of any disadvantages of a public kind which impede its progress."

In 1831 the workers in the domain of science were relatively few. The Royal Society, which was founded by Dr. Willis, Dr. Wilkins, and others, under the name of the "Invisible, or Philosophical College," about the year 1645, and which was incorporated in December, 1660, with the approval of King Charles II., was almost the only meeting-place for those interested in the progress of science; and its Philosophical Transactions, begun in March, 1664–5, almost the only medium of publication. Its character was described in the following words of a contemporary poem:—

"This noble learned Corporation
Not for themselves are thus combined
To prove all things by demonstration,
But for the public good of the nation,
And general benefit of mankind."

The first to hive off from the Royal Society was the Linnean Society for the promotion of botanical studies, founded in 1788 by Sir James Edward Smith, Sir Joseph Banks, and other Fellows of the Royal Society; in 1807 it was followed by the Geological Society; at a later date the Society of Antiquaries, the Chemical, the Zoological, the Physical, the Mathematical, and many other Societies were founded. And it was felt by those capable of forming a judgment that, as well expressed by Lord Playfair at Aberdeen in 1885, "Human progress is so identified with scientific thought, both in its conception and realisation, that it seems as if they were alternative terms in the history of civilisation." This is only an echo through the ages of an utterance of the great Englishman, Roger Bacon, who wrote in 1250 A.D.: "Experimental science has three great prerogatives over all other sciences: it verifies conclusions by direct experiment; it discovers truths which they could never reach; and it investigates the secrets of Nature, and opens to us a knowledge of the past and of the future."

The world has greatly changed since 1831; the spread of railways and the equipment of numerous lines of steamships have contributed to the peopling of countries at that time practically uninhabited. Moreover, not merely has travelling been made almost infinitely easier, but communication by post has been enormously expedited and cheapened; and the telegraph, the telephone, and wireless telegraphy have simplified as well as complicated human existence. Furthermore, the art of engineering has made such strides that the question "Can it be done?" hardly arises, but rather "Will it pay to do it?" In a word, the human race has been familiarised with the applications of science; and men are ready to believe almost anything if brought forward in its name.

Education, too, in the rudiments of science has been introduced into almost all schools; young children are taught the elements of physics and chemistry. The institution of a Section for Education in our Association (L) has had for its object the organising of such instruction, and much useful advice has been proffered. The problem is, indeed, largely an educational one; it is being solved abroad in various ways—in Germany and in most European States by elaborate Governmental schemes dealing with elementary and advanced instruction, literary, scientific, and technical; and in the United States and in Canada by the far-sightedness of the people: both employers and employees recognise the value of training and of originality, and on both sides sacrifices are made to ensure efficiency.

In England we have made technical education a local, not an Imperial, question; instead of half a dozen first-rate institutions of University rank, we have a hundred, in which the institutions are necessarily understaffed, in which the staffs are mostly overworked and underpaid; and the training given is that, not for captains of industry, but for workmen and foremen. "Efficient captains cannot be replaced by a large number of fairly good corporals." Moreover, to induce scholars to enter these institutions, they are bribed by scholarships, a form of pauperism practically unknown in every country but our own; and to crown the edifice, we test results by examinations of a kind not adapted to gauge originality and character (if, indeed, these can ever be tested by examination), instead of, as on the Continent and in America, trusting the teachers to form an honest estimate of the capacity and ability of each student, and awarding honours accordingly.

The remedy lies in our own hands. Let me suggest that we exact from all gainers of University scholarships an undertaking that, if and when circumstances permit, they will repay the sum which they have received as a scholarship, bursary, or fellowship. It would then be possible for an insurance company to advance a sum representing the capital value, viz. 7,464,931*l*., of the scholarships, reserving, say, twenty per cent. for non-payment, the result of mishap or death. In this way a sum of over six million pounds, of which the interest is now expended on scholarships, would be available for University purposes. This is about one-fourth of the sum of twenty-four millions stated by Sir Norman Lockyer at the Southport meeting as necessary to place our University education on a satisfactory basis. A large part of the income of this sum should be spent in increasing the emoluments of the chairs; for, unless the income of a professor is made in some degree commensurate with the earnings of a professional man who has succeeded in his profession, it is idle to suppose that the best brains will be attracted to the teaching profession. And it follows that unless the teachers occupy the first rank, the pupils will not be stimulated as they ought to be.

Again, having made the profession of a teacher so lucrative as to tempt the best intellects in the country to enter it, it is clear that such men are alone capable of testing their pupils. The modern system of "external examinations," known only in this country, and answerable for much of its lethargy, would disappear; schools of thought would arise in all subjects, and the intellectual as well as the industrial prosperity of our nation would be assured. As things are, can we wonder that as a nation we are not scientific? Let me recommend those of my hearers who are interested in the matter to read a recent report on Technical Education by the Science Guild.

I venture to think that, in spite of the remarkable progress of science and of its applications, there never was a time when missionary effort was more needed. Although most people have some knowledge of the results of scientific inquiry, few, very few, have entered into its spirit. We all live in hope that the world will grow better as the years roll on. Are we taking steps to secure the improvement of the race? I plead for recognition of the fact that progress in science does not only consist in accumulating information which may be put to practical use, but in developing a spirit of prevision, in taking thought for the morrow; in attempting to forecast the future, not by vague surmise, but by orderly marshalling of facts, and by deducing from them their logical outcome; and chiefly in endeavouring to control conditions which may be utilised for the lasting good of our people. We must cultivate a belief in the "application of trained intelligence to all forms of national activity."

The Council of the Association has had under consideration the formation of a Section of Agriculture. For some years this important branch of applied science, borrowing as it does from botany, from physics, from chemistry, and from economics, has in turn enjoyed the hospitality of each of these sections, itself having been made a sub-section of one of these more definite sciences. It is proposed this year to form an Agricultural Section. Here there is need of missionary effort; for our visits to our colonies have convinced many of us that much more is being done for the farmer in the newer parts of the British Empire than at home. Agriculture is, indeed, applied botany, chemistry, entomology, and economics, and has as much right to independent treatment as has engineering, which may be strictly regarded as applied physics.

The question has often been debated whether the present method of conducting our proceedings is the one best adapted to gain our ends. We exist professedly "to give a stronger impulse and a more systematic direction to scientific inquiry." The Council has had under consideration various plans framed with the object of facilitating our work, and the result of its deliberations will be brought under your attention at a later date. To my mind, the greatest benefit bestowed on science by our meetings is the opportunity which they offer for friendly and unrestrained intercourse, not merely between those following different branches of science, but also with persons who, though not following science professionally, are interested in its problems. Our meetings also afford an opportunity for younger men to make the acquaintance of older men. I am afraid that we who are no longer in the spring of our lifetime, perhaps from modesty, perhaps through carelessness, often do not sufficiently realise how stimulating to a young worker a little sympathy can be; a few words of encouragement go a long way. I have in my mind words which encouraged me as a young man, words spoken by the leaders of Associations now long past—by Playfair, by Williamson, by Frankland, by Kelvin, by Stokes, by Francis Galton, by Fitzgerald, and many others. Let me suggest to my older scientific colleagues that they should not let such pleasant opportunities slip.

Since our last meeting the Association has to mourn the loss by death of many distinguished members. Among these are:—

Dr. John Beddoe, who served on the Council from 1870 to 1875, has recently died at a ripe old age, after having achieved a world-wide reputation by his magnificent work in the domain of anthropology.

Sir Rubert Boyce, called away at a comparatively early age in the middle of his work, was for long a colleague of mine at University College, and was one of the staff of the Royal Commission on Sewage Disposal. The service he rendered science in combating tropical diseases is well known.

Sir Francis Galton died at the beginning of the year at the advanced age of eighty-nine. His influence on science has been characterised by Prof. Karl Pearson in his having maintained the idea that exact quantitative methods could —nay, must—be applied to many branches of science which had been held to be beyond the field of either mathematical or physical treatment. Sir Francis was General Secretary of this Association from 1863 to 1868; he was President of Section E in 1862, and again in 1872; he was President of Section H in 1885; but, although often asked to accept the office of President of the Association, his consent could never be obtained. Galton's name will always be associated with that of his friend and relative, Charles Darwin, as one of the most eminent and influential of English men of science.

Prof. Thomas Rupert Jones, also, like Galton, a member of this Association since 1860, and in 1891 President of the Geological Section, died in April last at the advanced age of ninety-one. Like Dr. Beddoe, he was a medical man with wide scientific interests. He became a distinguished geologist, and for many years edited the Quarterly Journal of the Geological Society.

Prof. Story Maskelyne, at one time a diligent frequenter of our meetings, and a member of the Council from 1874 to 1880, was a celebrated mineralogist and crystallographer. He died at the age of eighty-eight. The work which he did in the University of Oxford and at the British Museum is well known. In his later life he entered Parliament.

Dr. Johnstone Stoney, President of Section A in 1897, died on July 1, in his eighty-sixth year. He was one of the originators of the modern view of the nature of electricity, having given the name "electron" to its unit as far back as 1874. His investigations dealt with spectroscopy and allied subjects, and his philosophic mind led him to publish a scheme of ontology which, I venture to think, must be acknowledged to be the most important work which has ever been done on that difficult subject.

Among our corresponding members we have lost Prof. Bohr, of Copenhagen; Prof. Brühl, of Heidelberg; Hofrat Dr. Caro, of Berlin; Prof. Fittig, of Strassburg; and Prof. van 't Hoff, of Berlin. I cannot omit to mention that veteran of science Prof. Cannizzaro, of Rome, whose work in the middle of last century placed chemical science on the firm basis which it now occupies.

I knew all these men, some of them intimately; and, if I have not ventured on remarks as to their personal qualities, it is because it may be said of all of them that they fought a good fight and maintained the faith that only by patient and unceasing scientific work is human progress to be hoped for.

It has been the usual custom of my predecessors in office either to give a summary of the progress of science within the past year or to attempt to present in intelligible language some aspect of the science in which they have themselves been engaged. I possess no qualifications for the former course, and I therefore ask you to bear with me while I devote some minutes to the consideration of ancient and modern views regarding the chemical elements. To many in my audience part of my story will prove an oft-told tale; but I must ask those to excuse me, in order that it may be in some wise complete.

In the days of the early Greeks the word "element" was applied rather to denote a property of matter than one of its constituents. Thus, when a substance was said to contain fire, air, water, and earth (of which terms a childish game doubtless once played by all of us is a relic), it probably meant that they partook of the nature of the so-called elements. Inflammability showed the presence of concealed fire; the escape of "airs" when some substances are heated or when vegetable or animal matter is distilled no doubt led to the idea that these airs were imprisoned in the matters from which they escaped; hardness and permanence were ascribed to the presence of earth, while liquidity and fusibility were properties conveyed by the presence of concealed water. At a later date the "Spagyrics" added three "hypostatical principles" to the quadrilateral; these were "salt," "sulphur," and "mercury." The first conveyed solubility, and fixedness in fire; the second, inflammability; and the third, the power which some substances manifest of producing a liquid, generally termed "phlegm," on application of heat, or of themselves being converted into the liquid state by fusion.

It was Robert Boyle, in his "Skeptical Chymist," who first controverted these ancient and mediæval notions, and who gave to the word "element" the meaning that it now possesses—the constituent of a compound. But in the middle of the seventeenth century chemistry had not advanced far enough to make his definition useful, for he was unable to suggest any particular substance as elementary. And, indeed, the main tenet of the doctrine of "phlogiston," promulgated by Stahl in the eighteenth century, and widely accepted, was that all bodies capable of burning or of being converted into a "calx," or earthy powder, did so in virtue of the escape of a subtle fluid from their pores; this fluid could be restored to the "calces" by heating them with other substances rich in phlogiston, such as charcoal, oil, flour, and the like. Stahl, however false his theory, had at least the merit of having constructed a reversible chemical equation:—

$$\text{Metal} - \text{phlogiston} = \text{Calx}; \quad \text{Calx} + \text{phlogiston} = \text{Metal}.$$

It is difficult to say when the first element was known to be an element. After Lavoisier's overthrow of the phlogistic hypothesis, the part played by oxygen, then recently discovered by Priestley and Scheele, came prominently forward. Loss of phlogiston was identified with oxidation; gain of phlogiston with loss of oxygen. The scheme of nomenclature ("Méthode de Nomenclature chimique"), published by Lavoisier in conjunction with Guyton de Morveau, Berthollet, and Fourcroy, created a system of chemistry out of a wilderness of isolated facts and descriptions. Shortly after, in 1789, Lavoisier published his "Traité de Chimie," and in the preface the words occur: "If we mean by 'elements' the simple and indivisible molecules of which bodies consist, it is probable that we do not know them; if, on the other hand, we mean the last term in analysis, then every substance which we have not been able to decompose is for us an element; not that we can be certain that bodies which we regard as simple are not themselves composed of two or even a larger number of elements, but because these elements can never be separated, or rather, because we have no means of separating them, they act, so far as we can judge, as elements; and we cannot call them 'simple' until experiment and observation shall have furnished a proof that they are so."

The close connection between "crocus of Mars" and metallic iron, the former named by Lavoisier "oxyde de fer," and similar relations between metals and their oxides, made it likely that bodies which reacted as oxides in dissolving in acids and forming salts must also possess a metallic substratum. In October, 1807, Sir Humphry Davy proved the correctness of this view for soda and potash by his famous experiment of splitting these bodies by a powerful electric current into oxygen and hydrogen, on the one hand, and the metals sodium and potassium on the other. Calcium, barium, strontium, and magnesium were added to the list as constituents of the oxides, lime, barytes, strontia, and magnesia. Some years later Scheele's "dephlogisticated marine acid," obtained by heating pyrolusite with "spirit of salt," was identified by Davy as in all likelihood elementary. His words are: "All the conclusions which I have ventured to make respecting the undecompounded nature of oxymuriatic gas are, I conceive, entirely confirmed by these new facts." "It has been judged most proper to suggest a name founded upon one of its obvious and characteristic properties, its colour, and to call it chlorine." The subsequent discovery of iodine by Courtois in 1812, and of bromine by Balard in 1826, led to the inevitable conclusion that fluorine, if isolated, should resemble the other halogens in properties, and much later, in the able hands of Moissan, this was shown to be true.

The modern conception of the elements was much strengthened by Dalton's revival of the Greek hypothesis of the atomic constitution of matter, and the assigning to each atom a definite weight. This momentous step for the progress of chemistry was taken in 1803; the first account of the theory was given to the public, with Dalton's consent, in the third edition of Thomas Thomson's "System of Chemistry" in 1807; it was subsequently elaborated in the first volume of Dalton's own "System of Chemical Philosophy," published in 1808. The notion that compounds consisted of aggregations of atoms of elements united in definite or multiple proportions, familiarised the world with the conception of elements as the bricks of which the Universe is built. Yet the more daring spirits of that day were not without hope that the elements themselves might prove decomposable. Davy, indeed, went so far as to write in 1811: "It is the duty of the chemist to be bold in pursuit; he must recollect how contrary knowledge is to what appears to be experience. . . . To inquire whether the elements be capable of being composed and decomposed is a grand object of true philosophy." And Faraday, his great pupil and successor, at a later date, 1815, was not behind Davy in his aspirations when he wrote: "To decompose the metals, to re-form them, and to realise the once absurd notion of transformation—these are the problems now given to the chemist for solution."

Indeed, the ancient idea of the unitary nature of matter was in those days held to be highly probable. For attempts were soon made to demonstrate that the atomic weights were themselves multiples of that of one of the elements. At first the suggestion was that oxygen was the common basis; and later, when this supposition turned out to be untenable, the claims of hydrogen were brought forward by Prout. The hypothesis was revived in 1842, when Liebig and Redtenbacher, and subsequently Dumas, carried out a revision of the atomic weights of some of the commoner elements, and showed that Berzelius was in error in attributing to carbon the atomic weight 12·25 instead of 12·00. Of recent years a great advance in the accuracy of the determinations of atomic weights has been made, chiefly owing to the work of Richards and his pupils, of Gray, and of Guye and his collaborators, and every year an international committee publishes a table in which the most probable numbers are given on the basis of the atomic weight of oxygen being taken as sixteen. In the table for 1911, of eighty-one elements, no fewer than forty-three have recorded atomic weights within one-tenth of a unit above or below an integral number. My mathematical colleague, Karl Pearson, assures me that the probability against such a condition being fortuitous is 20,000 millions to one.

The relation between the elements has, however, been approached from another point of view. After preliminary suggestions by Döbereiner, Dumas, and others, John Newlands in 1862 and the following years arranged the elements in the numerical order of their atomic weights, and published in *The Chemical News* of 1863 what he termed his law of octaves—that every eighth element, like the octave of a musical note, is in some measure a repetition of its forerunner. Thus, just as C on the third space is the octave of C below the line, so potassium, in 1863 the eighth known element numerically above sodium, repeats the characters of sodium, not only in its physical properties—colour, softness, ductility, malleability, &c.—but also in the properties of its compounds, which, indeed, resemble each other very closely. The same fundamental notion was reproduced at a later date, and independently, by Lothar Meyer and Dmitri Mendeléeff; and to accentuate the recurrence of such similar elements in *periods*, the expression "the periodic system of arranging the elements" was applied to Newlands' arrangement in octaves. As everyone knows, by help of this arrangement Mendeléeff predicted the existence of then unknown elements, under the names of eka-boron, eka-aluminium, and eka-silicon, since named *scandium*, *gallium*, and *germanium*, by their discoverers, Cleve, Lecoq de Boisbaudran, and Winckler.

It might have been supposed that our knowledge of the elements was practically complete; that perhaps a few more might be discovered to fill the outstanding gaps in the periodic table. True, a puzzle existed, and still exists, in the classification of the "rare earths," oxides of metals occurring in certain minerals; these metals have atomic weights between 139 and 180, and their properties preclude their arrangement in the columns of the periodic table. Besides these, the discovery of the inert gases of the atmosphere, of the existence of which Johnstone Stoney's spiral curve, published in 1888, pointed a forecast, joined the elements like sodium and potassium, strongly electronegative, to those like fluorine and chlorine, highly electropositive, by a series of bodies electrically as well as chemically inert, and neon, argon, krypton, and xenon formed links between fluorine and sodium, chlorine and potassium, bromine and rubidium, and iodine and cæsium.

Including the inactive gases, and adding the more recently discovered elements of the rare earths, and radium, of which I shall have more to say presently, there are eighty-four definite elements, all of which find places in the periodic table if merely numerical values be considered. Between lanthanum, with atomic weight 139, and tantalum, 181, there are in the periodic table seventeen spaces; and although it is impossible to admit, on account of their properties, that the elements of the rare earths can be distributed in successive columns (for they all resemble lanthanum in properties), yet there are now fourteen such elements; and it is not improbable that other three will be separated from the complex mixture of their oxides by further work. Assuming that the metals of the rare earths fill these seventeen spaces, how many still remain to be filled? We will take for granted that the atomic weight of uranium, 238·5, which is the highest known, forms an upper limit not likely to be surpassed. It is easy to count the gaps; there are eleven.

But we are confronted by an *embarras de richesse*. The discovery of radio-activity by Henri Becquerel, of radium by the Curies, and the theory of the disintegration of the radio-active elements, which we owe to Rutherford and Soddy, have indicated the existence of no fewer than twenty-six elements hitherto unknown. To what places in the periodic table can they be assigned?

But what proof have we that these substances are elementary? Let us take them in order.

Beginning with radium, its salts were first studied by Madame Curie; they closely resemble those of barium—sulphate, carbonate, and chromate insoluble; chloride and bromide similar in crystalline form to chloride and bromide of barium; metal, recently prepared by Madame Curie, white, attacked by water, and evidently of the type of barium. The atomic weight, too, falls into its place; as determined by Madame Curie and by Thorpe, it is 89·5 units higher than that of barium; in short, there can be no doubt that radium fits the periodic table, with an atomic weight of about 226·5. It is an undoubted element.

But it is a very curious one. For it is *unstable*. Now, stability was believed to be the essential characteristic of an element. Radium, however, disintegrates—that is, changes into other bodies, and at a constant rate. If 1 gram of radium is kept for 1760 years, only half a gram will be left at the end of that time; half of it will have given other products. What are they? We can answer that question. Rutherford and Soddy found that it gives a condensable gas, which they named "radium emanation"; and Soddy and I, in 1903, discovered that, in addition, it evolves helium, one of the inactive series of gases, like argon. Helium is an undoubted element, with a well-defined spectrum; it belongs to a well-defined series. And radium emanation, which was shown by Rutherford and Soddy to be incapable of chemical union, has been liquefied and solidified in the laboratory of University College, London; its spectrum has been measured, and its density determined. From the density the atomic weight can be calculated, and it corresponds with that of a congener of argon, the whole series being: helium, 4; neon, 20; argon, 40; krypton, 83; xenon, 130; unknown, about 178; and niton (the name proposed for the emanation to recall its connection with its congeners and its phosphorescent properties), about 222·4. The formation of niton from radium would therefore be represented by the equation: radium (226·4) = helium (4) + niton (222·4).

Niton, in its turn, disintegrates, or decomposes, and at a rate much more rapid than the rate of radium; half of it has changed in about four days. Its investigation, therefore, had to be carried out very rapidly, in order that its decomposition might not be appreciable while its properties were being determined. Its product of change was named by Rutherford "radium A," and it is undoubtedly deposited from niton as a metal, with simultaneous evolution of helium; the equation would therefore be:

niton (222·4) = helium (4) + radium A (218·4).

But it is impossible to investigate radium A chemically, for in three minutes it has half changed into another solid substance, radium B, again giving off helium. This change would be represented by the equation:

radium A (218·4) = helium (4) + radium B (214·4).

Radium B, again, can hardly be examined chemically, for in twenty-seven minutes it has half changed into radium C^1. In this case, however, no helium is evolved; only atoms of negative electricity, to which the name "electrons" has been given by Dr. Stoney, and these have minute weight which, although approximately ascertainable, at present has defied direct measurement. Radium C^1 has a half-life of 19·5 minutes, too short, again, for chemical investigation; but it changes into radium C^2, and in doing so each atom parts with a helium atom, hence the equation:

radium C^1 (214·4) = helium (4) + radium C^2 (210·4).

In 2·5 minutes radium C^2 is half gone, parting with electrons, forming radium D. Radium D gives the chemist a chance, for its half-life is no less than sixteen and a half years. Without parting with anything detectable, radium D passes into radium E, of which the half-life period is five days; and, lastly, radium E changes spontaneously into radium F, the substance to which Madame Curie gave the name "polonium," in allusion to her native country, Poland. Polonium, in its turn, is half changed in 140 days, with loss of an atom of helium, into an unknown metal, supposed to be possibly lead. If that be the case, the equation would run:

polonium (210·4) = helium (4) + lead (206·4).

But the atomic weight of lead is 207·1, and not 206·4; however, it is possible that the atomic weight of radium is 227·1, and not 226·4.

We have another method of approaching the same subject. It is practically certain that the progenitor of radium is uranium, and that the transformation of uranium into radium involves the loss of three α particles, that is, of three atoms of helium. The atomic weight of helium may be taken as one of the most certain; it is 3·994, as determined by Mr. Watson in my laboratories. Three atoms would therefore weigh 11·98, practically 12. There is, however, still some uncertainty in the atomic weight of uranium; Richards and Merigold make it 239·4, but the general mean, calculated by Clarke, is 239·0. Subtracting 12 from these numbers, we have the values 227·0, and 227·4 for the atomic weight of radium. It is as yet impossible to draw any certain conclusion.

The importance of the work, which will enable a definite and sure conclusion to be drawn, is this: For the first time, we have accurate knowledge as to the descent of some of the elements. Supposing the atomic weight of uranium to be certainly 239, it may be taken as proved that, in losing three atoms of helium, radium is produced, and, if the change consists solely in the loss of the three atoms of helium, the atomic weight of radium must necessarily be 227. But it is known that β rays, or electrons, are also parted with during this change; and electrons have weight. How many electrons are lost is unknown; therefore, although the weight of an electron is approximately known, it is impossible to say how much to allow for in estimating the atomic weight of radium. But it is possible to solve this question indirectly by determining exactly the atomic weights of radium and of uranium; the difference between the atomic weight of radium *plus* 12, *i.e.* plus the weight of three atoms of helium, and that of uranium, will give the weight of the number of electrons which escape. Taking the most probable numbers available, viz. 239·4 for uranium and 226·8 for radium, and adding 12 to the latter, the weight of the escaping electrons would be 0·6.

The correct solution of this problem would in great measure clear up the mystery of the irregularities in the periodic table, and would account for the deviations from Prout's Law, that the atomic weights are multiples of some common factor or factors. I also venture to suggest that it would throw light on allotropy, which in some cases, at least, may very well be due to the loss or gain of electrons, accompanied by a positive or negative heat-change. Incidentally, this suggestion would afford places in the periodic table for the somewhat overwhelming number of pseudo-elements the existence of which is made practically certain by the disintegration hypothesis. Of the twenty-six elements derived from uranium, thorium, and actinium, ten, which are formed by the emission of electrons alone, may be regarded as allotropes or pseudo-elements; this leaves sixteen, for which sixteen or seventeen gaps would appear to be available in the periodic table, provided the reasonable supposition be made that a second change in the length of the periods has taken place. It is, above all things, certain that it would be a fatal mistake to regard the existence of such elements as irreconcilable with the periodic arrangement, which has rendered to systematic chemistry such signal service in the past.

Attention has repeatedly been drawn to the enormous quantity of energy stored up in radium and its descendants. That, in its emanation, niton is such that if what it parts with as heat during its disintegration were available, it would be equal to three and a half million times the energy available by the explosion of an equal volume of detonating gas—a mixture of one volume of oxygen with two volumes of hydrogen. The major part of this energy comes, apparently, from the expulsion of particles (that is, of atoms of helium) with enormous velocity. It is easy to convey an idea of this magnitude in a form more realisable by giving it a somewhat mechanical turn. Suppose that the energy in a ton of radium could be utilised in thirty years, instead of being evolved at its invariable slow rate of 1760 years for half-disintegration, it would suffice to propel a ship of 15,000 tons, with engines of 15,000 horse-power, at the rate of 15 knots an hour for thirty years—practically the lifetime of the ship. To do this actually requires a million and a half tons of coal.

It is easily seen that the virtue of the energy of the radium consists in the small weight in which it is contained; in other words, the radium-energy is in an enormously concentrated form. I have attempted to apply the energy contained in niton to various purposes; it decomposes water, ammonia, hydrogen chloride, and carbon dioxide each into its constituents; further experiments on its action on salts of copper appeared to show that the metal copper was converted partially into lithium, a metal of the sodium column; and similar experiments, of which there is not time to speak, indicate that thorium, zirconium, titanium, and silicon are degraded into carbon; for solutions of compounds of these, mixed with niton, invariably generated carbon dioxide, while cerium, silver, mercury, and some other metals gave none. One can imagine the very atoms themselves, exposed to bombardment by enormously quickly moving helium atoms, failing to withstand the impacts. Indeed, the argument *à priori* is a strong one; if we know for certain that radium and its descendants decompose spontaneously, evolving energy, why should not other more stable elements decompose when subjected to enormous strains?

This leads to the speculation whether, if elements are capable of disintegration, the world may not have at its disposal a hitherto unsuspected source of energy. If radium were to evolve its stored-up energy at the same rate that gun-cotton does, we should have an undreamt-of explosive; could we control the rate we should have a useful and potent source of energy, provided always that a sufficient supply of radium were forthcoming. But the supply is certainly a very limited one; and it can be safely affirmed that the production will never surpass half an ounce a year. If, however, the elements which we have been used to consider as permanent are capable of changing with evolution of energy, if some form of catalyser could be discovered which would usefully increase their almost inconceivably slow rate of change, then it is not too much to say that the whole future of our race would be altered.

The whole progress of the human race has indeed been due to individual members discovering means of concentrating energy and of transforming one form into another. The carnivorous animals strike with their paws and crush with their teeth; the first man who aided his arm with a stick in striking a blow discovered how to concentrate his small supply of kinetic energy; the first man who used a spear found that its sharp point in motion represented a still more concentrated form; the arrow was a further advance, for the spear was then propelled by mechanical means; the bolt of the crossbow, the bullet shot forth by compressed hot gas, first derived from black powder, later from high explosives, all these represent progress. To take another sequence: the preparation of oxygen by Priestley applied energy to oxide of mercury in the form of heat; Davy improved on this when he concentrated electrical energy into the tip of a thin wire by aid of a powerful battery, and isolated potassium and sodium.

Great progress has been made during the past century in effecting the conversion of one form of energy into others with as little useless expenditure as possible. Let me illustrate by examples: A good steam engine converts about one-eighth of the potential energy of the fuel into useful work; seven-eighths are lost as unused heat and useless friction. A good gas engine utilises more than one-third of the total energy in the gaseous fuel; two-thirds are uneconomically expended. This is a universal proposition; in order to effect the conversion from one form of energy into another, some energy must be expended uneconomically. If A is the total energy which it is required to convert, if B is the energy into which it is desired to convert A, then a certain amount of energy, C, must be expended to effect the conversion. In short, $A=B+C$. It is eminently desirable to keep C, the useless expenditure, as small as possible; it can never equal zero, but it can be made small. The ratio of C to B (the economic coefficient) should therefore be as large as is attainable.

The middle of the nineteenth century will always be noted as the beginning of the golden age of science, the epoch when great generalisations were made, of the highest importance on all sides, philosophical, economic, and scientific. Carnot, Clausius, Helmholtz, Julius Robert Mayer abroad, and the Thomsons, Lord Kelvin and his brother James, Rankine, Tait, Joule, Clerk Maxwell, and many others at home, laid the foundations on which the splendid structure has been erected. That the latent energy of fuel can be converted into energy of motion by means of the steam engine is what we owe to Newcomen and Watt; that the kinetic energy of the fly-wheel can be transformed into electrical energy was due to Faraday, and to him, too, we are indebted for the re-conversion of electrical energy into mechanical work; and it is this power of work which gives us leisure, and which enables a small country like ours to support the population which inhabits it.

I suppose that it will be generally granted that the Commonwealth of Athens attained a high-water mark in literature and thought which has never yet been surpassed. The reason is not difficult to find; a large proportion of its people had ample leisure, due to ample means; they had time to think and time to discuss what they thought. How was this achieved? The answer is simple: each Greek Freeman had, on an average, at least five helots who did his bidding, who worked his mines, looked after his farm, and, in short, saved him from manual labour. Now we in Britain are much better off; the population of the British Isles is in round numbers 45 millions; there are consumed in our factories at least 50 million tons of coal annually, and "it is generally agreed that the consumption of coal per indicated horse-power per hour is, on an average, about 5 lb." (Royal Commission on Coal Supplies, Part I.). This gives seven million horse-power per year. How many man-power are equal to a horse-power? I have arrived at an estimate thus: A Bhutanese can carry 230 lb. *plus* his own weight, in all 400 lb., up a hill 4000 feet high in eight hours; this is equivalent to about one twenty-fifth of a horse-power; seven million horse-power are therefore about 175 million man-power. Taking a family as consisting, on the average, of five persons, our 45 millions would represent nine million families, and dividing the total man-power by the number of families, we must conclude that each British family has, on the average, nearly twenty "helots" doing his bidding, instead of the five of the Athenian family. We do not appear, however, to have gained more leisure thereby; but it is this that makes it possible for the British Isles to support the population which it does.

We have in this world of ours only a limited supply of stored-up energy, in the British Isles a very limited one—namely, our coalfields. The rate at which this supply is being exhausted has been increasing very steadily for the last forty years, as anyone can prove by mapping the data given on p. 27, table D, of the General Report of the Royal Commission on Coal Supplies (1906). In 1870 110 million tons were mined in Great Britain, and ever since the amount has increased by three and a third million tons a year. The available quantity of coal in the proved coalfields is very nearly 100,000 million tons; it is easy to calculate that if the rate of working increases as it is doing, our coal will be completely exhausted in 175 years. But, it will be replied, the rate of increase will slow down. Why? It has shown no sign whatever of slackening during the last forty years. Later, of course, it must slow down, when coal grows dearer owing to approaching exhaustion. It may also be said that 175 years is a long time; why, I myself have seen a man whose father fought in the '45 on the Pretender's side, nearly 170 years ago! In the life of a nation 175 years is a span.

This consumption is still proceeding at an accelerated rate. Between 1905 and 1907 the amount of coal raised in the United Kingdom increased from 236 to 268 million tons, equal to six tons per head of the population, against three and a half tons in Belgium, two and a half tons in Germany, and one ton in France. Our commercial supremacy and our power of competing with other European nations are obviously governed, so far as we can see, by the relative price of coal; and when our prices rise, owing to the approaching exhaustion of our supplies, we may look forward to the near approach of famine and misery.

Having been struck some years ago with the optimism of my non-scientific friends as regards our future, I suggested that a committee of the British Science Guild should be formed to investigate our available sources of energy. This Guild is an organisation, founded by Sir Norman Lockyer after his tenure of the Presidency of this Association, for the purpose of endeavouring to impress on our people and their Government the necessity of viewing problems affecting the race and the State from the standpoint of science; and the definition of science in this, as in other connections, is simply the acquisition of knowledge, and orderly reasoning on experience already gained and on experiments capable of being carried out, so as to forecast and control the course of events, and, if possible, to apply this knowledge to the benefit of the human race.

The Science Guild has enlisted the services of a number of men, each eminent in his own department, and each has now reported on the particular source of energy of which he has special knowledge.

Besides considering the uses of coal and its products, and how they may be more economically employed, in which branches the Hon. Sir Charles Parsons, Mr. Dugald Clerk, Sir Boverton Redwood, Dr. Beilby, Dr. Hele-Shaw, Prof. Vivian Lewes and others have furnished reports, the following sources of energy have been brought under review: the possibility of utilising the tides; the internal heat of the earth; the winds; solar heat; water-power; the extension of forests, and the use of wood and peat as fuels; and, lastly, the possibility of controlling the undoubted, but almost infinitely slow, disintegration of the elements, with the view of utilising their stored-up energy.

However interesting a detailed discussion of these possible sources of energy might be, time prevents my dwelling on them. Suffice it to say that the Hon. R. J. Strutt has shown that in this country, at least, it would be impracticable to attempt to utilise terrestrial heat from bore-holes; others have deduced that from the tides, the winds, and water-power small supplies of energy are no doubt obtainable, but that, in comparison with that derived from the combustion of coal, they are negligible; nothing is to be hoped for from the direct utilisation of solar heat in this temperate and uncertain climate, and it would be folly to consider seriously a possible supply of energy in a conceivable acceleration of the liberation of energy by atomic change. It looks utterly improbable, too, that we shall ever be able to utilise the energy due to the revolution of the earth on her axis, or to her proper motion round the sun.

Attention should undoubtedly be paid to forestry and to the utilisation of our stores of peat. On the Continent, the forests are largely the property of the State; it is unreasonable, especially in these latter days of uncertain tenure of property, to expect any private owner of land to invest money in schemes which would at best only benefit his descendants, but which, under our present trend of legislation, do not promise even that remote return. Our neighbours and rivals, Germany and France, spend annually 2,200,000*l*. on the conservation and utilisation of their forests; the net return is 6,000,000*l*. There is no doubt that we could imitate them with advantage. Moreover, an increase in our forests would bring with it an increase in our water-power, for without forest land rain rapidly reaches the sea, instead of distributing itself so as to keep the supply of water regular, and so more easily utilised.

Various schemes have been proposed for utilising our deposits of peat: I believe that in Germany the peat industry is moderately profitable; but our humid climate does not lend itself to natural evaporation of most of the large amount of water contained in peat, without which processes of distillation prove barely remunerative.

We must therefore rely chiefly on our coal reserve for our supply of energy, and for the means of supporting our population; and it is to the more economical use of coal that we must look in order that our life as a nation may be prolonged. We can economise in many ways: By the substitution of turbine engines for reciprocating engines, thereby reducing the coal required per horse-power from 4 to 5 lb. to 1½ or 2 lb.; by the further replacement of turbines by gas engines, raising the economy to 30 per cent. of the total energy available in the coal, that is, lowering the coal consumption per horse-power to 1 or 1¼ lb.; by creating the power at the pit-mouth, and distributing it electrically, as is already done in the Tyne district. Economy can also be effected in replacing "beehive" coke ovens by recovery ovens; this is rapidly being done; and Dr. Beilby calculates that in 1909 nearly six million tons of coal, out of a total of sixteen to eighteen millions, were coked in recovery ovens, thus effecting a saving of two to three million tons of fuel annually. Progress is also being made in substituting gas for coal or coke in metallurgical, chemical, and other works. But it must be remembered that for economic use gaseous fuel must not be charged with the heavy costs of piping and distribution.

The domestic fire problem is also one which claims our instant attention. It is best grappled with from the point of view of smoke. Although the actual loss of thermal energy in the form of smoke is small—at most less than a half per cent. of the fuel consumed—still the presence of smoke is a sign of waste of fuel and careless stoking. In works, mechanical stokers, which ensure regularity of firing and complete combustion of fuel, are more and more widely replacing hand-firing. But we are still utterly wasteful in our consumption of fuel in domestic fires. There is probably no single remedy applicable; but the introduction of central heating, of gas fires, and of grates which permit of better utilisation of fuel will all play a part in economising our coal. It is open to argument whether it might not be wise to hasten the time when smoke is no more by imposing a sixpenny fine for each offence; an instantaneous photograph could easily prove the offence to have been committed, and the imposition of the fine might be delayed until three warnings had been given by the police.

Now I think that what I wish to convey will be best expressed by an allegory. A man of mature years, who has surmounted the troubles of childhood and adolescence without much disturbance to his physical and mental state, gradually becomes aware that he is suffering from loss of blood; his system is being drained of this essential to life and strength. What does he do? If he is sensible he calls in a doctor, or perhaps several, in consultation; they ascertain the seat of the disease, and diagnose the cause. They point out that while consumption of blood is necessary for healthy life, it will lead to a premature end if the constantly increasing drain is not stopped. They suggest certain precautionary measures; and if he adopts them he has a good chance of living at least as long as his contemporaries; if he neglects them his days are numbered.

That is our condition as a nation. We have had our consultation in 1903; the doctors were the members of the Coal Commission. They showed the gravity of our case, but we have turned a deaf ear.

It is true that the self-interest of coal consumers is slowly leading them to adopt more economical means of turning coal into energy. But I have noticed, and frequently publicly announced, a fact which cannot but strike even the most unobservant. It is this: When trade is good, as it appears to be at present, manufacturers are making money; they are overwhelmed with orders, and have no inclination to adopt economies which do not appear to them to be essential, and the introduction of which would take thought and time, and which would withdraw the attention of their employees from the chief object of the business—how to make the most of the present opportunities. Hence improvements are postponed. When bad times come, then there is no money to spend on improvements; they are again postponed until better times arrive.

What can be done?

I would answer: Do as other nations have done and are doing; take stock annually. The Americans have a permanent Commission initiated by Mr. Roosevelt, consisting of three representatives from each State, the sole object of which is to keep abreast with the diminution of the stores of natural energy, and to take steps to lessen its rate. This is a non-political undertaking, and one worthy of being initiated by the ruler of a great country. If the example is followed here the question will become a national one.

Two courses are open to us: first, the *laissez-faire* plan of leaving to self-interested competition the combating of waste; or second, initiating legislation which, in the interest of the whole nation, will endeavour to lessen the squandering of our national resources. This legislation may be of two kinds; penal, that is, imposing a penalty on wasteful expenditure of energy supplies; and helpful, that is, imparting information as to what can be done, advancing loans at an easy rate of interest to enable reforms to be carried out, and insisting on the greater prosperity which would result from the use of more efficient appliances.

This is not the place, nor is there the time, to enter into detail; the subject is a complicated one, and it will demand the combined efforts of experts and legislators for a generation; but if it be not considered with the definite intention of immediate action, we shall be held up to the deserved execration of our not very remote descendants.

The two great principles which I have alluded to in an earlier part of this address must not, however, be lost sight of; they should guide all our efforts to use energy economically. Concentration of energy in the form of electric current at high potential makes it possible to convey it for long distances through thin, and therefore comparatively inexpensive, wires; and the economic coefficient of the conversion of mechanical into electrical, and of electrical into mechanical, energy is a high one; the useless expenditure does not much exceed one-twentieth part of the energy which can be utilised. These considerations would point to the conversion at the pit-mouth of the energy of the fuel into electrical energy, using as an intermediary turbines, or preferably gas engines, and distributing the electrical energy to where it is wanted. The use of gas engines may, if desired, be accompanied by the production of half-distilled coal, a fuel which burns nearly without smoke, and one which is suitable for domestic fires, if it is found too difficult to displace them and to induce our population to adopt the more efficient and economical systems of domestic heating which are used in America and on the Continent. The increasing use of gas for factory, metallurgical, and chemical purposes points to the gradual concentration of works near the coal mines in order that the laying-down of expensive piping may be avoided.

An invention which would enable us to convert the energy of coal directly into electrical energy would revolutionise our ideas and methods, yet it is not unthinkable. The nearest practical approach to this is the Mond gas-battery, which, however, has not succeeded, owing to the imperfection of the machine.

In conclusion, I would put in a plea for the study of pure science, without regard to its applications. The discovery of radium and similar radio-active substances has widened the bounds of thought. While themselves, in all probability, incapable of industrial application, save in the domain of medicine, their study has shown us to what enormous advances in the concentration of energy it is permissible to look forward, with the hope of applying the knowledge thereby gained to the betterment of the whole human race. As charity begins at home, however, and as I am speaking to the *British* Association for the Advancement of Science, I would urge that our first duty is to strive for all which makes for the permanence of the British Commonweal, and which will enable us to transmit to our posterity a heritage not unworthy to be added to that which we have received from those who have gone before.

SECTION A.

MATHEMATICS AND PHYSICS.

OPENING ADDRESS BY PROF. H. H. TURNER, D.Sc., D.C.L., F.R.S., PRESIDENT OF THE SECTION.

The Characteristics of the Observational Sciences.

IT will doubtless startle my audience to hear that this Section has only once in its history been addressed by an astronomical President upon an astronomical topic. I hasten to admit that I am not using the term astronomical in its widest sense. Huxley once declared that there were only two sciences, Astronomy and Biology, and it is recorded that "the company" (which happened to be that of the Royal Astronomical Society Club) "agreed with him." One may agree with the company in assenting to the proposition in the sense in which it is obviously intended without losing the right to use the name astronomy in a more restricted sense when necessary; and at present I use it in its classical sense. At Brighton, in 1872, Dr. De La Rue addressed Section A on Astronomical Photography in words which are still worthy of attention, though they are all but forty years old; and this is the only instance I can find in the annals of the Section. There have, of course, been occasional astronomical Presidents such as Airy, Lord Rosse, and Dr. Robinson, but these presided in early days before the Address existed, or when it was brief and formal; and the only allusions to astronomical matters were the statements, by Robinson and Airy, of what the Association had done in subsidising the reduction of Lalande's observations and the Greenwich lunar observations. In 1887 Sir Robert Ball occupied this chair, but he selected from his ample scientific wardrobe the costume of a geometer, and left his astronomical dress at home. A great man whose death was announced almost as I was writing these words, Dr. Johnstone Stoney, spoke (in 1879 at Sheffield) of the valuable training afforded by the study of mechanics and of chemistry, with that keen insight which made him so valuable a member of our Section. Other Presidents whom we have been glad to welcome as astronomers at certain times and seasons did not choose the occasion of their presidency for any very definite manifestation of astronomical sympathy.

The Addresses of Sir George Darwin (in 1886) and of Prof. Love (in 1907) on the past history of our earth certainly have an astronomical bearing, but if we distinguish between the classical astronomy and its modern expansions they would be assigned to the latter rather than to the former; and so do the few astronomical allusions in Prof. Schuster's Address at Edinburgh in 1892. Even if we include, instead of excluding, all doubtful cases, there will still appear a curious neglect of astronomy by Section A in the last half-century, all the more curious when it is remarked that the neglect does not extend to the Association itself, seeing that there have been three Astronomical Presidents of the Association who had not been previously chosen to fill this chair. The neglect is not confined to astronomy, but extends, as some of us recently pointed out, to the other sciences of observation; and we thought that, as a corollary, it would be better for the Section to divide, in order that these sciences might not continue the struggle for existence in an atmosphere to which they were apparently ill-suited. But the Section decided against the suggestion, and I have no intention of appealing against the decision. This explicit statement will, I trust, suffice to prevent misunderstanding if I proceed to examine the possible causes of neglect—for I cannot but regard the record as significant of some cause which it will be well to recognise even if we cannot remove it. Personally I think the cause is not far to seek, and my hope is to make it manifest; but as the statement of it involves something in the nature of an accusation, I will beg leave to make it as gently as possible by using the words of others, especially of those against whom the mild accusation is to be made.

Let me begin by quoting from the admirable Address—none the less admirable because it was only one-quarter of the length to which we have become accustomed—delivered by my late Oxford colleague, the Rev. Bartholomew Price, at Oxford in 1860, wherein he referred to the constitution of this Section as follows:—

"The area of scientific research which this Section covers is very large, larger perhaps than that of any other; and its subjects vary so much that while to some of those who frequent this room certain papers may appear dull, yet to others they will be full of interest. Some of them possess, probably in the highest degree attainable by the human intellect, the characteristics of perfect and necessary science; while others are at present little more than a conglomeration of observations, made indeed with infinite skill and perseverance, and of the greatest value: capable probably in time of greater perfection, nay, perhaps of the most perfect forms, but as yet in their infancy, scarcely indicating the process by which that maturity will be arrived at and containing hardly the barest outline of their ultimate laws."

A little later in the Address Prof. Price made it quite clear which were the sciences "in their infancy."

"And finally we come to the facts of meteorology and its kindred subjects, many of which are scarcely yet brought within any law at all."

There is here much that will command ready and universal assent; but is there not also a rather unnecessary social scale? The science of planetary movement had not yet been "brought within any law at all" (as we now use the term) in Tycho Brahé's time; but was the astronomy of Tycho Brahé socially inferior to that of Kepler? It is difficult to fix the eye on such a question without its being caught by the splendour of Newton towering so near; and the idea of a scale descending from that great height is almost irresistibly suggested. But in spite of this grave difficulty, I ask whether there is of necessity any drop whatever from the plane of Kepler, who realised the laws, to that of Tycho, who never reached any suspicion of the true laws, but had nevertheless such faith in their existence that he cheerfully devoted his life to labours of which he never reaped the fruits? Is it not a dangerous doctrine that the work done previous to the formulation of a law is in any way inferior? Take the case of a man like Stephen Groombridge, who made thousands of accurate observations of stars in the early part of last century. Fifty years later something of the value of his work began to emerge from a comparison with later observations which showed what stars had moved and how; but it was not until nearly a century had elapsed that something about the laws of stellar movement was extracted from his patient work, combined with a repetition of similar works at Greenwich. *Then*, with the skilful assistance of Mr. Dyson and Mr. Eddington, Groombridge at last came into the fruits of his labours; but had he been asked during his lifetime for credentials in the shape of laws, on pain of being classed as an inferior in the social scientific scale, he would have been lamentably unprepared. Or consider the case of M. Teisserenc de Bort, when he began sending up his balloons. "Show me your laws," cries the mathematician. "But they are just what I hope to find," replies M. de Bort. "Yes, but surely you have formulated some law you wish to test?" pursues the invigilator. "How am I to give you proper scientific rank unless you can produce at least a tentative law?" "On the other hand I wish to keep a perfectly open mind," maintains M. de Bort. "Then I fear I cannot admit you to our class at present; you must join the infants' class, and I can only give you my best wishes that you may reach maturity some day." Unperturbed, M. de Bort continues to send up his balloons, and almost immediately discovers the great fact about the isothermal region which will be a permanent factor in the meteorology of the future. The mathematician is now ready to admit him, as a worthy person who has found a law about the constitution of the atmosphere. But was not the merit in sending up the balloons, whatever came of it? Is it not sometimes more courageous to take risks of failure? The mathematician, safe in his stronghold which possesses "probably in the highest degree attainable by the human intellect the characteristics of perfect and necessary science," is like a man who has inherited a good old-established business, and he has a distaste for the methods of those who have to try new ventures. No doubt many who make such trials fail; but, on the other hand, great fortunes have been made in that way.

It may seem, however, that too much is being deduced from a single quoted opinion, which may easily have been personal and not representative. Let me, therefore, take another which presents a different aspect of the same matter. I take the opening words of Sir G. H. Darwin's Address to this Section at Birmingham in 1886.

"A mere catalogue of facts, however well arranged, has never led to any important scientific generalisation. For in any subjects the facts are so numerous and many-sided that they only lead us to a conclusion when they are marshalled by the light of some leading idea. A theory is then a necessity for the advance of science, and we may regard it as the branch of a living tree, of which facts are the nourishment."

Those who have read the letters of Charles Darwin will recognise that this opinion was also held by the father, and may have been adopted by the son. It is no part of my purpose to raise any question of originality: I mention the point merely to take the opportunity it gives me of showing that I do not approach lightly an opinion held by two such men. With the utmost respect, I wish to question whether the criterion indicated goes deep enough. Often have we had ocular demonstration of the value of a theory in stimulating the advance of science; but is advance wholly dependent on the existence of a theory? I have tried to indicate already a deeper motive power by such instances as the work of Tycho, who had no theory, but who perceived the need of observation. And I will now definitely formulate the view that the perception of the need for observations, the faith that something will come of them, and the skill and energy to act on that faith—that these qualities, all of which are possessed by any observer worthy the name, have at least as much to do with the advance of Science as the formulation of a theory, even of a correct theory. The work of the observer is often forgotten—it lies at the root of the plant; it is easier to notice the theories which blossom and ultimately produce the fruit. But without the patient work of the observer underground there would be neither blossom nor fruit. It is also easy to fix attention on the mechanical nature of much observation; but this is not the principal feature of observing any more than is numerical computation of mathematics. There are men like Adams who perform gigantic numerical computations faultlessly, but there are others who would take equal rank as mathematicians who cannot do three additions correctly; and, again, others who could compute well and quickly, but prefer to hand over that part of their work to someone else. Similarly some great observers themselves look through the telescope, and some merely direct others how to do so; the spark of divine fire is not dependent on this detail, but on the possession of the qualities above mentioned—perception, faith, skill, and energy.

By way of bringing out more fully the nature of the assertion made by Sir George Darwin, let me beg your attention to a striking incident in recent astronomical history. We all know how the great astronomer we lost last year, Sir William Huggins (one of those already mentioned as having occupied the presidential chair of the Association without having filled that of Section A), initiated the determination of velocities of the heavenly bodies in the line of sight by means of the spectroscope. We know, further, how the accuracy of these determinations was improved by the application of photography, so that it has recently become possible to measure the velocity of the earth in its orbit (as it alternately approaches and recedes from a given star) with a precision which matches that of other known methods. Now Mr. W. W. Campbell, on his appointment as Director of the Lick Observatory in 1900, perceived the desirability of observing the line-of-sight velocities of as many stars as possible, believed that that outcome would be in some way for the advancement of science, and resolutely acted on that belief, so that for many years the resources of his great establishment have been devoted to this work. He has not turned aside from it even to publish provisional results, and has thereby incurred some adverse criticism. But, having now accumulated a large mass of observation, he is proceeding to let them tell their own tale, and a wonderful story it is. We have, unfortunately, not time to listen to more than a fraction of it at the moment; but that fraction is well worthy of our attention. When the stars are grouped in classes according to their spectral type, their average velocities differ; and if the spectral types are arranged in that particular order which for quite independent reasons we believe to be that of development of the stars, there is a steady increase in the velocities. To put the matter in a nutshell, the older a star is the quicker it moves. There are no doubt several assumptions made in reducing the matter to this simple statement, but I venture to think that they do not affect the point I now wish to make, which is as follows. There is no doubt whatever that the catalogue of facts accumulated by Mr. Campbell, when arranged in an obvious order, has led to a most important scientific generalisation—a direct negative at this date of Sir George Darwin's opening sentence, however true it may have been when he wrote it. If we read on, his next sentence doubtless entitles him to say that it was the marshalling of the facts which led to the conclusion. It is not altogether clear to me in what way this marshalling differs from the permitted "arrangement" of the catalogue; but the third sentence seems to imply that the distinction lies in the existence of a theory. But certainly Mr. Campbell had no theory; so far is he from having had a theory that he finds it extremely difficult, if not at present actually impossible, to formulate one which will satisfactorily account for the extraordinary fact brought to light by the simple arrangement of his catalogue.

Witness his words in Lick Observatory "Bulletin," No. 196, dated April 20 last:—

"The correct interpretation of the observed facts referred to in this 'Bulletin' seems not easy of accomplishment, and the brief comments which follow make no pretensions to the status of a solution.

"That stellar velocities should be functions of spectral types is one of the surprising results of recent studies in stellar motions, for we naturally think of all matter as equally old gravitationally. Why should not the materials composing a nebula or a Class B star have been acted upon as long and as effectively as the materials in a Class M star? . . . The established fact of increasing stellar velocities with increasing ages suggest the questions: Are stellar materials in the ante-stellar state subject to Newton's law of gravitation? Do these materials exist in forms so finely divided that repulsion under radiation pressure more or less closely balances gravitational attraction? Does gravity become effective only after the processes of combination are well under way?"

Mr. Campbell is far from being helpless in the situation he has created; he is ready with suggestions, though he modestly puts them as questions; but they are obviously consequent, and not antecedent, to the advance which he has made. Even if the like has never happened before, *this* scientific advance is at any rate due to little more than the accumulation of facts which arranged themselves, as Bacon hoped would naturally happen. But does it detract from the merits of this fine piece of observational work that it was suggested by no leading theory? And I will ask even further: Would its merits have been less if no such immediate induction had presented itself? To this second question I can scarcely expect a general answer in the affirmative; it is so natural to judge by results, and so difficult to look beyond them to the merits of the work itself, that I shall not easily carry others with me in claiming that the merits of the observer shall be assessed independently of his results. And yet I affirm unhesitatingly that until this attitude is reached, we cannot do justice to the observer. I believe it will be reached in the future, and I shall endeavour to give reasons for this forecast; but I admit frankly that our habit of judging by results will be hard to break. It extends even to the observer himself, and leads to the withholding of his observations from publication, so that he may himself extract the results from them. In the pure interests of the advance of knowledge, it would be far better to publish the material, so that many brains rather than one might work upon it. But the observer knows that by this course he risks losing almost the whole value of his patient work, which would pass as unearned increment to the particular person who was lucky enough to make the induction. Hence arise quarrels such as those between Flamsteed and Newton; the former refusing to publish his observations until he had himself had an opportunity of discussing them, while Newton and Halley exerted their powerful influence in the contrary sense. This situation by no means belongs to a bygone age; it may and does arise to-day, and will continue to arise so long as the recognition of the observer's work is inadequate. It was mentioned a few minutes ago that Mr. Campbell had incurred adverse criticism by accumulating a considerable mass of unpublished observations. Let me be careful not to suggest that his primary motive was the desire to have the first use of them, for I happen to know that there was at least one other good and sufficient reason for his action in the difficulty of finding funds for publication, a difficulty with which observers are only too familiar. But, whatever the reason, there were those who regretted the delay in publication as hindering the advance of science. The whole question is a delicate one, and might have been better left unraised at the moment but for a most curious sequel, which puts clearly in evidence the importance of the observer and the desirability of allowing him to discuss his own work. To make this clear, a small digression is necessary.

During the last half-dozen years astronomers have been startled on several occasions by pieces of news of a particular kind, indicating the association of large, widely scattered groups of stars in a common movement. The discussion of these movements is to occupy the special attention of this Section at one of our meetings, which is an additional reason for brevity in the present allusion. Possibly, also, most members of the Section have already heard of Prof. Kapteyn's division of the great mass of bright stars into two distinct groups flying one through the other; and, again, of the discovery by Prof. Boss of a special cluster of stars in the constellation Taurus, moving in parallel lines like a flock of migrating birds. The fascination of this latter discovery, and of one or two others like it, is that when the information supplied by the spectroscope is combined with that furnished by the long watching of patient observers, we can determine the distance of the cluster and its shape and dimensions. We realise, for instance, that there is a large flat cluster migrating just over our heads, so that one member of it (Sirius) is close to our Sun—that is to say, only three or four light-years from him. "Close" is a relative term; and the distance travelled by light in three years is from some standpoints by no means despicable. But it is small in comparison with the dimensions of the cluster, which is about one hundred light-years from end to end. The study of these clusters will doubtless occupy our close attention in the immediate future; and it is very natural that the discovery of one should lead to the search for others. Accordingly, we heard last autumn with the deepest interest, but with modified surprise, the announcement of common movement in a class of stars of a particular spectral type. The announcement rested to some extent on the work done at the Lick Observatory, much of which has been published in an abbreviated form. But Mr. Campbell, in the Lick Observatory "Bulletin" already quoted, gives reasons why he cannot accept the conclusion, which is vitiated, in his opinion, by the existence of a systematic error in the observations. Now on such a point as this the observer himself is at any rate entitled to a hearing, and is often the best judge. To take proper precautions against systematic errors is the business of the observer, and his efficiency may very well be estimated by his success in this direction—this would be a far safer guide than to judge by results. But sometimes such errors, which are very elusive, do not suggest themselves until the observations have been completed, and must be detected from the observations themselves. This, again, is rightly the business of the observer, and the desire to free his observations from such error is a perfectly sound and scientific reason for withholding publication. In the present instance the error is a peculiarly insidious one; and, indeed, we are not even certain that it is an error. It is a possible alternative interpretation of the facts that the stars with Class B spectrum are in general moving outwards from the Sun, and the additional fact that there is a comparatively large volume of space round the Sun at present empty of B stars would seem to favour this alternative. But, as already mentioned, the observer himself prefers rather to credit his observations with systematic error, which gives a spurious velocity of 5 km. per second to stars of this type. Now it will readily be understood how an error of this kind may appear doubled: two vehicles travelling in opposite directions approach or recede from one another with double the speed of either, and if one were erroneously supposed to be at rest, the other would be judged to travel twice as fast. In this way the B stars in a particular portion of the sky were judged to be travelling with a common motion of 10 km. per second, which would have been a discovery of far-reaching importance if true, but which the observer relegates to the category of systematic errors.

The illustration will suffice to remind us that the work of the observer is far from being merely mechanical: it demands also skill and judgment—skill in defeating systematic error, and a fine judgment, born of experience, of the success attained. All this is independent of the generalisations which may or may not be arrived at. Bradley's skill as an observer enabled him to discover the Aberration of Light and the Nutation of the Earth's Axis; it was enhanced rather than lessened when he went on to make further observations which, had he lived, would have conducted him to the discovery of the Variation of Latitude. After his death the world waited more than a century for this discovery to be made; but Mr. Chandler, who played a leading part in it, has declared that Bradley was almost certainly on its track. It would almost seem that an observer is only properly appreciated by another observer. There are doubtless many who, assisted by the knowledge that Bradley's skill had twice previously conducted him to a discovery, would be ready to admit the value of his later work, although he did not live to crown it; but how many of these could properly appreciate Bradley without such assistance?

I venture to think that the great brilliance of Newton has dazzled our vision so that we do not see some things quite clearly.

"Had it not been for Newton," writes De Morgan in his "Budget of Paradoxes," p. 56, "the whole dynasty of Greenwich astronomers, from Flamsteed of happy memory, to Airy, whom Heaven preserve, might have worked away at nightly observation and daily reduction without any remarkable result: looking forward, as to a millennium, to the time when any man of moderate intelligence was to see the whole explanation. What are large collections of facts for? To make theories *from*, says Bacon; to try ready-made theories *by*, says the history of discovery; it's all the same, says the idolater; nonsense, say we!"

But nothing of this will fit in with what we know of

Bradley's work; he discovered aberration, not by any help from Newton, but by accumulating a mass of observations. He had no ready-made hypothesis, or rather he had a wrong one, viz. that the stars would show displacement due to parallax; and after this was proved wrong, as it was at the very outset, he had nothing in the way of a theory to guide him, and found great difficulty in devising one *after* he had collected his facts, which spoke for themselves so far as to reveal plainly the essential features of the phenomenon in question.

"Modern discoveries" (on the preceding page of the "B. of P.") "have not been made by large collections of facts, with subsequent discussion, separation, and resulting deduction of a truth thus rendered perceptible."

To this I venture to oppose not only such work as that of Bradley, but much in the recent history of astronomy; the discoveries about systematic proper motions, about moving clusters, about the growth of velocity with life-history, and so forth.

"There is an attempt at induction going on, which has yielded little or no fruit, the observations made in the meteorological observatories. The attempt is carried on in a manner which would have caused Bacon to dance for joy. . . . And what has come of it? Nothing, says M. Biot, and nothing will ever come of it: the veteran mathematician and experimental philosopher declares, as does Mr. Ellis, that no single branch of science has ever been fruitfully explored in this way."

De Morgan was a mathematician, and I have noticed that mathematicians are apt to be crisp in their statements: but he is a bold man who says "nothing will ever come of it." Perhaps an equally crisp statement on the other side may be pardoned. I adventure the remark that if nothing has hitherto come of such observations, it is because observers have been misled by the very teaching of De Morgan and others who share his views: they have been told that they will do no good without a theory until they have come to believe it; whereas the truth probably lies in a quite different direction. To present my reasons for this proposition I must ask you first to consider in some detail the method of discussing meteorological observations suggested some years ago by Prof. Schuster. He gave an account of it to the Department of Cosmical Physics over which he presided in 1902, so that I must face some repetition of what he said; but the matter is so important that I trust this may be pardoned.

Let us compare the records produced on a gramophone disc by the playing of a single instrument and by that of an orchestra. The first will be comparatively simple, and when suitably magnified will show a series of waves which in certain parts of the record form sequences of great regularity. These represent occasions when the single instrument played a long sustained note, the pitch of which is indicated by the frequency of the wave. If the instrument plays more loudly, while still keeping to the same note, the heights of the waves will increase, though their frequency will not be altered. The exact shape of each wave will represent the quality of tone which characterises the instrument: and if another instrument were to play the same note it would be different. But so long as we keep to the same instrument, whenever the same note recurred we should find, generally speaking, the same shape of wave: and we could resolve it into its constituents, one being the main wave and others harmonics of different intensities. The analysis of such a record would thus be a comparatively simple matter, on which we need scarcely dwell further. Very different is the case of the orchestral record. There are numerous instruments, playing notes of different pitch, intensity, and character, each of which, if playing alone, would produce its own peculiar record. But when they play together the records are all combined into one. The needle can only make one record, but it is a true sum of all the individuals; for when the instrument is set to reproduce the playing of the orchestra, a trained ear can perceive the playing of the separate instruments—when the strings are playing alone, and when the wind joins them: when the horn comes in, and whether there are two players or only one: nay, even that one of the second violins is playing somewhat flat! This could not happen unless the individual performances were essentially and truly existent in the combined record; and yet this consists of only one single wavy line. The waves are, however, now of great complexity, and it seems at first sight hopeless to analyse them. The mathematician knows, however, that such analysis is possible, and is quite simple in conception, though it may be laborious in execution. Selecting a note of any given pitch, a simple calculation devised by Fourier will reveal when and how loudly that particular note was being played. This being so, it is only necessary to repeat the process for notes of different pitch. But though this can be stated so simply, the carrying out in practice may involve immense labour, by reason of the number of separate notes to be investigated. It is not merely that these will extend from low growls by the double bass to high squeaks by the fiddles, but that their variety within these wide limits will be so great. The series is really infinite. We might, indeed, prescribe a certain scale of finite intervals for the main notes, as in a piano: but the harmonics of the main tones would refuse to obey this artificial arrangement, and would form intermediate pitches, which must be properly investigated if our analysis is to be complete. Moreover, the orchestral instruments will not keep to any such prescribed intervals, but will insist on departing from them more or less, according to the skill of the performer. There is a story told of an accompanist who vainly tried to adjust the key of his accompaniment to the erratic voice of a singer. At length, in exasperation, he addressed him as follows: "Sir, I have tried you on the white notes, and I have tried you on the black notes, and I have tried you on white and black mixed: you are singing on the cracks!" Some instruments will almost certainly "sing on the cracks," so that we shall not easily escape from the examination of a very large number of possibilities indeed—we may well call them *all* the possibilities within the limits of audibility. The illustration is already sufficiently developed for provisional use. My suggestion is that science has only dealt so far with the easy records, and that the genuine hard work is to come. If we can imagine a number of deaf persons turned loose among a miscellaneous collection of gramophone records, with instructions to make what they could of them, we can readily imagine that they would pick out those of single instruments first. We must make the researchers deaf, so that they may not use the beautiful mechanism of the human ear, which has as yet no analogue in scientific work. Possibly something corresponding to this wonderful and still mysterious mechanism may ultimately be devised, and then the course of scientific research may be fundamentally altered: but for the present we must regard ourselves as deaf, and as condemned to work by patient analysis of the records. It is perfectly natural, and even desirable, to begin with the easy ones; and the finding of an easy one would no doubt in our hypothetical case be a sensational event, reflecting credit on the lucky discoverer, who would be hailed as having detected a new law, *i.e.* a new simple case. But sooner or later these will be used up, and we must attack the more complex orchestral records in earnest. Shall we find that the best music is still to come, as our illustration suggests?

But we must return to Prof. Schuster's suggested plan of work. It is closely similar to that already sketched for dealing with a complex gramophone record. Let us consider the record of any meteorological element, such as temperature or rainfall. When these records are put in the form of a diagram in the familiar way we get a wavy line, which has much in common with that traced by a gramophone needle on a smaller scale. The sight of the complexities is almost paralysing, especially when those who would otherwise attack the problem are deterred by the emphatic assertion that it is useless to do so without the equipment of some guiding hypothesis. Most of the obvious hypotheses have, of course, already been tried, and the majority of them have failed. It is to Prof. Schuster that we owe the vitally important advice to disregard hypotheses and make a complete analysis of the record. Of course the labour is great, but the genuine observer is not afraid of labour: he has a right to ask, of course, that it shall not be interminable; and when we are told that we must examine an almost infinite series of possibilities, there would seem to be some danger of this. But in practice the work always resolves itself into a series of finite steps, owing to the finite extent of the observations. A definite illustration will make this clear. Suppose we have ninety years of rainfall, and we test the record for a frequency of nine years, which would run through its period ten times; we must certainly test independently for a frequency of ten years, which would only run through its period nine times, and thus lose one whole period on the former wave; and so, also, for a possible frequency of nine years and a half, and of nine years and a quarter. But a frequency of nine years and one day would not be distinguishable from that of nine years, for the phase would only change 1° in the whole available period of observation. Indeed, the same might be said of all frequencies between nine years and nine years and one month: for the extreme difference of phase would not exceed 40°. But in course of time, when the series of ninety years' observations become 900 years, the differences of phase will approach or exceed a complete cycle, and we must accordingly narrow the intervals between frequencies chosen for examination.

The length of the series of observations is thus an important factor in our procedure, for which Prof. Schuster has indicated a beautiful analogy. Our illustrations hitherto have been provided by the science of sound, but we may also gather them from that of optics. Testing a series of rainfall observations for a periodicity is like examining a source of light for a definite bright line. The process of computation indicated by Fourier gives us what corresponds to the measured brilliance of the bright line, and the complete process of analysis corresponds to the determination of the complete spectrum of the source of light, which may consist of bright lines superimposed on a continuous spectrum. And the length of the series of observations corresponds simply to the resolving power of the optical apparatus. The only point in which the analogy breaks down is unfortunately that of ease and simplicity. In the optical analogy, an optical instrument performs for us with completeness and despatch the analysis, which in its counterpart must be performed by ourselves with much numerical labour.

Let us consider how we should most conveniently proceed to the complete delineation of a spectrum. We should ultimately need an apparatus of the greatest possible resolving power, but it might not be advisable to begin with it; on the contrary, a small instrument which enabled us to glance through the whole spectrum might save much time. Suppose, for instance, that there was a bright line in the yellow; our small instrument might suffice to show us that it was due either to sodium or helium, but no more: the decision between these alternatives must be reserved for the larger instrument. On the other hand, if no line is seen in the yellow at all, we have ruled out both possibilities at once, and so economised labour. Hence it is natural to use first an instrument of low resolving power, and afterwards one of higher.

Now in the work for which this serves as an analogy this procedure is actually imposed upon us by the march of events. It has been pointed out that the resolving power of the optical apparatus corresponds exactly to the length of our series of observations. Hence our resolving power is continually increasing. Quite naturally we begin with a short series of observations, which shows us our lines blurred and confused: to define and resolve them we have but one resource—"wait and see"; wait and accumulate more observations, to lengthen the series. But the lengthening must be in geometrical progression; we must double our series to increase the resolving power in a definite ratio, and double it again. We begin to get a glimpse of the important part to be played by the observer in the future, and of his increase in numbers.

Let us glance at a few illustrations of the use of this method. Prof. Schuster has applied it, for instance, to the observations of sun-spots. Now it may fairly be said that the general law of sun-spots was thought to be known; the variation in a cycle of about $11\frac{1}{3}$ years has long been considered to represent the facts: it catches the eye at once in a diagram, and though there are also obvious anomalies, they had not been deemed worthy of any particular attention (with one exception presently to be mentioned) until Prof. Schuster undertook his analysis. To his surprise, when he calculated the periodogram of sun-spots, he found two entirely new facts:—

Firstly, that there were other distinct periodicities, notably of about four, eight, and fourteen years.

Secondly, that the eleven-year cycle had not been continuously in action, but that during the eighteenth century it had been much less marked than the eight-year and fourteen-year cycles.

A further most interesting fact seems to emerge, viz. that several of the periodicities are harmonics of a major period of some thirty-three years or more, and it seems just possible that a connection may ultimately be established with the Leonid meteor-swarm, which revolves in this period. But it would take us too far from our main point to follow these most interesting corollaries; the point well worthy of our special attention is this, that we have here an undoubted advance in knowledge resulting, not from observations made with regard to any particular theory, but from the simple collection of facts and the arrangement of them in all possible ways, the very method which has been despised and condemned. Let us contrast with this the method hitherto adopted, which has been to hunt for some particular possible cause which will give the eleven-year period. Thus Prof. E. W. Brown suggested[1] in 1900 that the eleven-year cycle was due to the tidal action of Jupiter, altered periodically by two causes:—

	Period	Mag. of force
By Jupiter's eccentricity ..	11·86 years ...	0·33
By the motion of Saturn ...	9·93 ,, ...	0·11

and he suggests his contention by an ingenious and striking diagram, which seems to explain not only the main cycle, but its anomalies. (This Paper is, in fact, the exception above referred to.) But if his contention is correct, the periodogram should show bright lines at 11·86 and 9·93 years, which it does not. This is worth noting, since it is sometimes said that there is nothing new in Prof. Schuster's method, which is true enough in one sense, since it is simply the analysis of Fourier. The novelty consists, *firstly*, in calling attention to the necessity of applying the analysis in all cases, a necessity which I venture to think was overlooked in this instance by so able a mathematician as Prof. Brown; and, *secondly*, in the insistence on the examination of *all* periods, irrespective of any particular theory or preconception. And in this second character the method seems to me to cut at the root of the canons of procedure which have found favour hitherto.

As a second instance I present with much more diffidence a few results which seem to emerge from a very laborious analysis of the rainfall at three or four stations, for which Prof. Schuster and myself are jointly responsible. There is some evidence for a cycle of 600 days in the Greenwich rainfall, to which a further cycle in the quarter period (150 days) lends support. On analysing the Padua records it is found that these cycles do not exist; but it seems quite possible that there are cycles of rather shorter period, viz. 594 days and $148\frac{1}{2}$ days, the relation of four to one being maintained. The separate links in this chain are none of them very strong, but they seem to hang together, and there is certainly a case for further investigation. But would this case have been likely to present itself in any other way than by the examination of the whole periodogram? I find it very difficult to think, even now the periods are suggested, of any theoretical cause; to let the facts speak for themselves took much time and labour, but I venture to think that we might have waited far longer, and cudgelled our brains much more, before we got the clue by formulating hypotheses of causation.

A new method is not adopted widely all at once. Prof. Whittaker has, I am glad to say, begun to apply the method to variable star observations, and is already hopeful of having obtained valuable information in the case of the star SS Cygni. Possibly we may hear something from him at this meeting. Meanwhile, I take the opportunity to remark that the history of variable star observation affords us many lessons as to the desirability of simply accumulating observations and letting them speak for themselves, instead of being guided by a theory on hypothesis. Let me give an instance. One of the fathers

[1] Monthly Notices R.A.S., lx., p. 600.

of variable star-observing, the late N. R. Pogson, made a series of excellent observations of the star R Ursæ Majoris in the years 1853 to 1860. He then seems to have formulated a particularly unfortunate hypothesis, viz. that he knew all about the variation; and he accordingly only made sporadic observations in succeeding years. Now this star, along with many others, varies in a manner which may be illustrated from the occurrence of sunrise. The average interval between two sunrises is exactly twenty-four hours; but this is only the average. In March the sun is rising two minutes earlier every day, and the interval is therefore two minutes short of twenty-four hours; as the year advances the daily gain slackens, and at midsummer the interval is exactly twenty-four hours; then the sun begins to rise *later* each day, and the interval exceeds twenty-four hours, and so on, so that there is a regular yearly swing backwards and forwards through a mean value, and, as in the case of all such swings, there is a sensible halt at the extreme values. Now when Pogson made his observations of R Ursæ Majoris in 1853–60 it was time of halt at an extreme; the period remained stationary, and the variation repeated itself eleven times in closely similar fashion, so that Pogson concluded it would continue in the same way. How many instances suffice for an induction? Many inductions have been based on fewer than eleven. Unfortunately, the period was just beginning to change sensibly, and we lost much valuable information, for no one else repaired Pogson's neglect adequately; and the whole swing of period occupies about forty years, so that the opportunity of studying the changes he missed has only quite recently returned. We are thus reminded how disastrous may be a break in the record. It should be one of the articles of faith with an observer that the record is sacred, and must not be broken. Most of them, indeed, act on that principle already; but there are heretics, and it pained us to find even Prof. Schuster himself tinged with heresy. On the very occasion when he did so much for the observer by presenting his beautiful method, he suggested that it might even be advisable to drop observing for a time in order to apply the method to accumulated observations. He may possibly be right, but the observer had better believe him wrong. There ought to be an "observer's promise," like the promise of the boy scout; and one part of it should be not to interrupt the record, and another should be to publish the observations regularly, and never to let them accumulate beyond five years.

The method of Prof. Schuster is not the only one that has been recently proposed for dealing with large masses of observations. We have also the methods of Prof. Karl Pearson. These have been far more widely adopted for use than the periodogram, and they have also been more adversely criticised. As regards criticism, I think it is fair to say that it has chiefly been directed towards the nature of the material on which Prof. Pearson has used his process than on the process itself, and at present we need not be concerned with it. The processes themselves are sound enough; one of them, for instance, is much the same as the old method of least squares in a simple form. But if the same criticism is made as has been made on the method of the periodogram, viz. that it is not new, we can reply in almost the same words in the two cases: the mathematical calculus may not be new; the novelty is the insistence on the application of it, and the application to all possible cases. Prof. Pearson ceases to look for one principal factor only, and examines all possible factors, just as Prof. Schuster examines all possible frequencies. Let us recur for a moment to the words of Sir George Darwin previously quoted.

"A mere catalogue of facts, however well arranged, has never led to any important scientific generalisation. For in any subject the facts are so numerous and many-sided that they only lead us to a conclusion when they are marshalled by the light of some leading idea."

Let us take, for instance, a catalogue of variable stars such as those of Mr. Chandler. Particulars for each star are given in separate columns, exclusive of the name and number. We might wait long for a leading idea to guide us in marshalling the facts, and, so far as I know, we have waited till now without any such idea occurring to anyone. But Prof. Pearson insists on the plain duty of determining the correlation between each and every pair of these columns, and any others we may be able to add. Anybody could have made the suggestion, and there was plenty of elementary mathematical machinery in existence for carrying it out; but, so far as I know, nobody did, any more than the critics of Columbus suggested how to stand up an egg. But the suggestion having been made by Prof. Pearson, it was so clearly sound that I did what lay in my power to follow it up, with the result that certain correlations were at once indicated which at least pave the way for further inquiry. If we cannot say more than this, it is simply because the catalogue of facts was not large enough. So far from the observers having wasted their energies by observing without any theory to guide them, more work of the same kind would have been welcome, for it would have reduced the probable error of the correlations indicated. As an example, I may quote the following. It has already been mentioned that a variable star maximum, though it may recur after a more or less definite period, on the average, is subject to a swing to and fro like the time of sunrise. Let us call the average interval *the day* of the star and the period of swing *the year*, without implying anything more by these names than appears in the analogy. Then I found[1] that the day and the year were correlated, the value of the coefficient being

$$r = 0{\cdot}56 \pm 0{\cdot}08.$$

Having obtained this clue, it was interesting to use it for the elucidation of individual problems. The *days* of many stars are by this time pretty well known, but their *years* are very uncertain. In nine or ten cases the assessment of the vaguely known *year* was under revision, and in all, without exception, the revised assessment tended in the direction of the formula. In one case (S Serpentis) the formula suggested the solution of a long-standing puzzle.[2] Finally, the inquiry is suggested whether our own sun may be treated as a variable star with a period or *day* of eleven years, in which case its time of swing a *year* should be about seventy-five years if the formula is strictly linear. There are found to be indications of a swing of this order of magnitude, though the time given by the periodogram method is fifty-four years.[3] If the relation between *year* and *day* is not strictly linear, these figures could easily be reconciled for a case lying so far outside the limits within which the formula was deduced. But the ultimate successful establishment of the connection is of less importance for our present purpose than to notice the fruitfulness of the method of suggestion, which is as mechanical as Bacon himself could have wished.

Let us admit frankly that there is an appearance of brutality about such methods. Is our method of search to be merely the old and prosaic one of leaving no stone unturned? We have been led to believe that there should be more of inspiration in it; that a true man of science should have some of the qualities of that fascinating hero of fiction, Mr. Sherlock Holmes, who picks up his clue and follows it unerringly to the triumphant conclusion. Such qualities will do the man of science no possible harm: indeed, they will be of the utmost value to him. The point to which I am now calling attention is the change in nature of the opportunities for using them, which are becoming every day more confused. Sir Conan Doyle, in the exercise of his art, keeps our attention fixed on a single trail: he conceals from us by mere omission the numerous trails which cross it. We admire the skill of the Indian who pursues an enemy through the trackless forest; but his success depends on the simplicity brought by this very tracklessness, and would be imperilled if there were numerous tracks. It may be remarked, however, that there is a still higher sagacity—that of the hound who, even among a number of tracks, can pick out the right one by scent. Let us imagine for a moment that the scientific man can be endowed in the future, by training or by some new invention, with a faculty of this kind, so that he may unerringly pursue a single trail even when it is crossed and recrossed by others. Then, in the terms of this metaphor, I draw attention to the fact that he has still to determine which is the right trail, and that in general he can only do so by pursuing each in turn to

[1] Monthly Notices R.A.S., lxviii., p. 544. [2] *Ibid.*, p. 156. [3] *Ibid.*, p. 659

the end. To take an example from recent scientific anecdote: I relate the story as I was told it, and, even if incorrect in detail, it will serve its purpose as a parable. The Röntgen rays were discovered originally by their photographic action, but afterwards it was found that they would render a screen of calcium tungstate phosphorescent. I was told that this discovery had been made in this wise: Mr. Edison had a large collection of different chemicals and a number of assistants; he set his assistants busily to work to try each substance in turn until the right one was found. Now this is not only a genuine scientific process, but it is *the fundamental process*. Let it be frankly admitted that our instincts are against it. We should much prefer to hear that some *hypothesis* had pointed the way, even a false hypothesis such as actually led to the discovery of the possibility of achromatism in lenses. Or if *memory* had played a part: The other day Prof. Fowler identified the spectrum of a comet's tail with one taken in his laboratory, of which he had some recollection, and our human sympathies fasten at once on this idea of recollection as a praiseworthy element in the discovery. Nay, even mere *accident* appeals to us more than brutal industry; if Mr. Edison had wandered into his laboratory, picked up a bottle at random, and found it answer his purpose, I venture to say that we should have instinctively awarded him more merit; there would have been just a chance that he was inspired. Let us by all means welcome hypothesis, memory, inspiration, and accident whenever and wherever they will help us; but they may fail, and then our only resource is to help ourselves by the unfailing method of examining all possibilities. The aid of the others is adventitious, and comes, like that of the gods, most readily to those who help themselves.

The maxim of "leaving no stone unturned" was enunciated from a rather different point of view some dozen years ago by an American geologist, Prof. T. C. Chamberlin, of Chicago, in a short paper for students entitled "The Method of Multiple Working Hypotheses."[1] After recalling how much the march of science in early days was retarded by the tyranny of a theory formulated too hastily, and how in later times attempts have been made to remedy this evil by holding the theory, provisionally only, as a working hypothesis, Prof. Chamberlin points out that even the working hypothesis has serious disadvantages:—

"Instinctively there is a special searching-out of phenomena that support it, for the mind is led by its desires. . . . From an unduly favoured child it readily grows to be a master and leads its author whithersoever it will. . . . Unless the theory happens perchance to be the true one, all hope of the best results is gone. To be sure truth may be brought forth by an investigator dominated by a false ruling idea. His very errors may indeed stimulate investigation on the part of others. But the condition is scarcely the less unfortunate.

. . . .

"To avoid this grave danger the method of multiple working hypotheses is urged. It differs from the simple working hypothesis in that it distributes the effort and divides the affections. . . . In developing the multiple hypotheses, the effort is to bring up into view every rational explanation of the phenomenon in hand and to develop every tenable hypothesis as to its nature, cause or origin, and to give all of these as impartially as possible a working form and a due place in the investigation. The investigator thus becomes the parent of a family of hypotheses: and by his parental relations to all is morally forbidden to fasten his affections unduly upon any one. In the very nature of the case, the chief danger that springs from affection is counteracted."

For the further elucidation of Prof. Chamberlin's proposals I must refer my audience to his original paper, which is well worthy of careful attention. He does not shirk consideration of the drawbacks—"No good thing is without its drawbacks," he writes. And it may be added that no good thing is entirely new or entirely old. Perhaps it is better to say that it is generally both new and old. The Method of Multiple Hypotheses is new because it is still necessary to remind scientific workers of all kinds that, so long as they restrict themselves to the examination of one hypothesis only, they can never reach complete logical proof: they can only attain a high measure of probability. What is often called verification[1] is not complete proof, but only increase in probability; for complete proof it is necessary to show that no other hypothesis will suit the facts equally well, and thus we are bound to consider other possible hypotheses even in the direct establishment of one.

[1] University of Chicago Press. 1897.

But the method is also old in that it has long been adopted in practice, however partially and unconsciously, by scientific workers of all kinds. When, as a boy at school, I began to make physical measurements under Mr. J. G. MacGregor (now Professor of Physics at Edinburgh), I learnt from him one golden rule: "Reverse everything that can be reversed." The crisp form of the rule may be new to many who have long used it in their work: and its use is simply that of "multiple hypotheses." For when the current in a wire is reversed, the hypothesis is tacitly made that the effect observed may be due to the direction of the current: and when a measured spectrum photograph is turned round and remeasured, it is an admission of the hypothesis that the direction of measurement may be partly responsible for the observed displacements of the spectrum lines. By the various reversals we endeavour, in Prof. Chamberlin's words, "to bring up into view every rational explanation of the phenomenon in hand" which can be brought up into view in this way. But truly "no good thing is without its drawbacks," and one drawback to the recognition of this principle is that, by a process of mental confusion, it seems sometimes to be regarded as a distinct merit in a piece of apparatus that it can be reversed in a large number of ways. It must be remembered that the hypotheses thus examined and ruled out are chiefly instrumental ones superadded to those of Nature: and the latter are already sufficiently numerous, without our ingenious additions.

The view which I have endeavoured to put before you of the inevitable course of scientific work is that it will depend more and more on the patient process of "leaving no stone unturned." It may not be an inspiring view, but it should be at least encouraging, for it follows that no good honest work is thrown away. And it is just this encouragement of which the observer, as opposed to the worker in the laboratory and the mathematician, stands sometimes in sore need. The worker in the laboratory can often clear away his hypothesis on the spot: he can reverse his current then and there; but this is often impossible for the observer, who can and does reverse his spectrum plate for measurement, but to reverse the motion of the earth which affected the lines must wait six months, and to reverse also the motion of the star may have to wait six years, or sixty, or sixty thousand. In many cases he must leave the reversal to others, and thus not only can he not test all his hypotheses, but he may not even be able to formulate them. His aim cannot therefore be to establish within his lifetime some new law, and his work is not therefore to be appreciated or condemned by his success or failure in this respect. There are truer aims and surer methods of judgment. Something is inevitably lost when we endeavour to express these aims in the concrete; but, for the sake of illustration, we may say that the true observer is always endeavouring to reach the next decimal place, and is ever on the alert for some new event. Of the pursuit of the next decimal place it is needless to say more: the aim is as familiar in the labora-

[1] To show that the facts agree with the consequences of our hypothesis is not to prove it true. To show that is often called *verification*: and to mistake verification for proof is to commit the fallacy of the consequent, the fallacy of thinking that, because the hypothesis were true, certain facts would follow, therefore, since those facts are found, the hypothesis is true. . . . A theory whose consequences conflict with the facts cannot be true: but so long as there may be more than one giving the same consequences, the agreement of the facts with one of them furnishes no ground for choosing between it and the others. Nevertheless, in practice, we often have to be content with verification; or to take our inability to find any other equally satisfactory theory as equivalent to there being none other. In such matters we must consider what is called the weight of the evidence for a theory which is not rigorously proved. But no one has shown how weight of evidence can be mechanically estimated; the wisest men, and best acquainted with the matter in hand, are oftenest right.—"An Introduction to Logic," by H. W. B. Joseph, Fellow and Tutor of New College, Oxford, Clarendon Press, 1906, p. 486.

tory as in the observatory. But I often think that the recognition of new events is scarcely given its proper place in the annals of science if we have due regard to the consequences. I have protested that in much of his work the observer cannot be judged by the fruits of his labour, though there is an instinctive tendency to judge in this way; but here is a case where he might well be content to be so judged, and yet the consistent award is withheld. Think for a moment of the very considerable additions to our knowledge which have accrued from the discovery by Prof. W. H. Pickering of an Eighth Satellite to Saturn. The discovery led directly to the recognition of the retrograde motion; and to explain this we were led to revise completely our views of the past history of the Solar system. Incidentally, it stimulated the search for other new satellites, resulting in the discovery of a curious pair to Jupiter, and next of the extraordinary Eighth Satellite; while it was the investigation of the orbit of this curiosity which suggested an eminently successful method of work on Cometary orbits. If we judge scientific work by its results, we must take into account all this subsequent history in our appreciation of Prof. Pickering's achievement. But whether we do so or not is probably a matter of indifference to him, for the true observer is, above all things, an amateur, using the word in that splendid sense to which Prof. Hale recently introduced us. There have been many attempts to define an amateur. One was given by Prof. Schuster in his eloquent address to this Section at Edinburgh in 1892:—

"We may perhaps best define an amateur as one who learns his science as he wants it and when he wants it. I should call Faraday an amateur."

We need not quarrel with his definition, and certainly not with the noble instance with which he points it. But after all I prefer the definition of Prof. Hale[1]:—

"According to my view, the amateur is the man who works in astronomy because he cannot help it, because he would rather do such work than anything else in the world, and who therefore cares little for hampering traditions or for difficulties of any kind."

The wholly satisfactory nature of this view is that it provides not only a definition, but an ambition and a criterion. We feel at once the ambition to become amateurs, for I deny stoutly that the distinction is conferred at birth: it comes with work of the right kind. And we may know what is work of the right kind by this, if by nothing else: that by diligently performing it we shall become amateurs who find it impossible to stop: "who work in astronomy because we cannot help it." Before an army of such men even the vast hordes of dusky possibilities of which we are beginning to catch glimpses must yield. The fight may seem, and no doubt is, without end; and the opportunities for glorious deeds by which outlying whole troops of the enemy are demolished at once are becoming rarer. We are confronted with the necessity of attacking each possibility singly which threatens the stopping of the conflict through sheer weariness. Clearly the army of amateurs is the right one for the work; weariness cannot touch them: they will go on fighting automatically because "they cannot help it."

SECTION B.

CHEMISTRY.

OPENING ADDRESS BY PROF. J. WALKER, D.Sc., F.R.S., PRESIDENT OF THE SECTION.

Theories of Solutions.

TWENTY-ONE years ago the Chemistry Section of the British Association at its meeting in Leeds was the scene of a great discussion on the nature of solutions. It was my first experience of a British Association meeting, and I well remember the stimulating effect of the lively discussion on all who took part in it. To-day, speaking from the honourable position of President of the Section, I conceive I can do no better than indicate the position of the question at the present time. And this appears to me the more appropriate as our science has had this year to mourn the departure of van 't Hoff, the founder of the modern theory of solution, whose name will remain one of the greatest in theoretical chemistry—in time to come, it will, I think, be considered almost the greatest. He had expressed the hope that he might attend this meeting as he did that twenty-one years ago. The hope is not fulfilled: his activity is merged in the final equilibrium of death. But his ideas are part and parcel of the chemical equipment of every one of us, and we know that whatever form the fundamental conceptions of chemistry may assume, the quantitative idea of osmotic pressure will be to the theory of solution what the quantitative idea of the atom is to chemical composition and properties. For I must emphasise the fact that chemistry is essentially a quantitative science, and no chemical theory, no partial chemical theory even, can be successful unless its character is quantitative. To quote the words of Lord Kelvin: "I often say that when you can measure what you are speaking about, and express it in numbers, you know something about it; but when you cannot measure it, when you cannot express it in numbers, your knowledge is of a meagre and unsatisfactory kind; it may be the beginning of knowledge, but you have scarcely in your thoughts advanced to the stage of science."

A general theory of solutions must be applicable to all solutions—to those in which solvent and solute exist in practically mere intermixture, as well as to those in which solute and solvent are bound together in what we cannot sharply distinguish from ordinary chemical union. Between these extremes all grades of binding between solvent and solute exist, and it may be well to give a few examples illustrating the various types of solution.

Where no affinity exists between solvent and solute, the solution is practically of the same type as a mixture of two gases which are without chemical action on each other. The solute is merely diluted by the solvent and retains its properties unchanged. An example of this type of solution may be found in the solution of one saturated hydrocarbon in another, say of pentane in hexane. On mixing the two liquids there is no evidence of union between them, the volume of the mixture is practically the sum of the volume of the components, the heat of solution is practically *nil*, the vapour pressure of each constituent is reduced merely as if by dilution with the other constituent, and so on. That there is some action between the two components even in this extreme case must be admitted, but it may be referred entirely to action of a physical kind, such as one finds on mixing one gas with another at considerable pressures. Action of a chemical nature is absent. If it be said that even saturated hydrocarbons have some chemical affinity for each other, recourse may still be had for examples to mixtures of two inactive elements, say liquid argon and liquid krypton, where chemical affinity is non-existent.

At the other extreme we have such solutions as those of sulphuric acid and water. Here there is every physical evidence of chemical union. The volume of the mixture is by no means the sum of the volumes of the components, the amount of heat evolved on mixing is very great, the separate liquids, which are practically non-conductors, yield on mixing a solution which is a good conductor, and so on. There is obviously here a great influence of the solvent water on the solute sulphuric acid, and this influence we can only account for by assuming that it is essentially chemical in character.

As the influence in such a case is necessarily reciprocal, then if even one of the constituents of the solution is inactive chemically there can plainly be no action of a chemical nature on mixing. Thus, no matter what solvent we take, it can exercise no action other than that of a physical kind on argon, say, which has been dissolved in it; and, again, if liquid argon is chosen as solvent no substance dissolved in it can be affected by it chemically, and we thus obtain only the properties of a physical mixture. It is convenient therefore to classify liquid solvents according to their chemical activity. The saturated hydrocarbons, which are chemically very inert, and, as their name paraffin implies, little disposed to chemical action of any kind, may be taken as typically inactive solvents, analogous to liquid argon. Water, on the other hand, as its numerous compounds (hydrates) with all kinds of substances testify, may be taken

[1] Monthly Notices R.A.S., lxviii., p. 64.

as a typically active solvent. The ordinary organic solvents exhibit intermediate degrees of activity.

For the purpose of illustrating the effect of solvents on a dissolved substance one may conveniently take a coloured substance in a series of colourless solvents. If the substance is unaffected by the solvent, we might reasonably expect the colour of the solution to be the same as the colour of the vapour of the substance at equal concentration. Iodine, for instance, gives rise to the familiar violet vapour. Its solution in carbon disulphide has a colour practically similar, but its solution in alcohol or water is of a brown tint quite different from the other. In the indifferent hydrocarbons and in chloroform the colour is like that in carbon disulphide, in methyl or ethyl alcohol it is brown. We conclude therefore roughly that iodine dissolved in saturated hydrocarbons, in chloroform, carbon tetrachloride and carbon disulphide is little affected by the solvent, whereas in water and the alcohols it is greatly affected, probably by way of combination, since in all the solvents two atoms of iodine seem to be associated in the molecule. That combination between the iodine and the active solvents has really occurred receives confirmation from the behaviour of iodine in dilute solution in glacial acetic acid. If the colour of this solution is observed in the cold it is seen to be brown, resembling in colour the aqueous solution. If the solution be now heated to the boiling-point, the colour changes to pink, which may be taken to indicate that the compound of iodine and acetic acid which is stable at the ordinary temperature becomes to a large extent dissociated at 100°.

Now, as I have said, a general theory of solution must be applicable to all classes of solution, and herein lies the importance of van 't Hoff's osmotic pressure theory. It applies equally to mixtures of gases, to mixtures of inert liquids, and to mixtures such as those of sulphuric acid and water; and it has the further advantage that so long as the solutions considered are dilute there are simple relations connecting the osmotic pressure with other easily measurable properties of the solutions. It has been unfortunately the custom to oppose the osmotic pressure theory of solution to the hydrate, or more generally the solvate, theory, in which combination between solute and solvent is assumed. The solvate theory is, in the first place, not a general theory, and in the second place it is perfectly compatible with the osmotic pressure theory. It is in fact with regard to a general theory of solutions on the same plane as the electrolytic dissociation theory of Arrhenius. This theory of ionisation applies to a certain class of solutions, those, namely, which conduct electricity, and is a welcome and necessary adjunct in accounting for the numerical values of the osmotic pressure found in such solutions. Similarly the hydrate, or more generally the solvate, theory is applicable only to those solutions in which combination between solvent and solute occurs, and will no doubt in time afford valuable information with regard to the osmotic pressure, especially of concentrated solutions in which the affinity between solvent and solute is most evident. It can tell us nothing about solutions in which one, or both, components is inactive, just as the electrolytic dissociation theory can tell us nothing about solutions which do not conduct electricity.

The great practical advantage bequeathed to chemists by the genius of van 't Hoff is the assimilation of substances in dilute solution to substances in the gaseous state. Here all substances obey the same physical laws, and a secure basis is offered for calculation connecting measurable physical magnitudes, irrespective of the chemical nature of the substances and of the solvents in which they are dissolved, provided only that the solutions are non-electrolytes. If the solutions are electrolytes, the dissociation theory of Arrhenius, developed independently of the osmotic pressure theory of van 't Hoff, gives the necessary complement, and for aqueous solutions offers a simple basis for calculation. Van 't Hoff has given to science the numerically definable conception of osmotic pressure; Arrhenius has contributed the numerically definable conception of coefficient of activity of electrolytes in aqueous solution, or what is now called the degree of ionisation.

Of late there has been a tendency in some thermodynamical quarters to belittle the importance of the conception of osmotic pressure. It is quite true that from the mathematical thermodynamical point of view it may be relegated to a second place, and even dispensed with altogether, for it is thermodynamically related to other magnitudes which can be substituted for it. But it may be questioned if without the conception the cultivators of the thermodynamic method would ever have arrived at the results obtained by van 't Hoff through osmotic pressure. Van 't Hoff was only an amateur of thermodynamics, but the results achieved by him in that field are of lasting importance, and his work and the conception of osmotic pressure have given a great stimulus to the cultivation of thermodynamics to chemistry.

And here we trench on a question on which a certain confusion of thought often exists. To the investigator it is open to choose that one of several equivalent methods or conceptions which best suits his personal idiosyncrasy. To the teacher such a choice is not open. He must choose the method or conception which is most clearly intelligible to students, and is at the same time least likely to lead to misconception. Osmotic pressure is a conception which the chemical student of mediocre mathematical attainments can grasp, and it is not difficult to teach the general elementary theory of dilute solutions by means of it and of reversible cycles without liability to radical error or misconception. I should be sorry on the other hand to try to teach the theory of solutions to ordinary chemical students by means of any thermodynamic function. The two methods are thermodynamically equivalent, and the second is mathematically more elegant and in a way simpler, but it affords less opportunity than the first for the student to submit his methods to any practical check or test, and in nine cases out of ten would lead to error and confusion. The difficulty of the student is not the mathematical one; with the excellent teaching of mathematics now afforded to students of physics and chemistry the mathematical difficulty has practically disappeared—the difficulty lies in critically scrutinising the conditions under which each equation used is applicable.

Of the mechanism of osmotic pressure we still know nothing, but with the practical measurement of osmotic pressure great advances have been made in recent years. In particular the admirable work of Morse and Frazer is of the first importance in establishing for solutions up to normal concentration the relationship between osmotic pressure and composition, and its variation with the temperature. Much may be anticipated from the continuation of these accurate and valuable researches, the experimental difficulties of which are enormous.

We are indebted to America not only for these researches, and for the voluminous material of H. C. Jones and his collaborators dealing with hydrates in solution, but also to A. A. Noyes and his school for accurate experimental work and for systematic treatment of solutions on the theoretical side. They, and also van Laar, have shown how solutions not coming within the ordinary range of dilute solutions to which van 't Hoff's simple law is applicable, may in some cases at least be made amenable to mathematical treatment. Van 't Hoff chose one simplification of the general theory by considering only very dilute solutions, for which very simple laws hold good, just as they do for dilute gases. Even a single gas in the concentrated or compressed form diverges widely from the simple gas laws; much more then may concentrated solutions diverge from the simple osmotic pressure law. The other simplification is to consider solutions of which the components are miscible in all proportions and are without action on each other; and this method has been developed with marked success from the point of view of osmotic pressure and other colligative properties.

The outstanding practical problem in the domain of electrolytic solutions is to show why the strong electrolytes are not subservient to the same laws as govern weak electrolytes. If we apply the general mass-action law of chemistry to the electrically active and inactive parts of a dissolved substance (the ions and un-ionised molecules) as deduced from the conductivities by the rule of Arrhenius, we find that for a binary substance a certain formula connecting concentration and ionisation should be followed, a formula which we know by the name of Ostwald's dilution law. This law seems to be strictly applicable to solutions of feeble electrolytes, but to solutions of strong electrolytes it is altogether without application. Wherein lies the fundamental difference between these two classes of solutions? Two kinds of explanation may be put forward. First, the ionised proportion may not be given accurately for strong electrolytes by the rule of Arrhenius; or second, the strong electrolytes do not obey the otherwise general law of active mass, which states that the activity of a substance is proportional to its concentration. The first mode of explanation has been practically abandoned, for other methods of determining ionisation give values for strong electrolytes in sufficient agreement with the values obtained by the method of Arrhenius. The other explanation is that for some reason the law of active mass is, apparently or in reality, not obeyed by some or all of the substances in a solution of a strong electrolyte. An apparent disobedience to the law of mass-action would, for example, be caused by the formation of complexes such as Na_2Cl_2, or Na_2Cl^+ or $NaCl_2^-$ in a solution of sodium chloride. Mere hydration, *e.g.* the formation of a complex $NaCl_1\ 2H_2O$, would not affect the mass-action law in dilute solution, and the electrolyte would obey the dilution law in solutions of the concentration usually considered. A somewhat similar explanation, which takes into account the properties of the solvent, is that the ionising power of the solvent water undergoes a noticeable change when the concentration of the ions in it increases beyond a certain limit.

I should wish now to draw attention to a point of view which has not, so far as I am aware, been fully considered. To begin with we may put to ourselves the question: Is it the ions in the solution which are abnormal or is it the non-ionised substance? A simple consideration would point at once to it being the non-ionised portion. We have, for example, in acetic acid a substance which behaves normally, so that the ions H^+ and Ac^- as well as the undissociated molecule HAc are normal. Similarly in ammonium hydroxide the ions NH_4^+ and OH^- as well as the non-ionised NH_3 and $NH_4\ OH$ all behave normally. When we mix the two solutions there is produced a substance, ammonium acetate, which behaves abnormally. Now, on the assumption that the equilibrium we are now dealing with is

$$NH_4^+ + Ac^- \rightleftharpoons NH_4Ac,$$

which of these molecular species is abnormal in the relation between its concentration and its activity? Probably not the ions NH_4^+ and Ac^-, because these were found to act normally in the solutions of acetic acid and ammonia. The presumption is rather that the abnormal substance is the undissociated ammonium acetate, for this occurs only in the abnormal acetate solution, and not in the normal acetic acid and ammonia. This view, that it is the non-ionised portion of the electrolyte which exhibits abnormal behaviour, and not the ions, has been reached on other grounds by Noyes and others, and I hope in what follows to deduce reasons in its support.

One is apt, because the ions are in general the active constituents of an electrolyte, to lay too much stress on their behaviour in considering the equilibrium in an electrolytic solution. We are justified in attributing the fact that acetic acid is a weak acid, whilst trichloracetic acid is a powerful one, rather to the properties of the un-ionised substances than to the properties of the ions. The divergence of trichloracetic acid from the simple dilution law may similarly be due to an inherent property of the un-ionised acid, a single cause being not improbably at the bottom of both the great tendency to split into ions in water and also the abnormal behaviour towards dilution.

However that may be, I think the following reasoning goes far to show that the non-ionised portion of the electrolyte is that which is primarily abnormal in its behaviour, the ions acting in every way as normal. The dilution formulæ of Ostwald or of van 't Hoff is essentially equilibrium formulæ. One side of the equilibrium represents the interaction of the ions to form the non-ionised substance, the other side represents the splitting up of the non-ionised substance into ions. In order to fix our ideas, we may consider a salt which obeys the empirical dilution-formula of van 't Hoff. If c_u represents the molar concentration of the un-ionised portion, and c_i the molar concentration of each ion, then according to van 't Hoff's empirical formula,

$$\frac{c_i^3}{c_u^2} = \text{const.}$$

If the law of mass-action were obeyed we should have, on the other hand, Ostwald's dilution formula,

$$\frac{c_i^2}{c_u} = \text{const.}$$

According to this last formula, the activity of each substance concerned varies directly as its molar concentration, and a normal result is obtained on dilution. According to van 't Hoff's formula as stated above, the activity of none of the substances concerned varies directly as its concentration; but since the constancy of the expression is the only test of its accuracy, there are obviously other methods of stating the relation which will throw the abnormal behaviour either on the ions or on the non-ionised substance. Thus, if we write the equivalent form

$$\sqrt{\frac{c_i^3}{c_u^2}} = \text{const., or } \frac{c_i^{1.5}}{c_u} = \text{const},$$

the un-ionised substance is here represented as behaving normally, and the ions abnormally; whilst if we write the formula in the form

$$\frac{c_i^2}{c_u^{1.33}} = \text{const.}$$

the ions are represented as behaving normally, and the non-ionised substance abnormally. Now it is very important that a choice should be made amongst these three expressions, all equivalent amongst themselves so far as the mere constancy of the expression is concerned, as tested by measurements of electrolytic conductivity. Looked at from the kinetic point of view we have in the first form,

$$\frac{dx}{dt} = kc_i^3$$

$$-\frac{dx}{dt} = k'c_u^2,$$

both direct and reverse actions abnormal. In the second form, we have

$$\frac{dx}{dt} = kc_i^{1.5}$$

$$-\frac{dx}{dt} = k'c_u,$$

the ionisation being normal, the recombination abnormal. And in the third form we have

$$\frac{dx}{dt} = kc_i^2$$

$$-\frac{dx}{dt} = k'c_u^{1.33},$$

the ionisation being abnormal and the recombination normal.

Now, if it were possible to measure directly the velocity of either ionisation or recombination, we should at once be able to select the equilibrium formula which was really applicable. Unfortunately such velocities are so high as to be beyond our powers of measurement. Yet it seems possible to seek and obtain an answer from reaction velocities which are measurable. One assumption must be made, but it seems to me so inherently probable that few will hesitate to make it. It is this, if a substance in a given solution has normal activity with respect to one reaction, it has normal activity with respect to all reactions in which it can take part in that given solution. Similarly, if a substance in a given solution exhibits abnormal activity with respect to one reaction, it will exhibit abnormal activity with respect to all.

Granting this assumption, we have then to find a reaction in which either the ionised or un-ionised portion of an abnormal electrolyte is converted into a third substance with measurable velocity. Such a reaction exists in the transformation of ammonium cyanate into urea in aqueous and aqueous-alcoholic solutions, which was investigated some years ago by myself and my collaborators, and found to proceed at rates which could easily be followed experimentally. First of all comes the question: Is the urea formed directly from the ions or from the un-ionised cyanate? As Wegscheider pointed out, it is impossible from reaction-velocity alone to determine which portion passes directly into urea, if the velocities of ionisation and recombination are infinitely greater than that of the urea-formation, as is undoubtedly the case. Other circumstances make it highly probable that the ions are the active participants in the transformation, but we may leave the question open, and discuss the results on both assumptions.

Suppose, first, that the un-ionised cyanate is transformed directly into urea. Then we have the successive reactions

$$NH_4^{\cdot} + CNO' \rightleftharpoons NH_4CNO \rightarrow CO(NH_2)_2.$$

The slight reverse transformation of urea into cyanate may for the present purpose be neglected, as it in no way influences the reasoning to be employed.

If the un-ionised substance behaves normally, then the conversion of the ammonium cyanate into urea, when referred to the un-ionised substance, will appear unimolecular and obey the law of mass-action: when referred to the ionised substance it will not appear to be bimolecular and will not obey the law of mass-action.

Suppose, now, that the direct formation of the urea is from the ions. Then we are dealing with the actions

$$NH_4CNO \rightleftharpoons NH_4^{\cdot} + CNO' \rightarrow CO(NH_2)_2.$$

Again, let us assume the un-ionised substance to be normal. Once more, if the transformation is referred to the non-ionised substance it will appear as monomolecular; when referred to the ionised substance it will not appear as bimolecular, as it should if the mass-action law were obeyed.

It is a matter of indifference, then, so far as the point with which we are dealing is concerned, whether the ionised or the non-ionised cyanate is transformed directly into urea. If the non-ionised cyanate behaves normally the action when referred to it will in either case appear to be strictly monomolecular.

If the ionised cyanate, on the other hand, behaves normally, the reaction when referred to it will be bimolecular and normal; when referred to the non-ionised cyanate it will not be monomolecular, and therefore will be abnormal.

The actual experiments show that whether water or a mixture of water and alcohol be taken as solvent, the reaction when referred to the ions is strictly bimolecular; when referred to the non-ionised substance it is not monomolecular, *i.e.*, proportional to c_u, but rather proportional to a power of c_u other than the first, namely, $c_u^{-1 \cdot 4}$.

This is, to my mind, a very strong piece of evidence that in the case of the abnormal electrolyte, ammonium cyanate, the abnormality of the ionisation equilibrium is to be attributed entirely to the non-ionised portion. But ammonium cyanate differs in no respect, with regard to its electrolytic conductivity, from the hundreds of other abnormal binary electrolytes with univalent ions; and I am therefore disposed to conclude that it is to the non-ionised portion in general of these electrolytes that the abnormality is to be attributed.

As I have already indicated, this conclusion is not altogether novel, but in my opinion it has not been sufficiently emphasised. Even in discussions where it is formally admitted that the divergence from the dilution law may be due to the non-ionised portion, yet the argument is almost invariably conducted so as to throw the whole responsibility on the ions. The point which ought to be made clear is whether the constant k of the equation

$$\frac{dx}{dt} = kc_i^2,$$

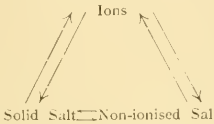
or the constant k' of the reverse equation

$$-\frac{dx}{dt} = k'c_u,$$

is really constant. If the former, then the ions are truly normal, and primary explanations of the abnormality of the strong electrolytes can scarcely be sought in high total ionic concentrations and the like, though a connection between the two no doubt exists, both being determined by the same cause.

In my illustration I have assumed that there holds good a dilution law of the kind given by Storch, of which van 't Hoff's dilution law is a particular case. Here the active mass is represented as a power of the concentration other than the first power. The argument I have used is altogether independent of this special assumption; the active mass of the abnormal substance may be any function of its concentration, and the same conclusion will be reached.

Nernst's principle of the constant ionic solubility product affords additional evidence that the ions act normally in solution. In deducing this principle it is generally assumed that it is the constant solubility of the non-ionised salt that determines the final equilibrium. This assumption, though convenient, is not necessary. The equilibrium is a closed one, thus:—



The solid is not only in equilibrium with the non-ionised salt but also with the ions. Now, in the deduction of the change of solubility caused by the addition of a substance having one ion in common with the original electrolyte the mass-action law for ionisation is assumed. This is of course justified when we deal with feeble electrolytes, but in the case of salts and strong acids which do not follow the mass-action law the experiments are found still to be in harmony with the theoretical deductions. This is not only so when the two substances in solution are both abnormal, but also when one is abnormal and the other normal, no matter which is used to produce the saturated solution. In fact, the principle of the constant ionic solubility product may be employed with equal success to calculate the effect on the solubility of one electrolyte of the addition of another electrolyte with a common ion, whether both electrolytes are normal, both abnormal, or whether one is normal and the other abnormal. At first sight, this apparent obedience of abnormal electrolytes to the mass-action law seems strange, but a little consideration shows that if it is only the non-ionised portion of a salt that is truly abnormal, the theoretical result is to be expected. Suppose that the ions do behave normally in the ionisation, then they must also act with normal active mass with reference to the solid, with which they may be regarded as in direct equilibrium according to the closed scheme referred to above. A change, then, in the concentration of any one of the ions, brought about by the addition of a foreign salt with that ion, will necessarily bring about the change in solubility of the salt calculated from the mass-action law, so far at least as experiment can tell us, for any variation from theory is caused by the change in the nature of the solvent due to the addition of the foreign substance. We ought, then, on the assumption that the ions behave normally, to expect that the principle of the constant solubility product would yield results of the same degree of accuracy in dilute solutions whether the electrolytes considered were normal or abnormal. This, as I have said, is actually the case.

To put the whole matter briefly, in the equilibrium between electrolytes agreement will be obtained between theory and experiment whether we use the mass-action law, or an empirical law such as van 't Hoff's dilution formula, provided only that we attribute the abnormality to the non-ionised portion of the electrolyte. Thus we can deduce the ordinary formulæ for hydrolysis or for isohydric solutions as readily for abnormal as for normal electrolytes, and find the most satisfactory agreement with experiment in both cases.

By this one simple assumption, then, for which I have offered some direct justification, it is possible to find a basis for calculation with abnormal electrolytes. The problem of *why* certain electrolytes should be normal and others abnormal is, of course, in no way touched by this assumption. That is a matter for further investigation and research.

Another great desideratum of the theory of solutions is to find a general basis for the calculation of hydrates. The present position of the theory of hydrates in solution may perhaps most aptly be compared to the theory of electrolytic dissociation for solvents other than water. That hydrates exist in some aqueous solutions is undoubted, but no general rule or method exists for determining what the hydrates are and in what proportions they exist. Similarly the theory of electrolytic dissociation applied to other than aqueous solutions affords no general means of determining what the ions are and how great is the degree of ionisation. It is only for aqueous solutions that Arrhenius was able to give a practically realisable definition of degree of ionisation, and it is on this definition that the whole effective work on aqueous electrolytes is based; and until some general practically applicable principle of a similar character is attained for hydrates, the work done on that subject, however interesting and important it may be in itself, must necessarily be of an isolated character.

Arrhenius did not originate the doctrine of electrolytic dissociation or free ions: that was enunciated in 1857 by Clausius, and remained relatively barren. What he did was to introduce measurable quantities into the doctrine, and to show its simple quantitative applicability to aqueous solutions; immediately it became fertile. And as soon as a simple quantitative principle is developed for hydrates in solution, that doctrine will become fertile also.

It is surely now time that all the irrelevant and intemperate things that have been said and written by supporters of the osmotic pressure and electrolytic dissociation theories on the one hand, and by those of the hydrate theory on the other, should be forgotten. Far from being irreconcilable, the theories are complementary, and workers may, each according to his proclivity, pursue a useful course in following either. One type of mind finds satisfaction in using a handy tool to obtain practical results; another delights only in probing the ultimate nature of the material with which he works. For the progress of science both types are necessary—the man who determines exact atomic weights as well as the man who speculates upon the nature of the atoms. That the want of knowledge as to what the exact nature and mechanism of osmotic pressure is, should prevent accurate experimental work being done on it, or interfere with its use in theoretical reasoning, is equally ridiculous with the proposition that because in the theory of osmotic pressure we have a good quantitative tool for the investigation of solutions, therefore we should abandon altogether the problem of its nature.

The fundamental ideas of a science are the gift to that science of the few great masters; the many journeymen investigators may be trusted to utilise them according to their abilities. Having once given his great principles to the world, van 't Hoff remained practically a spectator of their development; but by his single act he provided generations of chemists with useful and profitable fields for their labour.

NOTES.

SIR ARCHIBALD GEIKIE, K.C.B., president of the Royal Society, Prof. Svante A. Arrhenius, and Prof. Elias Metchnikoff have been elected honorary members of the Vienna Academy of Sciences.

WE regret to announce the death, on August 23, at sixty-three years of age, of the Rev. F. J. Jervis-Smith, F.R.S., late university lecturer in mechanics and Millard lecturer in experimental mechanics and engineering, Trinity College, Oxford.

THE death is announced, at the age of eighty-two years, of Dr. G. F. Blandford. Dr. Blandford early devoted himself to the study of insanity, and was for many years lecturer on psychological medicine at St. George's Hospital. His chief work, "Insanity and its Treatment," was published first in 1871, and passed through several editions. In 1895 he delivered the Lumleian lectures on "The Diagnosis, Prognosis, and Prophylaxis of Insanity" before the Royal College of Physicians. In 1877 he was president of the Medico-psychological Association, and his address for the year was on "Lunacy Legislation." In 1887 he delivered an address before the International Congress of Medicine at Washington on "The Treatment of Recent Cases of Insanity in Private and in Asylums."

THE death is announced of Prof. Georges Dieulafoy, in his seventy-second year. Prof. Dieulafoy was well known in French medical circles, and was professor of clinics in the Necker Hospital, succeeding Prof. Trousseau in 1896. He was known as an author by the six volumes of his "Leçons cliniques de l'Hôtel-Dieu" and his "Manuel de pathologie interne," which has reached a seventeenth edition. He was a member of the Paris Academy of Medicine and a Commander of the Legion of Honour.

WE regret to record the death of Mr. J. R. Mortimer, of Driffield, on August 20, in his eighty-seventh year. Mr. Mortimer was one of the few remaining antiquaries of the old type, and during the past half-century he thoroughly investigated the archæological treasures of the East Riding of Yorkshire, in an area adjoining the field of Canon Greenwell's investigations. Mr. Mortimer excavated more than 300 Bronze-age burial mounds, and a number of Anglo-Saxon cemeteries, and also carefully mapped the elaborate series of prehistoric earthworks which occur on the Yorkshire Wolds in all directions. To a smaller extent he excavated Roman and later sites, and also made extensive collections from the chalk and other secondary formations in his district. These he transferred to a special building at Driffield, which has long been the rendezvous of antiquaries and geologists interested in East Yorkshire. This museum also contains a very large collection of stone and bronze axes, flint arrows, spears, &c., which number tens of thousands, all of which have been obtained in the vicinity. Mr. Mortimer was the author of numerous papers and memoirs, a complete list of which will be found in *The Naturalist* for May last. His principal work, however, is the massive volume "Forty Years' Researches in the British and Saxon Burial Mounds of East Yorkshire," which was published a few years ago by Browns. Besides elaborate tables of measurements of crania, &c., and hundreds of plans and sections of the barrows and earthworks, this volume has illustrations of more than a thousand Bronze-age drinking cups, food vessels, cinerary urns, and bronze and stone implements, from beautiful drawings made by his daughter, Miss Agnes Mortimer. This book, and his magnificent museum, will ever remain monuments to his memory.

THE death is announced of Mr. John Griffiths, the well-known fossil collector of Folkestone. He rendered important service to Mr. F. H. Hilton Price and Mr. J. Starkie Gardner in their researches on the Gault and associated formations, and he discovered a large proportion of the most important Gault fossils now in the British Museum and the Museum of Practical Geology.

THE Scunthorpe Urban District Council has appointed Mr. T. Sheppard, of the Hull Municipal Museums, as expert adviser to the new public museum at Scunthorpe.

IT is announced that on Saturday, September 9, an aërial postal service will be started between Hendon and Windsor. This scheme, which has the sanction of the Postmaster-General, was conceived by Mr. D. Lewis Poole and Captain W. G. Windham, and a contract has now been made with the Grahame-White Company for the carriage of mails by suitable pilots. Post-cards and envelopes, bearing a design of Windsor Castle, have been prepared, and will be on sale, at the price of 6½*d.* and 1*s.* 1*d.* respectively, in the establishments of a number of large firms in London. The letters must be posted in special boxes provided in these establishments, from which they will be collected and conveyed daily to Hendon by motor-van. The mail-bags will be also flown daily, weather permitting, to Windsor from the Hendon ground, and the correspondence distributed from there through the ordinary postal channels. All proceeds from the sale of the postcards and envelopes will be devoted to charity. Captain Windham, the most active mover in the present scheme, inaugurated the first aërial post in India last February.

A SEISMOGRAPH has recently been installed in the Tunnel Colliery, Nuneaton, the object being to ascertain if the apparently inexplicable falls of coal and roof in mines have any relation with the occurrence of earthquakes. Whether or no the problem admits of solution in this direction, there can be no doubt that the comparison of earthquake records obtained on the surface and in mines will lead to interesting results.

IN the July number of *The Cairo Scientific Journal*, Mr. J. Craig discusses some results derived from the anthropometrical material which he had previously investigated and published in *Biometrika*. The measurements dealt with 9000 prisoners of Egyptian nationality, and were taken by the Anthropometric Bureau of the Ministry of the Interior from about 1902 to 1908. The relations of the Copts to the Moslem population, of the urban to the rural population, and of the people of Lower Nubia to the rest of Egypt, were studied, and though the data were not sufficient to support definite conclusions, indications were found of a differentiation into eastern, centre, and western delta districts; Girga and Qena provinces stood apart from Lower Nubia and Aswan on one hand, and from the rest of Upper Egypt on the other. The recent census is utilised to show the amount of migration of males from one province to another.

IT is satisfactory to learn from the report of the Maidstone Museum, Library, and Art Gallery for the period comprised between November, 1908, and October, 1910, that investigations have been undertaken in relation to the origin and purpose of the megalithic monuments of the district, more especially the one at Coldrum. Excavations undertaken beneath the dolmen occupying the centre of the stone circle at that spot revealed evidence of human interments, but nothing indicative of systematic burial or of the date when the interments were made. The skulls have been submitted to an expert, whose opinion as to their age and race had not been received when the report went to press. A model of the Coldrum structures has been presented to the museum by Mr. F. J. Bennett.

A FINE skull of the horned Dinosaur, *Triceratops prorsus*, has just been added to the gallery of fossil reptiles in the British Museum (Natural History). The specimen was discovered in the Laramie formation (Upper Cretaceous) of Wyoming, U.S.A., by Mr. Charles H. Sternberg, who undertook a special expedition for the purpose of making this addition to the museum collection. It is nearly complete, only the middle of the occipital crest, the left horn-core, and the left quadrate bone being restored in plaster. The skull proper measures $3\frac{1}{2}$ feet in length, while the crest extends backwards for another 3 feet, and rises above the level of the tips of the horns. The brain-cavity has been carefully cleaned by the preparator, Mr. Frank O. Barlow, and a cast has been made in plaster. The total length of the cavity is only 10 inches, and its extreme width across the cerebral hemispheres is $2\frac{1}{2}$ inches. For some time the museum has possessed a plaster copy of the restored skeleton of Triceratops as mounted in the National Museum at Washington, but the new specimen is the first actual skull of this remarkable reptile which has been exhibited in Europe. Portions of two skulls of the same genus, also discovered by Mr. Sternberg, have lately been acquired by the Senckenberg Museum, Frankfurt, where they are now being prepared.

The Times of August 28 gives an interesting and very graphic account of a remarkable hailstorm in the Pyrenees on August 16. The narrative of the storm is written by Mr. D. W. Wheeler, who, with his wife and Mr. O. P. Tidman, were encamped in the valley of Arayas, by the side of the Ordesa River. The valley lies on the Spanish side of the Pyrenees, in the Provincia de Huesca, five or six miles directly south of the Cirque of Gavarnie, and has an altitude of 4400 feet. Two storms were experienced, the first shortly after 11 a.m., and this was preceded by a clouding in of the sky and darkness. Mr. Wheeler says that midway in the darkness was the clear-cut straight line of cloud which invariably tells of hail. At first a few isolated hailstones were experienced, but soon the air suddenly became full of hailstones, and in a few minutes the storm had passed. The average size of the hailstones in the first storm is described as that of a marble, but mixed with these was a scattering of much larger stones, almost as large as golf-balls. Another storm, which followed fairly quickly on the first, was more severe. At first marble-sized hail fell and lightning blazed. Suddenly the whole land was bombarded by great hailstones as large as lawn-tennis balls. The violence of the hail is described as surpassing anything that had been previously heard of. All the mountains around were white with the covering of stones, which lay over everything like a sheet, so that in an hour summer had become winter. The smaller branches of trees had fallen as if they had been clipped by hedgers. The open grassland is described as pitted with holes, some of them a couple of inches in depth, and of about the same diameter. Testing the weight of the stones in two instances, in one six stones went to the kilogram, in the other five, which gives 5 and 7 ounces respectively. The size was that of a tennis-ball, and almost uniform. The storm wrought much destruction in the Pyrenean valleys. Seventy sheep were said to have been killed on the heights immediately above the position occupied by the writer of the narrative. Above the village of El Plan, thirty-five cows and some mules were killed. The size of the hailstones is said to have varied in different parts, according to different peasants' accounts, from "hen's eggs" to that of the closed fist. The Paris *Bulletin International* gives no indication of any atmospheric disturbance over the Spanish Peninsula. Mr. Wheeler directs attention to a hailstorm which occurred in Moravia in 1889, which is described in "Chambers's Encyclopædia," where the hailstones are said to be the size of a man's fist, and weighing 3 lb. Mr. Wheeler suggests that this should be three to the lb. The Hon. Rollo Russell, in his work on "Hail," describes a storm in the Orkneys in October, 1890, in which stones fell the size of a goose's egg, and the weight of the largest stones was estimated at 8 oz., and some penetrated the ground to the depth of 4 inches, whilst the depth of the hail in the open fields was 9 inches.

THE drought of July in this country and the serious drought in India are referred to in *Symons's Meteorological Magazine* for August. A map shows the parts of the United Kingdom in which more than ten consecutive days without rain occurred; in some districts in England, Wales, and the south of Ireland the rainfall was under 5 per cent. of the average, but was rather above the average in the west of Scotland. The duration of twenty-five days of drought was general to the west of a line drawn from the Solent to Dunstable (Bedfordshire); several places had no rain for the whole month, and the same district suffered droughts in May and June, and again in August. In India the feebleness of the south-west monsoon has caused great anxiety. Reports in *The Times* and other papers showed that up to July 28 the area most affected was west of a line drawn from Bombay through Jubbulpore to Darbhanga: nearly half of the whole country. A report dated August 21 showed, however, that conditions had greatly improved in several provinces, although famine appears to be certain in Kathiawar and Gujarat. In parts of the United Provinces and the Punjab the canals and rivers were also well supplied with water from the melting of the snow of last spring in the Himalayas.

THE Australian Monthly Weather Report for July, 1910 (lately received), contains an interesting article by Mr. E. T. Quayle on the amount of dust suspended in the atmosphere at Melbourne. One of Dr. Aitken's dust counters was in regular use at the Weather Bureau from March to July, 1909; one observation was usually made in the morning and another in the afternoon of each day. The average number of particles per cubic inch during this period was 674,000; the number steadily increased from an average of 460,000 during the first fortnight to 909,000 in the last, indicating a tendency to a winter maximum. This increase appeared to be seasonal, probably due to the diminished power of the sun in causing convectional movements of the air, and to greater relative humidity, rather than to smoke from chimneys. Taking only those days on which the wind direction remained the same, the morning observations gave an average of 638,000, and the afternoon 536,000. Wind direction had a considerable effect, the north wind being least dusty, and the north-east the most so, calms being by far the most dusty. The fact that the northerly winds in Melbourne are the least dusty is entirely contrary to the general impression on this subject. The greatest number of dust particles obtained in any one observation was 1,902,000 on a calm morning during a dense fog; the lowest recorded was 128,000, on a wet day.

IN conformity with the new regulations introduced by the Indian Museum Act of 1910, the report of the superintendent of the zoological and anthropological section of the museum at Calcutta for 1910–11 is issued in two divisions, one dealing with the progress and general condition of the establishment as a whole, and the other with the aforesaid section. In the former, after reference to the complete reorganisation of the various sections of the museum and the progress on a new wing, it is stated that the most unsatisfactory feature is the relatively small number of Europeans by whom the galleries are visited, the ratio being 15,485 Europeans to 786,519 natives. In the sectional portion of the report it is mentioned that the augmentation of the scientific staff has rendered it possible to provide instruction in the methods of zoological research, and likewise to institute inquiries relating to the fishing industries of the country. The report also contains two letters relating to the volumes on invertebrates in the "Fauna of British India," with reference to the advisability of engaging for this work the services of naturalists personally acquainted with India, and also whether the work could be best done in Calcutta or London.

IN the Transactions of the Lincolnshire Naturalists' Union for 1910 attention is directed by the president to the excellent manner in which the Lincoln Museum is discharging its proper and legitimate function as an exposition of everything connected with the natural history and antiquities of the county, strictly limiting its scope to the productions of that area. To this issue Mr. G. W. Mason contributes the fourth part of his catalogue of Lincolnshire Lepidoptera.

IN *The Field* of August 19 Mr. Pocock expresses the opinion that the animal commonly known in this country as the chita (*Cynaelurus jubatus*) is closely allied to the more typical cats, the puma, and the lynx, whereas lions, tigers, leopards, and jaguars are as markedly different. This conclusion is largely based on the fact that in the former group the hyoid apparatus is intimately connected with the skull, and that these animals purr instead of roaring. In the second group, on the contrary, the hyoid is suspended to the skull by means of a pair of long elastic cartilages, this structure being apparently connected with the power of roaring. The partial retractility of the claws of the chita is regarded as an adaptive feature connected with speed, for which this animal is specially built. It may be mentioned that in India the name chita (meaning spotted) is applied indifferently to the leopard and to *Cynaelurus jubatus*, for which reason "hunting leopard" is a preferable designation for the latter.

IN *The Zoologist* for August Captain Stanley Flower records his impressions of zoological gardens, museums, and aquariums in various parts of Europe visited by himself during the last three years, these including Birmingham, Brighton, Brunn-am-Gebirge (Austria), Cologne, Halifax, Lyons, Marseilles, Munich, Naples, Paris, Southampton, Stuttgart, and Vienna.

THE first of a series of "Behaviour Monographs" (New York: Hy. Holt and Co., 1911) in connection with *The Journal of Animal Behaviour* is by Mr. F. S. Breed, and deals with the development of certain instincts and habits in chicks. The results of a great number of experiments are tabulated and plotted. The author considers that the initial accuracy of the instinctive pecking has been exaggerated, and regards the improvement observed in the early days of life as due rather to the maturing of the organic mechanism than to the effects of habit. The efficiency of pecking has reached nearly 60 per cent. of accuracy by the beginning of the third day, about 80 per cent. on the eleventh day, after which it rises to a limit of about 85 per cent. The experiments on the rate of learning to respond differentially to objects of different brightness, colour, and size are carefully devised. The results of tests with differences of form were, however, negative. There was no conclusive evidence that the previous establishment of differential response to different colours facilitated that of responding to different sizes.

IN a paper on the birds inhabiting the bush (forest) districts of New Zealand, published in *The Emu* for July, Mr. J. C. M'Lean states that the number of such species is much less than in Australia. Originally there were only about a score of birds with strictly arboreal habits to be found in the whole of the North Island, and of these many which were once common are now rare, while one or two may possibly be extinct. An impression has, indeed, prevailed among ornithologists that nearly all the New Zealand bush-birds are *in extremis*; but this, it is satisfactory to learn, is not shared by Mr. M'Lean, who is of opinion that, although many are retreating before the axe and forest-fires, yet they are still to be met with in considerable numbers in the higher and more remote bush-country, where, it may be hoped, steps will be taken for their preservation.

IN vol. lvi., No. 21, of the Smithsonian Miscellaneous Collections Mr. E. W. Nelson describes a humming-bird from an elevation of about 3000 feet on Cerro Azul, in the Chepo district of Panama, which is referred to a new genus and species, *Goldmania violiceps*. The new bird is allied to the members of the large genus Saucerottea, but distinguished by certain peculiarities of the under tail-coverts and primary quills, and the short feathers of the tarsus, which leave the outer side of that segment exposed.

With the exception of the crown, forehead, and lores, which are iridescent violet, the general colour of the upper parts is metallic-green.

Paramaecium aurelia and *P. caudatum* are the subject of several observations by L. Woodruff (*Journ. of Morphol.*, June; *Journ. Exper. Zoology*, July; Proc. Soc. Exper. Biology, viii.). He finds that these protozoa grow well in a medium of beef extract, that the rate of reproduction in hay infusion is influenced by the volume of the culture medium, and that the organisms excrete substances which are toxic to themselves. The great majority of individuals of *aurelia* and *caudatum* can be distinguished both by shape and by size, but the power of reproduction of the two is practically identical. The macronucleus is subject to such variation that it affords no diagnostic feature; the micronuclear apparatus, on the other hand, affords crucial diagnostic characters.

A COLLECTION of six short papers is published in vol. xiii., part x., of the Contributions from the United States National Herbarium. A lichen contribution by Mr. A. W. C. Herre deals with the family Gyrophoraceæ in California; the single species *Umbilicaria semitensis*, and twelve species of Gyrophora, are described. Some interesting facts are noted by Mr. W. H. Brown as the result of observations upon plant life in four shallow lakes in North Carolina. Lake Ellis, the most fertile, is three miles long with a maximum depth of 2 to 3 feet. Three zones of vegetation are clearly distinguishable, dependent primarily on substratum, not on depth of water, which is fairly uniform. The central zone, underlaid by sand, carries a sparse growth of *Eriocaulon compressum* mingled with Eleocharis in shallower spots. The substratum becomes muddier in the intermediate zone, where *Philotria minor*, *Panicum hemitomon*, and *Eleocharis interstincta* are conspicuous, and in the thicker sediment of the marginal zone *Eleocharis mutata*, *Castalia odorata*, grasses, and sedges are the most prominent plants.

As the conditions of the various regions of the United States cause marked vegetation differences, there is a corresponding variety about the problems attacked by the various agricultural experiment stations. Both at the Connecticut and Wisconsin stations, as well as elsewhere in the old settled regions, the problem is to restore the lost fertility of the soil consequent on many years of pioneer agriculture. Especially are some of the Wisconsin clay soils deficient in phosphates, so that small dressings of rock phosphate are producing unexpectedly large returns. The management of sandy soils and of peat soils is also receiving attention, and under Prof. Whitson's direction some very useful work on soil improvement is being carried out. Another direction is given to the work at Connecticut. Considerable attention is being paid to dairying and fruit-growing, both of which systems tend to make the most of the soil and at the same time maintain its fertility. A batch of bulletins is recently to hand dealing with the renovation of old orchards and the planting of new ones, and with various dairy problems of practical importance.

THE July number of *The Cairo Scientific Journal* contains a preliminary note by Dr. W. Bean on the soils of the Gezira. A large tract on the left bank of the Blue Nile from Wad Medani to Kamlin is to be irrigated, and very wisely a thorough examination of the soil has been undertaken, samples being collected down to a depth of more than a metre along several lines across the area included in the scheme. The soils, both the more and the less fertile as the natives classify them, are well supplied with potash and phosphates, but, like most Egyptian and Sudan soils, are markedly deficient in organic matter and nitrogen, so that the results which may be obtained from their cultivation will largely depend on their treatment with respect to this deficiency. Rotation with a leguminous crop has not been used on most Sudan soils, but the experiment when made on a small scale near Khartoum gave results exceeding all expectations.

THE report of the Chemical Laboratories of the Survey Department of Egypt is this year published separately. Mr. A. Lucas, in discussing the work for 1910, reviews the various stages by which the work has developed since its commencement in 1899. Almost all the work is done for Government departments, and as approximately 40 per cent. of the materials offered or delivered are found to be adulterated or of very inferior quality, the laboratories furnish a valuable safeguard on expenditure made. In spite of this the importance of systematic analysis of supplies and accurately drawn up specifications is only being slowly realised, and the samples of material examined still bear but a small proportion to the number which would represent an adequate control of the supplies purchased.

IN continuation of an earlier contribution dealing with the Allioniaceæ of the United States, Mr. P. C. Standley has prepared a synopsis of the Mexican and Central American species of the family ordinarily known as the Nyctaginaceæ, that is published in the Contributions from the United States National Herbarium (vol. xiii., part xi.). Twenty-two genera are differentiated, but some of these are changes of name that are not sufficiently explained. Among the new species are additions to Allionia, Boerhaavia, Neea, and Pisonia. An interesting ubiquitous species is *Pisonia aculeata*, that owes its distribution to the viscid glands on the fruit.

THE prospects of viticulture in Rio Grande do Sul, the southernmost State of Brazil, are discussed by Senor A. de Azambuja in a pamphlet reprinted from articles in the *Gazeta do Commercio*, published at Porto Allegre. The first vine, introduced about sixty years ago, was the American variety Isabella. Other American and some European varieties were tried later, and the cultivation was taken up by Italian colonists. Different varieties have been grown with the object of discovering those suitable for producing table fruit, wine, and currant grapes. In recommending the Isabella and other American varieties of the *labrusca* species, the author claims that first-class wines can be produced when the details of manufacture are improved.

A SUMMARY of Dr. Kienitz's important investigations into the shapes and types of *Pinus sylvestris* is provided by Mr. B. Ribbentrop in the Transactions of the Royal Scottish Arboricultural Society (vol. xxiv., part ii.). The two extreme types are represented by the strong-branched, broad-crowned tree common in Scotland, and the slender pyramidal shape characteristic of the Baltic pine. The chief result of Dr. Kienitz's researches and experiments has been to demonstrate the heredity of special forms or races, even when transferred to different conditions of climate and soil, and thereby to prove the necessity for getting the best and most suitable seed. It is noted that the much-branched tree is better fitted to hold its own in the struggle for light, and is the prevailing form in milder localities, whereas the slender form is developed under more rigorous conditions, where heavy snowfalls constitute a primary source of danger.

The volume of *Mitteilungen* of the Berne Scientific Society for 1910 contains an interesting attempt by P. Gruner to render the principle of relativity intelligible to the less mathematical reader. The twenty-one pages of "elementary" presentation still offer a formidable array of complex arguments, many of which are by no means easy to follow. Gruner imagines the inhabitants of earth and Mars as engaged in an attempt to unify and connect their respective time and space scales without the aid of astronomical observations of any other bodies, but with the free use of wireless telegraphy for mutual communications. He shows how, owing to relative motion, the scales must differ, and deduces Einstein's transforming equations in a simple manner. The scheme and argument could, no doubt, be still further simplified, and the simpler the better. Even this simplification tends to bring out the essential weakness of the theory, which assumes that successive light waves from a moving source are not concentric, and at the same time postulates, on the basis of Michelson's experiment, that this eccentricity cannot be discovered. Everything would be so much simpler if the speed of the body were added to the speed of the light it emitted, a supposition which, indeed, does not appear to contradict any astronomical observations.

Although the "exploring electrode" method of determining the distribution of electrical potential in the kathode dark space of a vacuum tube through which an electric discharge is passing has been suspected for some time, and has recently been superseded by the measurement of the deflection of a beam of kathode rays shot transversely through the discharge, it is important that the reason for the divergent results obtained by the former method should be ascertained. Prof. Wehnelt shows in a paper in the *Verhandlungen der Deutschen Physikalischen Geselischaft* for July 30 that any small obstruction placed in the kathode dark space acquires a positive charge, and its potential is therefore higher than that of the point at which it is placed. Between the kathode and the obstruction the rise of potential is linear, but between the obstruction and the kathode glow it is curved, showing that electric charges are present in this portion of the discharge.

OUR ASTRONOMICAL COLUMN.

Astronomical Occurrences for September:—

Sept. 2. 22h. 0m. Saturn stationary.
4. 4h. 37m. Uranus in conjunction with the Moon (Uranus 4° 35′ N.).
9. 3h. 0m. Mercury in inferior conjunction with the Sun.
13. 1h. 48m. Saturn in conjunction with the Moon (Saturn 4° 22′ S.).
14. 0h. 39m. Mars in conjunction with the Moon (Mars 4° 32′ S.).
15. 0h. 0m. Venus in inferior conjunction with the Sun.
17. 9h. 28m. Neptune in conjunction with the Moon (Neptune 5° 46′ S.).
20. 23h. 11m. Venus in conjunction with the Moon (Venus 13° 14′ S.).
23. 16h. 18m. Sun enters sign of Libra.
25. 2h. 0m. Mercury at greatest elongation W. of the Sun (17° 52′).
,, 12h. 0m. Mercury in perihelion.
,, 16h. 5m. Jupiter in conjunction with the Moon (Jupiter 2° 11′ N.).

Brooks's Comet, 1911*c*.—During several of the clear evenings which obtained at the latter end of last week, Brooks's comet was faintly visible to the naked eye of an observer who knew where to look for it. Ordinary opera-glasses showed it as a distinct nebulosity, and in the field of a 3½-inch refractor it was a really brilliant object, some 5′ or 6′ in diameter, having a distinct nucleus. On Sunday night, at Gunnersbury, Mr. W. E. Rolston found the comet, as seen with opera-glasses, to be no less conspicuous than ω^1 Cygni (mag. 5·6), which it immediately preceded.

Encke's Comet, 1911*d*.—Observations of Encke's comet, made by Dr. Gonnessiat at the Algiers Observatory, are recorded in No. 4518 of the *Astronomische Nachrichten*. On August 1, under excellent atmospheric conditions, the comet was seen before ninth-magnitude stars which were rising at the same time, and if seen in a dark sky would probably have equalled in brightness stars of the seventh or eighth magnitude.

Dr. Backlund briefly discusses the recent observations, and gives an ephemeris extending to September 21. At present the comet is apparently about 2° south-east of ν Leonis, and is travelling south of, and almost parallel to, the ecliptic, down through Virgo towards Libra; on September 14 it will be some 5° south of Spica.

The Aspect of Nova Lacertæ.—On a photograph taken with fifty minutes' exposure on August 11, Herr Kostinsky found that the image of Nova Lacertæ was surrounded by a well-defined luminous aureole (black on the negative) similar to that which surrounded the images of Nova Persei in 1901. This aureole is not to be seen on similar negatives secured in January and February; therefore Herr Kostinsky deduces it may be taken as an indication that the nova has now become a gaseous nebula in the spectrum of which only bright radiations of hydrogen and the nebula lines are represented. The photographic magnitude of the nova on August 11 was about 10·5 (*Astronomische Nachrichten*, No. 4518).

Kiess's Comet, 1911*b*.—An improved set of elements and an ephemeris are given for comet 1911*b*, by Dr. Kobold, in No. 4518 of the *Astronomische Nachrichten*. The comet reached its most southerly point on August 24, and is now travelling northwards slowly. For the next fortnight its apparent path lies through the constellation Telescopium. This comet was discovered independently by Herr Raimond Moravansky in Moravia on August 5, and the observation sent to Kiel; but this was nearly a month later than the discovery by Mr. Kiess.

The Early Visibility of the New Moon.—From calculations based on the data given by Mr. Horner for his remarkably early detection of the new moon, on February 10, 1910, Mr. Whitmell finds, after correcting for parallax, &c., that the difference in altitude between sun and moon at the moment of observation was only 3° 16′, the moon being 1° 46′ above, and the sun 1° 30′ below, the horizon. The corrected azimuth difference was only 9° 8′, and the moon's age sixteen hours, so that this observation is probably unique in its detection of the crescent so soon after "new moon" (*The Observatory*, No. 438).

Variable Stars.—Observers of variable stars will find part ii., vol. lv., of the Annals of the Harvard College Observatory, prepared by Miss Cannon, useful. It contains a table in which are set out the maxima and minima of a large number of variable stars. For each variable the elements and the dates of observed maxima and minima are tabulated, with a special column showing the differences between the observed and calculated dates.

In No. 4515 of the *Astronomische Nachrichten* Herr Max Mündler publishes the results of a number of observations of variable stars made by him, with a 6-inch comet seeker, at Mundenheim during 1909–10.

WATER SUPPLY IN THE UNITED STATES.

To its excellent series of pamphlets on water supply the United States Geological Survey has just added three papers, one (No. 270) descriptive of the hydrographical features of the Great Basin, an immense tract of country 208,000 square miles in area (just as large as Germany), and extending over parts of the States of Utah, Nevada, Idaho, Oregon, and California; the other two, practical manuals entitled, respectively, "Underground Waters" (Paper No. 258) and "Well-Drilling Methods" (Paper No. 257).

Of the first pamphlet, it is only necessary to remark that it follows on the same lines as those adopted for similar reports, recently reviewed in these columns, on other of the dozen districts into which the United States has been divided by the Geological Survey for the purpose of hydrographical research, and that it is equally excellent in compilation and treatment.

The two papers on well waters contain much useful information on the means of finding and securing for domestic consumption a satisfactory supply of water from underground sources. The pamphlet on well-drilling is especially practical in its description of the outfit and appliances required for the purpose, and of the methods to be followed according to the exigencies of particular localities, exigencies which, it is to be observed, are frequently of an exceptional nature. The literature on the subject of well-sinking is by no means extensive, and Mr. Bowman has exploited a field of his own, comprising those features of American practice which are associated with pioneer work in districts where many of the ordinary resources of highly developed communities are not readily available. The scope of the manual is not limited to water wells—all classes of borings for oil, gas, and water are treated, though naturally the hydraulic aspect of the subject is that which receives most prominent consideration. The interaction of borings undertaken for different ends is noted, and the flooding of oil wells by carelessly constructed and abandoned water shafts is made the subject of very necessary advice and caution. The text is freely, yet judiciously, illustrated by diagrams and photographs; and though one of the former, otherwise complete, rather amusingly indicates a platform carrying a couple of men in mid-air without any visible means of support, yet where misconception is unlikely it would be ungracious to cavil at so slight a defect. The manual is one deserving of cordial commendation.

MAGNETIC OBSERVATIONS.

The magnetic observations made during 1910 at the Khedivial Observatory, Helwan, are included in a small pamphlet of seven pages, which gives for each month and the year the mean values of the magnetic elements, the diurnal variations in declination, horizontal force and vertical force, and particulars of the ranges of these elements on the eight most disturbed days of the year. In the diurnal variation tables values are given for both midnights, the aperiodic element not being eliminated. This is rather unusual. These tables go to 0·1′ in declination and to 1γ (1×10^{-5} C.G.S.) in the force components. As the days tabulated in the month average twenty-eight, the expediency of going to 0·01′ and to $0{\cdot}1\gamma$ seems worthy of consideration, especially as the diurnal ranges are small. Disturbances at Helwan, at least in 1910, seem to rule small. The largest ranges in the selected disturbed days were only 13′ in declination, 187γ in horizontal force, and 58γ in vertical force. So far as internal evidence enables one to judge, its magnetic work does increasing credit to the Egyptian Survey Department, and it is to be hoped that it will continue to be prosecuted under favourable conditions.

In Blatt 3 of the Royal Observatory of Wilhelmshaven the assistant director, Prof. Bidlingmaier, continues the discussion of the magnetic disturbance character of the year 1910, initiated in Blatt 1 and 2, already noticed (March 16, p. 90). His method, it will be remembered, extends to individual hours the international scheme which assigns a magnetic character to individual days. Dr. Bidlingmaier's original view seems to have been that the disturbance character of a magnetic element might be based on the extent of its departure at the hour concerned from the corresponding mean monthly value on quiet days. He now regards this view as unsatisfactory, owing to its disregarding the influence of previous disturbance and making no allowance for Chree's discovery that the regular diurnal inequality varies according to the magnetic character of the day. His present estimate of hourly disturbance character seems based on the size of the maximum departure of the element during the hour from its mean value for the hour. He arrives at a numerical estimate of what he terms "Erdmagnetische Aktivitat" for the months of 1910, and compares it with Wolfer's sun-spot frequency. The hourly character of the first six months of 1911 is shown graphically in the manner applied in Blatt 1 and 2 to 1910.

The results of observations made at the U.S. Coast and Geodetic Survey's magnetic observatories at Cheltenham (Maryland), Sitka (Alaska), and Honolulu during 1907 and 1908 are published in volumes similar to those of previous biennial periods. Besides hourly readings and diurnal inequalities for the two years in question, the Cheltenham volume gives particulars of the mean annual values of the elements since the observatory began operations in 1901. A list is given of the fifty-eight principal magnetic disturbances of 1907 and 1908, with the times of their beginning and ending, and the curves obtained on nineteen of these occasions are reproduced, the times shown being G.M.T. The time scale adopted, 15 mm. to the hour, is more open than in previous years. The largest storms of the period were those of September 11 and 28, 1908. A list of earthquakes recorded by a Bosch-Omori seismograph is also given. The Sitka volume contains the usual tables of hourly readings and diurnal inequalities, and mean monthly values for the two years. A list is given of the sixty-two principal magnetic storms of the period, and the curves for sixteen of these are reproduced on a scale of 15 mm. to the hour. Sitka is a highly disturbed station, and during the principal storms there is at times considerable loss of trace; also the traces from the several elements being on one sheet—the usual practice with Eschenhagen magnetographs—there is a good deal of intercrossing of the traces. During the early part of 1908 there was also some loss of trace owing to defects in the driving clock, and a new one had to be substituted. Particulars are also given of the earthquake records obtained with a Bosch-Omori seismograph. Besides the ordinary tables of hourly readings, diurnal inequalities, &c., the Honolulu volume contains a list of the principal magnetic storms of the two years, and reproduces the curves for a number of these. Honolulu is a relatively quiet station, and loss of trace seems rare. The volume also contains a register of earthquakes recorded by a Milne seismograph.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

The death is announced of Prof. J. P. Schweitzer, professor of chemistry in the University of Missouri from 1872 until 1910, when he became professor emeritus. Prof. Schweitzer was born in Berlin in 1840, and went to the United States in 1865. He was known for his work in analytical and agricultural chemistry.

Mr. F. Pullinger, chief inspector of the Technological Branch of the Board of Education; Mr. W. R. Davies, assistant secretary of the Technological Branch of the Board of Education; Prof. John Perry, F.R.S., professor of mechanics and mathematics in the Imperial College of Science and Technology; and Mr. W. Gannon, principal of the Woolwich Polytechnic, have been appointed members, for a period of three years, of the Examinations Board of its Department of Technology by the City and Guilds of London Institute. They succeed Mr. C. A. Buckmaster, Prof. W. Gowland, F.R.S., Mr. J. H. Reynolds, and Prof. W. Ripper, whose terms of office have expired.

It is announced in *The Pioneer Mail* of August 4 that Rao Saheb Vasanji Trikamji has generously placed at the disposal of the Governor of Bombay a sum of two and a quarter lakhs of rupees for the foundation of a scientific library in connection with the institute of science now being erected in Bombay. The conditions attached to this donation are that the science institute library shall be called Vasanaji Trikamji Mulji Library. A marble bust of Vasanji Trikamji Mulji and two marble tablets mentioning the amount of the donation and other particulars are to be placed in suitable positions. The Governor has publicly thanked Rao Saheb Vasanji Trikamji for his benefaction, which will enable provision to be made for the formation of an adequate scientific library in Bombay in connection with the institute of science.

With the adoption of the Budget for 1909–10, a system of automatic increases in salaries was inaugurated at the University of California. We learn from *Science* that an instructor's salary is to be increased automatically 20*l.* per year from 200*l.* to 300*l.*, and the salaries of assistant professors 20*l.* a year from 320*l.* up to 400*l.* The automatic increases are not to apply to members of the faculty below the rank of instructor, nor above the rank of assistant professor, and there is to be no automatic increase after instructors have arrived at a salary of 300*l*., and after assistant professors have arrived at a salary of 400*l*. Increases are not automatic in salaries of members of the faculty who are on part time only, nor in the case of instructors and assistant professors for a year of absence on leave. Increases of salary may, of course, be given in the cases cited above, in which no automatic increase is due as of right. Larger increases than of 20*l*. are sometimes made at the discretion of the president, with the approval of the regents.

The calendar for the session 1911–12 of the Glasgow and West of Scotland Technical College shows that the whole building now comprises more than seven acres of floor space. To quote the calendar, it "forms the largest structure in Great Britain devoted to education." It has cost, with the equipment, about 400,000*l*. The plan of confining each department to one floor has been followed in nearly every case, with the result that the internal arrangements generally are well adapted to promote efficiency in working. County secondary education committees in Scotland are authorised by the Education (Scotland) Act of 1908 to grant bursaries tenable at this college to students resident within their districts. It may be noticed, too, that a large number of firms in the area in which the college is situated have expressed their willingness to allow a selected number of their apprentices facilities for carrying out a scheme of college study conjoined with practical work. The courses of study in engineering are held during the winter session of the college, and thus student-apprentices are left free to spend the intervening summers in works. Some of these firms are willing to recognise, wholly or partially, the time spent in college as part of the apprenticeship period, but such recognition will be contingent upon satisfactory reports being received from the college in each case.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, August 21.—M. Armand Gautier in the chair.—The president announced the death of Albert Ladenburg, correspondant in the section of chemistry, and gave a short account of his work.—H. **Deslandres** and L. **d'Azambuja**: The velocities of rotation of the black filaments (flocculi) in the upper layer of the solar atmosphere. A historical sketch of the work done on the dark flocculi since their discovery by Hale and Ellermann in 1903, with special reference to the work done at the Meudon Observatory since 1908. Five diagrams are given showing successive positions of a filament on different dates, and four tables analysing various negatives.—J. **Boussinesq**: The spontaneous vibrations of a free bar, cooling by contact at its extremities and by radiation or convection at its lateral surface.—Kr. **Birkeland**: The sun and its spots. A description of experiments made with a magnetic globe as a kathode in a large discharging vessel, and a discussion of the possible bearing of these experiments on the theory of the sun. Seven photographs of the luminous phenomena observed are reproduced, and the author concludes that in the evolution of the solar system, electrical and magnetic forces must be regarded as playing a part comparable with gravitation.—A. de la Baume **Pluvinel** and F. **Baldet**: The spectrum of the Kiess comet (1911*b*). The Kiess comet was sufficiently bright during the second fortnight in July to allow of the photography of its spectrum by the prism-objective method. The wave-lengths and aspect of the bands measured are given in a table. The comet gave no continuous spectrum. Portions of the Swan spectrum and cyanogen spectrum are identified, and comparisons are made with the Johannesburg (1910*a*) and Morehouse (1908*c*) comets.—Michel **Fekete**: Some generalisations of a theorem of Weierstrass.—Georges **de Bothezat**: A method for the experimental study of the deadening of the oscillations of certain systems in motion in a fluid.—Em. **Bourquelot**: The glucoside from the leaves of the pear tree, its presence in the leaves of several varieties, its presence in the trunk and root. The existence of a true arbutine in the leaves, branches, and roots of the pear has been proved.—E. L. **Trouessart** and E. G. **Dehaut**: The wild and domesticated pigs of Sardinia and Corsica.—Édouard **Chatton**: Some parasites of marine copepods observed by M. Apstein.—E. **Roubaud**: New biological researches on the solitary wasps of Africa; evolution, variations, disturbances of the maternal instinct under the influence of hunger.—C. **Schlegel**: The development of *Maia squinado*.—Maurice **Arthus**: The intoxications produced by snake venom.—J. **Basset**: The determining cause of "typhoid fever of the horse" (influenza, grippe, pasteurellosis, pferdestaupe, pink eye).—Maurice **Piettre**: A mode of resorption of fatty reserves.

FORTHCOMING CONGRESSES.

August 31–September 6.—British Association. Portsmouth. President: Sir William Ramsay, K.C.B., F.R.S. Address for inquiries: General Secretaries, Burlington House, W.

September 4–6.—Centenary of the University of Christiania. President of Festival Committee: Prof. Brögger.

September 9–20.—International Congress of the Applications of Electricity. Turin. President of the Committee of Honour: H.R.H. the Duke of the Abruzzi. Honorary Secretary of the Committee: Signor Guido Semenza, Via S. Paolo 10, Milano. International Secretary: Col. R. E. Crompton, C.B., R.E., Crompton Laboratory, Kensington Court, W.

September 12–15.—Celebration of the Five-hundredth Anniversary of the University of St. Andrews.

September 18–23.—International Conference of Genetics. Paris. President: Dr. Viger. Secretary: M. Philippe de Vilmorin.

September 25–29.—German Naturalists and Physicians, Karlsruhe.

October 2–7.—Third International Congress of Hygiene. Dresden. General Secretary: Dr. Hopf, Reichsstrasse 4, Dresden.

October 12–18.—Italian Society for the Advancement of Science. Rome. President: Prof. G. Ciamician. General Secretary: Prof. V. Reina, Via del Collegio Romano 26, Roma.

October 15–22.—Tenth International Geographical Congress. Rome. President: Marquis Raffaele Cappelli. General Secretary: Commander Giovanni Roncagli, Italian Geographical Society, Rome.

December 27.—American Association for the Advancement of Science. President: Dr. C. E. Bessey, University of Nebraska. Permanent Secretary: Dr. L. O. Howard, Smithsonian Institution, Washington, D.C.

THE PARSONS STEAM TURBINE.

The Evolution of the Parsons Steam Turbine. By Alex. Richardson. Pp. xix+264+173 plates in the text. (London: Offices of *Engineering*, 1911.) Price 21s.

IN this volume there is contained an authentic record of steps taken in the development of a great invention. Lord Kelvin once described the work done by the Hon. Sir Charles Parsons in connection with the steam turbine as ranking in importance with the work of James Watt. The council of the Royal Society of Arts in awarding the Albert medal for 1911 to Sir Charles Parsons, for his experimental researches into the laws governing the efficient action of steam in engines of the turbine type, and for his invention of the reaction type of turbine, stated that by means of its practical applications the production of mechanical power had been cheapened, economy of fuel and higher speeds had been obtained in steamships, and the problem of rotary engines, which long had baffled many other inventors, had been solved. This expression of opinion by a council which includes many eminent engineers and physicists will command universal assent: it also emphasises the value attaching to the record of research and achievement which has been undertaken and completed by the author of this book. The principal facts were already available, having been published from time to time in the Proceedings of engineering societies and in engineering journals. But it is equally true that by collecting and arranging such materials the author has done a useful piece of work, and done it well. Not merely has he told the story in an interesting way, but he has secured the aid of Sir Charles Parsons and several of his colleagues, and has thus made the reeord complete, adding many new facts. One characteristic of the book deserves special mention: its style and method will enable readers to master the main steps in the development of the steam turbine, even though their knowledge of engineering is small. On the other hand, skilled mechanical engineers can find therein a wealth of illustration and a mass of valuable data obtained by Sir Charles Parsons and his assistants in their long and varied experimental researches.

It scarcely seems credible, but it is the fact, that so lately as 1884 Sir Charles Parsons began work on his first steam turbines, or that it was ten years later before trials were made with the first steamship driven by turbine machinery. During the earlier period progress was naturally slow: many difficulties had to be overcome, and outside or accidental causes of delay occurred. The inventor was not daunted by these difficulties, and he fortunately obtained support from friends who had confidence in his ability to face and solve problems which had baffled previous investigators. Sir Charles Parsons, like many other inventors, discovered that although many previous attempts had been made to construct steam turbines, little exact or trustworthy data had been put on record by his predecessors. Consequently it became necessary for him to arrange and undertake further and costly experiments. The system which had previously found most favour with his predecessors was that known as the "impulse type" of turbine, in which rotary motion was produced by the impact of steam jets on suitably shaped cavities situated at the periphery of revolving wheels, or by the reaction of steam-jets issuing into the atmosphere. Sir Charles Parsons originated the idea of splitting up the fall in steam pressure, by employing a great number of wheels or turbines placed in series. To quote Mr. Richardson's words, Sir Charles Parsons made "the assumption that in each turbine the action would approximate to that in a turbine using an incompressible fluid such as water, and that the aggregate of such simple turbines, which together constituted the complete machine, would give an efficiency approximating to that obtained in water turbines."

This fundamental assumption proved to be accurate; but when the fact had been established its embodiment in successful machines which were individually of large power demanded great skill and patient experiment. Unfortunately, after the first reaction turbines had been made and proved successful, difficulties of a business nature interfered for some time with the development of the system. Sir Charles Parsons then introduced turbines of the "radial flow" type instead of the longitudinal flow type with which his name will ever be associated. The first turbine was produced in 1884 and was applied to the generation of electricity, the design of the dynamo being modified by the inventor so that it might be suitable for association with turbines running at very high rates of revolution. These early turbo-generators were of comparatively small power and were relatively wasteful in steam consumption, although in their mechanical details they were the pioneers of the enormously powerful machines now in use on land in electro-generating stations. In 1885 a turbo-generator of four-kilowatts power required 200 lb. of steam per kilowatt-hour. In 1910 turbo-generators of 5000 kilowatts were produced by Sir Charles Parsons, and the steam consumption per kilowatt-hour was but little more than 13 lb. Limits of space prevent any detailed explanation being given of the successive improvements which have led to this remarkable economy in steam consumption; but readers desirous of tracing these steps will find every information in the pages of the volume under review.

In the application of the Parsons steam turbine to ship propulsion even more remarkable progress has been made. The first vessel (the famous *Turbinia*), completed in 1897, was a hundred feet long and weighed about forty-four tons; her engines developed 2300 horse-power, and her speed was $32\frac{3}{4}$ knots for runs of short duration. Ten years later the great Cunard trans-Atlantic steamships *Mauretania* and *Lusitania* were driven by turbine machinery developing 74,000 horse-power, the length of the vessels being about 785 feet, their weight 40,000 tons; and the mean speed on their fastest trans-Atlantic voyages 26 knots. The latest armoured cruisers of the *Lion* class in the Royal Navy furnish the most notable illustrations of the application of the Parsons steam turbine to warships: their engines will develop more than 70,000 horse-power, and are estimated to drive vessels weighing 26,400 tons at speeds approaching 30 knots per hour for short periods and from 26 to 27 knots for great distances. A table in the book shows that on June 30, 1910, the Parsons type of turbine had been applied to 333 steamships, and that their aggregate horse-power exceeded 4,700,000. The first order for a turbine destroyer was given by the British Admiralty in 1899; the first merchant steamer fitted with turbine machinery was built by Messrs. Denny in 1901; and this simple statement of facts indicates the unprecedented progress which has been made by the new type of marine steam engine. That progress proceeds at an accelerated rate; and in July, 1911, 378 steam vessels, with an aggregate of more than 5,800,000 horse-power in Parsons turbines, had been built or were building.

As time has passed and experience has been gained modifications and improvements have naturally been made by the inventor. It becomes obvious from the story told by Mr. Richardson that from first to last broad views, original research, and readiness to test the relative merits of alternative arrangements, have marked the work done by Sir Charles Parsons. The mechanical ingenuity which has been displayed by him in the details of designs for steam turbines is illustrated in many ways, and no one can fail to be impressed by the mastery of fundamental principles affecting the economic use of steam in engines of the turbine type displayed by him, and the skill shown in the design of mechanical engineering details, as well as processes of manufacture, which have been no less essential to the success of the new invention. In the marine steam turbine the principles upon which economy and efficiency depend are, of course, identical with those which hold good in steam turbines applied for land purposes; but in connection with ship propulsion the designer has not only to take into account the efficient use of steam in turbines, but the general propulsive efficiency secured by the combination of efficient turbines with suitable screw propellers driven by the turbines. In marine steam turbines it is consequently found necessary to accept lower rates of revolution than can be applied with advantage in land turbines because a very rapid rate of rotation tends to diminished propeller-efficiency. This was one of the most serious problems which had to be faced in the design and construction of the *Turbinia*; its solution occupied a long period, and led to many modifications in that remarkable vessel before success was finally achieved and the revolution in marine steam engines above described was made possible.

Great differences exist in the conditions of service of various classes of ships, and demand different designs of propelling machinery. Hitherto the turbine has been used almost entirely in vessels of high speed, but its use in vessels of moderate or low speed is now being considered. There also Sir Charles Parsons has done pioneer work and has taken the lead in producing practical examples. A cargo steamer of good type (the *Vespasian*) has been purchased, her reciprocating engine has been removed, and geared turbines have been fitted instead. These turbines run much faster than the propeller shafts, so that both the turbines and the screw propellers can be given high efficiency. A long period of working in actual service, as well as measured mile trials, have shown a considerable gain in economy and cargo capacity which was well worth having in cargo vessels even of low speed. Another arrangement suitable for vessels of the "intermediate" type—in which large passenger accommodation is combined with a great capacity for carrying cargo and moderate speed—is known as the "combination system." Low-pressure turbines are associated with reciprocating engines in such vessels, and the expansion of the steam can thus be carried much further than in engines of the reciprocating type. In the *Olympic* and *Titanic*, the largest vessels at present afloat in the mercantile marine, this combination system has been applied, and it had previously proved completely successful in vessels trading to Australia and Canada. These are but a few of the examples of the variety of the applications of the steam turbine in marine propulsion which are illustrated in this book; and other applications to mine ventilation, blast furnace operations, and other services are also described. The volume is handsomely produced and beautifully illustrated.

W. H. W.

SYSTEMATIC BOTANY.

Handbuch der systematischen Botanik. By Prof. R. R. v. Wettstein. Zweite Auflage. 1 Hälfte. Pp. 424. Price 20 marks. 2 Hälfte. Pp. viii+425–915. Price 24 marks. (Leipzig und Wien: F. Deuticke, 1910–11.)

THE first edition of this work appeared in 1901, and during the decade that has elapsed since, important advances have been made in the investigation of many groups in the vegetable kingdom, more especially in the Schizophyta and the Gymnospermæ. The first part comprises the Cryptogams and Gymnosperms, preceded by a general introduction of some fifty pages, in which the more recent discoveries and theories are discussed, explained, or mentioned. As the title indicates, the work is entirely devoted to systematic botany, and it may be added that it is not intended for the beginner, but for students already fairly well versed in the rudiments of the science.

The main object has been to construct, or rather to improve, a classification on phylogenetic principles. It is now generally admitted that it is impossible to give expression to this in a linear arrangement, especially as a monophyletic development can no longer be sustained. On this point Dr. Wettstein is very decided. He accepts it as probable, however, that the more highly organised plants—the Cormophytes—are of monophyletic descent, though it cannot be claimed that this point has been settled. On the other hand, he considers that it is beyond doubt that the so-called Thallophytes include types of very different origin. Consistent with these views, Wettstein discriminates seven "Stämme," or lines of development, namely, (i) Myxophyta; (ii) Schizophyta; (iii) Zygophyta; (iv) Phæophyta; (v) Rhodophyta; (vi) Euthallophyta; and (vii) Cormophyta; and he thinks it very probable that the Cormophytes may have been derived from one or the other of these stems, most probably from the Euthallophyta. The designation of these stems are mostly sufficiently descriptive to be intelligible; but one is naturally curious as to what the Euthallophyta include, as they are here placed next to the Cormophyta, on account "of possible genetic connections." Wettstein's brief diagnosis of this group runs:—

"One-celled or many-celled. Cells of the vegetative stages of development, clothed by a membrane, which is not composed of shell-like segments. Autotrophic (self-nourishing) or (in derived series of forms) heterotrophic. The autotrophic forms always furnished with chlorophyll in the assimilating cells. Simpler forms propagated vegetatively only; those of higher organisation sexually as well. Autotrophic forms (with isolated exceptions) adapted to the development of their reproductive organs in water. Not differentiated into root, stem, and leaf."

It is not assumed that the above characteristics (all or any one of them) are peculiar to the group; but as thus broadly defined, the Euthallophyta include two classes, the Chlorophyceæ and the Fungi. To the first belong the orders Volvoceæ, Ulothricaceæ, Siphoneæ, and the Characeæ. The Fungi are divided into parasitic and saprophytic Fungi, including those symbiotic with Cormophytes (Mycorrhiza, &c.), and Fungi symbiotic with Algæ, otherwise Lichens. The Myxophyta, formerly associated with Fungi, and now placed in the lowest series of vegetable organisms, are characterised thus:—

"One-celled or many-celled. Vegetative stages of development composed entirely of membraneless cells. Nourishment never autotropic. Sexual reproduction altogether wanting."

We have not space to enlarge on the treatment of the different groups of organisms; but it may be mentioned that the Schizomycetes (bacteria) are described and illustrated in some detail, though the figures are practically all copied from Migula, Meyer, and other writers on the subject, and are much the same as in the first edition.

It may be interesting to mention that the cells of some of the Schizomycetes are the smallest hitherto measured; those of *Spirillum parvum* being from 0·1 to 0·3 μ in thickness, whilst those of the organism causing lung-disease in cattle are described as even smaller.

Turning to the Gymnospermæ. It seems a pity that the term "flower" should still be employed to designate the organs of reproduction, with or without envelopes or appendages, especially as the interpretations of authors are so divergent; some viewing the female cone of an Abies, for example, as an inflorescence, others as a flower. Much confusion has arisen from this cause in the nomenclature of the components of a cone. Wettstein defines the flowers, "characteristic of all Anthophytes," as shoots, or parts of shoots, which bear the leaves on which the sexual organs of reproduction are formed. And he adds that accepting this definition, Selaginella is the only other genus among recent plants that has flowers In this connection it may be added that the fossil Bennettitinæ present some of the most singular of the "flowers" of Gymnosperms. They are either unisexual or bisexual. Those of *Cycadeoidea ingens* are interpreted as having a perianth of numerous plumose segments; twelve pinnate stamens, involute in æstivation, with very numerous anther-cells, and a solitary central gynæceum or ovule, whereas *C. Wielandii* has female "flowers" with a plumose perianth and numerous separate ovules, or gynæcia, looking much more like pistils.

Tumboa (Welwitschia) is mentioned as the only living gymnosperm in which the pollen is conveyed by insects to the ovules.

The foregoing was written before the second part of the work was received. This has undergone less modification than the first, and we must dismiss it with a few words. We note that the proposed new Order or Family, the Julianiaceæ, has been accepted and placed in the Juglandales, though Hallier had previously reduced it to the Terebinthaceæ. The entire work has undergone an enlargement from 778 pages to 914, with 571 additional figures. Most of the figures are exceedingly good, but unfortunately many of them have lost much of their beauty through being printed too black. Of course, in a comprehensive work like the present, a large proportion of the figures must be borrowed; but here the source of every one is indicated. It may be added that Dr. Wettstein writes a simple, clear German which is easily construed.

W. B. H.

PHOTOMICROGRAPHY.

Practical Photomicrography. By J. E. Barnard. Pp. xii + 322 + 10 plates. (London: Edward Arnold, 1911.) Price 15*s.* net.

KING SOLOMON'S remark that "of making books there is no end," applies to the subject of Photomicrography nowadays, as well as to any subject in his time, for many indeed are the books, both large and small, that are now available. Yet the author of "Practical Photomicrography" has had the courage to publish a handsome volume of some 300 pages which we think fills a unique place. Our reason for saying so is because we should call this book a dictionary upon the subject rather than a practical guide, and there is no such work as that in existence. For example, if we require an illuminant suitable for some special class of work, we have only to turn to our dictionary, open the chapter devoted to "sources of illumination," and there we find an epitome of all that is known upon the subject. So, too, with cameras for all classes of work, photographic stands, and, indeed, every other thing connected with photomicrography. But if we look for practical hints or useful "dodges," such as the author must know in abundance, we can find—if, indeed, any at all—only a very meagre supply. There is no taking the beginner by the hand when attempting his first photograph, and telling him how to proceed to obtain a uniform background, and how to adapt and regulate his screen or filter so as to increase or diminish contrast; no explaining to him such things as how to distinguish between the use of an ordinary inch on his microscope, and the employment of a planar or such-like combination of the same magnifying power; no helping him to make progress from low-power work to high-power magnifications, and the pointing out to him the many pitfalls he may expect in this section of the work. Nothing, or very little indeed of this nature is given; anyhow, in a collective and succinct form.

Proceeding seriatim through the book, the introduction over, the reader is told first about the microscope and general equipment, not so much in particular for any special type of work—such as high, low, or medium magnifications, but in a general way; and tables of magnification, cuts of different eye-pieces and such-like, occupy several pages. It must not be omitted to mention some good photographs of Abbe's test-plate, but we question the expediency of comparing the photographic performance of achromats with that of apochromats, unless the former are used in conjunction with a suitable screen to cut off the secondary spectrum, which we are unable to find was done in this instance. A student upon seeing these comparisons might be led to think that the achromat was of no service at all, whereas the image in the preferred colour with most of the newer form of modern achromats is of the finest description, and almost rivals that produced by the apochromat: but a screen *must* be used.

Whilst referring to the resolution possessed by combinations of different numerical aperture, an error has crept in on p. 60. The 80,000 should be 40,000, as a solid direct cone is being spoken about, and not oblique light. Abbe's law of *doubling* the number of waves to the inch of the light employed refers only to the use of oblique pencils, and not to direct illumination at all. Passing over this slip in the reading of the proofs, we come to the consideration of collecting systems, and here again we find a most comprehensive chapter full of interest and information; but we must remind the reader that the Köhler lenses are not of the simple kind that the author leads one to believe. A careful examination of their curves reveals at once that they are of what may be called the distorted type. Their originality and usefulness has led the makers to call them after their inventor's name.

The sources of illumination, as we have already said, are fully discussed in the chapter devoted to this branch of the subject, and the dark-room and photographic methods, with all connected with the production of the negative and positive, whether on glass or paper, carefully gone into. The master mind is here very much in evidence, although he offers but scanty information how to distinguish a slightly over-exposed from a slightly under-exposed plate; his opinions would have been welcome we feel sure, even to the experienced hand, for at times it is extremely difficult to decide.

Several methods of reducing vibration with apparatus located in other places than the basement are mentioned, but we did not notice the method of using several layers of carpet-felt under each leg of the apparatus. We have been told—and it is common knowledge—that several workers in busy streets employ this method which was suggested by Mr. Norman—with much satisfaction.

A chapter is written upon the manipulation of the apparatus in general, but it is of a scattered nature and not collected under specific heads, so that the reader is left to ferret out what he wants for any special kind of work. The information may be there, but not easy to find.

The use of filters and screens is dealt with, and, so far as it goes, is of great value and information; but it is to be regretted more particular mention is not made of the uses of the box of "gelatines" sold by Messrs. Wratten and Wainwright, of Croydon. In the booklet accompanying the arrangement opposite to the name of most dyes used for microscopy, is placed the number of the screen to be used to increase contrast if required, whilst, in addition, besides showing how to reduce contrast, a table is given showing how by the assembling of certain of the same films together, monochromatic light of given wave-length can be obtained at almost any part of the visible spectrum. It is obvious of what service this little "box" is to the practical man at work, and ought to be always named as part of the equipment.

The description of several special processes, stereoscopic photography, the photographing of culture tubes and cultures, are followed by some important remarks concerning the use of ultra-violet rays; and then comes a very comprehensive index and the plates.

We are bound to express our disappointment at the appearance presented by plate i. Everyone knows it is not altogether easy to obtain a uniformly and pleasantly tinted background, but in this instance the blocks have been cut away up to the very margin of the object, and even that is sliced up into moieties! Surely a student who looks for guidance wants an ideal to live up to, a standard at which to aim? If the teacher be guilty of exhibiting work of this description, how will he teach the tyro to do better? The author's strong point is certainly not that of photographing diatoms, but is rather that dealing with bacteriological specimens and such like. Take, for example, the photograph of *Trypanosoma gambiense*, or that of *Bacillus typhosus*, in plate vii.: we doubt if it be possible to find two more magnificent illustrations in any book upon the subject. So too with the Podura scales in plate viii. The manner in which the constriction around the head of the so-called "comma" or "note" is shown is beyond all praise, and so too is the delicate tapering off to a point of its extreme end: it is perfection. We wonder what the promoters of the new idea that this focus is not the correct one, and that they have found another two or three (according to how they misarrange their adjustments), will say to this magnificent work? Taking "Practical Photomicrography" as a whole, we cordially recommend it, and congratulate the writer; but the reader must approach it as a dictionary full of answers to questions he may desire to put, rather than as a guide, philosopher, and friend, for that it is not.

MODERN ELECTROMAGNETIC THEORY.

Outlines of the Theory of Electromagnetism: a Series of Lectures delivered before the Calcutta University. By Dr. G. T. Walker, F.R.S. Pp. viii+52. (Cambridge: University Press, 1910.) Price 3*s*. net.

THESE lectures were intended to present some of the more important developments of electromagnetic theory in a connected and convenient form for the use of advanced students in the University of Calcutta and of the lecturers in outlying colleges. Following the example of Abraham and Föppl's excellent treatise, the author prefixes a chapter on the notation and methods of vector analysis, employing clarendon type for vector quantities. These are adhered to closely throughout the book, with the slight excursions into Cartesian method which seem to be inevitable. The second chapter consists of some illustrations of the application of these methods to the magnetostatic field. This is followed by an account of the Hertzian form of the equations of the electromagnetic field both for stationary and for moving bodies, with an indication of instances in which they fail to agree with experiment, and, finally, the electron theory of Lorentz is expounded so far as the general equations of the field are concerned.

The book is welcome as partly supplying the great need of an English text-book setting forth clearly the present state of electromagnetic theory, which seems in the last few years to have emerged a little from the purely tentative stage. The accumulated evidence against the possibility of the determination of a unique velocity of matter relative to the æther is giving physicists a prepossession in favour of the Lorentz field-equations. The present work seems to be directed mainly towards familiarising a larger public with the theory on which these equations are based, as contrasted with the earlier theory of Hertz. The account given is concise and free from digressions, and well adapted to the author's purpose.

In one respect the book might have been improved, and have assisted more materially than it does in establishing a uniform usage among English writers on electromagnetism. The author speaks of the *polarisation of the aether, polarisation of the matter, and of total polarisation.* Now that the theory of the stagnant æther is generally accepted, the time would seem ripe for confining the term *polarisation* to the second of these quantities, even if the unsatisfactory term *displacement* has to be retained for the last, as is done by Lorentz in his "Theory of Electrons" (Leipzig, 1909). It would be a great advantage to students beginning to read the subject if English-speaking physicists would adopt a terminology analogous to that used in recent German accounts of the subject (*e.g.* Lorentz, "Enzyk der Math. Wiss."; Abraham, "Theorie der Elektrizität," Bd. 2), where the term *Erregung* is used for both displacement (electric) and induction (magnetic).

The author is slightly confusing in his use of symbols, making an otherwise very clear exposition more difficult to follow. Without warning, the notation for the magnetic induction is changed from $\mathbf{B}$ to $\mathbf{H}$, a new symbol, $\mathbf{H}_1$, being introduced for the magnetic force, and an equally novel one, $\mathbf{G}^1$, for the magnetisation. Closely following one another we find the three equations, $\text{div}\, e=\rho$, $\text{div}\,\mathbf{D}^1=-\rho$, $\text{div}(\mathbf{E}+\mathbf{D}^1)=\rho$, in each of which ρ has a different significance. An apparent desire for brevity has caused the omission of explanation which was probably present in the spoken lectures and would make the book much easier to read for one to whom the subject was unfamiliar. The process of finding the average electric force over a small element of volume, so fundamental to the Lorentz theory, would with advantage have received fuller explanation, if only by a bare definition of the averaged vectors.

Save for the few exceptions referred to, the book marks a distinct advance towards a text-book which shall give its readers a clear outline of modern theory as it is at present developed.

ELEMENTARY PRINCIPLES OF AVIATION.

(1) *Elementary Aëronautics, or the Science and Practice of Aërial Machines.* By A. P. Thurston. Pp. vii+126. (London: Whittaker and Co., 1911.) Price 3*s*. 6*d*. net.

(2) *The Principles of Aëroplane Construction.* With Calculations, Formulæ, and 51 Diagrams. By R. Kennedy. Pp. vii+137. (London: J. and A. Churchill, 1911.) Price 5*s*. net.

(1) "ELEMENTARY AËRONAUTICS" is a careful collection of available information, together with some elementary theorems in aërodynamics which are, on the whole, good. It is necessary in considering early theories in aëronautics, that the reader should be carefully informed as to the limitations imposed by the initial assumptions, and also of departures from usual practice. This feature is not always sufficiently emphasised in the present work.

Generally speaking, frictional resistances are ignored without mention, and on p. 20 a new definition of stream lines is given which is quite foreign to the more usual definition adopted in mathematical aërodynamics. Further, the equation used in this case is only applicable to an incompressible fluid, and it is possible that for propellers such an assumption may not be justifiable.

A small point of printing is worth noting. Suffixes are not always clearly indicated, and might easily be misread for factors. An obvious case occurs at the bottom of p. 5, where $P\alpha \cos\alpha$ is written for $P_\alpha \cos\alpha$.

The first thirty-one pages provide a sound *résumé* of current data, accompanied by illustrations of the motion of air round obstacles. The advantage of aërocurves as compared with planes is clearly and correctly indicated. The work then proceeds immediately to less certain ground in the discussion of stability. The formula for damping of oscillations deduced on p. 37 appears to be wrong, as the damping effect of a plane is largely dependent on the forward speed—an effect which is ignored.

The chapter on propellers and helicopters is good only if it be clearly borne in mind that ideal conditions are assumed for most of the theoretical deductions. Air is supposed to be a frictionless fluid, and it needs some little care to distinguish between deductions from theory and experiment. With the assumptions clearly stated the chapters would be sound.

The applications of principles and tables to designs will be quite easily understood and appreciated, the calculations involving only the most elementary knowledge of algebra, and the guiding principles being quite trustworthy.

Laboratory apparatus does not make an impressive portion of the book, the notes given being of very general interest only, and in most cases insufficient to give any practical guidance to students new to experimental aërodynamics.

The remainder of the book is then occupied by descriptions of the successful flying machines and engines. As before, when the author was dealing with established data, the work is good, and as complete as is possible at the present time, the items of further interest being difficult to obtain.

The book is well worth reading by anyone starting on a study of aëronautics, as, in spite of its simple and elementary character, it is a fairly complete survey of the more trustworthy existing knowledge and practice.

(2) It is exceedingly difficult to appreciate the point of view of the author of this book. The mechanical principles involved are curiously contorted, and a brand new theory of lift is put forward which the author confesses may be defective. The theory is then justified by the remark that if modified as indicated "such a theory could not give any determinate data."

Many of the calculations are nevertheless right, and, in fact, are usually so on the assumptions adopted.

Passing over minor points, we find on p. 17 that velocity and acceleration have come to mean so much the same thing to the author, that the reader is told that if V be the vertical velocity of a weight W, which is moved by pushing an inclined plane under it, the vertical force on the plane when moving with constant forward velocity is greater than the force when the plane is at rest by $\frac{WV}{g}$. By sacrificing consistency, however, the author gets back to better dynamical principles when dealing with fluids.

In order to make the mass of fluid dealt with determinate, various arbitrary and improbable assumptions are made, and considering everything, the consequent numerical results are remarkably good. A wholesome respect for records of flights enables the author to extract multiplying factors to replace defects of theory.

On p. 23 is given an *a priori* proof that a "partial vacuum cannot be produced in the neighbourhood of an aëroplane in an open atmosphere. In view of experimental evidence that "partial" vacua are extremely important, an *a priori* proof is absolutely worthless. The argument is, however, consistent with a general attitude of doubt as to the value of experiments on models, the law of relative motion, and the resources of scientific inquiry not being fully appreciated. (Pp. 62–3, &c.)

The very difficult problem of obtaining automatic stability is dismissed in five lines as a simple problem having many simple solutions.

To anyone beginning the serious study of flight this book would appear to be a dangerous introduction.

L. BAIRSTOW.

OUR BOOK SHELF.

School of Agriculture, Cambridge. A Course of Practical Work in Agricultural Chemistry for Senior Students. By Prof. T. B. Wood. Pp. 56. (Cambridge: University Press, 1911.) Price 2*s.* 6*d.* net.

IN this modest booklet Prof. Wood sets out the practical exercises through which his students are expected to work during their course in the Cambridge School of Agriculture. It will be studied with interest by teachers of agricultural chemistry in other colleges, who have not as yet any very extensive text-book literature at their disposal. Further, many of them will be anxious to learn as much as possible of the secret of Prof. Wood's success, and to see the details of the course he has evolved since he has been responsible for the teaching of agricultural chemistry at Cambridge.

The exercises set are mainly analytical. Right from the outset the student has to use the accepted method, working it out in all its details; there are no short class-room methods such as would have to be discarded later. Much time is thus saved, for the student has nothing to unlearn when he leaves college and has to attack actual problems in a technical laboratory. The system is only possible, of course, when the student has already had a certain amount of experience of chemical work before turning to agricultural chemistry, but this ought always to be the case.

Where methods are so conventional as they necessarily are in agricultural chemistry, there is little room for originality, but Prof. Wood is not entirely hampered by custom, and has not hesitated to give newer methods where any advantage is to be gained. Thus he uses Neubauer's method for determining the potash and phosphoric acid in soils, which for some reason or other is not commonly used in England in spite of its accuracy and rapidity. He also describes the volumetric method of determining phosphoric acid, in addition to the ordinary gravimetric method. Other exercises include short studies of clay, sand, and humus, the retention of manures by soil, and experiments on oils and proteins. Sufficient detail is everywhere given to enable the student to work on his own account, but there is nothing superfluous, and the whole forty sections go into fifty pages. Altogether the book can be cordially recommended for advanced students, and also for the growing class of men who have to carry out agricultural examinations and analyses but do not want to purchase the large costly manuals. Most of the routine work of an agricultural laboratory is described.

E. J. R.

Physical Geography for Schools. By B. Smith. Pp. viii+190. (London: A. and C. Black, 1911.) Price 3*s.* 6*d.*

"WE have," wrote W. D. Cooley in 1875, "numerous treatises on physical geography which are in reality merely outlines of geology," and he attributed them to the influence of the ardent geologists of half a century earlier who had ennobled the rudiments of geography connected with their own pursuits with the title of physical geography.

Mr. Bernard Smith's text-book shows that there is still ground for Mr. Cooley's complaint, for it treats physical geography as mainly geology. It describes the physical process at work on the earth's surface, and deals inadequately with the distribution of the results and their influence on human development. The book is admirably illustrated, but a large proportion of its 221 figures are geological, and many of the best are from the collection of the Geological Survey. The photograph of the deck of a warship (p. 180) might have been replaced by one of more geographical value.

The book makes no claim to originality either in subject or method. It begins with short accounts of the solar system and the atmosphere; most of the book is devoted to a description of the composition, sculpture, and forms of the land, and it ends with a brief summary of the geological history of the British Isles. The author occasionally assumes too much knowledge of other sciences, and gives some explanations, as of the electro-magnetic theory of light, which are unnecessary in a geographical text-book.

On its lines the book is well done, but the paragraph on p. 12, "The atmosphere is heated chiefly in two ways—by the internal heat of the earth and by the sun's rays," would suggest that the internal heat has a powerful effect. The term caldera is used for a large crater, whereas it is better limited to a crater formed by subsidence. There are inevitably a few mistakes, such as the statement that the Colchester earthquake destroyed from twelve to thirteen thousand buildings; the title of a view of Stirling calls the river there the Tay, and the Midland Valley of Scotland is described as a lowland plain.

Die Elemente des Herzmuskels. By Prof. A. Dietrich. Pp. 46. (Jena: Gustav Fischer, 1910.) Price 1.20 marks.

The twelfth of the series of short monographs published under the editorship of Profs. Gaup and Nagel is a very able and interesting account of the minute structure of cardiac muscle, by Prof. Dietrich, of Charlottenburg. Perhaps of most value at the moment is his concise and judicious statement of our knowledge of the structure and distribution of the atrio-ventricular bundle, that complex system of peculiar fibres collecting the whole musculature of the heart under its extended grasp, as if for purposes of coordination. More original and of great interest is his discussion as to the meaning of the transverse lines which are still very generally accepted as limits to those individual cells by the juxtaposition of which the fibres of cardiac muscle are said to be formed. Faith in this view was somewhat shaken when it was found the structural element of major importance, the intra-cellular contractile fibrils, swept through these lines without interruption. More recently this view has been still further discredited by proof of their irregularity of occurrence in relation to the nuclei of the tissue.

Prof. Dietrich does not attempt to arrive at any very definite conclusion in this matter, but his treatment of the subject includes an excellent and impartial summary of views advanced by other recent investigators, and is illuminated by the results of his own experience and observations. It seems clear that these lines are definite incidents of structure of invariable occurrence and not artefacts due to conditions prevailing only at death or in the technique of the histologist. That is to say, Prof. Dietrich makes this clear, and his observations of their differential distribution in various districts of the wall of the heart, and discussion as to the circumstances more characteristically prevalent in each of these districts deserve special attention.

Black's Medical Dictionary. Edited by John D. Comrie. Pp. x+855. Fourth edition. (London: A. and C. Black, 1910.) Price 7s. 6d. net.

This book, which has now reached its fourth edition, contains an extraordinary amount of information in a comparatively small space. So far as we have been able to test it the details given seem generally to be accurate, and we consider that it well fulfils its avowed function of imparting medical knowledge in comparatively non-technical language, such as is required by the district nurse, health visitor, clergyman and missionary, ship's captain, colonist, traveller, and others. We think that some of the rare conditions mentioned, such as acromegaly, myasthenia, and syringomyelia, might well have been omitted, and the space gained have been devoted to such a subject as the management of labour, which is too briefly treated. Similarly, the pages devoted to the history of anæsthetics are of no real value, and had they been cut down to one-half, and a few practical hints given on the administration of anæsthetics (which occasionally has to be done by a missionary, ship's captain, &c.), the book would have gained in usefulness.

What will the Weather be? The Amateur Forecaster's Vade Mecum. By H. G. Busk. Pp. 36. (Cambridge: W. Heffer and Sons, Ltd., 1911.) Price 6d. net.

It is less than a year ago that the first edition of this useful booklet appeared. We notice that in the new edition tables for confirming a forecast, and a note on the significance of a barogram, have been added.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Early History of the Gibraltar Cranium.

The Gibraltar cranium is generally regarded by anthropologists as one of the most important discoveries yet made of the Neanderthal type of man. Unfortunately, its early history is imperfectly known. The two following letters help to make good this deficiency. For the first I am indebted to Colonel E. R. Kenyon, Commandant of the Royal Engineers at Gibraltar; for the second, to the Misses Busk, daughters of Mr. George Busk, F.R.S., who in 1868 presented the cranium to the Royal College of Surgeons, England, of which he was at one time president.

Engineer House,
Gibraltar,
April 2, 1910.

"In the Minutes of the Gibraltar Scientific Society, under date March 3, 1848, there is this record":—

Presented a Human Skull from Forbes Quarry, North Front, by the Secretary.

"On February 4, 1846, Lieut. Flint, R.A., was elected secretary, and there is no record of any change. The officers of the society were re-elected in February, 1847, and February, 1848.

"The last recorded meeting of the society was in May, 1853.

"The old plans have been examined, and no place named 'Forbes Quarry' can be found, but I think there can be no doubt that it is the disused limestone quarry shown on the Ordnance Survey south-east of the ancient 'Forbes Barrier.' The obsolete batteries near there are the 'Forbes Batteries,' and these are the only sites to which the name 'Forbes' is attached."

"E. R. Kenyon,
"Col., Chief Engineer."

"P.S.—Lieut. Flint died at Mauritius as a captain on January 12, 1857."

The famous Neanderthal remains were found in 1857, and are usually regarded as the first discovered remains of that remarkable race of early Europeans now known by the name of Neanderthal man (*Homo primigenius*, Schwalbe). It will be thus seen that the Gibraltar cranium was the first discovered trace of Neanderthal man, having been found nine years before the type-specimen.

The second letter is from Dr. Hugh Falconer to Mr. George Busk. The date of the letter was certainly 1864; Dr. Falconer and Mr. Busk were then preparing a report on a large collection of fossil remains from caves at Gibraltar for the British Association meeting at Bath in that year. In this collection was the famous cranium. The collection was made and sent home by Captain Brome, who was in charge of the garrison prison. Unfortunately, his scientific enthusiasm led to his dismissal from his post and from the Services; he had employed prisoners to help him in the scientific investigations which led to the discovery of the remarkable cave fauna of Gibraltar. Mr. Busk took a leading part in obtaining from fellow men of science financial sympathy on behalf of Captain Brome.

21 Park Crescent,
August 27 (1864).

"My Dear Busk,

"A hint or two about the names which I have been rubbing up for the Priscan Pithecoid skull, *Homo var. calpicus*, from Calpe, the ancient name for the Rock of Gibraltar. What say you?

"For the characters of the face: as all the *pros, orthos, katas*, &c., are already engaged in conjunction with *gnathos*, we must look elsewhere. Βλεμμα—*aspectus, vultus* for a foundation sound well and appropriate—*e.g.* Βλεμεαινῶ "truculus oculis circumspicio." I am sure Pithecoid must have looked terribly truculent.

"Now for the combination. *Pro-blemmatous* at a pinch might do, but I doubt the soundness of the combination, and I think a better might be *agrioblemmatous*, from αγριος, wild or savage, and Βλεμμα. By this happy combination you will unite the truculence of the eye and the savagery of the face. *Agrioblemmatous* is really not a bad idea—it points distinctly to a peculiar savage feature—

"Walk up! ladies and gentlemen. Walk up! and see Professor Busk's Grand, Priscan, Pithecoid, Mesocephalous (!), Prognathous, Agrioblemmatous, Platycnemic, wild Homo calpicus of Gibraltar; Sounds well, anyhow.

"But *mesocephalous* is French-like—radically wrong. The temporal is a mesocephalous bone of the head; but the skull itself cannot be mesocephalous, or a mid-headed portion of itself. *Diacephalous* is better than Broca's term.

"Yours ever,
"H. FALCONER."

The letter shows that the veteran Scot, the pioneer of the Siwalik fauna, had a sense of humour, a facility in coining names, and a very clear conception that *Homo calpicus* was a very distinct variety of mankind. The cranium was duly exhibited at the meeting of the British Association at Bath in 1869, but there is no record in the report of what Mr. Busk said about the skull (except as to where it was found and that it resembled the Neanderthal specimen) nor of Dr. Falconer's taxonomic suggestions.

A. KEITH.

Royal College of Surgeons, Lincoln's Inn Fields, W.C.

A New Mineral?

WHAT may prove to be a new mineral has been obtained from the Du Toits Pan Mine at Kimberley. The material is in two forms: irregular pieces up to half a pound in weight, and small round pellets, which, collected together in a heap, would be mistaken for mixed shot. Some specimens are dull like lead on the outside, while others have a resemblance to polished nickel. The prevailing inside texture is spongy-looking. Under the microscope some of the surfaces are seen to be pitted with holes where the spongy texture reaches the surface. On the other hand, some of the larger pieces have wrinkled surfaces, not pitted; others have bright surfaces intersected with tiny cracks. Many of the specimens are covered with a blackish coating of about the thickness of paint. This is probably graphite; it scrapes off easily enough.

The specific gravity is on the whole something higher than 6·7, but by exactly how much higher it is difficult to say, on account of the porosity of the material. The hardness ranges high, varying from about 6 on a fractured face and on the duller outside surfaces to upwards of 9 on some of the bright surfaces. It is attracted by the magnet to a moderate extent—some pieces very feebly. It is very brittle, and on fracture gives off a strong smell of carbide.

Mr. W. Versfeld, Government analyst, Cape Town, makes out the following analysis:—

	Per cent.
Iron	71·39
Silicon	20·03
Carbon	8·41
	99·83

This composition corresponds approximately with the symbol $Fe_{11}Si_6C_6$. It appears that in chemical properties this mineral is one of the most refractory of substances. The mineral acids, aqua regia, fused potassium bisulphate, have only a slight action upon it. Roasting at a very high temperature causes no change except a slight tarnishing. Fusion with sodic peroxide, however, causes a ready oxidation. Prof. Schwarz, to whom the material was submitted, has taken a great interest in the find, and calls it, therefore, very aptly, a ferriferous carborundum.

Unfortunately, none of the material has yet been found *in situ* (nor is it very likely to be, seeing that the supply has now nearly ceased); all of it, so far, has been picked out at Pulsator by the manager, Mr. J. Stewart, in separating the blue-ground for diamonds. Schwarz points out quite truly that in the absence of a specimen in the blue-ground matrix the history of the material is incomplete. Nevertheless, it seemed advisable to put the facts, so far as they are known, on record.

With regard to the origin of the material, Prof. Schwarz writes as follows:—"Dr. P. A. Wagner states in his paper on 'Kimberlite Occurrences in the Pretoria District' (Trans. Geol. Survey of S. Africa, vol. xiv., p. 62, 1911), that on melting up blue-ground in a crucible, metallic globules of iron were obtained usually enclosed in the olivines crystallised from the fused mass. Mr. Thornton Murray examined the largest of these globules and found it to consist of a perlitic grey cast-iron enclosing flakes of graphite; it weighed one gram, but the average globules were smaller. The new mineral from Du Toits Pan Mine is probably of the same nature produced naturally; some local source of heat, frictional or chemical, due to combustion of gas or otherwise, may have raised a portion of the blue-ground to fusion point, and thus produced the globules and masses by reduction of the ilmenite or even the silicates of iron. The refractory nature of the material renders it possible that it formed as an original constituent of the blue-ground, but the subsequent hydration of the olivine rock to the serpentine breccia would probably have acted more upon the substance than is apparent in the actual specimens. Re-fusion of the hydrated rock seems therefore a more probable explanation." J. R. SUTTON.

Kimberley, August 14.

A Miniature Rainbow.

JUST about three o'clock this afternoon (I had a few minutes previously asked the time at the village post office) I witnessed a remarkable and very beautiful phenomenon. Coming through a woodland walk, I was caught by a heavy downpour of rain. As it was passing away, the sun shone down from a suddenly clear sky over the tops of the trees behind and to the right. Instantly against a screen of dark alder foliage on the left in front, and distant not more than three yards from where I stood, a perfect miniature rainbow was formed, its highest part being just about level with my eyes. It appeared broader than an ordinary rainbow, and much the greater portion was of one deep violet colour, the remaining colours forming merely a narrow border above. Very vivid at first, it quickly faded away, as the shower came to an end.

Kilderry, Londonderry, August 28. W. E. HART.

The Fertility and Extinction of Forest Trees.

THE mountains of Madeira exemplify perhaps more clearly than the denuded Scottish hills the "irreparable loss" which your correspondent "D. W. T." (NATURE, June 1) deplores in the disappearance of the Scotch fir forests. For not only have we exhausted our splendid timber in prodigal excess of economic requirements, but we have further to face the fact that the straggling trees which still survive in remote or precipitous localities appear to have lost much of their former fertility, showing now no tendency to spontaneous spread nor any evidence of the prolific reproduction of former days. Hence we are confronted with the absolute extinction of woods not grown elsewhere—woods of very great botanic interest both in themselves and in relation to problems of origin and distribution.

Madeira (Materia) was the name given originally by the Portuguese discoverers to denote the densely wooded condition of their new possession.

The destruction of the forests began with the first colonists nearly 500 years ago, and was accentuated during the Spanish occupation in the second century of the island history. No replanting whatever has been attempted since, nor have any effective measures been put in force to stay the progress of destruction. The island population, moreover, has increased during the last fifty years from 75,000 to 150,000 people, and the land is everywhere being cleared and occupied.

Nevertheless, the introduction of the *Pinus Pinaster* has during the last 150 years had an important influence on the preservation of the surviving native vegetation, and the tree has become established on the heights from 1500 feet to 3000 feet above the sea in surprising vigour and profusion, supplying fuel and many requirements on which a more durable and valuable wood would be wasted. Some of your readers have seen at my mountain home the stately growth of the Pinaster planted only sixty years ago. The larger trees have a girth, 5 feet above the ground, of 12 to 15 feet, and vary from 80 to 130 feet in height. They lose all their lower branches in due course, many of them standing in majestic isolation to suggest the famous "Spear, to equal which the tallest pine hewn on Norwegian hills to be the mast of some great ammiral were but a wand." These Pinasters were giants when I came into possession thirty-five years ago, and their growth since has been in girth rather than in altitude, though their heads have not yet reached the Ezekiel stage of your correspondent "D. W. T."

In my view we should not trust to the maintenance of a single species in vigour and fertility, and hence I have brought many coniferous and other trees hither to test both quality and rate of growth, and thus their fitness to supplement or supplant our present supplies. Many of the newcomers, though growing into beautiful examples, do not merit extensive plantation, and I have not raised any specimens of Podocarpus, Widdringtonia, Libocedrus, Dacrydium, &c., the merits of which encourage their multiplication; but it is far otherwise with the Douglas fir, the *Taxodium sempervirens*, the *Abies Pinsapo*, *Cupressus macrocarpa*, &c., which are quite at home in their new environment and congenial soil, as also with the *Pinus canariensis* and the *P. longifolia*. The *P. insignis*, however, in this latitude is pre-eminently worthy of general adoption at the elevation of 2000 feet. I received seeds of this species from Kew in Sir J. Hooker's time, and one of the trees from this source has attained a growth of more than 100 feet in twenty-six years; and I have a goodly patch of young trees sown ten years ago which already vary from 25 to 30 feet in height.

But I have written enough to illustrate the importance of planting new varieties when threatened with declining fertility or extinction, though I cannot think the *Pinus silvestris* to be in any such danger. Irreparable loss is mainly the result of improvidence.

It is interesting to note that many of the Madeira trees which have become nearly sterile and almost extinct in the wild state become vigorous and abundantly fertile in cultivated ground.

The *Cerasus lusitanica*, the weeping Juniper (*J. Oxycedrus*), *Phoebe barbusana*, &c., are familiar examples of reviving fertility in altered circumstances.

I have sent from time to time specimens of the Madeira rare woods to the museum at Kew, and amongst them the ebony-like laurel wood of the *Oreodaphne foetens*, the heavy oleaceous wood of the *Notaelea excelsa*, and a long hammock-carrying pole made of Clethra wood, are worth attention.

The *Clethra arborea* is happily still quite common, and attractive at this season with its abundant show of fragrant lily-of-the-valley-like flowers.

Madeira, August 21. MICHAEL GRABHAM.

Non-Euclidean Geometry.

IN my "Theories of Parallelism" I expressed my sense of failure in controverting Bertrand's simple proof (by the consideration of infinite sectors and infinite strips) of Euclid's parallel axiom. This sense of failure has only increased since the publication of my little book.

I have also come across the statement that Poincaré has proved that no Beltrami "trumpet" surface in Euclidean space can completely image a hyperbolic space unless it has a line of discontinuity on it. I would welcome definite information about this. It seems to me an important objection. Had Poincaré this at the back of his mind when he dismissed space-theories as *matters of convenience* only in his brilliant volume "La Science et l'Hypothèse"?

There is something passing strange about the infinite regions of a hyperbolic space. If K is the space-constant and R the radius of a circle in Lobachewskian space, and if R is exceedingly large even compared with K, then the area of the circle appears as an *exponential* infinitude, something like $\pi K^2 \rho^{\frac{R}{K}}$

But if a regular polygon with an indefinitely great number of sides (N, say) can be inscribed in this circle of radius R, the area of each of the N component triangles is only K^2 times the divergence. And the divergence of each triangle cannot very well be supposed to exceed 2π, for then the angle-sum would be 3π. Hence the area of the polygon appears less than $2\pi K^2 N$.

Would readers offer an opinion?

Wrawby, near Brigg. W. B. FRANKLAND.

The Salary of an Assistant Lecturer.

I HAVE read with indignation the advertisement of the City of Bradford Education Committee on p. lxiv of NATURE of August 17 for an assistant lecturer in dyeing at a salary of "60*l.* per annum, with additional payment for evening work (two evenings per week)."

Do the members of this committee realise that they are offering to an assistant lecturer at their college less than the minimum wages—24*s.* a week—demanded by the railway strikers in the North for the lowest and least efficient railway employee?

They may reply that their lecturer can make a little more by extra work—evening work; but so can the railway employee, and the latter may do it without doing any extra work whatever.

According to the conditions of appointment, the person appointed will be required to devote the whole of his time to college work; the hours of actual attendance at the college are thirty-seven per week, the vacations may be curtailed "if necessity demands it," and the amount of the payment for the evening work is not given.

W. H. HODGSON.

Tredethlyn, Port Isaac, Cornwall, August 22.

Obsolete Botanical and Zoological Systems.

IN reply to the request of L. C. M. in your issue of August 3, the following references may be of interest to him. "Insect Architecture," Charles Knight and Co., Ludgate Street, 1845, contains a chapter upon systematic arrangement of insects, which contains the following:—Aristotle's, Linnæus's, De Geer's, Aldrovand's, Vallisnieri's, Fabricius's, Latrielle's, Swammerdam's, Ray and Willughby's, Cuvier's, Lamarck's, Sir Everard Home's, Clairville's, Leach's, Stephen's, and McLeay's classifications. Hoping this may be of use. M. NIBLETT.

52 Oxford Road, Chesterton, Cambridge.

THE SUK PEOPLES.[1]

MR. BEECH has written an extremely interesting book, the possession of which will be a necessity to every anthropologist and student of African languages; and the introduction to this work by Sir Charles Eliot is not a few vapid pages of commendatory remarks signed by a notable name, but an essential portion of the book itself.

Mr. Beech commences his work by a description of the Sūk people, and a sketch of their affinities with the surrounding peoples. He comes to the conclusion which was first published by the writer of this review in 1902, that the so-called Sūk peoples are really an assemblage of very diverse Negro and Negroid types whom the force of circumstances has driven into something like tribal cohesion in that picturesque country of deep ravines, high plateaux, volcanic peaks, and hot plains, between Lakes Rudolf and Baringo on the east, and the Elgon and Nandi plateaux on the west. Mr. Beech thinks that the traditions of the old men show that there were (in the main) two original tribes living in the western part of the Sūk country (the Elgeyo escarpment), the names of which were Chuk or Chok (the origin of the present name, which is a Masai corruption popularised by Joseph Thomson), and Seker; and that fugitives and adventurers from various surrounding districts entered the Sūk country, and intermarried with the two original tribes. "Every type is represented, from the tall, handsome Hamite, with almost perfect features, to the short, dwarf-like pygmy, with spread nose and bolting eyes."

The author is inclined to think that this last-named type characterised both the original Chuk and Seker. Elsewhere in the book, in connection with the illustrations, Mr. Beech refers to a "Bushman-like" type. Some of the first explorers who wrote on the subject of the Sūk people (including the reviewer) were apt to speak of the Bushmanlike type of Pygmy amongst them and amongst the neighbouring Andorobo (the Andorobo, be it observed, speak a language which is related to that of the Sūk, the Nandi, &c.). It is, we believe, the case that one or two trustworthy observers have noted types of physique amongst the Andorobo which offer a slight resemblance to the Bushman, but it now seems to be clear that the Pygmy type of Sūk, which also reappears amongst the Bantu tribes of Mount Elgon, as well as farther west in eastern Uganda, is decidedly not of Bushman affinities, but, on the contrary, obviously connected with the Congo Pygmy. This would seem to be the case with the dwarf tribes of southern Ethiopia first seen by the missionary Krapf, and of the Red Bongo, and other dwarf peoples of the Egyptian Sudan. There is no marked steatopygia amongst the Pygmy Sūk or any of the dwarf races just mentioned. In other anatomical features connected with the external genitalia of men and women (which it is not necessary to specify here, but which are clearly illustrated in Dr. Péringuey's work on the Stone Age in South Africa), they are almost the opposite pole amongst Negro races to the Bushman

Pastoral Suk (type 1). From "The Suk: their Language and Folklore."

The one or two illustrations of Pygmy types of Sūk in Mr. Beech's book are of value in emphasising this fact (the non-Bushman likeness of the Pygmy Sūk), the more so as they are taken from nude figures.

As regards the Sūk language, Mr. Beech comes to conclusions which seem to the reviewer to be thoroughly sound. He recognises the great affinity between Sūk and Nandi (to which we would venture to add the Ndorobo, Sotik, and other "Nandi" languages, and shows that the Turkana—that giant race of Lake

[1] "The Suk: their Language and Folklore." By M. W. H. Beech. With an introduction by Sir Charles Eliot. Pp. xxiv+151+3 maps+24 plates. (Oxford: Clarendon Press, 1911.) Price 12s. 6d. net.

Rudolf though it has so many affinities with the Sūk in regard to head-dress, costume, and customs, is far more nearly related to the Masai-Bari group in language. In fact, this book supplies a good deal of evidence which would show that Nandi and Sūk and the allied languages, though they must be classed in the same group with the Nilotic and Masai tongues, nevertheless stand very much apart from their congeners, and no doubt include a considerable element of pre-existing tongues quite unrelated to those sex-denoting languages which sprang into existence in the Nile Valley, influenced, it may be, in a slight degree by the Hamitic tongues of invading White men.

In a general way it may be said that the Masai-Bari-Turkana section of these Nilotic tongues is sex-denoting, and that the other groups (Shiluk-Dinka-Jaluo and Nandi-Sūk) are not; or, at least, that the principle of indicating the female sex in pronouns and prefixes has very much weakened. In reference to this argument may be mentioned the tendency on the part of certain German and English writers on African languages in recent times to persist in classing the Nilotic languages or members of the Nilotic family as "Hamitic," because they, like the totally unrelated Bongo language group of the western Egyptian Sudan, are sex-denoting. This idea in the syntax may have been inspired originally by invading Caucasians of Hamitic speech, but the result is attained, not—as in the case of Hausa and Musga—by the deliberate adoption of Hamitic feminine particles, but by the use of Negro vocables common also to the Bantu languages to indicate sex, such as *ol* or *lu* for the masculine (Bantu, *lume*), and *na* or *nya* (a word originally meaning "mother") for the feminine.

A great many interesting points in connection with African philology are indicated or are explained in this valuable little book, which may be finally commended for its lightness in the hand and for the mass of first-rate information which is packed into a small compass.

H. H. JOHNSTON.

WESTLAND—A NEW ZEALAND PROVINCE.[1]

WESTLAND is the province on the western coast of the South Island of New Zealand. Its name brings back a vision of a land covered by forests of tropical luxuriance, rising from a blue sea fringed by a white line of surf to blue mountains capped with fields of snow, of clean glaciers flowing steeply down into glades of tree ferns, and of a succession of pictures so varied and all so perfect in composition that we regard Westland as the most beautiful country it has been our privilege to see.

Miss M. Moreland tells in this volume the story of a ride through this district; and though she gives singularly little information, her book conveys a pleasing impression of her keen enjoyment of the scenery, and her enthusiastic admiration of the people. She dedicates her book to the New Zealanders who taught her to love their land. She rode from the Canterbury Plains across the Southern Alps to the western coast, and then down Westland, and back by the southern road to the eastern side of the New Zealand Alps. The book is illustrated by forty-eight excellent photographs and two maps. The author is not a geographer, and it was apparently only the special charm of the New Zealand flora that has roused her interest in botany; she was startled to find that the New Zealand lily is a tree, the Cordyline, that the pines equally exceed the stunted pines of Scotland, and that the flax, the name of which she always spells Formium, has a much longer and stronger fibre than the European flax. She expresses her great indebtedness for her knowledge of the plants to the work of Laing and Blackwell.

The Minarets: from the Tasman Glacier. From "Through South Westland."

While in Westland she visited a survey camp, and one of its members talked to her so enthusiastically about the silver cone of "Mount Aspiring" that she resolved to visit it, and after sundry misadventures reached the valley at its foot. She did not climb it. The first ascent was reserved for Captain Head. "For us," she says, "it is enough to have seen the great Silver Cone against the blue; we come no more." This

[1] "Through South Westland: a Journey to the Haast and Mount Aspiring, New Zealand." By A. Maud Moreland. Pp. xviii+221. (London: Witherby and Co., 1911.) Price 7s. 6d. net.

remark expresses the nature of the book. The author is satisfied with seeing; she has made no new routes and collected no new information, and some of her statements, such as that the egg of the Kiwi is as large as the adult bird, are untrustworthy; but she will doubtless feel repaid if her book leads others to visit Westland, and share her keen enjoyment of that beautiful land.

THE REV. F. J. JERVIS-SMITH, F.R.S.

BY the death of the Rev. Frederick Jervis-Smith on August 23, at sixty-three years of age, the world of science has lost an original and acute thinker and a man who had a genius for designing and constructing instruments of delicacy and precision. Trained as a mechanical engineer, he gave up the calling of his choice, went to Oxford and entered the Church for family reasons. The only son of the Rev. Prebendary Frederick Smith, of Taunton, he became the patron of the living of St. John's, Taunton, and was vicar for a few years. But he recognised that his real gifts were for science, and he took his workshop to Oxford, where he became Millard lecturer in experimental mechanics at Trinity College.

The teaching laboratory in Trinity fitted up by Jervis-Smith was worked in connection with the chemical laboratory in Balliol, and afterwards with the laboratory in St. John's, fitted up by Bosanquet, the three laboratories being close together. The passage opened between Trinity and Balliol in 1879 was known as "the scientific frontier."

In the Millard Laboratory Jervis-Smith constructed many of his well-known instruments, among which special mention must be made of his electric chronograph. Instead of the ordinary device of a heavy pendulum or rod falling under the accelerating force of gravity, Jervis-Smith made a carriage to run down rails so inclined that the velocity became constant after a certain travel. This carriage carried a smoked surface on which electromagnetic styli made their trace, as well as a vibrating tuning-fork. This uniformity of movement greatly simplified the conversion of the distance between the marks of the styli into time. The styli and the electromagnets were very small, and the retardation of the release on breaking the circuits was made by an ingenious system of winding the coils, both very small and nearly uniform.

Jervis-Smith had intended to use his chronograph in the investigation of the changes of velocity in the propagation of the flame in the explosion of gases; and, indeed, he made several sets of experiments on the propagation of the explosion of electrolytic gas under pressure in steel pipes, but he returned to the improvement of the instrument. Prof. H. B. Dixon carried out all his later researches on the velocity of the explosion-wave in gases with the help of electromagnetic styli constructed by Jervis-Smith. This chronograph has been largely used for measuring the flight of projectiles. Of his other instruments, the best known are the dynamometer and the integrator, but many of his ideas have been adopted in other measuring and recording instruments.

Jervis-Smith was endeared to his friends by his simple character, his dry humour, and the kindness of his heart. He would put himself to endless trouble to help a friend in any experimental problem, and he always managed to convey the idea that one was doing him a service by asking for his help. His skill and courage in saving life on the river at Oxford were recognised by the award to him of the Royal Humane Society's medal. He married Miss Annie Eyton Taylor, and leaves her and one son to mourn his loss.

THE BRITISH ASSOCIATION AT PORTSMOUTH.

THE week's meeting of the British Association at Portsmouth has now drawn to a close, and some general impressions of the gathering may not be out of place. In the first place, the weather conditions in Portsmouth, as in most other parts of the United Kingdom, have been exceptional as regards absence of rain and high thermometric readings. Only on one day has rain fallen during the whole of the week, which, speaking off-hand, has probably been a very rare occurrence even during the eighty odd years of the association's existence.

The attendance has been low, which is to be deplored, as on the whole the standard of the scientific work has been high. The address of the president (reported in full in our last number) was delivered in the Town Hall. The attendance at the sections, which began their work on Thursday morning, was not large, but the presidential addresses were of great interest and value. The largest number of members seems of recent years to be attracted to the sections dealing with the subjects which come into everyday life, and of which the "man in the street" is conscious. Thus in the economic and the education sections the speakers had fair audiences. Agriculture (Sub-section K) also appealed to a good many members.

With the fine weather, naturally the garden-parties were much appreciated, and on Saturday the all-day excursions were practically all up to the limit as regards numbers. One party was conducted over Goodwood House, and entertained at tea by Mr. Hussey Freke, the agent to the Duke of Richmond; another was the guest of the Duke of Norfolk at Arundel Castle. Other excursions were in the Isle of Wight and to the New Forest. It conduced much to the pleasantness of each excursion that certain gentlemen gave their local knowledge and services to act as guides to the several parties.

There were, as usual, two evening lectures—the first, on "The Physiology of Submarine Work," by Dr. Leonard Hill, attracting a fair audience; the second was by Prof. A. C. Seward on "Links with the Past in the Plant World."

During the meeting various lectures of considerable interest were arranged, and it seemed a pity that they were not more widely advertised. Mr. F. Enock lectured on "Fairy-flies," and Dr. Francis Darwin on "The Balance-sheet of a Plant."

There was a great demand for tickets for the naval display on Monday afternoon, which gave the visitors an insight into the mass of detail and training required by naval commanders of the present day. The party was taken on board the battleship *Revenge*, and watched an attack by torpedo-boat destroyers and four or five submarines specially told off for the occasion.

Most sections finished their work on Tuesday, but a few energetic ones had material to keep them going until Wednesday.

The meeting next year is to be held at Dundee, beginning on September 4, and the president will be Prof. E. A. Schäfer, F.R.S. The invitation of the City and University of Birmingham to meet there in 1913 was unanimously accepted at the council meeting on September 1. The council also resolved by a majority to recommend that agriculture be constituted a separate section of the association, and this recommendation has been adopted by the General Committee and the Committee of Recommendations, so that there will be twelve sections in future, agriculture being Section M.

SECTION C.

GEOLOGY.

OPENING ADDRESS BY ALFRED HARKER, M.A., F.R.S., PRESIDENT OF THE SECTION.

Some Aspects of Modern Petrology.

IN accordance with the custom which permits the occupant of this chair to open the proceedings with observations on some selected subject, I wish to invite your attention to certain points concerning the genetic relations of igneous rocks. The considerations which I shall have to lay before you will be in some measure tentative and incomplete; and indeed, apart from personal shortcomings, this character must necessarily attach to any discussion of the subject which I have chosen. For petrology is at the present time in a state of transition—the transition, namely, from a merely descriptive to an inductive science—and at such a time wide differences of opinion are inevitable. If I should seem to do less than justice to some views which I do not share, I hope this fault will be attributed to the limitations of time and space, not to any intention of abusing the brief authority with which I find myself invested.

The application of microscopical and special optical methods, initiated some fifty years ago by Dr. Sorby, gave a powerful impetus to the study of the mineral constitution and minute structure of rocks, and has largely determined the course of petrological research since that epoch. For Sorby himself observation was a means to an end. His interest was in the conclusions which he was thus enabled to reach relative to the conditions under which the rocks were formed, and his contributions to this problem will always rank among the classics of geology. The great majority of his followers, however, have been content to record and compare the results of observation without pushing their inquiries farther; and indeed the name "petrography," often applied to this line of research, correctly denotes its purely descriptive nature. A very large body of facts has now been brought together, and may be found, collated and systematised by a master-hand, in the monumental work of Rosenbusch. Beyond their intrinsic interest, the results thus placed on record must be of the highest value as furnishing one of the bases upon which may eventually be erected a coherent science of igneous rocks and igneous activity.

In earnest of this promise, recent years have witnessed a very marked revival of interest in what we must call at present the more speculative aspects of petrology. This manifests itself on the side of the petrographer in a growing disposition to seek a rational interpretation of his observations in the light of known physical principles, and on the side of the field geologist in a more constant regard for the distribution, mutual associations, and mode of occurrence of igneous rocks. I will add, as another hopeful sign of the times, a decided *rapprochement* between the laboratory and the field, too often treated in practice as distinct departments.

As regards the former, the movement which I have noticed is merely a return to the standpoint of Sorby, the father of modern petrology. It is true indeed that, before his time, the problem of the origin of igneous rocks had engaged the ingenuity of Scrope and Darwin, of Bunsen and Durocher, and many others; and the bold speculations of the heroic days of geology have justly exercised a lasting influence. The petrologist of to-day, however, has at his command a much ampler range of information than was possessed by his predecessors. In addition to the rich store of petrographical data already mentioned, he can press into service on the one hand the results of physical chemistry and on the other much additional knowledge which has been gathered concerning the structure of the earth's crust and the distribution of various rock-types, both in space and in time. Either of these branches of the subject would furnish material for a much longer address than my assurance could venture or your complacence would endure. I have chosen the geographical aspect of petrology; but, before proceeding to this, I will say a few words concerning the experimental side.

Data from the Experimental Side.

That the modern developments of physical chemistry, starting from the phase rule of Willard Gibbs, must in theory furnish all that is necessary to elucidate the crystallisation of igneous rock-magmas, has long been perceived by some petrologists. This recognition is in itself an advance. Natural rock-magmas, however, are far more complex solutions than those which chemists have employed in working out their laws, and the problem in its entirety is of a kind almost to daunt inquiry. Despite the courageous attempt made by Prof. Vogt, whose enthusiastic lead has done so much to inspire interest in the subject, it seems clear that the application of the laws of chemistry to the particular class of cases with which the petrologist is concerned demands as a prerequisite a large amount of experimental work in the laboratory. The high melting-points of the rock-forming minerals, their extreme viscosity, and other specific properties render such work extremely difficult and laborious. That most of the practical difficulties have now been overcome is due in the first place to Dr. A. L. Day and his colleagues of the Geophysical Laboratory at Washington, who have thus opened out what is virtually a new field of investigation. The methods of high temperature measurement have been perfected and the thermometric scale standardised up to 1550° C., thus embracing the whole range of rock-formation. Calorimetric measurements have been so far improved that it is now possible, for instance, to determine specific heats, even in the highest part of this range, with an accuracy ten times greater than has hitherto been usual at ordinary temperatures. Incidentally there has been, in the hands of Mr. F. E. Wright, a notable enlargement of the scope of ordinary petrographical methods, since it has been found necessary to devise special means of measuring with precision the crystallographic and optical constants of very minute crystals.

The American chemists have already determined the temperature-range of stability of numerous rock-forming minerals. Beginning with the simpler cases and working always with chemically pure material, they have established quantitatively the mutual relations of the various possible forms in a number of two-component systems and in one of three components. So far as these instances go, the mutual lowering of melting-points in a silicate-magma is now a matter of precise measurement, and it is no longer inferred, but demonstrated, that the order of crystallisation of the minerals depends upon their relative proportions in the magma. The perfect isomorphism of the plagioclase felspars has been finally established, and a certain degree of solid solution between quite different minerals has furnished the explanation of some apparent anomalies, such, for instance, as the variable composition of the mineral pyrrhotite. As a single illustration of how these investigations in the laboratory provide the working petrologist with new instruments of research, I will cite the conception of a geological temperature-scale, the fixed points on which are given by the temperature-limits of stability of various minerals. It is often possible, for example, to ascertain whether quartz in a given rock has crystallised above or below 575° C., this being the inversion-point between the α- and β- forms of the mineral. At about 800° there is another inversion-point, above which quartz is no longer stable, but gives place to cristobalite. In like manner we know that wollastonite in a rock must have crystallised below 1190°, pyrites below 450°, and so for other cases. We may confidently hope that, with the aid of such data, we shall soon be enabled, by simple inspection, to lay down in degrees the temperature-range of crystallisation of a given igneous rock.

There are now several laboratories where high-temperature research, of the rigorous order indicated, is being carried out; but the work is peculiarly arduous, and results come slowly. Some branches of the inquiry, notably those involving high pressures, and again the investigation of systems into which volatile components enter, are as yet virtually untouched. For these reasons it would be premature to hazard at this stage any more detailed forecast of the services to be rendered to petrology by synthetic experiment. I will accordingly leave this attractive subject, and pass on from the laboratory to the field.

Geographical Distribution of Igneous Rocks.

Here the existing situation is very different. Instead of following out definite lines already laid down, we are concerned in reducing to order a great mass of discrete facts drawn from many sources. The facts which enter into consideration are those touching the distribution of various igneous rocks in time, in space, and in environment, including their relation to tectonic features; the mutual association of different rock-types and any indications of law in the order of their intrusion or extrusion; and, in short, all observable relations which may be presumed to have a genetic significance. The digestion of this mass of data has already led to certain generalisations, some of which are accepted by almost all petrologists, while others must be regarded as still on their trial.

Of the former kind is the conception of petrographical provinces, which was put forward by Prof. Judd twenty-five years ago, and has exercised a profound influence on the trend of petrological speculation. It is now well established that we can recognise more or less clearly defined tracts, within which the igneous rocks, belonging to a given period of igneous activity, present a certain community of petrographical characters, traceable through all their diversity or at least obscured only in some of the more extreme members of the assemblage. Further, that a province possessing an individuality of this kind may differ widely in this respect from a neighbouring province of like date; while, on the other hand, a striking similarity may exist between provinces widely separated in situation or in age. It is natural to attribute community of chemical and mineralogical characters among associated rocks to community of origin. The simplest hypothesis is that which supposes all the igneous rocks of a given province to be derived by processes of differentiation from a single parent-magma. This may be conceived, for the sake of simplicity, as initially homogeneous, though doubtless some of the causes which contribute to promote heterogeneity were operative from the earliest stage. Granted this hypothesis, it follows that the points of resemblance among the rocks of a province will indicate the nature of the common parent-magma, while the points of diversity will throw light on the causes of differentiation. The observed sequence in time of the various associated rock-types will also have an evident significance, especially if, as there are good reasons for believing, differentiation in igneous rock-magmas is largely bound up with progressive crystallisation. Those petrologists, on the other hand, who attach importance to the absorption or "assimilation" of solid rock-matter by molten magmas, are bound to consider both the nature of the chemical variation and the local distribution of the different types with constant reference to the composition of the country-rocks. The balance of opinion, and I think of argument, would assign the variation, at least in the main, to differentiation; and there are well-known principles, chemical and mechanical, which theoretically must operate to produce a diversity of ultimate products from a magma originally uniform. How far these principles are in practice adequate to the demands which have been made on them, is a question not to be finally resolved without quantitative knowledge which is still a desideratum. Experiment may in time come to our aid. My design to-day is rather to offer some remarks upon a distinct, though allied, problem—viz., that presented by the petrographical provinces themselves.

The geographical distribution of different kinds of igneous rocks long ago engaged the attention of Humboldt, Boué, and other geologists, and the subject has always possessed a certain interest in view of the association of most metalliferous deposits with igneous rocks. It has, however, acquired a new importance in recent years in connection with questions of petrogenesis which are still under discussion. The problem is, in brief, to account for the existence of petrographical provinces and for the observed facts relative to their distribution. One theory, advocated especially by Dr. G. F. Becker, invokes primæval differences in composition between different parts of the globe, which have persisted throughout geological time. It involves the hypothesis that igneous rock-magmas result from the refusion of pre-existing rocks within a limited area. Indeed Becker discards altogether the doctrine of differentiation, and conceives the varied assemblage of rocks in a given province as produced by admixture from a certain number of primitive types. These, he says, should be recognisable by their wide distribution and constant character. It is clear, however, that, on the hypothesis of admixture, the primitive types must be those of extreme composition. These are, in fact, always the rarest and the most variable, pointing not to admixture but to differentiation as the cause of the diversity. A theory which attributes the special characteristics of petrographical provinces to permanent heterogeneity in the composition of the globe is difficult to reconcile with the small extent and sharp definition of some strongly characterised provinces, such as that of Assynt or of the Bohemian Mittelgebirge. A more fatal objection is that petrographical provinces are not in fact permanent. A good illustration is afforded by the midland valley of Scotland, an area our knowledge of which has been much enlarged by the recent work of the Geological Survey. It was the theatre of igneous activity in Lower Old Red Sandstone times and again in the Carboniferous, but, in respect of mineralogical and chemical composition, the two suites of rocks present a striking contrast. The Old Red Sandstone lavas are mostly andesites, though ranging from basalts on the one hand to rhyolites on the other, and the associated intrusions are mainly of diorite, quartz-diorite, and granite, with porphyrites and other dyke-rocks. In the Carboniferous, on the other hand, we find porphyritic basalts, mugearites, and trachytes (including phonolitic types), with picrites, teschenites, monchiquites, orthophyres, and other allied rocks. It would be possible to cite many other cases illustrating the same point.

The Alkaline and Calcic Branches.

The two Scottish suites of Upper Palæozoic rocks just mentioned fall into opposite categories with reference to what is now becoming recognised as the most fundamental distinction to be made among igneous rocks. The earlier set is typical of the andesitic division and the later of the tephritic; or, using other equivalent names, the one belongs to the calcic (or "alkali-calcic") branch and the other to the alkaline. I will adopt the latter terminology as being generally familiar to petrologists; but the characteristics of the two branches, which are too well known to need recapitulation here, are more clearly definable in mineralogical than in chemical language. This twofold division of igneous rocks is, of course, in no wise a final or exhaustive treatment of the subject; but as a first step towards a natural or genetic classification it seems to be established beyond question. No third branch in any degree comparable with the two and distinct from them has been proposed. The charnockites and their allies represent but a single rock-series, and Rosenbusch has not made clear his reasons for separating them from the calcic rocks. The "spilitic" suite of Dewey and Flett is made to embrace a somewhat miscellaneous collection of types, and any close genetic relationship among them can scarcely be considered as proved. It is perhaps permissible to suggest that, *e.g.*, the quartz-diabases are, here as in Scotland, quite distinct in their affinities from the types rich in soda. These latter, constituting the bulk of the proposed suite, would seem to belong quite naturally to the alkaline branch, the question of the magmatic or solfataric origin of the albite being in this connection immaterial.

A given petrographical province is either of calcic or of alkaline facies, typical members of the two branches not being found together. The apparent exceptions are, I think, not such as to modify very seriously the general rule. Mr. Thomas, in describing an interesting suite of rocks from Western Pembrokeshire, recognises the alkaline affinities of most of them, but assigns some of the more basic types to the opposite branch. In a very varied assemblage we not infrequently meet with a few extreme types which, occurring in a calcic province, recall the characters of alkaline rocks, or conversely. Such anomalies have been pointed out by Daly, Whitman Cross, and others. They are found among the later derived types, referable to prolonged or repeated differentiation, and they are to be expected especially where the initial magma was not very strongly characterised as either calcic or alkaline.

Having regard to the known exposures of igneous rocks over the existing land-surface of the globe, it seems that there is a very decided preponderance of the calcic over the alkaline branch. This, as we shall see, is probably a fact of real significance, but it is nevertheless noticeable that increasing knowledge tends partly to redress the balance. In our own country, in addition to the Scottish Carboniferous rocks and those probably of Ordovician age in Pembrokeshire, we have the remarkable Lower Palæozoic intrusions of Assynt, in Sutherland, of strongly alkaline character, as described by Dr. Teall and more recently by Dr. Shand; while Dr. Flett has recognised alkaline rocks of more than one age in Cornwall and Devon, and Mr. Tyrrell is engaged in studying another interesting province, of Permian age, in Ayrshire.

That the distinction between the alkaline and the calcic rocks embodies some principle of real and fundamental significance becomes very apparent when we look at the geographical distribution of the two branches. Taking what the German petrographers call the "younger" igneous rocks, *i.e.*, those belonging to the latest system of igneous activity, we find it possible to map out the active parts of the earth's crust into great continuous regions of alkaline rocks on the one hand and of calcic on the other. An alkaline region comprises numerous petrographical provinces, which may differ notably from one another, but agree in being all of alkaline facies. In like manner a common calcic facies unites other provinces, which collectively make up a continuous calcic region. Concerning the igneous rocks of earlier periods our knowledge is less complete, but, so far as it goes, it points to the same general conclusions.

These considerations enable us to simplify at the outset the problem before us. If we would seek the meaning and origin of petrographical provinces, we must inquire in the first place how igneous rocks as a whole come to group themselves under two great categories, which, at any one period of igneous activity, are found in separate regions of the earth's crust. The fact that a given district may form part of a calcic province at one period and of an alkaline one at another, precludes the hypothesis that the composition of igneous rocks depends in any degree upon peculiarities inherent from the beginning in the subjacent crust. The same objection applies with scarcely less force to various conflicting suggestions based on an assumed absorption or "assimilation" of sedimentary rocks by igneous magmas. Thus Jensen supposes the alkaline rocks to be derived by the assimilation or fusion of alkaline sediments at great depths. Daly propounds the more elaborate, and on a first view paradoxical, theory that alkaline have been derived from calcic magmas as a consequence of the absorption of limestone. These geologists agree in regarding the alkaline rocks as relatively unimportant in their actual development and in some sense abnormal in their origin. For Suess, on the other hand, it is the calcic rocks which owe their distinctive characters to an absorption of sedimentary material, enriching the magma in lime and magnesia. Apart from difficulties of the physical and chemical kind, all such theories fail to satisfy, in that they ignore the separation of the two branches of igneous rocks in different regions of the globe, each of which includes sediments of every kind. What then is the real significance of this regional separation? The obvious way of approaching the question is to inquire first whether the alkaline and calcic regions of the globe present any notable differences of a kind other than petrographical.

Relation between Tectonic and Petrographical Facies.

The close connection between igneous activity and displacements of the earth's crust has been traced by Suess, Lossen, Bertrand, de Lapparent, and others, and is a fact sufficiently well recognised. We have here, indeed, two different ways of relieving unequal stresses in the crust, and it is not surprising that they show a broad general coincidence both in space and in time. We can, however, go farther. Not only the distribution of igneous rocks in general, but the distribution of different kinds of rocks, is seen to stand in unmistakable relation to the leading tectonic features of the globe. It is very noticeable that petrographical provinces, and in particular provinces belonging to opposite branches, are often divided by important orographic lines. This is illustrated by the Cordilleran chain in both North and South America, and again by some of the principal arcs of the Alpine system in Europe. If, now, we examine the actual distribution more closely, in the light of Suess's analysis of the continents and oceanic basins, we perceive another relation still more significant. It is that, as regards the younger igneous rocks, the main alkaline and calcic regions correspond with the areas characterised by the Atlantic and Pacific types of coast-line respectively; I briefly drew attention to this correspondence in 1896, and a few years later Prof. Becke, of Vienna, arrived independently at the same generalisation. Recalling the two classes of crust-movements discriminated by Suess, he says it appears that the alkaline rocks are typically associated with subsidence due to radial contraction of the globe, and the calcic rocks with folding due to lateral compression. The greater part of Becke's memoir is devoted to a comparison of the two branches in respect of chemical composition; but here, I think, he has been misled by taking as representative of the whole alkaline "*Sippe*" or tribe the rocks of one small and peculiar province, that of the Bohemian Mittelgebirge. Some petrologists have followed Becke in adopting the terms Atlantic and Pacific as names, or at least synonyms, for the two branches of igneous rocks. Others, perhaps with some justice, deprecate the use of the same terms in a petrographical as well as a tectonic sense, so long as the implied relationship is still a matter of discussion.

I would point out in passing that the association of the alkaline rocks with areas of subsidence helps to explain the relatively small part which they play in the visible portion of the earth's surface. We may not unreasonably conjecture, for instance, that the volcanic islands scattered sparingly over the face of the Atlantic Ocean, from the Azores to Tristan d'Acunha, are merely fragments of a very extensive tract of alkaline rocks now submerged.

The generalisation associated with the name of Becke, in so far as it may ultimately commend itself to general acceptance, must have an important bearing on the problem of the origin of petrographical differences. The time is not ripe for any dogmatic pronouncement, but I will venture to indicate briefly the general trend of the inferences to be drawn. It seems clear that only a trivial effect at most can be allowed to original and permanent heterogeneity of the earth's crust, or to such accidents as the absorption by an igneous magma of a limited amount of the country-rock. The division between alkaline and calcic regions, and the separation of distinct provinces within such regions, point rather to the same general cause which, at a later stage, produced the diversity of rock-types within a single province, that is, to magmatic differentiation. Here, however, the differentiation postulated must be on a very wide scale, and must take effect in the horizontal direction. Its close connection with crust-movements clearly indicates differential stress as an essential element in the process. The actual mechanism can be at present only a matter of speculation, but I think the clue will be found in such observations as those of Mr. Barrow on the pegmatites of the Scottish Highlands. Conceive an extensive tract to be underlain by a zone which is neither solid nor liquid, but composed of crystals with an interstitial fluid magma. If this be subjected to different pressures in different parts of its horizontal extent, its uniformity will necessarily be disturbed, the fluid portion being squeezed out at places of higher pressure and driven to places of lower pressure. The precise nature of the differentiation thus set up will depend on the relative compositions of the crystalline and fluid portions, and the subject could not be very profitably discussed without fuller knowledge concerning the order of crystallisation in rock-magmas. Whether or not the explanation be ultimately found in this direction, the relation between the two tectonic types and the two branches of igneous rocks must, I think, find a place in the final solution of the problem.

I intimated at the outset that my remarks would not be confined to matters already settled and indisputable. It will be easily understood that some statements which I have made, for the sake of clearness, without qualification are subject to exceptions, and exceptions have, indeed, been urged by critics whose opinions are entitled to respect. The most uncompromising of these critics, Dr. Whitman Cross, has laid it down that: "Only generalisations without known exceptions in experience can be applied to the construction of a system that may be called natural." I hold, on the contrary, that such a science as Geology can be advanced only by the inductive method, which implies provisional hypotheses and successive approximations to the truth. A generalisation which brings together a mass of scattered observations, and endows them with meaning, is not invalidated by the discovery of exceptions. These merely prove that it is not a final expression of the whole truth, and may point the way to its revision and correction.

Take, for instance, our provisional law of the distribution of the two branches of igneous rocks in defined regions. It has been objected that leucitic lavas, having therefore very decided alkaline or Atlantic affinities, are known at several places within the limits of the main Pacific region, where they are associated with andesitic and other calcic rocks. Now, the only area for which we have anything like full information is the island of Java. Here, according to Verbeek and Fennema, the great plateau-lavas of Tertiary age are exclusively of andesitic types, and the same is true of the long chain of 116 volcanic centres, which represent the later revival of activity. As against this record there are five volcanoes, long extinct, which at one stage erupted leucitic lavas. Whether we suppose these to be aberrant derivatives from an andesitic magma, or, much more probably, an incursion from the neighbouring alkaline region, it seems reasonable to regard these very exceptional occurrences as of the second order of importance, and to set them aside in a first attempt to reduce the facts to order.

The discovery of various alkaline rocks on Hawaii, Samoa, Raratonga, Tahiti, and other islands in the midst of the Pacific Ocean raises, I think, a different question. So far as is known, these rocks are not found in close association with characteristic calcic types. Suess's masterly discussion of all the geographical and hydrographical data hitherto obtained makes it clear that an Atlantic as well as a Pacific element of structure enters into some parts of the Pacific basin. In certain areas, such as the Galapagos Archipelago, the coming in of the Atlantic *régime* is quite clearly reflected in an alkaline facies of the igneous rocks, and such exceptions are therefore of the kind which go to prove the rule. Both Max Weber and Lacroix have expressed the opinion that the andesitic branch of rocks is characteristic of the border of the great Pacific basin rather than the interior. It is possible that further knowledge may justify this conclusion, and still only confirm the relation which is claimed between the two tectonic types and the two petrographical facies. Meanwhile, we find clear evidence elsewhere that vertical subsidence and lateral thrust have sometimes occurred in the same region or in the same petrographical province: nor need we go far from home to learn that the complexity of structure thus implied is accompanied by a corresponding peculiarity of petrographical facies.

The North British Tertiary Province.

In order to illustrate this point in a concrete instance, I will discuss very briefly a single petrographical province, viz. that which occupied the northern part of Britain in early Tertiary times. Prof. Judd has regarded this as forming part of a larger "Brito-Icelandic province"; but, while recognising many affinities between our rocks and those of higher latitudes, I think that the North British area possesses enough individuality to be more properly treated as a distinct unit. The record of igneous action here is exceptionally complete and well displayed. Our knowledge of it is derived, in the first place, from Prof. Zirkel, Sir Archibald Geikie, and Prof. Judd, and more recently from the detailed work carried out by the Geological Survey of Scotland. This latter is, as regards the Isle of Mull, still in progress, and will doubtless, when completed, throw additional light on some questions still obscure.

The province includes all western and southern Scotland, with the northern part of Ireland, and extends southward as far as Anglesey and Yorkshire; but the chief theatre of igneous activity was the sunken and faulted tract of the Inner Hebrides, between the mainland of Scotland, on the one hand, and the Archæan *massif* of the Outer Isles on the other. It is here that the volcanic accumulations attain their greatest thickness, and here, closely set along a N.-S. line, are the plutonic centres of Skye, Rum, Ardnamurchan, and Mull. Farther south are the volcanic plateau of Antrim and the neighbouring plutonic centres of the Mourne Mountains and Carlingford, while the two centres of Arran and that of Ailsa lie on a parallel line only a little farther east. In addition, it is clear that igneous activity extended westward over a tract now submerged under the Atlantic, and here, too, plutonic centres were not wanting. One is exposed in St. Kilda, 50 miles west of the Outer Hebrides, and another has been inferred by Prof. Cole from a study of the stones dredged on the Porcupine Bank, 150 miles west of Ireland.

The connection of igneous action in this province with the subsidence of faulted blocks of country is too plain to be missed; and so far, excepting the tendency to a definite alignment of the foci of activity, we seem to be dealing with a typical example of the Atlantic *régime*. The actual tectonic relations are, however, of a more complex kind, and undoubtedly involve the element of lateral thrust as well as vertical subsidence. This is more particularly in the neighbourhood of those special centres which were marked at one stage by plutonic intrusions. The evidence is seen in sharp anticlinal folding; sometimes also in crush-brecciation along quasi-horizontal bands and (in Rum) contemporaneous gneissic structure in the plutonic masses themselves. The disturbances in Mull, as described by Mr. Bailey, are especially interesting. The whole eastern coast-line of the island is determined by a system of concentric curved axes of folding, affecting all the rocks up to the Tertiary basalts, which are in places tilted almost vertically. The curved axes are disposed with reference to the plutonic centre of the island, and a somewhat similar arrangement is found on the east side of the Skye centre. All these facts go to show that in the district surrounding any one of the special centres there was developed a complex system of stresses, which found relief partly in igneous action, partly in displacements of the solid rocks. Nor were the effects confined to the plutonic phase. At a later epoch the influence of these local stresses is sometimes indicated by the diversion of the very numerous dykes from their normal north-westerly direction to a radial arrangement about the special centres, as is seen partly in Skye and more strikingly in Rum. There are also local groups of dykes developed only in these districts, and these again sometimes have a radial arrangement. More remarkable are the groups of inclined sheets which are found about the same centres, usually intersecting the plutonic rocks and a small fringing belt, and constantly dipping inwards. Such sheets occur in immense numbers in the gabbro mountains of Skye and Mull, and they are to be recognised also in Rum and Ardnamurchan.

It is plain, then, that this province exemplifies at once the two tectonic types distinguished by Suess. There has been a general subsidence affecting the area as a whole, but not all parts equally, and with this we must connect those groups of igneous rocks which have a wide distribution throughout the province. But there have also been movements in the lateral sense, more strictly localised and more sharply accentuated, and to these belong evidently the plutonic rocks with various other groups which are their satellites. I have pointed out these facts elsewhere, but failed to follow out the logical conclusion on the petrographical side. Influenced by the strongly marked characters of the plutonic series, I assigned the North British Tertiary rocks, not without some misgivings, to the calcic or Pacific region. Suess, having regard probably to the broader tectonic features rather than to petrographical data, has included our area in the Atlantic region.

Concerning the calcic facies of the plutonic rocks there can be no question. They constitute a well-defined "rock-series," intruded in order of decreasing basicity, and ranging from ultrabasic to thoroughly acid. The ultrabasic rocks, as developed in Rum and Skye, have a lime-felspar as one of their chief components: there are no picrites (in the original sense of Tschermak) or other alkaline types. The eucrite group, found in Rum, Ardnamurchan, and the Carlingford district, is also characterised by a felspar near anorthite. Gabbros are represented at nearly all the several centres, and in Arran they are accompanied by norites. The granites and granophyres fall into two subgroups. The less acid is usually augitic, while the more acid, found in Arran, St. Kilda, and the Mourne Mountains, carries hornblende and sometimes biotite.

This series is known in various provinces of Pacific facies. A peculiarity of it is that it is a broken series, types of mean acidity being absent. This has an interesting consequence. In many places a granite magma, invading rocks so different from itself as gabbro or eucrite, has caused energetic mutual reactions, and a set of hybrid rocks has been produced, which serves in a limited sense to fill the gap in the series.

The only known exceptions to the calcic facies of our Tertiary plutonic rocks are perhaps significant in that they occur near the northern and southern limits of the principal belt of activity. The massive gently inclined sheets of granite and granophyre which make up part of the southern end of Raasay consist largely of microperthite, and contain abundant riebeckite, a distinctively alkaline mineral known at only one spot in Skye. The microperthitic granites of Arran do not carry riebeckite, but it is found in the well-known rock of Ailsa Craig, farther south.

The local groups of minor intrusions—acid, basic, and ultrabasic—related to the several plutonic centres have the same calcic facies as the plutonic rocks of which they are satellites. It appears, however, that they sometimes tend to a more alkaline composition towards the borders of their respective districts. Thus the Skye granite is surrounded by a roughly oval area, within which are found numerous dykes and sills of felsite and granophyre, in general augitic; but on the fringe of the area these rocks give place to orthophyres, with biotite or hornblende, and to bostonites.

Turn now to the rocks of regional distribution. The most important are, of course, the basalt lavas. They are all felspar-basalts, but a very general feature is the filling of their numerous amygdaloidal cavities with zeolites, such as analcime, natrolite, chabazite, and stilbite. These minerals are certainly not mere weathering-products. When I examined the basalts of Skye and the Small Isles some years ago, I regarded the zeolites as solfataric products, formed at the expense of the felspar by the action of volcanic water, while the rocks were still at a somewhat high temperature. Subsequent reconsideration has led me to regard these minerals rather as primary constituents of the rock, crystallised directly from the final residual magma, which had become relatively enriched in water by the abstraction of the anhydrous minerals. Such was the conclusion reached by Mr. James Strachan for the Antrim basalts, and a study of examples from Mull and Skye has enabled me to confirm and extend his interesting observations. Analcime in particular is not always confined to the steam-cavities, but in some cases occurs interstitially in the rock, where it is certainly not derived from felspar, and, indeed, has all the appearance of a primary constituent. The augite of these analcime-bearing basalts has in thin slices a purplish tint, with sensible pleochroism. From these and other features it appears that this group of rocks reveals on examination decided, though not very strongly marked, alkaline affinities.

Volcanic rocks of other than basaltic composition are not largely developed. They include both rhyolites and trachytes, the former without very distinctive characters, but the latter falling naturally into the alkaline division. In describing formerly a group of rhyolites and trachytes on the northern border of the Cuillins, I connected it with the neighbouring plutonic centre, but I have since found other trachytes in Skye: there is a fine development exposed in the glen above Bracadale. From this, and from the situation of the Antrim rhyolites, I infer that these felspathic and acid lavas, though distributed sporadically, belong to the regional or Atlantic suite.

Consider next the widespread group of basic sills. The common non-porphyritic dolerite sills have, in most districts, little that is indicative of alkaline affinities, though chemical analyses show a rather noteworthy amount of soda. In the porphyritic dolerites this characteristic is much more apparent, and, indeed, these rocks are almost identical with the "Markle type" so largely represented among the alkaline rocks of the Scottish Carboniferous province. Mugearite, a type still richer in alkalies, is likewise common to the two provinces. As we approach the limits of the principal belt of activity, alkaline characteristics become well marked even in the common non-porphyritic dolerites. This is shown in Raasay and the northern part of Skye by the coming in of the purple pleochroic augite, while farther north, in the Shiant Isles, analcime enters, and even, according to a record of Heddle, nepheline.[1] At the other extreme, in southern Arran, occur the analcime-dolerite sills of Clauchland and Dippin.

The regional basic dykes, which are mostly posterior in age to the sills, exhibit more variety of composition. Some with abundant porphyritic felspars resemble the Markle type of dolerite, and there are others of mugearitic nature, but these are only a minority. In Argyllshire there are basic dykes with purple pleochroic augite, and even some of camptonite and monchiquite; but these latter at least I should exclude as being probably of late Palæozoic age.[2] The undoubtedly Tertiary dykes, however, exhibit a variety which can be explained only as the result of repeated differentiation. The distribution of some of the groups indicates the existence at this late stage of subsidiary centres of differentiation, distinct from the plutonic centres. Thus trachyte dykes are found especially throughout a tract extending from the south-western part of Skye through the middle of Argyllshire, while there is an isolated area of these dykes about Drynoch, on the opposite side of the Skye mountains. Here we have an evidently alkaline type. On the other hand, there are rocks which, taken by themselves, must be assigned to the calcic division. Augite-andesites, for example, are well known, especially in parts of western Argyllshire, in Arran and the Cumbraes, and in the outlying districts of the north of Ireland, Anglesey, and the north-east of England. That these rocks have arisen as products of a subsidiary differentiation we have in some cases almost ocular demonstration; for in Arran and elsewhere augite-andesites are found in remarkably intimate association with complementary types, often pitchstones of alkaline composition.

Even from so brief and imperfect a sketch we may, I think, draw some conclusions which have a wider application. This province exemplifies at once the two main tectonic types, and also comprises representatives of the two great branches of igneous rocks. Those rocks which are related to broad movements of Atlantic type indicate a parent magma of decided, though not strongly marked, alkaline nature; while those related to local movements of Pacific type clearly come from a calcic magma. There are some facts which suggest that the rocks tend to become more alkaline as we recede from the chief centres of activity, and this suggestion applies to some calcic as well as alkaline groups of rocks. Finally, it appears that the relative simplicity of arrangement was disturbed at a late stage by the effects of subsidiary differentiation, the province tending then to break up into districts related to new centres. Operating upon an initial magma not very strongly characterised, this later differentiation has even given rise to aberrant rock-types which overstep the petrographical boundary-line between the two branches.

Petrogenesis and Systematic Petrography.

From such considerations as I have hastily passed in review, it is evident that a survey of igneous rocks as they actually occur in the field leads to a conception of their mutual relationships very different from that embodied in the current schemes of systematic petrography. It may be of some interest, in conclusion, to expand this remark a little farther, although I am sensible that in so doing I lay myself open to the charge of vain speculation.

From the petrogenetic point of view, the most fundamental division among igneous rocks is that between the alkaline and calcic branches. This result, independently arrived at on petrographical grounds by several authorities, seems to be firmly established by the broad distribution of the two branches in different regions of the globe. But, if this argument be admitted, it follows that the next step in a natural grouping of igneous rocks should be suggested by a comparison of the characteristics of the various provinces into which the great regions divide. Many of these provinces have now been partly studied, and their special characteristics can often be expressed in concise terms: *e.g.* among alkaline rocks the relative proportion of potash to soda may be a characteristic common to a whole province. More precisely, by averaging the

[1] The dolerite here is intimately associated with ultrabasic rocks, as has been described by Judd.

[2] A like remark applies to the highly alkaline dykes of the Orkneys, which do not agree even in direction with the Tertiary suite.

chemical analyses of the chief rock-types, weighted according to their relative abundance, it is possible to calculate approximately the composition of the parent-magma of a province. Noting that nearly identical assemblages of rocks sometimes occur in widely separate provinces and at different geological periods, we have some reason for expecting that the provincial parent-magmas may ultimately be reduced to a limited number of types. Whether these types will be sufficiently definite to serve as a basis of classification it is too early to say.

For the sake of argument, I have taken chemical composition as the criterion. It is certain, however, that a rock-magma consists, not of free oxides, but mainly of silicate-compounds, and the variation produced by magmatic differentiation is a variation in the relative proportions of such compounds. The characteristics common to a set of cognate rock-types will therefore be more properly expressed in mineralogical than in chemical terms. If, to fix ideas, we take as representative of a province its principal plutonic series, we shall often find that some particular mineral or some special association of minerals stands out as a distinctive feature. For instance, in the charnockite-norite series of southern India the characteristic ferro-magnesian mineral is hypersthene; in the granite-gabbro series of the British Tertiary it is augite; and in the granite-diorite series, which predominates among the "newer granites" of the Scottish Highlands, hornblende and biotite. These three sets of rocks, all of calcic facies, are easily distinguishable in isolated specimens.

Each such rock-series embraces types ranging from acid to ultrabasic. This variation is ascribed to a later differentiation of the parent-magma of the province, and, therefore, in an arrangement based on genetic principles, it will find expression, not in the main divisions of the scheme, but in the subdivisions. Here is an essential difference between an ideal petrogenetic classification and the petrographical systems which are, or have been, in use. If we are content to limit our study of igneous rocks to specimens in a museum, the distinction of acid, neutral, basic, and ultrabasic may seem to be one of first importance. It has, in fact, been employed for the primary divisions in some formal schemes, *e.g.* in that put forward by Löwinson-Lessing. In a less crude system, like that of Rosenbusch, this element disappears, but the underlying idea still remains. There is a division into families, such as the granite-family and the gabbro-family, but the term, in so far as it implies blood-relationship, is a misnomer. The augite-granite of Mull is evidently more closely related to its associated gabbro than it is, say, to the biotite-granite of Peterhead or the hypersthene-granite of Madras.

The differentiation which evolves a varied series of plutonic rocks from a common parent-magma is clearly not of the same kind as that which gave rise to the parent-magma itself. It appears that the external mechanical element is here a less important factor, and the variation set up is, therefore, more closely in accordance with the uninterrupted course of crystallisation. This is clearly indicated when we compare the order of intrusion of the several rocks of the series with the order of crystallisation of their constituent minerals. The history of the series is in a sense epitomised in the history of each individual type, corresponding in both cases with continued fall of temperature and progressive change in the composition of the residual magma. In a large number of rocks, more particularly those of complex constitution, the order of crystallisation follows Rosenbusch's empirical law of decreasing basicity, and the plutonic intrusions then begin with the most basic type and end with the most acid. I mention this only to point out that, while the larger divisions of our ideal classification will have a certain geographical and tectonic significance, the subdivisions will show a certain correspondence with the sequence in time of the various cognate rock-types.

To pursue the subject farther would serve no useful purpose. It is clear that, if a natural—by which I mean a genetic—classification of igneous rocks is ever to become a reality, much work must first be done, both in the field and in the laboratory, each petrographical province being studied from the definite standpoint of the evolution of its rock-types from one parent stock. Such researches as those of Brögger in the Christiania province may serve as a model. It would be rash to venture at present more than the most general forecast of the lines which future developments may follow; but I think it calls for no less hardihood to set limits to what may ultimately be possible in this direction. There are those who would have us abandon in despair all endeavour to place petrography upon a genetic basis, and fall back upon a rigid arbitrary system as a final solution of the difficulty. This would be to renounce for ever the claim of this branch of geology to rank as a rational science. I have said enough to show that I am one of those who take a more hopeful view of the future of petrology, confidently expecting it to show, like the past, a record of continued progress.

SECTION D.

ZOOLOGY.

OPENING ADDRESS BY PROF. D'ARCY WENTWORTH THOMPSON, C.B., PRESIDENT OF THE SECTION.

Magnalia Naturae; or, The Greater Problems of Biology.

THE science of Zoology, all the more the incorporate science of Biology, is no simple affair, and from its earliest beginnings it has been a great and complex and many-sided thing. We can scarce get a broader view of it than from Aristotle, for no man has ever looked upon our science with a more far-seeing and comprehending eye. Aristotle was all things that we mean by "naturalist" or "biologist." He was a student of the ways and doings of beast and bird and creeping thing; he was morphologist and embryologist; he had the keenest insight into physiological problems, though lacking that knowledge of the physical sciences without which physiology can go but a little way: he was the first and is the greatest of psychologists; and in the light of his genius biology merged in a great philosophy.

I do not for a moment suppose that the vast multitude of facts which Aristotle records were all, or even mostly, the fruit of his own immediate and independent observation. Before him were the Hippocratic and other schools of physicians and anatomists. Before him there were nameless and forgotten Fabres, Röesels, Réaumurs, and Hubers, who observed the habits, the diet, and the habitations of the sand-wasp or the mason-bee; who traced out the little lives, and discerned the vocal organs, of grasshopper and cicada; and who, together with generations of bee-keeping peasants, gathered up the lore and wisdom of the bee. There were fishermen skilled in all the cunning of their craft, who discussed the wanderings of tunny and mackerel, sword-fish or anchovy; who argued over the ages, the breeding-places, and the food of this fish or that; who knew how the smooth dogfish breeds two thousand years before Johannes Müller; who saw how the male pipe-fish carries its young before Cavolini; and who had found the nest of the nest-building rock-fishes before Gerbe rediscovered it almost in our own day. There were curious students of the cuttle-fish (I sometimes imagine they may have been priests of that sea-born goddess to whom the creatures were sacred) who had diagnosed the species, recorded the habits, and dissected the anatomy of the group, even to the discovery of that strange hectocotylus arm that baffled Delia Chiaje, Cuvier, and Koelliker, and that Verany and Heinrich Müller re-explained.

All this varied learning Aristotle gathered up and wove into his great web. But every here and there, in words that are unmistakably the master's own, we hear him speak of what are still the great problems and even the hidden mysteries of our science; of such things as the nature of variation, of the struggle for existence, of specific and generic differentiation of form, of the origin of the tissues, the problems of heredity, the mystery of sex, of the phenomena of reproduction and growth, the characteristics of habit, instinct, and intelligence, and of the very meaning of Life itself. Amid all the maze of concrete facts that century after century keeps adding to our store, these, and such as these, remain the great mysteries of natural science—the *Magnalia naturae*, to borrow a great word from Bacon, who in his turn had borrowed it from St. Paul.

Not that these are the only great problems for the biologist, nor that there is even but a single class of great problems in Biology. For Bacon himself speaks of the *magnalia naturae, quoad usus humanos*, the study of which has for its objects "the prolongation of life or the retardation of age, the curing of diseases counted incurable, the mitigation of pain, the making of new species and transplanting of one species into another," and so on through many more. Assuredly I have no need to remind you that a great feature of this generation of ours has been the way in which Biology has been justified of her children, in the work of those who have studied the *magnalia naturae, quoad usus humanos*.

But so far are biologists from being nowadays engrossed in practical questions, in applied and technical Zoology, to the neglect of its more recondite problems, that there never was a time when men thought more deeply or laboured with greater zeal over the fundamental phenomena of living things; never a time when they reflected in a broader spirit over such questions as purposive adaptation, the harmonious working of the fabric of the body in relation to environment, and the interplay of all the creatures that people the earth; over the problems of heredity and variation; over the mysteries of sex, and the phenomena of generation and reproduction, by which phenomena, as the wise woman told, or reminded, Socrates, and as Harvey said again (and for that matter, as Coleridge said, and Weismann, but not quite so well)—by which, as the wise old woman said, we gain our glimpse of insight into eternity and immortality. These, then, together with the problem of the Origin of Species, are indeed *magnalia naturae*; and I take it that inquiry into these, deep and wide research specially directed to the solution of these, is characteristic of the spirit of our time, and is the pass-word of the younger generation of biologists.

Interwoven with this high aim which is manifested in the biological work of recent years is another tendency. It is the desire to bring to bear upon our science, in greater measure than before, the methods and results of the other sciences, both those that in the hierarchy of knowledge are set above and below, and those that rank alongside of our own.

Before the great problems of which I have spoken, the cleft between Zoology and Botany fades away, for the same problems are common to the twin sciences. When the zoologist becomes a student, not of the dead, but of the living, of the vital processes of the cell rather than of the dry bones of the body, he becomes once more a physiologist, and the gulf between these two disciplines disappears. When he becomes a physiologist, he becomes, *ipso facto*, a student of chemistry and of physics. Even mathematics has been pressed into the service of the biologist, and the calculus of probabilities is not the only branch of mathematics to which he may usefully appeal.

The physiologist has long had as his distinguishing characteristic, giving his craft a rank superior to the sister branch of morphology, the fact that in his great field of work, and in all the routine of his experimental research, the methods of the physicist and the chemist, the lessons of the anatomist, and the experience of the physician are inextricably blended in one common central field of investigation and thought. But it is much more recently that the morphologist and embryologist have made use of the method of experiment, and of the aid of the physical and chemical sciences—even of the teachings of philosophy: all in order to probe into properties of the living organism that men were wont to take for granted, or to regard as beyond their reach, under a narrower interpretation of the business of the biologist. Driesch and Loeb and Roux are three among many men who have become eminent in this way in recent years, and their work we may take as typical of methods and aims such as those of which I speak. Driesch, both by careful experiment and by philosophic insight, Loeb, by his conception of the dynamics of the cell and by his marvellous demonstrations of chemical and mechanical fertilisation, Roux, with his theory of autodetermination, and by all the labours of the school of *Entwickelungsmechanik* which he has founded, have all in various ways, and from more or less different points of view, helped to reconstruct and readjust our ideas of the relations of embryological processes, and hence of the phenomenon of life itself, on the one hand to physical causes (whether external to or latent in the mechanism of the cell), or on the other to the ancient conception of a Vital Element alien to the province of the physicist.

No small number of theories or hypotheses, that seemed for a time to have been established on ground as firm as that on which we tread, have been reopened in our day. The adequacy of natural selection to explain the whole of organic evolution has been assailed on many sides; the old fundamental subject of embryological debate between the evolutionists or preformationists (of the school of Malpighi, Haller, and Bonnet) and the advocates of epigenesis (the followers of Aristotle, of Harvey, of Caspar F. Wolff, and of Von Baer) is now discussed again, in altered language, but as a pressing question of the hour; the very foundations of the cell-theory have been scrutinised to decide (for instance) whether the segmented ovum, or even the complete organism, be a colony of quasi-independent cells, or a living unit in which cell differentiation is little more than a superficial phenomenon; the whole meaning, bearing, and philosophy of evolution has been discussed by Bergson, on a plane to which neither Darwin nor Spencer ever attained; and the hypothesis of a Vital Principle, or vital element, that had lain in the background for near a hundred years, has come into men's mouths as a very real and urgent question, the greatest question for the biologist of all.

In all ages the mystery of organic form, the mystery of growth and reproduction, the mystery of thought and consciousness, the whole mystery of the complex phenomena of life, have seemed to the vast majority of men to call for description and explanation in terms alien to the language which we apply to inanimate things; though at all times there have been a few who sought, with the materialism of Democritus, Lucretius, or Giordano Bruno, to attribute most, or even all, of these phenomena to the category of physical causation.

For the first scientific exposition of Vitalism we must go back to Aristotle, and to his doctrine of the three parts of the tripartite Soul: according to which doctrine, in Milton's language, created things "by gradual change sublimed, To vital spirits aspire, to animal, To intellectual!" The first and lowest of these three, the ψυχὴ ἡ θρεπτική, by whose agency nutrition is effected, is ἡ πρώτη ψυχή, the inseparable concomitant of Life itself. It is inherent in the plant as well as in the animal, and in the Linnæan aphorism, *Vegetabilia crescunt et vivunt*, its existence is admitted in a word. Under other aspects, it is all but identical with the ψυχὴ αὐξητική and γεννητική, the soul of growth and of reproduction: and in this composite sense it is no other than Driesch's "Entelechy," the hypothetic natural agency that presides over the form and formation of the body. Just as Driesch's psychoid or psychoids, which are the basis of instinctive phenomena, of sensation, instinct, thought, reason, and all that directs that body which entelechy has formed, are no other than the αἰσθητική whereby *animalia vivunt et sentiunt*, and the διανοητική to which Aristotle ascribes the reasoning faculty of man. Save only that Driesch, like Darwin, would deny the restriction of νοῦς, or reasoning, to man alone, and would extend it to animals, it is clear, and Driesch himself admits,[1] that he accepts both the vitalism and the analysis of vitalism laid down by Aristotle.

The πνεῦμα of Galen, the *vis plastica*, the *vis vitae formatrix*, of the older physiologists, the *Bildungstrieb* of Blumenbach, the *Lebenskraft* of Paracelsus, Stahl, and Treviranus, "shaping the physical forces of the body to its own ends," "dreaming dimly in the grain of the promise of the full corn in the ear,"[2] these and many more, like Driesch's "entelechy" of to-day, are all conceptions under which successive generations strive to depict

1 "Science and Philosophy of the Organism" (Gifford Lectures), ii. p. 83, 1908.

2 *Cit.* Jenkinson (*Art.* "Vitalism" in *Hibbert Journal*, April, 1911) who has given me the following quotation: "Das Weitzenkorn hat allerdings Bewusstsein dessen was in ihm ist und aus ihm werden kann, und träümt wirklich davon. Sein Bewusstsein und seine Träume mögen dunkel genug sein"; Treviranus, "Erscheinungen und Gesetze des organischen Lebens, 831.

the something that separates the earthy from the living, the living from the dead. And John Hunter described his conception of it in words not very different from Driesch's, when he said that his principle, or agent, was independent of organisation, which yet it animates, sustains, and repairs; it was the same as Johannes Müller's conception of an innate "unconscious idea."

Even in the Middle Ages, long before Descartes, we can trace, if we interpret the language and the spirit of the time, an antithesis that, if not identical, is at least parallel to our alternative between vitalistic and mechanical hypotheses. For instance, Father Harper tells us that Suarez maintained, in opposition to St. Thomas, that in generation and development a Divine interference is postulated, by reason of the perfection of living beings; in opposition to St. Thomas, who (while invariably making an exception in the case of the human soul) urged that, since the existence of bodily and natural forms consists solely in their union with matter, the ordinary agencies which operate on matter sufficiently account for them.[1]

But in the history of modern science, or of modern physiology, it is, of course, to Descartes that we trace the origin of our mechanical hypotheses—to Descartes, who, imitating Archimedes, said, "Give me matter and motion, and I will construct the universe." In fact, leaving the more shadowy past alone, we may say that it is since Descartes watched the fountains in the garden, and saw the likeness between their machinery of pumps and pipes and reservoirs and the organs of the circulation of the blood, and since Vaucanson's marvellous automata lent plausibility to the idea of a "living automaton"—it is since then that men's minds have been perpetually swayed by one or other of the two conflicting tendencies, either to seek an explanation of the phenomena of living things in physical and mechanical considerations, or to attribute them to unknown and mysterious causes, alien to physics and peculiarly concomitant with life. And some men's temperaments, training, and even avocations, render them more prone to the one side of this unending controversy, as the minds of other men are naturally more open to the other. As Kühne said a few years ago at Cambridge, the physiologists have been found for several generations leaning, on the whole, to the mechanical or physico-chemical hypothesis, while the zoologists have been very generally on the side of the Vitalists.

The very fact that the physiologists were trained in the school of physics, and the fact that the zoologists and botanists relied for so many years upon the vague, undefined force of "heredity" as sufficiently accounting for the development of the organism, an intrinsic force the results of which could be studied, but the nature of which seemed remote from possible analysis or explanation—these facts alone go far to illustrate and to justify what Kühne said.

Claude Bernard held that mechanical, physical, and chemical forces summed up all with which the physiologist has to deal. Verworn defined physiology as "the chemistry of the proteids"; and I think that another physiologist (but I forget who) has declared that the mystery of life lay hidden in "the chemistry of the enzymes." But of late, as Dr. Haldane showed in his address a couple of years ago to the Physiological Section, it is among the physiologists themselves, together with the embryologists, that we find the strongest indications of a desire to pass beyond the horizon of Descartes, and to avow that physical and chemical methods, the methods of Helmholtz, Ludwig, and Claude Bernard, fall short of solving the secrets of physiology. On the other hand, in zoology, resort to the method of experiment—the discovery, for instance, of the wonderful effects of chemical or even mechanical stimulation in starting the development of the egg—and again the ceaseless search into the minute structure, or so-called mechanism, of the cell—these, I think, have rather tended to sway a certain number of zoologists in the direction of the mechanical hypothesis.

[1] "Cum formarum naturalium et corporalium esse non consistat nisi in unione ad materiam; ejusdem agentis esse videtur eas producere, cujus est materiam transmutare. Secundo, quia cum hujusmodi formae non excedant virtutem et ordinem et facultatem principiorum agentium in natura, nulla videtur necessitas eorum originem in principia reducere altiora.—Aquinas, *De Pot.* Q. iii., a. 11: cf. Harper, "Metaphysics of the School," iii. 1, p. 152.

But, on the whole, I think it is very manifest that there is abroad on all sides a greater spirit of hesitation and caution than of old, and that the lessons of the philosopher have had their influence on our minds. We realise that the problem of development is far harder than we had begun to let ourselves suppose: that the problems of organogeny and phylogeny (as well as those of physiology) are not comparatively simple and well-nigh solved, but are of the most formidable complexity. And we would, most of us, confess, with the learned author of "The Cell in Development and Inheritance," "that we are utterly ignorant of the manner in which the substance of the germ-cell can so respond to the influence of the environment as to call forth an adaptive variation; and again, that the gulf between the lowest forms of life and the inorganic world is as wide as, if not wider than, it seemed a couple of generations ago."[1]

While we keep an open mind on this question of Vitalism, or while we lean, as so many of us now do, or even cling with a great yearning, to the belief that something other than the physical forces animates and sustains the dust of which we are made, it is rather the business of the philosopher than of the biologist, or of the biologist only, when he has served his humble and severe apprenticeship to philosophy, to deal with the ultimate problem. It is the plain bounden duty of the biologist to pursue his course, unprejudiced by vitalistic hypotheses, along the road of observation and experiment, according to the accepted discipline of the natural and physical sciences; indeed, I might perhaps better say the physical sciences alone, for it is already a breach of their discipline to invoke, until we feel we absolutely must, that shadowy force of "heredity" to which, as I have already said, biologists have been accustomed to ascribe so much. In other words, it is an elementary scientific duty; it is a rule that Kant himself laid down[2] that we should explain, just as far as we possibly can, all that is capable of such explanation in the light of the properties of matter and of the forms of energy with which we are already acquainted.

It is of the essence of physiological science to investigate the manifestations of energy in the body, and to refer them, for instance, to the domains of heat, electricity, or chemical activity. By this means a vast number of phenomena, of chemical and other actions of the body, have been relegated to the domain of physical science and withdrawn from the mystery that still attends on life: and by this means, continued for generations, the physiologists, or certain of them, now tell us that we begin again to descry the limitations of physical inquiry, and the region where a very different hypothesis insists on thrusting itself in. But the morphologist has not gone nearly so far as the physiologist in the use of physical methods. He sees so great a gulf between the crystal and the cell, that the very fact of the physicist and the mathematician being able to explain the form of the one, by simple laws of spatial arrangement where molecule fits into molecule, seems to deter, rather than to attract, the biologist from attempting to explain organic forms by mathematical or physical law. Just as the embryologist used to explain everything by heredity, so the morphologist is still inclined to say—"the thing is alive, its form is an attribute of itself, and the physical forces do not apply." If he does not go so far as this, he is still apt to take it for granted that the physical forces can only to a small and even insignificant extent blend with the intrinsic organic forces in producing the resultant form. Herein lies our question in a nutshell. Has the morphologist yet sufficiently studied the forms, external and internal, of organisms in the light of the properties of matter, of the energies that are associated with it, and of the forces by which the actions of these energies may be interpreted and described? Has the biologist, in short, fully recognised that there is a borderland, not only between physiology and physics, but between morphology and physics, and that the physicist may, and must, be his guide and teacher in many matters regarding organic form?

Now this is by no means a new subject, for such men as Berthold and Errera, Rhumbler and Dreyer, Bütschli and Verworn, Driesch and Roux, have already dealt or

[1] Wilson, *op. cit.* 1906, p. 434. [2] In his "Critique of Teleological Judgment."

deal with it. But on the whole it seems to me that the subject has attracted too little attention, and that it is well worth our while to think of it to-day.

The first point, then, that I wish to make in this connection is that the Form of any portion of matter, whether it be living or dead, its form and the changes of form that are apparent in its movements and in its growth, may in all cases alike be described as due to the action of Force. In short, the form of an object is a "diagram of forces"—in this sense, at least, that from it we can judge of or deduce the forces that are acting or have acted upon it; in this strict and particular sense it is a diagram; in the case of a solid, of the forces that *have* been impressed upon it when its conformation was produced, together with those that enable it to retain its conformation; in the case of a liquid (or of a gas), of the forces that are for the moment acting on it to restrain or balance its own inherent mobility. In an organism, great or small, it is not merely the nature of the *motions* of the living substance that we must interpret in terms of Force (according to Kinetics), but also the *conformation* of the organism itself, whose permanence or equilibrium is explained by the interaction or balance of forces, as described in Statics.

If we look at the living cell of an Amœba or a Spirogyra we see a something which exhibits certain active movements, and a certain fluctuating, or more or less lasting, form; and its form at a given moment, just like its motions, is to be investigated by the help of physical methods, and explained by the invocation of the mathematical conception of force.

Now the state, including the shape or form, of a portion of matter is the resultant of a number of forces, which represent or symbolise the manifestations of various kinds of Energy; and it is obvious, accordingly, that a great part of physical science must be understood or taken for granted as the necessary preliminary to the discussion on which we are engaged.

I am not going to attempt to deal with, or even to enumerate, all the physical forces or the properties of matter with which the pursuit of this subject would oblige us to deal—with gravity, pressure, cohesion, friction, viscosity, elasticity, diffusion, and all the rest of the physical factors that have a bearing on our problem. I propose only to take one or two illustrations from the subject of *surface-tension*, which subject has already so largely engaged the attention of the physiologists. Nor will I even attempt to sketch the general nature of this phenomenon, but will only state (as I fear for my purpose I must) a few of its physical manifestations or laws. Of these, the most essential facts for us are as follows:—Surface-tension is manifested only in fluid or semi-fluid bodies, and only at the surface of these: though we may have to interpret surface in a liberal sense in cases where the interior of the mass is other than homogeneous. Secondly, a fluid may, according to the nature of the substance with which it is in contact, or (more strictly speaking) according to the distribution of energy in the system to which it belongs, tend either to spread itself out in a film, or, conversely, to contract into a drop, striving in the latter case to reduce its surface to a minimal area. Thirdly, when three substances are in contact (and subject to surface-tension), as when water surrounds a drop of protoplasm in contact with a solid, then at any and every point of contact certain definite angles of equilibrium are set up and maintained between the three bodies, which angles are proportionate to the magnitudes of the surface-tensions existing between the three. Fourthly, a fluid film can only remain in equilibrium when its curvature is everywhere constant. Fifthly, the only surfaces of revolution which meet this condition are six in number, of which the plane, the sphere, the cylinder, and the so-called unduloid and catenoid are the most important. Sixthly, the cylinder cannot remain in free equilibrium if prolonged beyond a length equal to its own circumference, but, passing through the unduloid, tends to break up into spheres: though this limitation may be counteracted or relaxed, for instance, by viscosity. Finally, we have the curious fact that, in a complex system of films, such as a homogeneous froth of bubbles, three partition-walls and no more always meet at a crest, at equal angles, as, for instance, in the very simple case of a layer of uniform hexagonal cells; and (in a solid system) the crests, which may be straight or curved, always meet, also at equal angles, four by four, in a common point. From these physical facts, or laws, the morphologist, as well as the physiologist, may draw important consequences.

It was Hofmeister who first showed, more than forty years ago, that when any drop of protoplasm, either over all its surface or at some free end (as at the tip of the pseudopodium of an Amœba), is seen to "round itself off," that is not the effect of physiological or vital contractility, but is a simple consequence of surface-tension—of the law of the minimal surface; and in the physiological side, Engelmann, Bütschli, and others have gone far in their development of the idea.

It was Plateau, I think, who first showed that the myriad sticky drops or beads upon the weft of a spider's web, their form, their size, their distance apart, and the presence of the tiny intermediate drops between, were in every detail explicable as the result of surface-tension, through the law of minimal surface and through the corollary to it which defines the limits of stability of the cylinder; and, accordingly, that with their production, the will or effort or intelligence of the spider had nothing to do. The beaded form of a long, thin pseudopodium, for instance, of a Heliozoan, is an identical phenomenon.

It was Errera who first conceived the idea that not only the naked surface of the cell, but the contiguous surfaces of two naked cells, or the delicate incipient cell-membrane or cell-wall between, might be regarded as a weightless film, whose position and form were assumed in obedience to surface-tension. And it was he who first showed that the symmetrical forms of the unicellular and simple multicellular organisms, up to the point where the development of a skeleton complicates the case, were one and all identical with the plane, sphere, cylinder, unduloid and catenoid, or with combinations of these.

It was Berthold and Errera who, almost simultaneously, showed (the former in far the greater detail) that in a plant each new cell-partition follows the law of minimal surface, and tends (according to another law which I have not particularised) to set itself at right angles to the preceding solidified wall, so giving a simple and adequate physical explanation of what Sachs had stated as an empirical morphological rule. And Berthold further showed how, when the cell-partition was curved, its precise curvature, as well as its position, was in accordance with physical law.

There are a vast number of other things that we can satisfactorily explain on the same principle and by the same laws. The beautiful catenary curve of the edge of the pseudopodium, as it creeps up its axial rod in a Heliozoan or a Radiolarian, the hexagonal mesh of bubbles, or vacuoles, on the surface of the same creatures, the form of the little groove that runs round the waist of a Peridinian, even (as I believe) the existence, form, and undulatory movements of the undulatory membrane of a Trypanosome, or of that around the tail of the spermatozoon of a newt—every one of these, I declare, is a case where the resultant form can be well explained by, and cannot possibly be understood without, the phenomena of surface-tension; indeed, in many of the simpler cases the facts are so well explained by surface-tension that it is difficult to find place for a conflicting, much less an over-riding, force.

I believe, for my own part, that even the beautiful and varied forms of the Foraminifera may be ascribed to the same cause; but here the problem is just a little more complex, by reason of the successive consolidations of the shell. Suppose the first cell or chamber to be formed, assuming its globular shape in obedience to our law, and then to secrete its calcareous envelope. The new growing bud of protoplasm, accumulating outside the shell, will, in strict accordance with the surface-tensions concerned, either fail to "wet" or to adhere to the first-formed shell, and will so detach itself as a unicellular individual (Orbulina), or else it will flow over a less or greater part of the original shell until its free surface meets it at the required angle of equilibrium. Then, according to this angle, the second chamber may happen to be all but detached

(Globigerina), or, with all intermediate degrees, may very nearly wholly enwrap the first. Take any specific angle of contact and presume the same conditions to be maintained, and therefore the same angle to be repeated, as each successive chamber follows on the one before, and you will thereby build up regular forms, spiral or alternate, that correspond with marvellous accuracy to the actual forms of the Foraminifera. And this case is all the more interesting, because the allied and successive forms so obtained differ only in degree in the magnitude of a single physical or mathematical factor; in other words, we get not only individual phenomena, but lines of apparent *orthogenesis*, that seem explicable by physical laws, and attributable to the continuity between successive states in the continuous or gradual variation of a physical condition. The resemblance between allied and related forms, as Hartmann demonstrated and Giard admitted years ago, is not always, however often, to be explained by common descent and parentage.[1]

In the segmenting egg we have the simpler phenomenon of a "laminar system," uncomplicated by the presence of a solid framework; and here, in the earliest stages of segmentation, it is easy to see the correspondence of the planes of division with what the laws of surface-tension demand. For instance, it is not the case (though the elementary books often represent it so) that when the totally segmenting egg has divided into four segments, the four partition walls ever remain in contact at a single point; the arrangement would be unstable, and the position untenable. But the laws of surface-tension are at once seen to be obeyed when we recognise the little *cross-furrow* that separates the blastomeres, two and two, leaving in each case three only to meet at a point in our diagram, which point is in reality a section of a ridge or crest.

Very few have tried, and one or two (I know) have tried and not succeeded, to trace the action and the effects of surface-tension in the case of a highly complicated, multi-segmented egg. But it is not surprising if the difficulties which such a case presents appear to be formidable. Even the conformation of the interior of a soap-froth, though absolutely conditioned by surface-tension, presents great difficulties, and it was only in the last years of Lord Kelvin's life that he showed all previous workers to have been in error regarding the form of the interior cells.

But what, for us, does all this amount to? It at least suggests the possibility of so far supporting the observed facts of organic form on mathematical principles as to bring morphology within or very near to Kant's demand that a true natural science should be justified by its relation to mathematics.[2] But if we were to carry these principles further, and to succeed in proving them applicable in detail, even to the showing that the manifold segmentation of the egg was but an exquisite froth, would it wholly revolutionise our biological ideas? It would greatly modify some of them, and some of the most cherished ideas of the majority of embryologists; but I think that the way is already paved for some such modification. When Loeb and others have shown us that half, or even a small portion, of an egg, or a single one of its many blastomeres, can give rise to an entire embryo, and that in some cases *any* part of the ovum can originate *any* part of the organism, surely our eyes are turned to the *energies* inherent in the matter of the egg (not to speak of a presiding entelechy), and away from its original formal operations of division. Sedgwick has told us for many years that we look too much to the individuality of the individual cell, and that the organism, at least in the embryonic body, is a continuous syncytium. Hofmeister and Sachs have repeatedly told us that in the plant, the growth of the mass, the growth of the organ, is the primary fact; and De Bary has summed up the matter in his aphorism, *Die Pflanze bildet Zellen, nicht die Zelle bildet Pflanzen*. And in many other ways, as many of you are well aware, the extreme position of the cell-theory, that the cells are the ultimate individuals, and that the organism is but a colony of quasi-independent cells, has of late years been called in question.

There are no problems connected with Morphology that appeal so closely to my mind, or to my temperament, as those that are related to mechanical considerations, to mathematical laws, or to physical and chemical processes.

I love to think of the logarithmic spiral that is engraven over the grave of that great anatomist, John Goodsir (as it was over that of the greatest of the Bernouillis), so graven because it interprets the form of every molluscan shell, of tusk and horn and claw, and many another organic form besides. I like to dwell upon those lines of mechanical stress and strain in a bone that give it its strength where strength is required, that Hermann Meyer and J. Wolff described, and on which Roux has bestowed some of his most thoughtful work; or on the "stream-lines" in the bodily form of fish or bird, from which the naval architect and the aviator have learned so much. I admire that old paper of Peter Harting's in which he paved the way for investigation of the origin of spicules, and of all the questions of crystallisation or pseudo-crystallisation in presence of colloids, on which subject Lehmann has written his recent and beautiful book. I sympathise with the efforts of Henking, Rhumbler, Hartog, Gallardo, Leduc, and others to explain on physical lines the phenomena of nuclear division. And, as I have said to-day, I believe that the forces of surface-tension, elasticity, and pressure are adequate to account for a great multitude of the simpler phenomena, and the permutations and combinations thereof, that are illustrated in organic Form.

I should gladly and easily have spent all my time this morning in dealing with these questions alone. But I was loath to do so, lest I should seem to overrate their importance, and to appear to you as an advocate of a purely mechanical biology.

I believe all these phenomena to have been unduly neglected, and to call for more attention than they have received. But I know well that though we push such explanations to the uttermost, and learn much in the so doing, they will not touch the heart of the great problems that lie deeper than the physical plane. Over the ultimate problems and causes of vitality, over what is implied in the organisation of the living organism, we shall be left wondering still.

To a man of letters and the world like Addison, it came as a sort of revelation that Light and Colour were not objective things, but subjective, and that back of them lay only motion or vibration, some simple activity. And when he wrote his essay on these startling discoveries, he found for it, from Ovid, a motto well worth bearing in mind, *causa latet, vis est notissima*. We may with advantage recollect it when we seek and find the Force that produces a direct Effect, but stand in utter perplexity before the manifold and transcendent meanings of that great word "cause."

The similarity between organic forms and those that physical agencies are competent to produce still leads some men, such as Stéphane Leduc, to doubt or to deny that there is any gulf between, and to hold that spontaneous generation or the artificial creation of the living is but a footstep away. Others, like Delage and many more, see in the contents of the cell only a complicated chemistry, and in variation only a change in the nature and arrangement of the chemical constituents; they either cling to a belief in "heredity," or (like Delage himself) replace it more or less completely by the effects of functional use and by chemical stimulation from without and from within. Yet others, like Felix Auerbach, still holding to a physical or quasi-physical theory of life, believe that in the living body the dissipation of energy is controlled by a guiding principle, as though by Clerk Maxwell's demons; that for the living the Law of Entropy is thereby reversed; and that Life itself is that which has been evolved to counteract and battle with the dissipation of energy. Berthold, who first demonstrated the obedience to physical laws in the fundamental phenomena of the dividing cell or segmenting egg, recognises, almost in the words of John Hunter, a quality in the living protoplasm, *sui generis*, whereby its maintenance, increase, and reproduction are achieved. Driesch, who began as a "mechanist," now, as we have

[1] Cf. Giard, "Discours inaugurale." *Bull. Scientif.* (3), 1, 1888.

[2] "Ich behaupte aber dass in jeder besonderen Naturlehre nur so viel *eigentliche* Wissenschaft angetroffen werden konne, als darin Mathematik anzutreffen ist."—Kant, in Preface to "Metaphys. Anfangsgründe der Naturwissenschaft" (Werke, ed. Hartenstein, vol. iv. p. 360).

seen, harks back straight to Aristotle, to a twin or triple doctrine of the soul. And Bergson, rising into heights of metaphysics where the biologist, *qua* biologist, cannot climb, tells us (like Duran) that life transcends teleology, that the conceptions of mechanism and finality fail to satisfy, and that only "in the absolute do we live and move and have our being."

We end but a little way from where we began.

With all the growth of knowledge, with all the help of all the sciences impinging on our own, it is yet manifest, I think, that the biologists of to-day are in no self-satisfied and exultant mood. The reasons and the reasoning that contented a past generation call for reinquiry, and out of the old solutions new questions emerge; and the ultimate problems are as inscrutable as of old. That which, above all things, we would explain, baffles explanation; and that the living organism is a living organism tends to reassert itself as the biologist's fundamental conception and fact. Nor will even this concept serve us and suffice us when we approach the problems of consciousness and intelligence and the mystery of the reasoning soul; for these things are not for the biologist at all, but constitute the Psychologist's scientific domain.

In Wonderment, says Aristotle, does philosophy begin,[1] and more than once he rings the changes on the theme. Now, as in the beginning, wonderment and admiration are the portion of the biologist, as of all those who contemplate the heavens and the earth, the sea, and all that in them is.

And if Wonderment springs, as again Aristotle tells us, from ignorance of the causes of things, it does not cease when we have traced and discovered the proximate causes, the physical causes, the Efficient Causes of our phenomena. For beyond and remote from physical causation lies the End, the Final Cause of the philosopher, the reason Why, in the which are hidden the problems of organic harmony and autonomy and the mysteries of apparent purpose, adaptation, fitness, and design. Here, in the region of teleology, the plain rationalism that guided us through the physical facts and causes begins to disappoint us, and Intuition, which is of close kin to Faith, begins to make herself heard.

And so it is that, as in Wonderment does all philosophy begin, so in Amazement does Plato tell us that all our philosophy comes to an end.[2] Ever and anon, in presence of the *magnalia naturae*, we feel inclined to say with the poet:

> οὐ γάρ τι νῦν τε κἀχθές, ἀλλ' ἀεί ποτε
> ζῇ ταῦτα, κοὐδεὶς οἶδεν ἐξ ὅτου 'φάνη.

"These things are not of to-day nor yesterday, but evermore, and no man knoweth whence they came."

I will not quote the noblest words of all that come into my mind, but only the lesser language of another of the greatest of the Greeks: "The ways of His thoughts are as paths in a wood thick with leaves, and one seeth through them but a little way."

SECTION E.

GEOGRAPHY.

OPENING ADDRESS BY COLONEL C. F. CLOSE, C.M.G., R.E., PRESIDENT OF THE SECTION.

I PROPOSE to devote the first part of this address to an examination of the purpose and position of Geography, with special reference to its relations with other subjects. It will not be possible entirely to avoid controversial matters; but, if some of the questions touched on are controversial, this only means that these questions have a certain importance. I shall try to describe the facts of the case impartially.

In the second part I shall try to indicate briefly what the Government, as represented by the great Departments of State, is doing for Geography.

PART I. *The Position of Geography with reference to other Subjects.*

It is no secret that the geographical world is not unanimous about the meaning and object of Geography. The definitions suggested by such writers as Mr. Chisholm, Prof. Davis, Prof. Herbertson, Mr. Mackinder, or Dr. Mill, are not in agreement. From time to time an attempt is made to formulate some statement which shall not commit the subscribers to anything very definite. But differences of opinion on the subject persist.

There are, of course, a great many ways of approaching the question. Let us, for example, examine the proceedings of such representative bodies as the British Association and the Royal Geographical Society, and of such assemblies as the International Geographical Congresses, and let us see if we can find out what is, as a fact, the scope of the subject as dealt with by these bodies. They are institutions which work in the full light of day, and they are too large to be dominated for any length of time by individuals. If we can find any working principle, any common term, amongst these societies, we shall have gone some way towards arriving at a solution of the problem.

A simple method of investigation is to discuss the character of the publications of these societies and of the lectures delivered before them. And I feel that I cannot do better than devote most of this brief analysis to the Royal Geographical Society and its admirably edited Journal. Here we are on safe ground. If an inhabitant of another planet wished to know what we understand by astronomy we could confidently refer him to the Monthly Notices of the Royal Astronomical Society. If he were curious about the condition of geology, we should give him the volumes of the Geological Society. And, if he were so rash as to ask what are the objects of the modern mathematician, we should hand him the papers published by the London Mathematical Society. The "Geographical Journal" occupies no lower a position with reference to Geography than do the other journals mentioned with reference to the sciences with which they deal.

In analysing the contributions to the Royal Geographical Society, it is important to start with an honest classification. In the endeavour to be impartial I have chosen the classification which was adopted for the last International Geographical Congress, *i.e.* that held at Geneva in 1908. This Congress was divided into fourteen sections. It will serve to clear the ground if we deal first with sections 12, 13, and 14; these are the Teaching of Geography, Historical Geography (which was mainly concerned with the history of travel and exploration), and Rules and Nomenclature. For the purpose of discovering what Geography is, these three sections will not be of any assistance. Every subject has its educational side, its history, and its rules and nomenclature. The subject proper was, therefore, divided into eleven sections. The eleven sections are the following:—

(1) Mathematical and Cartographical Geography.
(2) General Physical Geography.
(3) Vulcanology and Seismology.
(4) Glaciers.
(5) Hydrography (Potamography and Limnology).
(6) Oceanography.
(7) Meteorology and Climatology; Terrestrial Magnetism.
(8) Biological Geography.
(9) Anthropology and Ethnography.
(10) Economic and Social Geography.
(11) Explorations.

Before applying this classification to the work of the Geographical Society, I wish to call attention to the extremely frank way in which vulcanology, seismology, meteorology, climatology, terrestrial magnetism, anthropology, and ethnography are included in Geography. The list, in fact, covers ground occupied by several sections of the British Association.

I have investigated the work of the Geographical Society for the five complete years 1906 to 1910. The original contributions to the "Geographical Journal" have been examined for that period, omitting from consideration contributions on the subjects of teaching, the history of exploration, and rules and nomenclature.

There are altogether 296 original papers which come under one or another of the eleven headings given above. Of these papers, 171, or 57 per cent., deal with Explorations and Travels. There is a great drop to the next largest section, General Physical Geography, which

[1] "Met." I., 2,982b, 12, &c.
[2] Cf. Coleridge, "Biogr. Lit."

accounts for thirty papers, or about 10 per cent. Adhering to the order of the Geneva Congress, the complete list is as follows:—

Original Contributions to the Proceedings of the Royal Geographical Society during the five years 1906 *to* 1910.

Subject	Percentage
(1) Mathematical and Cartographical Geography	3
(2) General Physical Geography	10
(3) Vulcanology and Seismology	5
(4) Glaciers	3
(5) Hydrography (Potamography and Limnology)	5
(6) Oceanography	3
(7) Meteorology and Climatology; Terrestrial Magnetism	3
(8) Biological Geography	1
(9) Anthropology and Ethnography...	3
(10) Economic and Social Geography	7
(11) Explorations	57

The main conclusion is obvious enough. For the principal Geographical Society in the world, Geography is still mainly an affair of explorations and surveys; if to this item we add cartography, we account for 60 per cent. of the activities of the Society.

There is another important deduction which is natural and unforced: the papers on vulcanology and seismology and on glaciers could have been read with perfect appropriateness before the Geological Society; those on meteorology and climatology before the Meteorological Society; and those on anthropology and ethnography before the Anthropological Society. To make quite sure of this point I will cite a few titles of the papers read: "The Great Tarawera Volcanic Rift," by J. M. Bell; "Recent Earthquakes," by R. D. Oldham; "Glacial History of Western Europe," by Prof. T. G. Bonney; "Climatic Features of the Pleistocene Ice Age," by Prof. A. Penck; "Rainfall of British East Africa," by G. B. Williams; "Geographical Distribution of Rainfall in the British Isles," by Dr. H. R. Mill; "Geographical Conditions affecting Population in the East Mediterranean Lands," by D. G. Hogarth; "Tribes of North-Western Se-Chuan," by W. N. Fergusson.

This little list of typical subjects indicates clearly that there is a large group of contributions which would have found an appropriate home in the journals of the Geological, Meteorological, and Anthropological Societies; there is a possible corollary that, since men who make a life-study of these subjects are best capable of dealing with them, the authors of the above type of paper who submit their work to the Geographical Society in so doing appeal rather to the public at large than to men of their own special sciences.

We may therefore sum up the results of this brief investigation into the work of the Royal Geographical Society by saying that 60 per cent. of it is concerned with exploration and mapping, and that some of the remainder could be dealt with appropriately by the learned societies concerned, but that the Geographical Society serves as a popularising medium. It also serves a useful purpose as a common meeting-ground for vulcanologists, seismologists, oceanographers, meteorologists, climatologists, anthropologists, and ethnographers.

Another line of investigation may be profitably pursued. Who are, by common consent, the leading geographers of the world? No doubt the explorers come first in popular estimation, such men (omitting British names) as Peary, Charcot, Sven Hedin. Then after this type would come the men of learning who stand out in any International Congress. These men stand out because they have, by their own exertions, increased the sum of human knowledge. Omitting, for the moment, the consideration of exploration and mapping, we find that in an international congress a large number of the most celebrated geographers are eminent as geologists. In such a gathering we can also pick out those who have advanced the sciences of meteorology or anthropology. Now, suppose the position reversed. Let the functions of geology be supposed to be somewhat in dispute and those of geography perfectly definite, and further let us suppose that at an international meeting of geologists a large proportion of the men of real distinction were geographers. We may in this way get an idea of what geography looks like from the outside.

I think that at this point we may explain, in a preliminary way, the work of the Geographical societies, after the fashion of the "Child's Guide to Knowledge":—

Question. What is Geography?

Answer. There is no generally accepted definition of Geography.

Question. Can we not form some idea of the scope of the subject by considering the work of the Royal Geographical Society?

Answer. Yes; 60 per cent. of this work deals with explorations, surveys, and mapping, and of the rest a considerable portion consists of matter which could be discussed appropriately before the Geological, Meteorological, and Anthropological Societies.

Question. What, then, leaving maps out of consideration, are the useful functions of a Geographical society?

Answer. A Geographical society serves to popularise the work of men who labour in certain fields of science, and such a society forms a very convenient meeting-ground for them.

Question. What is a geographer?

Answer. The term geographer is sometimes applied to explorers; sometimes to men who compile books derived mainly from the labours of surveyors, geodesists, geologists, climatologists, ethnographers, and others; sometimes to those who compile distributional maps.

Question. Can a geographer who has not made a special study of one or more of such subjects as geodesy, surveying, cartography, geology, climatology, or ethnography, hope to advance human knowledge?

Answer. He can do much to popularise these subjects, but he cannot hope to do original work.

Another way of attempting to ascertain the meaning and object of Geography is to study the character of the instruction given in the universities, and we may suppose that this can be fairly judged by the contents of standard text-books. Let us take, for example, the "Traité de Géographie Physique" of M. E. de Martonne, formerly Professor of Geography at the University of Lyons, now Professor at the Sorbonne. The work in question was published in 1909, and is divided into four main sections—Climate, Hydrography, Terrestrial Relief, and Biogeography.

The first sentence of the book is "What is Geography?" Twenty-four pages are devoted to discussing this question, which the writer, with all his skill and learning, finds it difficult to answer definitely and convincingly. One receives the impression of the dexterous handling of a difficult question, and of a generally defensive attitude. In this book geography is said to depend on three principles. The principle of *extension*, the principle of *coordination*, and the principle of *causality*. As an illustration of the meaning of the principle of extension, we are told that "the botanist who studies the organs of a plant, its conditions of life, its position in classification, is not doing geographical work; but if he seeks to determine its area of extension, *il fait de la géographie botanique*." I believe that we have here reached a critical point. The claim is, that when, in the prosecution of a botanical study, a map is used to show the distribution of a plant, the use of such a map converts the study into a branch of geography. Well, it is a question of definition and convention, which cannot, I imagine, be settled except by the general agreement of all the sciences. We have to make up our minds whether a man who constructs a distributional map is doing "geography." One thing, I suppose, is not doubtful. When the map is made it will be better interpreted by a botanist than by a person ignorant of botany. In the same way the discussion of an ordinary geological map is best undertaken by a geologist, and so on. It would appear that geography, in the sense mentioned, is not so much a subject as a method of research.

It will be convenient here to say a few words about the relations between societies and schools of Geography, and those two important subjects geodesy and geology. Curiously enough, there is not, and has never been, in the United Kingdom a society or body specially charged with the study of geodesy. Geodesy, in fact, has no regular home in these islands. But the Royal Geographical Society has done a good deal in the past few years to stimulate an interest in the subject, thereby fulfilling what I believe to be one of the Society's most useful functions, that of popularisation.

If, however, an authoritative opinion were required on any geodetic question, where could it be obtained? Well, I suppose there is no doubt that the headquarters of this branch of learning is the International Geodetic Association; but the scientific work itself is being largely carried out at the Geodetic Institute at Potsdam, by the Survey of India, by the Geodetic Section of the Service Géographique, by the U.S. Coast and Geodetic Survey, and by similar bodies. Geodesy, especially in its later developments, is a definitely scientific subject which demands much study and application. It is but slightly touched upon by the schools of Geography. Perhaps I may here point out that geodesy is by no means mainly concerned with the shape of the spheroid. The chief problems are now those of isostasy and local attraction generally, the real shape of the sea-surface, the continuity of the crust of the earth, and changes of density therein.

The position in which Geography finds itself with regard to Geology can be clearly seen if reference is made to the new edition of the "Encyclopædia Britannica." In the eleventh volume of this work are two important articles, "Geography," by Dr. H. R. Mill, and "Geology," by Sir Archibald Geikie. In the article on "Geography" we find a description of geomorphology as that part of Geography which deals with terrestrial relief, and a remark is made that "opinion still differs as to the extent to which the geographer's work should overlap that of the geologist." In this article, however, most of the authorities quoted are geologists, and the author remarks that "the geographers who have hitherto given most attention to the forms of the land have been trained as geologists."

Turning to the article on "Geology," we find an important section on "Physiographical Geology," which is described as dealing with the investigation of "the origin and history of the present topographical features of the land." Now this is the exact field claimed for geomorphology. It has been observed by others, notably by Prof. de Martonne, that the interpretation of topographic forms has been most successfully undertaken by geologists, and he gives as an instance of this the good work done by the United States Geological Survey.

I do not know whether any geographer untrained as a geologist has contributed anything of value to geomorphology.

Another test which may be applied is the following: Let us imagine Geography to be non-existent, and note what the effect would be. Suppose there were no such things as Government Geographical Services, or Schools of Geography at the Universities, or Geographical Societies. The first and most obvious result would be that most, if not all, of our apparatus of exploration and mapping would have disappeared. But as we are all in agreement as to the necessity of this branch of human effort, let us restore this to existence and examine the effect of the disappearance of the rest.

So far as concerns geodesy, we should still possess the International Geodetic Association, the Geodetic Institute at Potsdam, and the United States Geodetic Survey, and similar bodies. But we should have lost the means of popularising geodesy in the proceedings of Geographical Societies; and, as there would be now no geographical text-books, elementary geodesy would not find itself between the same covers as climatology and geomorphology.

As regards geomorphology, or physiographical geology, not very much difference would be noted. The geologists would still pursue this important subject; but here again their writings would perhaps appeal to a more expert and less popular audience, although it is not to be forgotten that many admirable introductions to the subject have been written by geologists.

Much the same might be said about meteorology and climatology. There would be text-books devoted to these studies, but there might be a diminution of popular interest.

Such names as phyto-geography would disappear, but the study of botany (if we permit it the use of distributional maps) would not be affected. The loss to knowledge would be mainly that of getting to a certain extent out of touch with the public. The constitutions of the various learned bodies would remain the same, and so would their functions. The constitution of the Royal Society, which has never recognised geography as a subject, would be totally unaffected.

If we thus study the relations between Geography and other subjects we are almost bound to arrive at the conclusion that Geography is not a unit of science in the sense in which geology, astronomy, or chemistry are units. If we inquire into the current teaching of Geography, and examine modern text-books, we find that most of the matter is derived directly from the workers in other fields of study. And if we inquire into the products of Geographical societies, it becomes evident that one of the most important functions fulfilled by these useful bodies is to popularise the work of geodesists, geologists, climatologists, and others, and to provide a common meeting-ground for them. If Geography had been able to include geology and the other sciences which deal with earth-knowledge, it would then, indeed, have been a master science. But things have worked out differently.

I shall very probably be told that, in laying some stress on the above-mentioned aspects of the subject, I have forgotten that the main purpose of Geography is the study of the earth as the home of man, or the study of man as affected by his environment, and that, however necessary it may be to begin with a foundation of geodesy, geology, and climatology, we must have as our main structure the investigation of the effect of place conditions on the races of man, on human history and human industry, on economics and politics.

It is obviously and abundantly true that no student of history, economics, or politics can disregard the effect of geographical environment. But it is not, as a fact, disregarded by writers on these subjects. The question is, to a large extent, whether we should annex these portions of their studies, group them, and label them "Geography." Our right to do this will depend on the value of our own original investigations. We have the right to use the results obtained by others, provided that we add something valuable of our own.

Before this human aspect of geography—or, for that matter, any other aspect of the subject—is recognised by the world of science as an independent, indispensable, and definite branch of knowledge, it must prove its independence and value by original, definite, and, if possible, quantitative research.

Part II. *Geography and the Government Departments.*

Whatever definition of Geography is accepted, we are all in agreement that the map is the essential foundation of the subject. I propose now to indicate very briefly how the British Government, as represented by the great Departments of State, is, in this respect, assisting the cause of Geography. The Departments which are interested in maps and surveys are the following:—The Admiralty, the War Office, the Colonial Office, the India Office, the Board of Agriculture, and the Foreign Office.

The immense services rendered, not only to this country, but to the whole world, by the Hydrographic Department of the Admiralty are known to all. But it would be somewhat rash of a soldier to talk about hydrographic surveys, so I will confine my remarks to surveys on land.

First, it should be remarked that the British Government as a whole has for many years shown its interest in Geography, and has recognised the good work done by the Royal Geographical Society by contributing an annual sum of 500*l.* towards the funds of the Society. Next, it should be noted that from time to time British Governments have contributed large sums of money towards Arctic and Antarctic exploration. The most recent examples of this very practical form of encouragement will be remembered by all; I mean the Government expenditure on Scott's first Antarctic Expedition and the handsome sum contributed towards the cost of Shackleton's great journey.

Turning now to the *War Office*, the first matter to which I would call attention is that nearly all the accurate topographical surveys of the Empire have been started by soldiers. This applies to the United Kingdom, Canada, Australia, South Africa, Tropical Africa, and last, but greatest of all, India. The accounts of the struggles of soldiers at the end of the eighteenth century to obtain sanction for what is now known as the Ordnance Survey form very interesting reading. In fact, all over the world it was military requirements which produced the topographical map; and it is still the War Offices of the world which control the execution of almost all geographically important surveys. During the last few years the largest block of work undertaken by the War Office has been the accurate survey of the Orange Free State, which has an area of about 52,000 square miles—nearly the size of England—and an adjacent reconnaissance survey in the Cape of Good Hope covering an area of a hundred thousand square miles. There has been some inevitable delay (due to causes which need not be gone into now) in the publication of the sheets of this survey, but the work is being pushed on. The survey of the Orange Free State is fully comparable with the admirable surveys carried out by the French Service Géographique de l'Armée in Algeria and Tunis. Some work has also been done in the Transvaal. Other surveys carried out in recent years under the direct control of the War Office are those of Mauritius, St. Helena, a portion of Sierra Leone, Malta, and Hong Kong.

The most notable work which is now being carried out in the *Self-Governing Dominions* is the Militia Department Survey of Canada, with which excellent progress has been made.

The total area of the Crown Colonies and Protectorates under the rule of the *Colonial Office* amounts to about two million square miles. British African Protectorates form a large portion of this total, and I will indicate briefly what is being done to survey these tropical Protectorates. From the geographical point of view the brightest regions are East Africa, Uganda, and Southern Nigeria. In East Africa topographical surveys of the highlands and coast belt are being pushed on by military parties as part of the local survey department. The area of exact work done amounts now to some 30,000 square miles. In Uganda a military party has recently completed a large block of country, and in this Protectorate thoroughly trustworthy maps of 32,000 square miles are now available. In Southern Nigeria a completely reorganised survey department is tackling in a thoroughly systematic fashion the difficult task of mapping a forest-clad country. We shall shortly see the results.

For the information of those who have not travelled in Tropical Africa it should be remarked that surveying in such countries is attended by every sort of difficulty and discomfort, and too often by illness and serious discouragement. It is one thing to sit at home in a comfortable office and plan a scheme of survey, and quite another thing to carry it out on the spot. We do not, I am convinced, give enough honour and credit to those who actually get the work done in such trying circumstances. Honest, accurate survey work in the tropics puts a much greater strain on a man than exploratory sketching. To picture what the conditions are, imagine that you are to make a half-inch survey of the South of England: cover the whole country with dense forest; put mangrove swamps up all the estuaries; raise the temperature to that of a hot-house; introduce all manner of insects; fill the country with malaria, yellow fever, blackwater fever, and sleeping sickness; let some of your staff be sick; then have a fight with the local treasury as to some necessary payment, and be as cheerful as you can. That is one side of the medal. On the other side there is the abiding interest which the surveyor feels in the country, the natives, and the work; the sense of duty done; and the satisfaction of opening up and mapping for the first time a portion of this world's surface.

There is no time to mention other surveys in Africa, and I will pass on to a very interesting part of the world, the Federated Malay States. In this prosperous country much excellent geographical work is being done by the combined survey department which was established under a Surveyor-General in the year 1907. The department is in good hands, and the commencement of a regular topographical series is being undertaken.

I wish it were possible to prophesy smooth things about Ceylon. From our special point of view the situation leaves much to be desired. There is not yet published a single topographical map, and the topographical surveys are progressing at a rate which, under favourable conditions, may result in the maps being completed in the year 1970.

In closing this inadequate review of the principal surveys which are being undertaken in the Crown Colonies and Protectorates, I should mention that the coordinating factor is the Colonial Survey Committee, which every year publishes a report which is presented to Parliament.

The *India Office* is, of course, concerned with that great department the Survey of India. The Indian Empire has an area of about 1,800,000 square miles, and as, under the arrangements approved in 1908, the standard scale of survey is to be one inch to one mile, the area of paper to be covered will be 1,800,000 square inches. Actually this is divided into about 6700 sheets. The Survey of India has always been famous for its geodetic work and for its frontier surveys and methods. Its weak point used to be its map reproduction. This has been greatly improved. But personally I feel that if, for most military and popular purposes, a half-inch map is found suitable for England, as is undoubtedly the case, there is no reason why a half-inch map should not also be suitable for India. It is mainly a question of putting more information on the published map, and of engraving it and using finer means of reproduction. If this smaller scale were adopted all the information now presented could be shown, and the number of the sheets would be reduced from 6700 to 1675, a saving of 5000 sheets. It is difficult to avoid the feeling that the Survey of India is over-weighted with the present scheme. The scheme has, however, many merits. It will be impossible to carry it out unless the department is kept at full strength.

The *Board of Agriculture* is the Department which is charged with the administration of the Ordnance Survey. The Ordnance Survey spends some 200,000*l.* a year, and for that sum it furnishes the inhabitants of the United Kingdom with what are, without doubt, the finest and most complete series of large-scale maps which any country possesses. There is nothing in any important country (such as France, Germany, Italy, Russia, or the United States) to compare with our complete and uniform series of sheets on the scale of $\frac{1}{2500}$. These sheets are sold at a nominal price, and are, in effect, a free gift to landowners, agents, and all who deal with real property. They are also, of course, invaluable to county and borough engineers and surveyors. They really are a national asset which is not half enough appreciated. The whole conception of these large-scale plans has stood the test of time, and is greatly to the honour of a former generation of officers.

Much might be said about the small-scale maps of the Ordnance Survey, which are now published in a very convenient form. As mentioned below, the latest small-scale Ordnance map is the new international map on the million scale. Some sheets of this map will shortly be published.

The *Foreign Office* is concerned with the surveys of the Anglo-Egyptian Sudan, which are at present mainly of an explanatory character. The taking over of the Province of Lado has recently thrown fresh work on the Sudan Survey Department. The Foreign Office, which administers Zanzibar, has recently given orders for the survey of the Island of Pemba, a dependency of Zanzibar, and this is being carried out by a small military party.

But the greatest service to Geography rendered by the Foreign Office in recent years was the encouragement given to the project of the International Map by the assembly of an international committee in November, 1909. Sir Charles (now Lord) Hardinge presided at the opening session. There were delegates from Austria-Hungary, France, Germany, Great Britain, Canada and Australia, Italy, Russia, Spain, and the United States, and, as is known, the resolutions which were devised by the Committee were agreed to unanimously. After the conclusion of the work of the Committee the Government communicated the resolutions to all countries which had not been represented, and nearly all the replies which have been received are favourable. Maps in exact accordance with the resolutions are, it is understood, being produced by France, Hungary, Italy, Spain, the United States, and other countries, and, so far as we are concerned, by the General Staff and the Ordnance Survey. These maps will be shown at the International Geographical Congress which meets at Rome in October next.

I have now come to the end of this rapid sketch of the geographical work of the official world. It is work which, though often of an apparently humdrum character, outweighs in importance the sum total of all which can be undertaken by private agency or by societies. But it is the very legitimate business of societies to criticise and encourage.

It is, in fact, not only our manifest duty to encourage the systematic mapping of the world on which we live, but we should do all we can to ensure the perfection, and suitability for their special purposes, of the maps themselves. In the surveying of the earth's surface and its representation by means of maps we are treating of matters which are essentially and peculiarly our own.

It would appear that another great function of Geography, as represented by Geographical societies and congresses, is to serve as a popularising medium for such sciences as geodesy, geology, climatology, and anthropology, and also to serve as the means of bringing together the workers in these sciences. We may be told that, so far as this Association is concerned, the exact study of geodesy and meteorology is dealt with by Section A, geology by Section C, and anthropology by Section H, but there is, I believe, no other section which forms a more convenient general meeting-ground for all the workers in the various divisions of earth-knowledge. We ourselves have our own special work, work which is shared by no others, the great task of mapping the world. This task is such a necessary one, and it is of such genuine value to so many studies, that by assisting in it we are really furthering the Advancement of Science, which is the object of this great Association.

NOTES.

COLONEL C. F. CLOSE, C.M.G., R.E., has been appointed Director-General of the Ordnance Survey in succession to Colonel S. C. N. Grant, C.M.G., R.E.

DR. F. GRANT OGILVIE, C.B., has been appointed by the President of the Board of Education director of the Science Museum. He will continue to fill his present position of secretary for the Science Museum and the Geological Survey and Museum.

THE memory of Alessandro Volta was honoured on Friday last by a meeting held at his grave at Camnago, at which were present Signor Calissano, Minister of Posts and Telegraphs, M. Buebs, director of the Belgian telegraphs, Signor Pietro Volta (a nephew of the inventor), and many telegraphists from all parts of the world. Several speeches were delivered, and a memorial stone bearing an inscription recording the esteem in which Volta is held was inaugurated. The ceremony was followed by a luncheon, provided by the Mayor, and the placing of wreaths, at Como, on the Volta monument.

THE Brussels correspondent of *The Times* announces the death of Prof. F. Swarts, the holder for many years of the chair of general chemistry at the University of Ghent.

THE death is announced, at the age of sixty-four years, of Mr. T. Hurry Riches, locomotive superintendent of the Taff Vale Railway. Mr. Riches, who was held in high esteem as an engineer, for three successive years filled the presidency of the South Wales Institute of Engineers. He was also an ex-president of the Institute of Mechanical Engineers, a member of the Iron and Steel Institute, of the British Association, of the council of the University College of South Wales and Monmouthshire, of the council of governors of the Imperial College of Science and Technology, of the council of the Institute of Metals, and a governor of the National Museum of Wales. He served as chairman of the mechanical engineering section of the Franco-British Exhibition, and as reporter for Great Britain and the colonies to the International Railway Congress of 1910 upon railway motor-cars.

DR. GILMAN A. DREW, assistant director of the Woods Hole Marine Biological Laboratory, has been appointed resident assistant director of the laboratory, and will in future devote his whole time to the work at Woods Hole.

IT is announced in *Science* that Prof. A. J. Hitchcock, of the United States Department of Agriculture, has left for Panama to join the Smithsonian expedition for the biological survey of the Panama Canal zone. He will also investigate the grasses of the five Central American Republics on behalf of the department with which he is connected.

ACCORDING to advices received at Cordova, Alaska, the Smithsonian Institution's glacial expedition has had an unlucky accident. As Profs. R. F. Starr and Lawrence Madden were crossing the Yukon on their way to Fairbanks, their wagon was upset by the current. The explorers themselves got ashore in safety, but all their field notes, cameras, and exposed films were lost.

The Electrician, quoting from the French official gazette "L'Officiel," states that a committee dealing with the hygienic aspects of illumination has been appointed by the Minister of the Interior in France. The objects of the committee include the general effects of illumination on health, the framing of simple rules as to the best means of applying customary systems of lighting to various industrial operations, the nature and causes of short sight and impairment of vision, and their connection with defective living conditions, the study of methods of measuring illumination, &c.

A BRUSSELS correspondent of *The Times* states that a special commission was recently appointed to study the utilisation of aëroplanes for ensuring rapid communication with districts of the Belgian Congo that are still unprovided with railways and roads, and that it has been decided to await the results of certain tests to be carried out in France. Attempts will be made to traverse a desert about 1200 kilometres (750 miles) across, and to establish landing stations 400 kilometres apart, fitted with wireless telegraphy. The aëroplanes will have to convey three passengers and a relatively heavy load of victuals, water, tools, &c. It is hoped that this line will be established in 1912. A first subsidy of 16,000*l*. has been voted for the establishment of these communications.

ACCORDING to a Reuter telegram, the acting Russian Consul at Kwang-cheng-tse reports the outbreak at Changchun, Manchuria, of an unknown disease. The sufferers are attacked by headache and violent diarrhœa, and lose the power of speech. Death occurs in two or three days. The Chinese and Japanese doctors are, it is said, doubtful of the nature of the disease.

THE Board of Agriculture and Fisheries has decided to appoint a departmental committee to inquire into the circumstances of the recent outbreaks of foot-and-mouth disease, and to consider whether any further measures can be adopted to prevent their recurrence. The committee will be appointed and sit in the autumn under the chairmanship of Sir Ailwyn Fellowes.

THE fifty-second course of lectures and demonstrations for sanitary inspectors, held under the auspices of the Royal Sanitary Institute, will begin on Monday, September 18, and close on Friday, December 1. The course will be divided into two parts. The first part will consist of six lectures dealing with elementary physics and chemistry in relation to water, soil, air, ventilation, and meteorology. The second part will deal with meat and food inspection, including the taking of samples of water, food, and drugs for analysis. On October 6 a course of lectures to assist school teachers and other students entering for examinations in hygiene in its bearing in school life, and for women health visitors and school nurses, will be held at the Royal Sanitary Institute and Parkes Museum. A course of practical training for meat inspectors will be begun on October 13.

AT the National Congress of Applied Chemistry, which is to be held at Turin from September 23 to 28, a general discussion will take place on the fiscal and customs practice in regard to the industrial use of alcohol, and Prof. Miolati will give an experimental demonstration of the use of atmospheric nitrogen for industrial purposes.

A FUNGUS FORAY in connection with the Yorkshire Naturalists' Union is arranged to take place in Mulgrave Woods, Sandsend, near Whitby, from Saturday, September 23, to Thursday, September 28. The following papers and lecture will be delivered:—on September 23, notes on the Uredinaceæ, by Mr. R. H. Philip; fungi found in sewage-polluted West Riding streams, and in other places, by Mr. J. W. H. Johnson; and on September 25 Mr. George Massee will lecture on "Diseases of Plants caused by Fungi."

THE annual Fungus Foray of the South-Eastern Union of Scientific Societies will be held at Hastings on Saturday, September 30. The gathering will be preceded, on September 29, by the delivery (at the Museum, Hastings) of a popular lecture on "Fungi," by Mr. E. W. Swanton. Those intending to take part in the foray are requested to give intimation to this effect, by September 27, to Mr. G. Abbott, 2 Rusthall Park, Tunbridge Wells.

ADDRESSES will be delivered as follows at the reopening of certain of the London medical schools:—St. George's Hospital, on October 2, by Dr. H. A. Miers, F.R.S., on "Lucidity"; Middlesex Hospital, on October 2, by Dr. C. Berkeley; University College Hospital, on October 2, by Sir William Ramsay, K.C.B., F.R.S.; London (Royal Free Hospital) School of Medicine for Women, on October 2, by Sir William Butlin; London Hospital, on October 3, the "Schorstein" lecture by Dr. J. Mackenzie, and on October 4 a further lecture will be delivered on the subject of "Auricular Fibrillation."

THE Meteorological Office in its recent issue of the Weekly Weather Report gives a summary of the weather for the summer, comprised by the thirteen weeks from June 4 to September 2. The mean temperature for the period was above the average over the entire kingdom, the excess ranging from about 4° in the east of England to rather more than a degree in the north of Scotland. The extreme temperature exceeded 90° in all the English districts, and was as high as 98° in the Midlands and 97° in the east of England. The rainfall was deficient over the entire country, except in the north of Scotland, where the excess was only 0·05 inch. The largest deficiency was 3·16 inches in the south-east of England and 3·00 inches in the south-west of England. The aggregate measurement of rain ranged from 3·34 inches in the south-east of England to 10·62 inches in the north of Scotland. The number of rainy days was everywhere deficient, the greatest deficiency being 19, in the Channel Islands. The duration of bright sunshine was everywhere largely in excess of the average, the greatest excess being 225 hours in the south-east of England. The absolute duration ranged from 476 hours in the north of Scotland to 861 hours in the Channel Islands, and 838 hours in the south-east of England. At Greenwich the mean temperature for the summer, June to August inclusive, is 66·1°, which is 3·8° above the normal. The mean for the respective months was: June, 60·8°; July, 68·3°; August, 69·1°, the excess in the last-mentioned month being 6·2°. The August mean is fully 2° higher than any previous record for the corresponding month. The mean of the maxima readings is 81·1°, and there is no previous record of the mean exceeding 80°. There have already been 40 days this summer (April 2 to September 5) with the shade temperature above 80°, and in the last seventy years 1868 is the only year with an equal number of hot days, whilst 1846, 1857, and 1859 are the only other years with more than 30 such warm days. The shade temperature of 100° at Greenwich on August 9 establishes a record for absolute temperature. The aggregate rainfall at Greenwich for the three summer months is 3·74 inches, which is 2·80 inches less than the average; the driest month was July, with 0·26 inch. The rainfall this summer is the least since 1885, and 1869, 1864, and 1849 are the only other years since 1841 with so small a summer rainfall. The duration of bright sunshine for the three months is 818 hours, which is 175 hours more than usual; the respective amounts are: June, 223 hours; July, 335 hours; August, 260 hours.

PROF. W. BOYD DAWKINS, F.R.S., delivered his presidential address to the Cambrian Archæological Association at Abergele on August 29, taking as his subject "Some Points in the Pre-history of Wales." In the course of his remarks, he said that at the time when the Neolithic aborigines first found their way so far west in the British Islands, the whole land was covered with forest, the lower portions of the valleys were filled with morasses, and the only tracks were those of the wild animals. The land was some 60 feet above its present level, and the coast-line included the area of Anglesea. The Neolithic farmers and herdsmen were a small, oval-headed people, well formed, and had been clearly proved to be identical with the Iberian peoples of history. They were represented to-day by the small, dark element in the Welsh population. The next elements in the Welsh population were the taller, broad-headed people who lived in Wales in the Bronze age. Their civilisation was derived from the Continent, and they were identified with the earlier division of the Celtic peoples, the Goidels, termed by Rhys the Q Celts. In the prehistoric Iron age a new civilisation made its appearance. That, too, was probably introduced by invading tribes from the Continent, and these belonged to the Brythons, or P Celts, of Rhys. These represented the third element, and no new traceable element was added by the Roman occupation.

THE Bulletins of the Johns Hopkins Hospital for July and August (xxii., Nos. 244 and 246) contain matter of much medical interest. In No. 246 Dr. S. A. Knopf describes, under the name of "the starnook," a device for open-air treatment. It consists of a small room or chamber, sufficiently large to contain a small bed, built of wood or galvanised iron on a balcony, or against a window and supported on posts. The walls are louvred, and partly consist of shutters which can be opened, and the roof also can be raised and entirely opened in fine weather. The idea is that it may be used in towns and cities where there is no ground attached to the dwelling available for the erection of an ordinary "shelter."

IN *The Journal of Hygiene* for July (vol. xi., No. 2), among many papers of much scientific value, Mr. C. Walker describes experiments on the inoculation of "materies morbi" through the human skin by flea-bites. The results obtained indicate that there is very little risk of this occurring. Even with the plague bacillus and animals susceptible to infection with it, such as the rat and guinea-pig, the results were negative. The author suggests that this may be due to the fact that in his experiments the bites were usually single. In view of the accepted theory that plague is conveyed by fleas, these experiments are of considerable importance.

IN *The Journal of Anatomy and Physiology* for July (vol. xlv., part iv.), Mr. E. S. Mawe directs attention to a curious method of predicting the sex of infants. It seems that there is an ancient Japanese belief that the sex can be predicted by the arrangement of the hair on the neck of the child born immediately before. It is said that when the hairs converge the next child is usually a girl, and when they diverge, a boy. Mr. Mawe gives the results of an examination of 300 cases, and they certainly appear to afford a good deal of support to this belief. He suggests that there may be some Mendelian interpretation, but it is not easy to see what Mendelism can have to do with it.

THE August number of *The Quarterly Journal of Microscopical Science* (vol. lvii., part i.) contains several very interesting memoirs, and the illustrations are of a remarkably high standard of excellence. Dr. W. E. Agar describes the spermatogenesis of Lepidosiren, and it is worthy of note that in order to carry out this work it was necessary for him to undertake an expedition to the swamps of the Paraguayan Chaco. It is satisfactory to observe that he is able to confirm the accounts given by workers on other types of the fairing of "homologous" chromosomes in the process of reduction, which is of such deep significance from the point of view of the theory of heredity. Mr. Geoffrey Smith has a short paper on the rapid increase in size of the hen's comb prior to each period of egg-laying, in which he shows that the method by which poultry keepers are in the habit of predicting when a hen is about to lay is really based upon a sound foundation. The temporary increase in size of the comb is shown to be due to infiltration of fat into its connective tissue core. Protozoology is well represented by an elaborate memoir on the cæcal parasites of fowls, by Mr. C. H. Martin and Miss Muriel Robertson, and comparative anatomy by a paper on the fresh-water medusa, *Limnocnida tanganicae*, by Mr. C. L. Boulenger.

A PARLIAMENTARY return of the number of experiments performed on living animals during the year 1910 has recently been issued. The total number of experiments returned during 1910 for England and Scotland reaches the large total of 95,731. Of these, however, 90,792 are of the nature of inoculations, hypodermic injections, and other simple procedures; even the prick of a needle, or feeding with an entirely harmless material, if for the acquisition of new knowledge, is classed as an "experiment" under the Act. The inspectors report that they have everywhere found the animals suitably lodged and well cared for, and the licensees attentive to the requirements of the Act, as well as to the conditions appended to their licences. Only two slight irregularities have occurred during the year.

"REPTILES OF ALL LANDS" is the title of a fully illustrated popular article communicated by Mr. R. L. Ditmars to *The National Geographic Magazine* for August. After mentioning that reptiles are now a degenerate group, although probably more numerous in species than formerly, the author gives a sketch of the three principal ordinal groups living at the present day. The gharial of the Ganges is regarded as the largest existing member of the whole class, Mr. Ditmars refusing apparently to recognise the enormous dimensions which have recently been attributed to the South American anaconda. According to his view, the largest known serpent is the Malay python, which attains a length of about 30 feet, or the same as that of the gharial. Mr. Ditmars, in the legend to the illustration on page 625, repeats the misstatement, to which we have previously directed attention, that the South American bushmaster is the only viperine snake which lays eggs.

ACCORDING to the local Press, a flying fish (*Exocoetus volitans*) was recently taken in a mackerel-net off the village of Wyke Regis, close to Weymouth. Its total length was 11¾ inches. This appears to be the first definitely authenticated specimen taken on the British coast. A trigger-fish (*Balistes caprinus*) was also caught about the same time near Weymouth, this being the third Dorset example, the two others having been taken near the same place respectively in 1873 and 1905.

THE following method for the destruction of rats, adopted by M. de Kruyff, of the Agricultural Bureau of the Dutch Indies at Buitenzorg, Java, is given in a recent American consular report. All visible rat holes were first stopped with earth to ascertain which holes were inhabited. Half a teaspoonful of carbon bisulphide was poured in each of the holes found to be inhabited, and after a delay of a few seconds to allow the liquid to evaporate, the mixture of vapour and air was ignited. The result was a small explosion, which filled the hole with poisonous gases and killed all the rats almost instantly. A pound of bisulphide is sufficient for more than 200 rat holes; 131 dead rats were found in forty-three holes which were opened after the operation. It is further stated that satisfactory results in exterminating porcupines have been obtained by this method.

A CIRCULAR respecting the work of the Aberdeen University Bird-migration Inquiry has been issued by Prof. J. Arthur Thomson and Mr. A. L. Thomson. The object of the movement is the collection of more definite information on migration by the method of placing aluminium rings on the feet of a large number of birds, in the hope of hearing of the subsequent movements of some proportion of the birds. The rings are inscribed with the address "Aberdeen University," and a number (or number and letter combination) different in each case. The rings are placed on young birds found in the nest, or on any old ones that can be captured without injury. The following extracts are taken from the circular above-mentioned:—"(1) It is particularly requested that all who may shoot, capture, or kill, or even hear of any of our marked birds, should let us know of the occurrence. As accurate particulars of date and locality as possible are desired, but, above all, the number (or number and letters) on the ring. Indeed, except where it has been possible to re-liberate the bird uninjured, the ring itself should always be sent, or the ring and foot, or even the whole bird. We always refund postage if asked to do so." "(2) We invite the cooperation in the actual work of marking of any who are specially interested, and have some knowledge of birds, and also time and opportunity for the work. The necessary rings, schedules, postage stamps, &c., are supplied by us, without charge, and we undertake to let the marker know of each case of a bird marked by him being recovered, and to let him have copies of printed reports as far as possible."

A VERY complete account is given by Dr. H. Wallner in the *Mitteilungen der k.k. Geographischen Gesellschaft* (No. 7, Band 54) of the Alm region of Lungau, in the eastern Alps. Where these Alpine pastures are suitably developed there is an annual migration of flocks and their herdsmen from the valley to the high slopes in the early summer, and a return downwards in the autumn, thus constituting a class of semi-nomadic communities as described by Ratzel. The general position of these pastures, their climatic and physiographic conditions, are carefully worked out, and on this basis the distribution of the scattered settlements, the ways and means of communication, the periodical movement of both men and animals, have been thoroughly investigated, not merely by way of description, but by that strictly quantitative method which is so essential for the scientific development of human geography.

DR. E. RÜBEL has compiled a very comprehensive ecological account of the highly interesting Bernina Valley and adjacent country, that is published in Engler's *Botanische Jahrbucher* (vol. xlvii., parts i. and ii.). Seven chapters deal with topography, climate, geology—contributed by Dr. E. Blösch—plant societies, vertical distribution, geography, and a comparison of the floras on the north and south slopes. No fewer than seventy-five plant associations are described under twenty-three formations, and these are grouped under the classes of woods, bushes, shrubs, grasses and swamps, water and rock formations. The most important trees are *Pinus Cembra* and *Larix decidua*, that grow either separately or mixed, as in the beautiful woods towards the lower end of the Roseg Valley. The shrubby and grass associations are perhaps the most interesting. The highest vertical range is that of the *Carex curvula* association, which ascends somewhat higher than 10,000 feet. A list of 100 species that grow above the snow limit is given; to *Silene exscapa* and *Ranunculus glacialis* is assigned the maximum limit of 3500 metres. The illustrations are numerous and excellent, while an interesting item is provided in the record of light measurements.

A COLLECTION of papers dealing with the fauna and flora of Boulder County, Colorado, is published in the University of Colorado Studies (vol. viii., No. 4). Prof. T. D. A. Cockerell contributes a catalogue of protozoa, including mycetozoa and arthropoda; as the author notes, it is remarkable that a preliminary list of mycetozoa from this semi-arid region should contain more than fifty species; Badhamia, Physarum, Stemonitis, and Comatricha are well represented. A description of the lodge-pole pine forests of Boulder Park is provided by Miss K. Bruderlin. The lodge-pole pine, *Pinus Murrayana*, produces the climax formation at an elevation varying between 9000 and 10,000 feet; aspen, Engelman spruce, and subalpine fir form local associations. Species of Vaccinium, roses, and *Arctostaphylos uva-ursi* are the prevailing shrubs.

THE annual report of the county surveyor of Kent, Mr. Maybury, shows the effect of the wear and tear of the roads of this county due to motor traffic, and the consequent increase of the cost of their maintenance. More than 800,000 gallons of tar were used last year on 371 miles of road in Kent in painting the surface to prevent its disintegration. The report states that although this process has proved of very great service, and that the dust nuisance is now a thing of the past, yet on the most important roads where the commercial motor traffic is greatest, some more efficient means of preservation will have to be used than tar painting, and it may become necessary to cover the surface with granite macadam grouted with tar or pitch. As mentioned in a previous note, experiments are about to be conducted by the Road Board to ascertain the most effective method.

WORKS are now being carried out for the purpose of improving the harbour at Lagos, in South Africa. Owing to the dangerous and uncertain condition of the bar at the entrance to the harbour, it is impossible for ocean steamers to enter, and the whole of the traffic has to be transported to the steamers by means of surf boats, at a cost varying from five to thirteen shillings a ton. As the traffic is rapidly increasing, having risen from 154,000 tons in 1900 to more than 300,000 tons, this additional cost, besides the increased risk, is becoming a matter of very serious importance. In order to obtain safe access to the harbour, a mole is being constructed 10,000 feet long, which will project about 7000 feet beyond the present line of foreshore. This mole has a top width of 20 feet, with base of about 100 feet, and rises 9 feet 9 inches above low water, and is composed of granite rubble blocks. When this mole is completed further works are to be carried out on the other side of the entrance.

THE deterioration of stored coal and its liability to spontaneous combustion are questions of great practical importance, and have been the subject of numerous investigations in different countries. The University of Illinois Bulletin No. 46, which deals with the spontaneous combustion of coal, with special reference to bituminous coals of the Illinois type, by S. W. Parr and F. W. Kressmann, gives an account of an exhaustive set of experiments. It is shown that coal is continuously oxidised, a number of more or less distinct oxidation processes being involved. There is a certain critical temperature above which the oxidation is ultimately destructive. The effects of external sources of heat, state of division of the coal, presence of moisture and of iron pyrites are detailed, and a set of principles summarised, which must be observed in any attempt at the prevention of spontaneous combustion. The most important points are the avoidance of any external source of heat which may in any way contribute toward increasing the temperature of the coal, the elimination of coal dust or finely divided material, and dryness in storage. Storage under water would prevent both deterioration and spontaneous combustion, but its industrial practicability is still an open question, and can only be determined by actual experience. In a valuable appendix a historical review of the whole subject is given, together with a summary of the opinions of various workers on the same subject.

AT the July meeting of the International Photometric Commission, held at Zürich, an important paper was communicated by Messrs. W. J. A. Butterfield, J. S. Haldane, and A. P. Trotter on the corrections for the effects of atmospheric conditions on photometric flame standards. It is known that the light given by the standard flame (Harcourt pentane lamp or Hefner amylacetate lamp) depends upon the atmospheric pressure, the humidity, and the amount of carbon dioxide present. In these experiments a special steel compression chamber was fitted up in such a manner that one of these variables could be altered, the other two being kept constant, the corresponding changes in the illuminating power of the flame being balanced against an electric lamp worked under constant conditions. The results are summarised in two formulæ, for the Harcourt and Hefner lamps respectively, showing the actual light of the lamp, expressed in terms of the light under normal conditions, the pressure, and the existing percentages of carbon dioxide and aqueous vapour in the air. A few experiments were also carried out on the effect of variations in the atmospheric conditions on the light of gas and candle flames. It was found that the changes were in the same direction, and approximately of the same order, as those of the Harcourt standard, and the conclusion is drawn that small variations in the atmospheric conditions of a gas testing room will not appreciably affect the results of photometric comparisons in which the Harcourt or Hefner lamp is used as the standard of light, and that these standards will give as accurate results as are anyhow practically obtainable in determinations of the illuminating power of gas, if they are used in all ordinary circumstances without correction for any divergence from normal atmospheric conditions.

WITH reference to a statement to be found in our issue of May 25 (p. 412) in a review of "Salvarsan or 606 (Dioxy-Diamino-Arsenobenzol): its Chemistry, Pharmacy, and Therapeutics," by Dr. W. H. Martindale and W. W. Westcott, in which trypan red is named as a remedy for bovine piroplasmosis (Texas fever), a correspondent resident in Australia has written to ask where the drug can be obtained, its price, and any literature concerning it. In reply, we would point out that the reference to "trypan red" was made in error (see correction on p. 526 of NATURE for June 15); the drug for the treatment of piroplasmosis is "trypan blue," particulars as to the cost of which can probably be obtained from such a firm as E. Merck, 16 Jewry Street, London, E.C. The remedy is discussed by Nuttall and Hadwen in *Parasitology* for 1909. We are informed that *large* doses of quinine have also been found to exert a curative action on bovine piroplasmosis in Malaya and Guatemala.

OUR ASTRONOMICAL COLUMN.

THE SPECTRUM OF KIESS'S COMET.—With spectrographs attached to the equatorial of the Juvisy Observatory, MM. de la Baume Pluvinel and Baldet secured photographs of the spectrum of comet 1911*b*, which they discuss in a paper published in No. 8 of the *Comptes rendus* (August 21). On their best photograph, the two bright bands at λ 4735 and λ 3882 are accompanied by many fainter bands, which present one or two noteworthy features. Three feeble condensations at λλ 3914, 4005, and 4026 are apparently only in the tail; they probably correspond with the λ 3914 of the kathode spectrum of nitrogen and with the doublet (λ 4003 and λ 4023) given by Fowler. While agreeing with the majority of cometary spectra, that of comet 1911*b* is different in many respects from those of several recent comets. For instance, the great comet 1910*a* showed a most intense continuous spectrum, of which there is very little in the radiations from the Kiess comet. Again, in Morehouse's comet the doublets traced by Fowler were common to the nucleus and the tail; here they are peculiar to the tail. To explain this, the authors suggest that in the former case the decomposition of the cyanogen was very active, and so one got the products of the decomposition surrounding the nucleus; but in the case of comet 1911*b* the activity was not so great, and the cyanogen was not sufficiently decomposed until it had been repelled from the nucleus into the tail.

THE ZODIACAL LIGHT.—In No. 4520 of the *Astronomische Nachrichten* Herr Josef Sedláček describes the Zodiacal Light as observed at the Neuschloss in Steiermark Observatory during January and February. At 7h. 15m. (M.E.T.) on January 18 the light was about twice as bright as the brightest part of the Milky Way, and the cone reached up some 49·5° from the horizon; its colour was reddish. On other nights it was noted that the brightness of the light fluctuated considerably with intervals of 1·0 to 1·5 minutes.

METEORITE FINDS.—Publication 145 of the Field Museum of Natural History is devoted to a description, by Mr. O. C. Farrington, of some recent additions of meteorites to the museum of which he is curator.

The Leighton meteorite is a stone weighing about 30 oz. and having a length of 4 inches; it has a very marked brecciated appearance, and contains small grains of nickel-iron. This stone fell on January 12, 1907, at a place eight miles south of Leighton, Colbert County, Alabama.

The Quinn Canyon meteorite, found in August, 1908, in Nevada, is a much larger specimen, and is one of the large iron meteorites of the world. The longest diameter of its oval face is 47 inches, with a diameter at right angles to this of 35 inches, and a circumference of 132 inches; its weight is 3275 lb. In addition to numerous knobs, pittings, furrows, and cylindrical holes all over the iron, the bottom of the meteorite shows two patches of crust of black magnetic iron oxide. These patches are each about 1 inch square, and the oxide adheres so firmly that it can only be detached by the use of a cold chisel and hammer. An analysis shows that the meteorite contains about 91·6 per cent. of iron and about 7·3 per cent. of nickel, and very fine etching figures have been produced. It is supposed to have fallen in a recorded fall which occurred on February 1, 1894.

Mr. Farrington also gives an interesting list of recorded falls since the year 1800, and accepts 331 as properly authenticated. He also analyses the records in months, and finds that May and June show the greatest numbers of falls; November falls below, and August slightly exceeds, the average number. He also gives a complete list of the known falls that have taken place in the United States, with brief particulars of each.

THE LEEDS ASTRONOMICAL SOCIETY.—No. 18 of the Journal and Transactions of the Leeds Astronomical Society contains the report for the year 1910, and also some of the papers read during the session. Of these, several deal with comets; and there is an interesting paper by Mr. Whitmell dealing with lunar eclipses, in which historical eclipses and various features producing and attending eclipses are lucidly described.

AN OPEN-AIR TELESCOPE.—A project for a large, long-focus telescope is described by Prof. Todd in No. 187, vol. xxxii., of *The American Journal of Science*. In order to obtain great size at relatively low cost, Prof. Todd proposes to do away with the costly dome and use the telescope in the open air. At present he describes an altazimuth mounting in which the azimuth motion would be secured by a revolving vertical shaft working on rollers. To secure the easy working of this he proposes to take up most of the weight by flotation with an arrangement whereby the telescope could be clamped in a "safe" position, when not in use, by pumping out part of the supporting liquid. The tube would be built on the cantilever principle, of angle steel, and would be supported in the middle. He estimates that a 60-inch objective would cost about 125,000 dollars, and such a mounting as is proposed would probably cost a like amount. Instead of observing chair, rising floor, &c., he proposes to carry the observer in a light carriage attached to the revolving tailpiece of the telescope, and he discusses the practicability of erecting such an instrument at some such altitude as that of Fuji-yama in Japan (12,400 feet).

LUMINOUS METEOR TRAINS.—Some further work on the origin of luminous and persistent meteor trains is described by Dr. Trowbridge in *The Popular Science Monthly* for August. Dr. Trowbridge has been able to reproduce the phenomena by causing gases at very low pressure to phosphoresce, and he suggests that in the upper air, generally at about fifty or sixty miles' altitude, the conditions are favourable for this action, the phosphorescence being produced by ionisation caused by weak electric currents or intense temperature generated by the meteor's flight.

THE OXFORD UNIVERSITY OBSERVATORY.—Further evidence as to the energy and versatility characteristic of the Oxford University Observatory is forthcoming in the pile of abstracts and papers just received from them. These form part of the volumes issued under the title of "Miscellaneous Papers of the University Observatory, Oxford," and include important papers on the measurement of star photographs, eclipse work, variable star discussions, and mathematical astronomy.

In his report of the work during the year ended April 30, Prof. Turner states that the work of replacing defective plates in zone 25° (the last Oxford zone) was completed, and the volume of measures ready for immediate publication. The question of making differential measures by photographic means of the places of the reference stars has long been under consideration, and an apparently satisfactory method is to be given an extensive trial.

METEOROLOGICAL REPORTS AND YEAR-BOOKS.

VIENNA *Central Meteorological Office* (1908).—The forty-fifth year-book (new series) of this important service appears in the same form as heretofore; it includes daily observations and monthly and yearly results in the international form for a number of stations, hourly observations for Vienna, and temperature and rainfall observations at other stations. Purely rainfall statistics are published by the Hydrographic Office, and observations in Hungary and elsewhere are also separately published. Observations of the upper air are actively carried on by manned and registering balloons. Weather forecasts were sent free to all post and telegraphic offices between April and November, in addition to the daily publications of the usual weather report (with chart). A separate appendix issued with this volume contains the results of thunderstorm observations in Lower Austria in 1902–5, by Dr. A. Defant. These include two maps showing the districts of the first appearance and final disappearance of the storms. The greater elevations of ground are seen to offer favourable conditions for the formation of the storms, and to promote their development in a remarkable manner. Very few storms originate in the more level districts; these check their development, and become the places of dissolution of the storms which approach from other parts.

Meteorological Office (1910).—Summaries of the results have been published of the geophysical and meteorological observations in continuation of the reports of the observatory department of the National Physical Laboratory, in accordance with arrangements made between H.M. Treasury and other authorities. The tables in this volume are given in the usual form, and include observations for Eskdalemuir, magnetic results for Falmouth and Valencia, and the customary table of recent magnetic values for observatories in all parts of the world. In the year 1911 Eskdalemuir will replace Kew with regard to magnetic observations. The following data for Kew are extracted from interesting notes drawn up by Dr. C. Chree:—mean westerly declination, 16° 3·2′; inclination, 66° 58·7′; horizontal force, 0·18503. Solar radiation observations with an Angström pyrheliometer made between 11h. 30m. a.m. and 12h. 30m. p.m., expressed in gram-calories per square centimetre per minute, ranged from 1·105 in August to 0·575 in December; the absolute values were 1·296 in May and 0·484 in December The largest seismograph disturbances occurred on January 22, amplitude (E.-W. displacement) > 17 mm.; June 24, 11 mm., and December 13, 7·5 mm. Dr. Shaw states that the considerations of the most suitable forms for the future publication of the results obtained at the associated observatories, in view of international relationships, is now occupying attention.

Liverpool Observatory (1910).—The report of this valuable institution, maintained in great efficiency by the Mersey Docks and Harbour Board, appears in the same form as in previous years (NATURE, October 27, 1910). The annual means of the principal meteorological elements were practically normal; absolute maximum temperature, 77·3° in June (11·8° below the highest record); minimum, −5·9° in January (7·2° above the lowest record). An interesting experiment was made in the autumn, in connection with the determination of time, by observing the signals sent out by radio-telegraphy from the Eiffel Tower and from the German station at Merddeich; the signals were received at Waterloo station with great clearness. The amplitudes and other details of the seismological disturbances of January 22, June 24, and December 13 agree closely with those recorded at Kew; in the first case the amplitude exceeded the width of the paper.

Norwegian Meteorological Institute (1910).—These valuable observations are published in two volumes, as in previous years:—(1) the year-book containing daily observations with monthly and yearly summaries according to the international scheme, and hourly readings for Christiania; (2) daily amounts of rain and snow with summaries, and normal percentages for as many years as are available. This volume is accompanied by maps showing the annual isohyets for each 200 mm. These give a clear idea of the great variation according to geographical position (see NATURE, July 28, 1910) which it is difficult otherwise to obtain from the great mass of tables. They clearly show the influence of the rain-bringing winds of the Atlantic, and of the configuration of the land. One of the tables, giving the values at selected stations in 1910 in percentages of the normal amounts, shows yearly differences ranging from 59 to 169 per cent. of the normal. We have also received a "summary of air-temperature and rainfall for 1909" in a very handy form, being an excerpt from a periodical publication.

Toronto Observatory (1909).—The results of this valuable series of meteorological observations are given for each month and the year, together with the average for the past seventy years: mean temperature, January, 1909, 26·5°; July, 67·8°; year, 45·9° (average, 45·1°); absolute maximum, 95·8°, in August (highest on record, 99·2°); minimum, −8·7°, on February 1 (lowest on record, −26·5°). Depth of snow, 69·1 inches (mean 66·0 inches); rainfall, 26·01 inches (mean, 26·86 inches). The sunshine during the year was 2068 hours, 44 per cent. of the possible amount. Mean westerly declination was 6° 59·4′; inclination, 74° 37·5′; horizontal force, 0·162988 dyne.

Bremen Observatory (1910).—The observations are published in the same form as in previous years (NATURE, October 27, 1910) as one of the valuable series of German meteorological year-books; it contains, in addition, results for the lustrum 1906–10, and for the thirty-five years 1876–1910, with hourly means for twenty years. The following data are for the 35-year period:—mean temperature: year, 47·7°; January, 32·9°; July, 62·6°; mean of absolute maxima for July, 82·9°; of minima for January, 11·3°. Rainfall: annual amount, 27·23 inches; maximum in twenty-four hours, 3·39 inches. Results of observations with pilot balloons are exchanged daily by telegraph with the aëronautical observatory at Lindenberg.

THE AMERICAN INDIAN LANGUAGES.

THE admirable volume referred to below[1] forms the first portion of a systematic account of the American Indian languages. It has been in preparation for many years, and has grown out of an attempt to prepare a revised edition of Major J. W. Powell's "Introduction to the Study of Indian Languages." The filling of the schedules contained in the "introduction" caused an accumulation of much linguistic material without throwing much light upon the morphology, the phonetics, or the psychological basis of the languages. In this new work special emphasis is placed upon the importance of an analytical study of the languages. The work has been rendered possible by the cooperation of numerous investigators under the auspices of various institutions, particularly the American Museum of Natural History and the University of California.

The subject is introduced by Dr. Franz Boas in a very able exposition of the principles of linguistics as applied to ethnological problems. Though written with especial reference to the problems of American ethnology, this will be found of much value to the general student. In dealing with the three factors of physical type, language, and

[1] "Handbook of American Indian Languages." By F. Boas. Part i. Pp. vii+1069. (Washington: Government Printing Office, 1911.) (Smithsonian Institution, Bureau of American Ethnology, Bulletin No. 40.)

culture, now so often found non-correlative, Dr. Boas does not consider that we are justified in assuming that in primitive communities these three phenomena were necessarily more closely associated than they are now. He recognises that mankind cannot be classified by any one of these factors alone.

In a section on the characteristics of language, Dr. Boas has an important chapter on phonetics generally, and discusses the way in which languages differ in expressing groups of ideas by the grouping of phonetic elements. He takes the sentence as the natural unit for the expression of an idea, and discusses the sentence and its components—words or particles, stems or affixes—especially with regard to the American languages. In these, owing to the close association of the phonetic elements in a sentence, it is not easy clearly to define the terms "word" and "sentence."

In dealing with grammar, Dr. Boas illustrates by means of American languages the nominal categories of gender, plurality, case and tense, and the personal and demonstrative pronouns and verb. This leads to the conclusion that in placing a language, phonetics, vocabulary, and grammatical concepts must each be considered.

In a section on classification the author deals with comparison, mutual influence, the origin of similarities by dissemination or parallel development, and the influence of environment and common psychic traits. Then follows a very practical section on the importance of linguistics as a means, as well as a part, of ethnological studies.

The introduction finally deals with the characteristics of American languages. Dr. Boas does not agree that all these are polysynthetic or incorporating, but points out their common features. He gives a list of fifty-five linguistic families which may be distinguished in North America north of Mexico.

The larger portion of the volume specially appeals to the student of American linguistics. It contains ten grammars of typical languages, each dealt with by a specialist in the group to which it belongs. Thus Dr. P. E. Goddard deals with Athapascan (Hupa), Dr. J. R. Swanton with Tlingit and Haida, and in collaboration with the editor with the Siouan (Dakota). Dr. Boas himself is responsible for the Tsimshian, Kwakiutl, and Chinook languages, Dr. R. B. Dixon for the Maidu, Dr. W. Thalbitzer for the Eskimo, whilst the Algonquian (Fox) is the joint work of Dr. W. Jones and Dr. Truman Michelsen. These works form an excellent preliminary to the detailed study of the several groups. A general plan of presentation is followed in the grammars, modified, however, by the characteristic morphology of the language discussed. Each and all of them will serve as models for future students.

In congratulating the Bureau of American Ethnology and the editor and writers of the present volume on such an excellent account of the languages, one regrets to find that several of the grammars deal with languages which are largely spoken in Canada, and that neither the British Government nor universities have any place for similar detailed studies of the native languages of the Empire. When will any of these provide for the student such matter for study as is to be found in the systematic issue of the instructive and interesting volumes of the American Bureau or in the valuable collections of native texts published by such institutions as the Universities of California or Columbia? Sidney H. Ray.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Mr. G. E. Nicholls, of the zoological department of King's College, London, has been appointed professor of biology at Agra College, University of Allahabad.

The chemical laboratories of the Athens University were destroyed by fire on August 28. A *Times* correspondent estimates the damage at 80,000*l.*

It is announced in *The Popular Science Monthly* that Prof. L. H. Bailey has tendered his resignation of the directorship of the New York College of Agriculture to the trustees of Cornell University.

An offer by Mr. Andrew Carnegie to erect at a cost of 15,000*l.* three suburban branch libraries in Manchester has been accepted by the Manchester Library Committee. The offer is to be considered at the next meeting of the City Council.

At the forthcoming celebration of the quincentenary of the foundation of St. Andrews University, the honorary degree of LL.D. will be conferred upon the following men of science:—Sir T. Clifford Allbutt, K.C.B., F.R.S.; Sir Thomas Barlow, Bart., K.C.V.O., F.R.S.; Prof. A. Crum Brown, F.R.S.; Major P. A. MacMahon, F.R.S.; Prof. R. Meldola, F.R.S.; Prof. W. H. Perkin, F.R.S.; Prof. W. J. Pope, F.R.S.; Lieut.-Colonel D. Prain, C.I.E., F.R.S.; Prof. R. Saundby; Prof. Sir J. J. Thomson, F.R.S.

The London Inter-Collegiate Scholarships Board announce that combined examinations in anatomy and physiology, and in arts and preliminary scientific subjects, will be held on Tuesday, September 19, for Medical Entrance Scholarships and Exhibitions of an aggregate total value of more than 1700*l.*, tenable at University College, King's College, and in the Medical Schools of Westminster Hospital, St. George's Hospital, London School of Medicine for Women, University College Hospital, and King's College Hospital. Particulars and entry forms may be obtained from the deans of the respective medical schools, or from the secretary of the Board, Mr. A. E. G. Attoe, University College, Gower Street.

A circular letter (No. 24) prescribing new regulations for the Royal Navy Medical Service has been issued by the Admiralty. The changes in the organisation and conditions of service take effect, where not already in operation, as from July 1, 1911, except when otherwise stated in the letter. It being considered essential for the scientific development of the Naval Medical Service that it shall possess a School of Medical Instruction and Research situated in the vicinity of London, where it will be in touch with the principal civil medical schools and with the Army Medical School at Millbank, it has been decided to establish a Naval Medical School at the Royal Naval College, Greenwich, in close proximity to the "Dreadnought" Seamen's Hospital and the London School of Tropical Medicine, and in a position, therefore, to carry out its educational and scientific work in close connection with those establishments. There are already in existence at Greenwich excellent chemical and physical laboratories, and the additional laboratories required for medical research will be provided in the college buildings and furnished with the necessary equipment and scientific apparatus. There will be specially appointed to the Naval Medical School as the nucleus of the instructional staff a professor of bacteriology and clinical pathology, and a professor of hygiene. When the structural alterations in that part of the building which has been selected for the purpose have been completed and the school is ready for use, a proportion of the instructional work now carried out at Haslar will be transferred to Greenwich, and such of the instructional staff and equipment as may be considered advisable will be removed to that establishment. It is not proposed, however, that the laboratory at Haslar shall be dismantled. A certain amount of instructional work must still be carried out at that establishment, and at least one medical officer will be retained there for the instruction of acting surgeons. When the Medical School at Greenwich is opened, the first two months of the course for naval surgeons will be passed at that establishment, this period being devoted to the study of tropical medicine, bacteriology and clinical pathology, hygiene, and skiagraphy. The remaining four months will be passed at Haslar, as at present.

The technical colleges throughout the country are now issuing new prospectuses giving details of the courses of work which have been arranged for the forthcoming session. The prospectus of the Municipal Technical Institute, Belfast, for example, is a volume of 350 pages, provided with excellent illustrations of the laboratories, workshops, and so on, and serves excellently to show how successfully the Belfast authorities are carrying out the chief object of the institute, which is to provide instruction in the principles of those arts and sciences which bear directly or indirectly upon the trades and industries of Belfast, and to show by experiment how these principles may be applied to their advancement. A day technical course has been established to supply instruction in the science and technology of mechanical engineering, electrical engineering, the textile industries, and pure and applied chemistry, and is designed to give a sound training to youths who aim at filling positions of responsibility in the city's industries. Among other interesting particulars given in the prospectus of the Technical College, Sunderland, are those referring to the diploma of associate of the college. Students may obtain this diploma in the subjects of engineering, electrical engineering, naval architecture, and chemistry by passing through certain prescribed courses of study. A candidate's claim for a diploma is judged by regularity of attendance, by his successes in the annual class examinations, home-work marks, and evidence of reasonable skill in practical work. An external examiner is appointed to act as assessor in the associateship examinations, which are conducted by the respective heads of departments. It is satisfactory to note that at this college the County Borough of Sunderland grants every year a number of scholarships to apprentices of engineering and shipbuilding firms in Sunderland and the neighbourhood. The apprentice-student scholars attend classes during the winter six months, and during the summer they return to the works at which they are apprenticed. The time spent in the college is reckoned as part of the apprenticeship; the rate of advance in wages is the same as if the apprentices were continuously employed in the shops, and during the summer special facilities in the works are given to the apprentices for traversing all the various stages of work.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, August 28.—M. Armand Gautier in the chair.—Arnaud **Denjoy**: The *Analysis situs* of the plane.—Jules **Andrade**: A new regulator for chronometers. Two spiral springs are employed in the place of one. The use of Arnold's terminal curves is avoided, and the sinusoidal law of the balance spring is maintained.—M. **Bourgeois**: Determination of the geographical co-ordinates in the colonies by the use of wireless telegraphy. Trial of the method between Paris (Observatory) and Brussels. A compact and portable form of apparatus is described for the determination of differences of longitude. Full details are given of the application of the method to the measurement of the difference of longitude between Paris and Brussels.—A. G. **Webster**: A new mixed problem of the telegraphists' equation.—M. **Tsvett**: A new colour reagent for callose. The blue solution obtained by the spontaneous oxidation by the air of an aqueous solution of resorcinol rendered alkaline by ammonia is proposed as a stain for the distinction of callose in microscopical specimens. Cellulose remains colourless on treating with this reagent; callose is stained blue, an exposure of from thirty to sixty seconds being sufficient. In combination with Congo red, the blue solution is suitable for double staining.—Pierre **Kennel**: The function of the adipose reserve of the adipo-lymphoid bodies. In Batrachians, the adipose reserve is utilised whenever the animal is exposed to bad conditions of nutrition, particularly during hibernation. This reserve also serves in the development of the sexual elements, especially in the elaboration of the deutoplasm of the egg.—Casimir **Cépède**: The cycle of evolution and the systematic affinities of the Haplosporideæ of Donax.—Em. **de Martonne**: The chronology of the Pliocene and Quaternary *thalwegs* of Arc and Isère.

CALCUTTA.

Asiatic Society of Bengal, August 2.—Anand **Koul**: Ancient monuments in Kashmir. The paper contains a short account of twenty-nine monuments which exist in ruins in Kashmir. Some of the monuments are said to have been very old.—Maulavi Qâsim **Hasir**: Fîrûz Shâh's menagerie. The system of providing metropolitan towns with zoological gardens was not unknown to Muslim rulers of India. According to a contemporary writer, the earliest was founded in the middle of the fourteenth century by Sultân Fîrûz Shâh (A.C. 1351–88), who built a *Kûshk* (kiosk) at Firûzâbâd, and acquired animals to be preserved there.—Dr. Satis Chandra **Vidyabhusana**: Gadâdhara, prince of Indian schoolmen. Gadâdhara was born in the village of Laksmichāpara, in the district of Bogra in eastern Bengal, in the seventeenth century A.D. He came to Navadwipa, where he made a special study of logic (Nyáya). He was called the prince of Indian schoolmen, in whom modern logic reached its climax. He was such a thorough-going logician that when on his death-bed he was asked to meditate on the prime cause of the universe, he is said to have exclaimed "Atoms, atoms, atoms!!!"

LORD KELVIN'S PAPERS.

Mathematical and Physical Papers by the Rt. Hon. Sir William Thomson, Baron Kelvin, O.M., P.C., G.C.V.O., &c. Arranged and revised with brief annotations by Sir Joseph Larmor, Sec. R.S., M.P. Vol. iv., "Hydrodynamics and General Dynamics." Pp. xvi+563. Vol. v., "Thermodynamics, Cosmical and Geological Physics, Molecular and Crystalline Theory Electrodynamics." Pp. xv+602. (Cambridge University Press, 1910–11.) Price 18*s*. each.

THE publication of volumes iv. and v. of Lord Kelvin's "Mathematical and Physical Papers," bringing as it does the collection of these memoirs nearly to an end, is important both to the student of mathematical physics and to the scientific historian. It gives the former access to papers of great value scattered through the Transactions and Proceedings of learned societies, or imbedded in the more easily obtainable but also more unexpected pages of the journals of pure and technical science. The latter will seize the opportunity to compare the utterances of the master during the last decade or two of the nineteenth century and the first seven years of the twentieth, with the last developments of the related theories of electrical action and the ultimate constitution of matter. To those who have come to these developments from the point of view of the Maxwellian electromagnetic theory of light, and find in atomic facts and hypotheses a supplement and to some extent a basis for the undulatory propagation of electric and magnetic action in a non-conducting and uniform medium, some of these utterances will occasion much thought, if they are not, indeed, a source of a good deal of perplexity.

Consider, for example, the Appendix A of the "Baltimore Lectures," and its continuation in volume iv. of the "Papers." One statement is enough to cite: "Stress in ether, being thus freed from the *impossible task of transmitting both electrostatic and magnetic force,* is (we may well imagine) quite competent to perform the simple duty of transmitting magnetic force alone." (The italics are in the original.) The Maxwellian electrician has the notion ingrained in his mind that, when magnetic force is propagated in the medium, electric force is propagated also as a necessary concomitant, and *vice versa,* and therefore supposes that whatever machinery is effective for the one must be equally concerned with the other. Moreover, as Lord Kelvin states in a note to the first article of this appendix, the "so-called 'electromagnetic theory of light'" is to be grafted on to the elastic solid theory of the æther. It is, however, to be remembered that Maxwell came to his theory by way of Faraday's experimental researches and Lord Kelvin's mathematical interpretations, and it may be that these utterances, dark as they may appear to some of us, will in time to come throw light on some of the still unsettled questions of electricity.

The student of these papers has a difficult task; but it is one which, if it be not thrown up in despair, will stimulate his power of independent criticism of physical doctrine.

The arrangement of the papers is both chronological and according to subjects. Hence volume iv., which is mainly devoted to hydrodynamics, goes back to the vortex-motion papers of 1867 and 1869. The first of these contains the famous suggestion that the vortex-rings of Helmholtz are the only true atoms. Their non-creatibility in a perfect fluid does not seem to be regarded as a difficulty, but rather as a recommendation—a creative power above nature brings them into existence, and once they are in existence, their indestructibility by natural agency is assured.

It is rather remarkable that Helmholtz's great paper of 1858, on the integration of the hydrodynamic equations of vortex motion, should not have attracted the active attention of physical mathematicians in this country at an earlier date than 1867. In that year Tait published his translation of the memoir, and made experiments on vortex-rings rendered visible by smoke in his class-room. It was seeing and, so to speak, handling these rings that suggested Kelvin's conception of the vortex-atom constitution of matter, and, with Tait's account of Helmholtz's investigations, led to the paper on vortex-motion in the Edinburgh Transactions for 1869, which will ever rank as one of the great classical memoirs of hydrodynamics. In this Kelvin's point of view and method are curiously different from those of Helmholtz. The results of the latter are derived in the most approved classical manner from the equations of motion of a perfect fluid, unsimplified by the hypothesis of a velocity-potential. It is straightforward mathematical discussion; but the march is that of a clear-eyed intellectual giant, and the stages reached are duly chronicled and described in language which shows how completely the author understood the physical meaning of his mathematical results.

Kelvin, on the other hand, starts from the physical conceptions of linear and angular momentum, and from these ideas, and the impulses required to produce the momenta, the whole subject is developed. The physical meaning of the expressions $\xi = \frac{1}{2}(dw/dy - dv/dz)$, . . . , namely that, multiplied by the moment of inertia about diameters parallel to the axes of coordinates, they are the component angular momentum of an infinitesimal sphere of the fluid with its centre at the point x, y, z, had been given by Stokes in 1845, and thus the existence of a velocity potential the criterion for which is the vanishing of ξ, η, ζ, had been shown to affirm the non-existence of angular momentum in the fluid to which the criterion applied. This physical interpretation is referred to and used by Kelvin, and in a sense is the keynote of his discussion of the subject.

Perhaps the most important of all the results in the memoir is the theorem of Thomson regarding "circulation"—that is, the line integral, along a specified curve or line of the fluid, of the component of flow along the curve at each element. If the path be not closed the time-rate of growth of the flow along any specified path which moves with the fluid is obtained by subtracting the value of the excess of the kinetic energy per unit mass of the fluid, supposed incompressible and under no applied force, above the pressure at the initial end of the curve of integration, from the value at the terminal end. This theorem, in its modification for a compressible fluid in which the pressure is a function of the density, and which is situated in a field of applied force, has been truly said to comprehend the whole of the dynamics of a perfect fluid.

For the vortex-motion application the use is immediate. If the curve be closed the time-rate of growth of circulation for the moving circuit is zero; but the integral which is thus shown to remain constant is half the surface integral of the component of ξ, η, ζ, along the normal to each element of a surface of which the curve is the bounding edge. Hence as the fluid moves this surface-integral remains constant, and if once zero is always zero.

Thus the Kelvin theorem obtains the result for a finite mass of the fluid that is obtained in another way by Helmholtz, and it gives the subject a physical significance at once clear and convincing. The theorem may, however, be made to give at once many well-known results in ordinary fluid motion, which are usually obtained by other methods.

Almost every paper in volume iv. is of a kind to arrest and hold the attention. The papers entitled hydrokinetic solutions are particularly interesting, both on account of their contents and from the fact that they are an excellent example of the best manner of the author, the manner of which the pupils of his higher mathematical class had the most frequent experience. It is probable, however, that the letter to Tait on the influence of wind on waves in water supposed frictionless, and on ripples, was written off as soon as some observations of the kind described in the letter had been made, probably in the yacht *Lalla Rookh*, and had been interpreted by the analysis written down immediately, and therefore in more or less impromptu manner. Scott Russell (though Lord Kelvin was not aware of the fact when he wrote) had noticed, nearly thirty years before, that surface tension must play the most important part in the propagation of the very short waves often seen on a smooth sheet of water; but this short paper proved that as the wave-length diminishes from a great to a very small value, the speed of propagation diminishes to a minimum for a certain wave-length, and then continually increases. This wave-length Lord Kelvin took as that of separation between ripples and ordinary waves.

Anyone can study the matter experimentally from a boat drifting steadily forward in smooth water at a speed of about half a mile per hour, while the wave system is generated by a fishing line stretched by a weight hanging in the water. How many physicists have done this and taken photographs of the wave patterns ("ripples in front and waves of the same velocity behind") with the excellent lenses and cameras which are carried about on every holiday excursion?

The paper on an alleged error in Laplace's theory of the tides the present writer well remembers was dictated in some little excitement by Lord Kelvin just after he had read Ferrel's observations on Laplace's process in the United States Coast Survey Report for 1874, in which certain objections taken by Airy in his article on tides and waves in the *Encyclopedia Metropolitana* were quoted and approved. The point was a curious one, as to whether a certain coefficient K_4 was or was not indeterminate so far as the solution of the differential equation for certain tides was concerned. It is now generally admitted that the constant was not indeterminate, and is correctly determined by Laplace's "exquisitely subtle method."

Perhaps a note might have been added, in connection with the short paper in volume iv. on the precessional motion of a liquid, on the *two* liquid gyrostats which Lord Kelvin was so fond of showing to visitors. In each water is enclosed within a spheroidal shell, but in one the shell is oblate, in the other prolate, with about 5 per cent. deviation from sphericity in each case, and the shell rotates about the axis of figure. The motion of the liquid is stable in the first case, and the gyrostat takes precessional motion like an ordinary gyrostat, while in the other the motion is unstable. The first result showed that the precessional motion of the earth does not furnish a valid argument for the earth's rigidity. The remarkable result has been established that the motion of a liquid in a prolate case is stable if the degree of prolateness be so great that the axial length of the hollow filled by the water is more than three times the diameter. As Greenhill has pointed out, this fact is important in fixing the shape and size of the gas-bags for a dirigible balloon.

The most remarkable series of papers in the two volumes are, however, those on waves in water. Here the exponential solutions given by Fourier for the linear conduction of heat are modified and applied to the long chain of abstruse problems dealt with. The discussion of the front and rear of a free procession of waves, and the papers on the initiation and growth of a train of waves, sheds much light on difficult questions regarding groups of waves, and the manner in which they arise and are propagated from a given form. In the hands of Mr. Green and others it is possible that the analysis may have important applications in the wave theory of light, in connection with Lord Rayleigh's theory of the origin of the periodicity of light which has passed prisms and gratings and other optical instruments. A detailed account of these papers is a fit task for the specialist in hydrodynamics: that they should have been written by Lord Kelvin during the last ten years of his life is not the least wonderful thing about them. To those who came in contact with him, it appeared that he worked more slowly, but not less surely: the impetuosity of his genius was abated, not its natural force.

Of the papers in volume v. we have said nothing, and our space is exhausted. As a rule they are shorter, and in some cases of a slighter character; for example, the excerpts from the technical journals on various questions of electrical practice; but the reader who wishes to follow Lord Kelvin in his more abstract speculations will find plenty of occupation in this volume also. There are his papers on molecular and crystalline theory, which are heroic attempts to find mechanical explanations of such things as the pyroelectricity and piezoelectricity of crystals, and the known chemical and physical properties of gases, liquids, and solid crystalline substances.

That one man should have attacked with so much success so many subjects of transcendent difficulty is a great marvel. But our wonder is mingled with regret that his mind should have been distracted so much as it was from the great themes with which it was pre-eminently fitted to deal. The turning from one thing to another probably, however, did not result in so much dissipation of its energy as might be supposed. He obtained mental refreshment by change of the objects of thought, and often when he returned to the consideration of difficulties obtained their solution with unexpected facility.

The work of editing has been excellently performed by Sir Joseph Larmor. He has appended notes here and there, but with a reverent frugality, and in their substance they are short and to the point.

A. G.

THE NUCLEI OF THE PROTISTA.

Die Konstitution der Protistenkerne, und ihre Bedeutung für die Zellenlehre. By Prof. Max Hartmann. Pp. v+54. (Jena: Gustav Fischer, 1911.) Price 1.60 marks.

THIS paper is an extended version of a lecture delivered by Dr. Hartmann at the International Zoological Congress in 1910. It is an attempt to obtain a simple interpretation of the many complex nuclear conditions recorded in the Protista.

By "constitution" Dr. Hartmann means "morphogenetic constitution," and it appears from his paper that "Protista" means—as is so usual—chiefly the Protozoa.

Dr. Hartmann's views are not easily given or criticised in a short space, for they contain much that is purely hypothetical and highly controvertible. He insists, in the first place, upon the universal occurrence of a centriole in all protists—a contention that is not likely to find universal acceptance. The cyclical changes (centrifugal and centripetal streaming) undergone by this body are also insisted upon.

Nuclei are classified as "monoenergid" and "polyenergid"—"energid" being used in a sense different from that of its inventor, Sachs. Monoenergid or univalent nuclei (*e.g.* in *limax* amœbæ) consist of two components—idio-generative (chromosomes) and locomotor-generative (centrioles, polar caps, &c.). The power of polar division is an important attribute of the locomotor component. Polyenergid nuclei (*e.g.* those of Radiolaria) are those which are really not simple, but multivalent, containing many individualised univalent nuclei inside them. These are the "chromosomes" (*e.g.* in Aulacantha), which are really not chromosomes but nuclei.

Mitosis in the Protozoa is accordingly univalent or multivalent, according as the nucleus is monoenergid or polyenergid. From which it follows that the nuclei and their mitoses are not homologous throughout the Protista. There is no true amitosis in any protist—the process now so called being designated "promitosis."

We are glad to see that Dr. Hartmann now rejects the "box within box" trophokinetic binuclearity hypothesis which he formerly advocated so strongly, and now regards binuclearity—formerly of universal occurrence—as exceptional in the Protista. "Generative chromidia" he regards as monoenergid nuclei which have escaped from a polyenergid nucleus. The formation of new nuclei from chromidia is therefore "explained"—the nuclei are really there all the time, but at last become visible. There are also numerous other curious interpretations of protozoan nuclei resulting from Dr. Hartmann's hypothetical considerations. Thus, the mitotic figure of Acanthocystis is really not an ordinary mitotic figure, but a composite figure composed of two nuclei which simulate one. It may be noted, however, that the interpretation of monoenergid nuclei as consisting of two components is, in reality, merely a variant of Dr. Hartmann's former binuclearity hypothesis, become more complex by the introduction of polyenergid nuclei.

The relation of protozoan nuclei to metazoan nuclei and the constitution of the latter, is only briefly and hesitatingly considered. Dr. Hartmann thinks that all the chromosomes of a univalent protozoan nucleus are homologous with only one chromosome in a metazoan nucleus. Chromosomes in the former correspond with chromioles in the latter. Metazoan nuclei are, for the most part, polyenergid—the chromosomes being nuclei (or energids in Hartmann's sense). "Only the simple monoenergid atypical amœbæ and similar forms can be considered as elementary organisms in the sense of the cell theory." The union of the ovum and spermatozoon in Metazoa is not homologous with the conjugation of two protozoan gametes: for the latter are monoenergid, the former polyenergid.

Dr. Hartmann's ideas are discussed at some length in numerous special cases in the Protozoa, with the aid of figures copied from other works. There are several misprints in the text, and I may point out that "Herr Newin" referred to on page 18 is my friend and former pupil Mr. K. R. Lewin. His conclusions are at present indefinite, and do not warrant what Dr. Hartmann says of them.

Whether Dr. Hartmann's speculations will turn out to be well-founded or not, future work will determine. For our own part, we by no means agree with all his interpretations. But they will, no doubt, give rise to further discussion and analysis of a difficult problem, and thereby perhaps lead eventually to a better understanding of the nuclei of the Protista.

C. Clifford Dobell.

CYCLONES AND SUGAR-CANES.

The Sugar Industry of Mauritius: a Study in Correlation. Including a Scheme of Insurance of the Cane Crop against damage caused by Cyclones. By A. Walter. Pp. xvi+228. (London: A. L. Humphreys, 1910.) Price 12*s.* 6*d.* net.

MAURITIUS, situated just within the tropics and on an edge of the southern anticyclonic system, is in certain circumstances visited by tropical cyclones. Occasionally great damage to the growing sugar crops is done by such visitations, and though extremely violent storms are exceptional, yet the fact that they may and do occur makes the cyclone season one of dread and anxiety in the island. In the year 1892, for example, about one-half of the total crop was destroyed, to say nothing of damage to buildings, and other losses. True, this storm was one of quite unusual severity; but fear of a similar calamity tends, nevertheless, to have a paralysing effect upon the sugar industry. "Behind every attempt at improvements and every fresh outlay of capital, hovers the spectre of the 1892 disaster."

In these circumstances the question of insurance becomes one of primary importance. With a view to obtaining some rational basis for proposals of insurance the investigation described in the volume before us was undertaken: it is an attempt to determine quantitatively the relative effects of rainfall, temperature, and cyclonic wind-velocity upon the amount of the sugar-crop.

Obviously the problem is a complicated one. The author attacks it by a study of the climatic statistics for a number of years, in correlation with the crop harvested in each of those years. By successive approximations, after allowing for exceptional influences, it has been found possible to evaluate the effects of the several climatic factors upon the crop.

Taking first the question of rain, the changes in the amount of crop were found to follow in a general sense those of the rainfall, but the ratio *crop/rainfall* varied considerably from year to year. There is, however, not merely the total quantity of rain to be considered; the number of rainy days was soon seen to be as important as the total rainfall. From an agricultural point of view a month in which five inches of rainfall was distributed over twenty days would be a wetter month than if the whole had fallen in one day. Hence in order to obtain the combined effect of quantity and chronological distribution, the idea of "degree of wetness" for each month was introduced by means of the expression $R.t^1/t$, where R is the total rainfall for the month, t the number of days, and t^1 the number of rainy days. But further, in excessive falls a part of the rain is non-effective, and it was necessary to eliminate this portion, partially at least. The method adopted depended upon the consideration that if it were possible to determine the depth of soil to which a given fall penetrated, the amount which passed beyond the limit of the cane roots might be rejected. Increase of temperature in the soil at certain depths was taken as a guide to the points beyond which the fall penetrated.

The effect of high wind velocity on the cane is regarded as falling under one or all of the following heads:—(*a*) Tearing of the leaves; (*b*) bending of the stem about its weakest part; and (*c*) loosening and rupture of the roots. The magnitude of the effect (*a*) depends upon the pressure P of the wind, the duration h of the high velocity, and the epoch t in the plant's growth at which it occurs, since the riper the cane the greater the damage; effects (*b*) and (*c*) depend also on the amount of change θ in the direction of the wind, the greatest damage being caused when the cane is bent in directions differing by 180°. Whence the total effect on the crop is deduced to be expressible by the formula $\kappa P^2 h(2+\sin\frac{1}{2}\theta)\sin\frac{1}{2}t$. The value of the constant κ is obtained from the crop results given in three cyclone years, after eliminating the rainfall and temperature effects. This formula is suggested as a basis for determining the loss due to a cyclone, the values of P, h, and θ being taken from the official observatory records. The practical application for purposes of insurance is explained in detail.

The work is an ingenious and interesting statistical study which may prove to have practical value. A prediction of the crop yield for 1908, based on the methods explained, turned out to be correct within 3 per cent. There seems no reason why, if circumstances demanded it, the methods should not be applicable to other crops than sugar.

IRRIGATION ON THE INDUS.

Punjab Rivers and Works. By E. S. Bellasis. Pp. vii+65+47 figs. (Allahabad: printed at the Pioneer Press, 1911.)

THE author presents this work as a treatise setting forth the general rules and principles on which the inundation canals and flood embankments of the Punjab are designed and maintained, since no such work has hitherto existed. This we may take as equivalent to saying that the regulations and practice of the Punjab Irrigation Service have not yet been systematised and brought into book form, since the present volume deals with this aspect of the subject, and does not, unfortunately, cover the wider field of the hydrography of the Indus in its bearing on the utilisation of its water.

While the first chapter deals very briefly with the rivers of the Punjab and their physical characteristics, the next three discuss in considerable detail the inundation or flood canals, the flood embankments, and the river-training works; the last chapter and seven appendices deal with the ordinary procedure, and give certain regulations, orders, and specifications as issued for the work of the Service. The information relating to canals deals with their maintenance, silt deposit, erosion, their section, alignment, and the various modifications which have to be adopted in dealing with the water of a river which has a high seasonal flood and carries a heavy silt load. These characteristics also necessitate flood embankments to control the river flood and protect certain areas in time of the inundation; while no less important are the river-training works to restrict the erosive action of the river on its banks at points where it may damage existing distributing works and towns or villages.

The information so brought together should be of much interest to irrigation engineers, and would have been valuable to a wider circle if fuller material had been provided for those not personally conversant with the Punjab. The case of the gradual destruction of the town of Dera Ghazi Khan on the west bank of the Indus by the gradual erosion of its right bank furnishes an interesting case of river action by the annual flood, and is illustrated by a series of ten plans showing the disposition of the river at this point from 1882 to the present time.

Elsewhere general statements and descriptions are in the majority, and we should have welcomed more quantitative treatment of some of the interesting points which are raised. The regimen of a part of a river cannot be properly understood without some knowledge of the whole, and the lack of this is especially apparent in the first chapter, where a general map of the basin, some information regarding its size, form, relief, structure, &c., would have given a valuable setting to the study of the utilisation of its water which follows. The subjects of rainfall and discharge are dealt with in two brief paragraphs, while we look in vain for maps showing the distribution of the rainfall or diagrams explaining the variations of discharge at different points and at different seasons. A number of plans and diagrams illustrate the report, but in only one case is the scale of the former indicated on it, though in some other cases it can be found from the text. References to other works on the Indus would have been a useful addition. H. G. L.

ELEMENTARY STATISTICS.

An Introduction to the Theory of Statistics. By G. Udny Yule. Pp. xiii+376. (London: C. Griffin and Co., Ltd., 1911.) Price 10*s.* 6*d.* net.

OF all the works a man may set himself to write, the most difficult must surely be an elementary text-book on statistics. The writer of a text-book on almost any scientific subject has to face the difficulties resulting from a recent rapid development of the science of which he is writing, but in statistics he has the further difficulty that many practical methods have been reached by mathematical analysis that is unsuitable for an elementary text-book. Nor is this all, for the subject appeals to so many diverse interests that points simple or useful to one student are merely troublesome or inconsequent to another.

Mr. Yule has made an attempt to explain some of the methods used in practice, without demanding much mathematical knowledge of his readers. This course explains the advantages as well as the limitations of his work, for it has enabled him on one hand to display his natural facility of explanation, and, on the other, it has debarred him from giving more than a sketch of some of the most important parts of the subject; it has even led him to avoid giving certain formulæ and methods that are of almost everyday use.

The book is divided into three parts, the first of which deals with the theory of attributes. We confess that this type of statistical work does not greatly appeal to us, for while good may be done with these methods by a statistician of Mr. Yule's ability, we are doubtful if the notation and formulæ he gives are of real help to a student. To most minds statistical errors in reasoning, for instance, are best explained arithmetically, and many of Mr. Yule's examples in part i. will help his readers more than his algebra or letterpress. The second part deals with the theory of variables, "ideal frequency distributions," averages, standard deviations, and correlation coefficients. There is a chapter on partial correlation which should be helpful to many readers, but we wish room had also been found for an account of some of the most recently discovered methods of calculating correlation coefficients. The last part of the book deals with the theory of sampling, and is mainly concerned with probable errors.

Possibly because of the mathematical work involved, Mr. Yule does not deal with the fitting of curves to statistical data, but a student who has proceeded so far as to study partial correlations and the correlation surface should, we think, have some idea how to do this. The gap will perhaps be filled in a future edition, and revision in some other respects will, we think, also be wanted. For instance, on p. 38 a formula is given for measuring the degree of association, and if it is applied to the example of imbecility and deaf-mutism on p. 34, the value is 0·9, indicating a high degree of association. On p. 213, instead of giving the ordinary formula for working out coefficients of correlation from fourfold tables, Mr. Yule gives a simple expression which he implies can be used in some cases. Unfortunately, in the particular case mentioned above to which a student might be tempted to apply it, the value, instead of being about 0·9, is only 0·02, and gives quite a wrong impression. It was, we think, a great mistake to give the formula on p. 213, as it is open to considerable criticism.

Another example of a case where readers might be misled occurs on p. 67, where a student might easily misunderstand Mr. Yule's discussion of isotropic distributions, and think that they affected the calculation of a coefficient of contingency.

While we are very ready to admit that, within the limitations he has placed on himself, Mr. Yule has given much that is of interest and value, we also feel that there is much in his work which lends itself to criticism—more, in fact, than one would expect to see in an elementary text-book. The two cases that we have given above are merely examples of this, but although we have felt it necessary to criticise, it is a pleasure to add that we have been much interested in reading Mr. Yule's work, and have throughout appreciated his numerous arithmetical examples and the trouble that must have been taken to arrange the book in so clear a form and to supply it with such excellent diagrams.

OUR BOOK SHELF.

Leitfaden für das mikroskopisch-zoologische Praktikum. By Prof. W. Stempell. Pp. iv+84. (Jena: Gustav Fischer, 1911.) Price 2.80 marks.

THE medical practice of teaching histology in a separate section of the course is, we regret to see from the author's preface, becoming adopted in biological teaching; and to this circumstance Prof. Stempell refers for the origin of his book, since he has adapted its contents to meet the requirements of beginners who wish to traverse rapidly a course in comparative microscopy apart from the dissections, museum work, and naked-eye observations with which microscopic work has been hitherto so usefully associated.

At first all is smooth sailing. A lucid introduction on apparatus paves the way to five lessons on protozoa. The methods of obtaining, examining, and preparing the material are admirably explained. The paragraphs are numbered, so that references to procedure can be made at once, and the most instructive and accessible members are dealt with before those which present greater difficulties. A few pages later, however, we find Anthozoa, Ctenophora, Turbellaria, and Trematodes dealt with in a single section, which we must suppose represents three to four hours' work. On the other hand, far more attention is given to the Nematoda than is usual in an elementary course. The section devoted to vertebrate histology is very incomplete.

The illustrations have a special value, since they are in every case photographic reproductions of actual preparations, but as no attempt is made to explain what they show such figures cannot be said to be useful to the student. The chief use of the book lies in the methods which it suggests for the collection and preservation of material. In this respect it will be of considerable service, but as an attempt to present a working course in comparative histology, we should be sorry to see Prof. Stempell's recommendations carried out without considerable modification.

F. W. G.

Early Essays on Social Philosophy. Translated from the French of Auguste Comte by H. D. Hutton. A new edition with additional notes, and with an introduction by Frederic Harrison. Pp. 352. (London: George Routledge and Sons, Ltd.; New York: E. P. Dutton and Co., n.d.) Price 1s. net.

THESE six essays, written by Comte between the ages of nineteen and twenty-one, appeared in vol. iv. of the "Positive Polity," published in 1877. Their special interest is that they prove the unity of their author's life-work—the coherency and consistency of his scientific philosophy and his social polity—as against the view of Littré, that the two are disparate, the later work a backsliding from the principles of the earlier.

The third essay is the longest and the most important. It contains in exact and decisive form the famous Law of the Three States, which "all subsequent thinkers have regarded as Comte's triumphant discovery," and is the basis and the justification of Positivism. From the nature of man's intellect each branch of knowledge in its development is necessarily obliged to pass through three stages—the theological, the metaphysical, and the scientific or positive.

The fourth and fifth essays give a *résumé* of the entire system of the "Positive Polity" as meaning a social and religious reorganisation of society based upon a scientific study of human nature.

Mr. Frederic Harrison supplies an excellent little introduction to this new edition.

Technique de Psychologie Expérimentelle de Toulouse, Vaschide et Piéron. By Ed. Toulouse and H. Piéron. Second edition, tome i., pp. xii+303; tome ii., pp. xvi+288. (Paris: Octave Dion et Fils, 1911.) Price 10 francs the two volumes.

THIS edition, now expanded to double the former size and comprised in two volumes, is virtually a new book. Far more space is devoted to the description of apparatus than formerly. Pieces of apparatus are illustrated, many of which are quite unknown in the psychological laboratories of this country. Not only for this reason, however, is the work likely to be of little value to elementary students of the subject on this side of the Channel. The authors err in laying no stress whatever on an acquaintance with the psycho-physical methods, and on the importance of obtaining introspective data in psychological experiment. It appears to be their object merely to "describe apparatus," much as the authors of a book on experimental physics would do, leaving on one side methods of procedure as if they could be picked up haphazard in the laboratory, and neglecting the introspective data obtainable from the subject of the experiment as if they did not exist! For the instructor or the advanced student, however, the work is of considerable interest. The apparatus, unfamiliar in this country, is excellently described; and there are several novel experiments which appear to have promising value.

Rainless Thunderstorms.

FROM the letter signed "E. G." in your issue of August 31, it would appear that the Meteorological Office has not abandoned the ion condensation theory of the origin of atmospheric electricity. Now, there are many difficulties in accepting that theory. For instance, before condensation can take place on ions, there must first be dustless air; otherwise the necessary supersaturation cannot take place; and one naturally asks, Has anyone ever found dustless air in our atmosphere? So far as records go of air up to 10,000 feet, this has not yet been found, and it does not seem likely that it ever will be found, as the hot air carrying up the aqueous vapour to form clouds always carries up with it plenty of dust to act, if one may use the simile, as the return ticket to bring the water back to the surface of the earth. As much of this dust is very fine, only falling a few centimetres in a day at low level, it is likely to go wherever the moist air goes—in even the more rarefied regions of the upper clouds. Further, there is the constant supply of fine dust from the upper regions due to the disintegration of meteors, so that the air at cloud levels is likely always to have plenty of dust and condensation on ions seems impossible.

Another difficulty of importance is, Has anyone ever shown that it is possible for a cloud to form on ions under the conditions in which condensation takes place in the atmosphere? It is true that clouds can be formed on ions under experimental conditions; but in these the expansion must be made with explosive quickness, because if the expansion is made slowly only a few ions become centres of condensation, and these rapidly grow to the size of raindrops in the highly supersaturated air; and these drops in falling relieve the supersaturation of the air some distance round them all along their path, so preventing other ions becoming centres of condensation, and only rain, not cloud, is produced. It would appear that these and other difficulties are worth considering before accepting the ion condensation theory of the electrification of clouds.

With regard to rainless thunderstorms, though no rain falls, is that a proof that no rain has been formed? May not rain have fallen from the clouds, but evaporated before reaching the earth? One sometimes sees after dry weather clouds passing overhead from which rain seems to be falling, yet not a drop reaches the earth. If the thunder clouds be high and the lower air very dry, such as we have lately experienced, we can easily see that raindrops will undergo evaporation while falling and may be dried up before reaching the earth; and as the horizontal direction of the movement of the thunder clouds is generally different from that of the lower air, the falling rain may not get a chance of saturating the lower air, even though the storm may continue some time.

For the benefit of those who may make a study of thunderstorms, it may be of interest to record, as illustrating the influence of the geographical situation of a place on the formation of thunderstorms, that the district round Falkirk has a strange exemption from such storms. So far as I can remember, there has only been one good thunderstorm within my memory, and that goes back a long way, and on that occasion the storm covered a great part of the country. Once or twice in a year a few distant peals may be heard; and once this year we had a storm which lasted half an hour, with about six peals and some lightning, but that storm was an exception. With the one exception above mentioned, there are no great storms in that district such as are experienced in most parts of the country. It should be mentioned that Falkirk lies in the shallnw valley connecting the Firths of Forth and Clyde, through which it is proposed to cut the low-level canal, and that there are no high hills near.

John Aitken.

Loch Awe Hotel, Loch Awe, Argyllshire, September 5.

A Pseudo-Aurora.

The explanation which Sir Lauder Brunton calls for in No. 2183 of Nature seems to be very simple indeed. On the evening of August 21, which he mentions, thunderstorms of extreme violence came over the region of Lugano and its environs. That region is due south-east of Beatenberg, as is also the Mönch. The flashes seen were most certainly those of lightning, and the auroral appearance is very easily explained. Anybody may, in a mountainous country, whenever there is a slight haziness in the atmosphere, remark the shadows thrown on the mist by a light —sun or moon—when still behind a mountain top, *i.e.* rather low down in the sky. Such was the case with the storm over Italian Switzerland, and the intense lightning on August 21 was noticed as far away as the Canton de Vaud. The flashes, lighting up the sky through the gaps between the mountains, with the corresponding dark rays of the shadows, following in uninterrupted succession, may well have given an impression of seeing auroral rays.

The Destruction of Kingfishers near London.

I have just received a letter from a man who has been very busy amongst the kingfishers that visit his grounds within ten miles of the Bank of England. I enclose the original letter, and now quote therefrom:—"I have caught sixteen quite lately [apparently since the middle of August]. Six went to —— alive; the others I have skinned. Would you make me an offer for nine?" Since receiving this letter I have been given three carcases, and understand that these birds were supplied alive to a dealer by my correspondent; this brings the total up to nineteen birds, *at least*, removed from the bird-population of the London district by one man. A disagreeable fact is that all appear to have been killed not illegally.

The weapon employed was, of course, the deadly "kingfisher net"; and my chief reason in writing this note is to suggest that steps might well be taken to prohibit both the use and the possession of this instrument. It is practically useless for everything except the capture of kingfishers; and so simple is it to buy, or make, or use, and so secret and so certain in its action, that by its means a man destitute of the elements of woodcraft could, and frequently does, utterly clear a stream of its chief feathered ornaments. I do not know of any fowling engine more effective against its proper quarry than the kingfisher net, nor can I think of one that needs less actual supervision. This latter point explains why it is so often in the hands of the unprivileged collector and the poacher, and I have heard of it being used while its owner and operator was actually under the constant eye of a keeper—of course, one unaware of the intentions of his suspect.

I cannot think that I exaggerate if I say that the kingfisher is the most defenceless of British birds, for no bird is easier to kill. This is with the net; without the aid of a net an organised kingfisher hunt would be unremunerative, if not quite impossible, for many destructive men do not dare to use a gun. Freed from the danger of the net, the kingfisher would be in a peculiarly secure position, and would certainly increase until perhaps common enough to be familiar by sight to all who have the desire to see one alive. Its food consists of small fishes and other aquatic animals, and the pisciculturist is the only person who would suffer from the increase of the bird. No good can come of attempting to ignore the fact that in and about fish hatcheries the kingfisher is an intolerable nuisance, and its destruction becomes at times an economic necessity, for it is not always possible to protect the fish by wire netting. But the prohibition of the net need not prevent the killing of the birds, for the keeper could easily use a gun. The kingfisher provides a simple target, although, fortunately, its habits protect it largely from the casual or wandering gunner. Without loading this letter (which is no more than a hint or a suggestion) with other details, I must end by saying that I have often considered the matter in all its aspects, and I believe that the total prohibition of the kingfisher net would lead at once to an increase in numbers of this ornamental bird, and that this prohibition would entail no hardship on the pisciculturist, who is the only person likely to be affected by the increase of the kingfisher. Perhaps something could be done in this matter by those who have the leisure to occupy themselves with the laudable work of active bird protection.

A Bright Meteor.

Walking northwards on Saturday evening, September 2, I was looking towards the constellation of Cassiopeia when a bright meteor appeared at a point a few degrees west of η Perseus, and moved slowly westwards, gradually increasing in brightness until its disappearance at a point near α Canes venatici.

Its maximum brilliancy was about four times that of Jupiter, and its colour almost pure white.

The time occupied in its transit was between six and seven seconds, and a bright golden trail persisted for about two seconds more.

The time of the phenomenon was 20h. 27m. (G.M.T.).

Non-Euclidean Geometry.

I owe sincere apologies for carelessness in the latter portion of my letter in last week's issue of Nature.

In hyperbolic space, the area of a circle of very large radius R appears as

$$2\pi K^2\left(\cosh\frac{r}{K}-1\right),$$

i.e. practically

$$\pi K^2 e^{\frac{R}{K}},$$

which is an *exponential* infinitude.

On the other hand, the area of a regular N-gon inscribed therein appears as something less than

$$\pi K^2 N,$$

which is a *linear* infinitude.

Is not hyperbolic infinity paradoxical?

W. B. Frankland.

Examinations.

SIR WILLIAM RAMSAY's outspoken criticism on the value of examinations will be welcomed by many, but it is uncertain whether the general public could tolerate the present educational system in their absence.

When the chemical department becomes the department of chemical research, and the student realises that he is receiving a training in such practice, examinations as conducted in the majority of cases may possibly lose their present-day significance.

While practical training remains based upon text-book instruction, which hardly calls for anything more than observation on the part of the student, examinations are necessary. There is no other method of testing the student's memory.

Observation has been defined as "the performance of what is prescribed." It is the chief factor in a system of empiricism, but it cannot be expected to occupy this position for all time in a programme dealing with experimental investigation. It may be that a correct method of instruction has yet to be devised.

Examinations lose their chief value when they fail to supply the student with an estimate of the value of his personal qualifications, enabling him to confirm his original intention or change the direction of his life's work while there is yet time. W. P. DREAPER.

September 6.

Habits of Dogs.

I CANNOT answer Miss Everett's questions on this subject, but would like to "ask another." Is it known to be a common thing for dogs to carry hedgehogs in their mouths? I have a fox-terrier who amused himself in our garden by making life a burden to a hedgehog until the latter disappeared. He would not only roll the hedgehog about with his paws, but must have carried it a certain distance in his mouth, for one evening I found him in triumph at the back door of the garden with his lips all marked with pricks and bleeding, and the hedgehog lying in a ball at the top of three rather steep stone steps twenty or thirty yards from the summer-house where he lodged. If this is a usual form of play with dogs, it is a curious one. WALTER KIDD.

Heatherdown, Alum Bay, I.W., September 5.

Miniature Rainbows.

YOUR correspondent Mr. W. E. Hart may be interested to know that magnificent rainbows, which appear to be within easy reach, may often be observed inside water-cooling towers, the necessary conditions being a fairly heavy shower of the cooled water and an opening at one side of the tower sufficiently high to let the sunlight stream in over the observer's head. B. P. H.

Newcastle-on-Tyne.

Underpayment of Teachers.

MR. HODGSON's letter on p. 315 directs attention to a case of underpayment of teachers in collegiate institutions. Possibly the City of Bradford Education Committee would argue that, as universities generally offer about 150*l.* a year to lecturers, judging by the advertisement columns of NATURE, 60*l.* a year, with the privilege of earning a little more in the evenings, is sufficiently liberal for the work that they require.

150*l.* is a good stipend for a youth for the first few years after leaving college, or as a retaining fee for a man who has private means; but is it fair to expect men with high university qualifications, years of teaching experience, and a record of original work, to struggle to make both ends meet for the best part of their lives?

Twenty years ago, a lecturer might reasonably expect to become a professor or to branch out into technical work; but at the present time there are not enough professorships to divide among the many highly specialised men who have taken up university teaching during the past ten years, and a technical career must be commenced on leaving college.

The prospects of secondary teachers, though poor, are better; those of elementary teachers are better still; while none of them are so good financially as those of the boy who leaves school at sixteen or seventeen and enters a bank or an insurance office.

Since for university teaching a man needs a long and expensive training, must be a graduate with first-class honours, and must be capable of original work, and since many cannot hope to obtain professorships and the like, the remuneration offered to such men is woefully insufficient, and is likely in the future to cause students of ability to avoid university teaching as a career.

RUBBER.[1]

THE Rubber and Allied Trades Exhibition and the International Rubber Congress, held conjointly and recently concluded, are doubtless responsible for the simultaneous appearance of four books on rubber. One of these is a welcome attempt, as its title implies, to cover the whole range of the subject, and

FIG. 1.—Jelutong Tree, showing improved method of tapping. From "Rubber."

Mr. Philip Schidrowitz is to be congratulated on having produced a volume which should rank as a standard work for some time to come.

The first nine chapters, half the book, are of special interest to the lay reader, and are based, as the author points out in his preface, upon six lectures delivered by him in 1910 at Finsbury Technical College. The historical sketch in chapter i., and the two following chapters on production and consumption, and the general nature of the rubber industry, will be found most useful. The notes on wild, and what the author terms industrial rubbers, such as Guayule, Jelutong, and Madagascar vine rubbers, suffer somewhat from his lack of personal acquaintance with the actual

[1] "Rubber." By Dr. P. Schidrowitz. Pp. xv+303. (London: Methuen and Co., Ltd., 1911.) Price 10*s.* 6*d.* net.

conditions abroad. For instance, in dealing with bark crushing no distinction is made between the East African scrub vines with semi-fluid latex, and the larger dense forest vines in which the latex is thin and watery; nor are the paragraphs dealing with *Castilloa elastica* and *Funtumia elastica* free from misconceptions.

The chapter on the plantation industry is a book in itself, and will be read with the greatest interest. While laying no claim to being able to treat this truly extensive subject "in encyclopædic fashion," the author is to be congratulated upon the way he has singled out for mention, in few and telling words, the salient points under each of his headings. Under that of "Competition from other Sources," we read: "The first rubber to go will undoubtedly be that which is not prepared in a cleanly fashion. 'Africans' as we know them now will be a thing of the past, and that very shortly. It does not, however, follow that the rubber forests of Africa will no longer furnish their quota to the world's supply. On the contrary, it seems to me that the system of rationally working forest areas on semi-plantation lines . . . is likely to be extended."

Mr. Schidrowitz is very well known as a rubber chemist, and in the second half of the book he finds himself, as it were, on more congenial soil. In dealing with the chemistry of rubber, theory of vulcanisation, manufacture of rubber goods, substitutes and waste-rubber disposal, much new matter is introduced which is likely to be invaluable, not only to the general reader, but to the manufacturer and the chemist. The importance of the waste rubber industry is emphasised, and in this connection the author says: "If we assume that the crude rubber employed in the manufacture of goods in the British market yearly amounts to 12,000 tons, and this reappears in the shape of finished rubber articles, containing on the average perhaps not more than 30 per cent. of rubber, it is plain that there must be something like 30,000 to 40,000 tons of waste rubber annually. Of this, perhaps, one-half is recoverable, the remainder actual waste."

The chemical analysis of both vulcanised and raw rubbers, mechanical tests, and kindred subjects are also dealt with at length, while at the end of the book is an appendix of ten pages dealing with the wording of contracts and specifications which might also be described as interesting reading, which says much for the author's happy style of literary construction.

On p. 140 the reader with planting interests at stake will find: "The manufacture of synthetic rubber on a commercial scale will only be possible if a suitable low-priced raw material, capable of transformation at a low cost and with a high yield, can be found. So far these conditions do not appear to have been fulfilled."

With the Middle East and its Hevea plantations just now so prominent in rubber finances one is apt to forget that the sources of rubber are many and various. Trees, vines, shrubs, tubers, rhizomes, &c., belonging botanically to different classes of plants and growing in different continents, all appear in the list of productions of this commodity. This being so, and without implying that the book under review would have been more successful in any other form, it is clear that future publications on rubber will be likely to attain the greatest measure of utility if confined to one or other branch of this already stupendous subject.

FIG. 2.—Three-year-old rubber trees. From "Rubber."

Mr. Schidrowitz's book is excellently written, and is illustrated largely from photographs taken by him during a tour in Malaya and Sarawak (Borneo).

THE LIVES OF BRITISH BIRDS.[1]

THE third and fourth sections of this pleasant work on popular British ornithology comprise the dipper, the thrush family, the warblers, the hedge sparrow, the starlings, the golden oriole, and the waxwing. The work is professedly and necessarily very largely a compilation, and a vast amount of most interesting and valuable information has been gathered together from widely scattered and often very inaccessible sources. This is carried out in a manner deserving all praise, the more so that a reference is always given to the publication from which the information is gleaned. Nevertheless, we sometimes miss, in the accounts of some of our more familiar species, the charm often found in a first-hand narration, and in the case of some of the articles, *e.g.* that on the dipper, we do not find impressed upon a good many field naturalists whose acquaintance with the species in question has been of some duration. What is alluded to here as the lesser whitethroat's "loud rattling call" is usually regarded as the final portion of the bird's song, analogous to the bright, clear, piping notes with which the blackcap—though not invariably—concludes its strain.

In the excellent article on the marsh warblers—full of most interesting and valuable information—the author shows that he is remarkably at home with the subjects of his essay.

Many people must have noticed the habit the robins have in winter of keeping closely to one part of the garden, homestead, fields, or woodland, where they mean to live through the cold weather. Mr. Kirkman has gone into this matter closely, and gives in section iii. an interesting account of the result of his in-

them, or expressed by them, as much evidence of a personal acquaintance with the subject thereof as we might perhaps expect from those who undertook to write such accounts of well-known British species.

Again, one author writes, "I have not heard the song of the black redstart." This is a pity, because he has to fall back upon Naumann, who must surely have been prejudiced against the bird; and consequently no justice has been done to one of the most charming of bird songs.

In the article on the whitethroats, blackcap, and garden warbler, the author writes: "Difficult as it may be to distinguish between the songs of these four warblers. . . ." This implied statement will surprise

vestigations. He writes: "The robin, unlike any other British winter species that I know of, is found from about the end of August to the middle of February in solitary possession of a more or less well-defined feeding area, from which all others of his own species are excluded. Pressure of cold weather may sometimes force him to associate with his fellows in order to share the crumbs put out by the charitable, but he can hardly be said to suffer them gladly. He is happy only when alone. Hence the old saying, that 'one bush will not harbour two robins.'" From August to March he kept the robins about a farm under observation, and he was able at last to map out their adjoining estates—a plan of which is given. The boundaries of these estates, it is seen, are nearly everywhere imaginary lines, and they overlap, but every robin clearly recognised to within a

[1] "The British Bird Book." Edited by F. B. Kirkman. Section iii., pp. 297–449; Section iv., pp. 169. (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 10s. 6d. net each part.

yard or two the position of his boundary, and made the fact quite clear to any other robin who did not. Moreover, the author found that it was not easy to drive them out of their own little estate, to which they invariably returned immediately.

The intention of making life habits the chief feature in the work is fully carried out in the last two sections. A notice inserted in the last part informs readers that in order to render the notes on Distribution more complete, the range of each species outside its breeding area will be briefly indicated.

Mr. A. W. Seaby's pictures are as charming,

spirited, and lifelike as ever—quite the most original and refreshing bird pictures we have seen for long—and there are excellent plates of the rosy pastor, golden oriole, and waxwing by some of the other artists who contribute to the work.

A MONUMENT TO JANSSEN.

AN influential committee has been formed to raise to the memory of Janssen a durable monument which shall recall to the minds of those who see it the enormous and brilliant services rendered to astronomy by the great French *savant.*

A man of rare breadth of mind, it was not simply to any one branch of the oldest science that Janssen turned his attention, but he will be remembered chiefly for his fruitful researches in astronomical physics. That brilliant discovery, shared by Lockyer, in 1868, will probably be the *lucida* of his labours, the method of observing solar prominences, of drawing and measuring those enormous solar flames, without waiting for the rare and uncertain seconds of a total solar eclipse. Only those whose work it is to observe and to study solar phenomena know how much of our present knowledge is due to the timely discovery of this method. By this have the labours of the discoverers, of Respighi, of Young, of Tacchini, Ricco, Hale, and Deslandres, and of many others become productive. Janssen from India and Lockyer from West Hampstead sent messages to the French Academy which arrived almost simultaneously, and immediately a new era in the rapidly expanding knowledge of the sun's physical and chemical attributes was opened.

Janssen also studied with great assiduity and marvellous results the laws of the absorption and transmission of light travelling through gaseous media, and thereby laid foundations on which have since been erected wonderful superstructures. As an organiser he was in the forefront. His photographs of the solar surface were magnificent and have never been excelled. It is to Janssen that we owe the establishment of the solar observatory on Mont Blanc, whither, in spite of his lameness, he made many ascents.

All this will count as an imperishable monument to those who know aught of astronomical physics. We heartily sympathise with the aims of the committee which has charged itself with receiving subscriptions to this end, and below give the names of those who have already joined:—MM. Armand Gautier, président de l'Académie des Sciences; G. Lippmann, vice-président; G. Darboux, secrétaire perpétuel; Ph. Van Tieghem, secrétaire perpétuel; C. Wolf, doyen de la Section d'Astronomie; Henri Poincaré, de l'Académie Française; G. Bigourdan, de l'Institut; J. Violle, de l'Institut; B. Baillaud, directeur de l'Observatoire de Paris; Prof. Chauveau, de l'Institut; De Selves, préfet de la Seine; Daumet, de l'Institut; Edmond Perrier, directeur du Muséum; Prof. Bouchard, de l'Institut; Alfred Grandidier, de l'Institut; Prof. Lannelongue, Sénateur; Dr. Roux, directeur de l'Institut Pasteur; R. Radeau, de l'Institut; G. Lemoine, de l'Institut; H. Deslandres, directeur de l'Observatoire de Meudon; M. Hamy, de l'Institut; P. Puiseux, astronome à l'Observatoire de Paris.

PIERRE ÉMILE LEVASSEUR.

BY the death of Pierre Emile Levasseur both geography and economic science in France have sustained a severe loss. Born on December 8, 1828, Prof. Levasseur devoted his energies during a long life to demonstrating the importance of a right appreciation of geography in its application to man and of economic science. As early as 1863 he published a "Précis d'Histoire de France" and a "Précis de Géographie," and throughout many years of active work in economic geography he always aimed at the highest precision in his studies with the view of building up a truly scientific type of geography and insisting upon the educational value of the subject when so treated. He especially directed his efforts towards a thorough understanding of the economic geography of France, but he also travelled widely in order to study economic conditions occurring in other lands; a journey to the United States in 1853 resulted in an important work, "L'Ouvrier Américain," and the same line of investigation, followed up both historically and economically, produced important studies on the working classes in France up to the time of the Revolution, and a later work dealt with their condition under the Third Empire. Working in such fields, his attention was early directed to statistics, and in his important work "La Population Française" he not only treats of the geographical aspects of the question, but deals with it statistically and points out the importance of the proper use of statistics in all questions of applied geography. In all that relates to human geography, the definiteness which we meet in physical geography is only attained with difficulty, and by the careful and prudent use of the best statistical material available. In this direction Levasseur's work furnishes many examples of the highest value as giving a truly scientific form to investigations which, from the numerous factors involved, are too often treated superficially.

H. G. L.

THE BRITISH ASSOCIATION AT PORTSMOUTH.

As we went to press last week, the concluding meeting of the British Association at Portsmouth was being held; and the thanks of the Association were being expressed to the local authorities for the work they had done and the trouble they had taken to make the visit to Portsmouth pleasant and memorable. Everyone agrees that the Portsmouth meeting was most enjoyable; and well it might be, considering that it was held at a seaside resort during the season when "sunny Southsea" is full of attractions. In spite of great difficulties, the Mayor (Alderman T. Scott Foster) was able to arrange for the accommodation of the secretaries and other officials in the best hotels, and to provide hospitality for distinguished visitors. There was little private hospitality, and the grant of 3500*l.* made to the Mayor by the Corporation of Portsmouth for the entertainment of the visitors can scarcely have covered the expenses involved.

The best thanks of the world of science are due to the Mayor and the Corporation for the public spirit they have shown in making provision for the meeting, in spite of a certain amount of local opposition to the necessary expenditure. The actual work of local arrangements has, of course, fallen largely upon the shoulders of the local secretaries, namely, the town clerk (Mr. G. Hammond Etherton) and the medical officer of health (Dr. Mearns Fraser). Only those who have had to be responsible for the organisation of a meeting such as that concluded last week can understand how well the thanks received by the local secretaries are merited. The total attendance at the meeting was 1,241.

Of the attractions provided for the entertainment of the visitors, the naval display, which was viewed from the battleship *Revenge*, was most impressive; and it will long remain in the memories of the large party privileged to see it. The Association owes this distinctive feature to the Commander-in-Chief, Admiral Sir William Moore, who, in acknowledging the vote of thanks to him and the officers and men of the Royal Navy for the display, paid a generous tribute to the work of science. "When I am at sea," said Sir William, "Lord Kelvin's compass and sounding-line make me think of him with gratitude twenty times a day"; and, referring to Sir William White, who proposed the vote of thanks, he remarked, "He has given us the greatest essential in the design of our ships, namely, a steady gun-platform."

On account of the naval display, it was impossible for the Committee of Recommendations to decide upon the grants for scientific purposes on the Monday, so the subjoined list, which was adopted by the General Committee on Wednesday afternoon, was not available for publication last week. The total is 40*l.* less than last year.

SECTION G.

ENGINEERING.

OPENING ADDRESS BY PROF. J. H. BILES, LL.D., D.Sc., M.INST.C.E., PRESIDENT OF THE SECTION.

IT has happened during recent years that accidents have happened to ships and they have mysteriously disappeared. The complete disappearance without leaving any trace has led to the assumption that the vessel has capsized. The circumstances of such cases obviously preclude the existence of any direct evidence. The only subjects of investigation can be (1) the condition of the ship prior to the accident, and (2) the probability that such a condition could be one which in any *known possible circumstances* could lead to disaster. The first is determinable by evidence in any particular case. The second involves a consideration of the whole question of the behaviour of ships at sea. What is the effect upon any given ship of a known series of waves? What waves is a ship likely to meet?

This subject has occupied the attention of scientific engineers, and it may be said to have been considered a solved problem. We have thought that if a ship has a certain metacentric height and a certain range of positive stability she is quite safe from the action of a series of waves of any kind which we know to exist. If, however, a known ship (and perhaps more than one) has these safety-ensuring qualities and mysteriously disappears, it may be desirable to review the grounds of our belief to see whether any *known possible combination* of circumstances may cause disaster.

Let us then first briefly review the grounds of our belief. Fifty years ago Mr. Wm. Froude showed that the large angles occasionally reached in rolling are not due to a single wave-impulse, but are the cumulative effect of the operation of successive waves. The period T of a small oscillation of a ship in water free from wave disturbance and resistance is $\pi\sqrt{\frac{k^2}{gh}}$, where k is the radius of gyration and h is the metacentric height (*i.e.*, the height of the metacentre above the centre of gravity). The period T of a wave is $\sqrt{\frac{2\pi l}{g}}$, where l is the length of the wave and g is the acceleration due to gravity. The line of action of the resultant of the supporting pressures acting on a ship in undisturbed water is the vertical through the centre of gravity of the volume of the water displaced by the ship. In wave-water it is in the normal to the effective wave-slope (which is approximately the wave-surface). The oscillation of this normal as the waves pass causes a varying couple tending to incline the vessel. If the vessel is very quickly inclined by this couple she will place herself in or near the normal and the inclining couple will be of zero value. If, however, her movements are very slow, the normal may make one or more oscillations before any appreciable effect is produced on the vessel. The tendency to incline in one direction caused by the normal acting on one side of the vertical is checked by the rapid oscillation of the normal to the other side of the vertical. It is, therefore, evident that the relation between the period of the ship and that of the wave normal is a dominating feature in the resulting movement of the ship. Mr. W. Froude's mathematical solution of this relation is the basis of our belief that we understand the behaviour of a ship in the *uniform* system of waves when the vessel is placed broadside on to the waves. To obtain this solution he assumed that within the limits considered, the moment of stability varied as the angle of inclination. In the curve of righting levers of a ship, usually known as a curve of stability, this condition holds generally for angles up to about 10°. The curve usually reaches a maximum value at about 30° to 40° and vanishes at 60° to 80°, so that for large angles of roll the assumption does not hold. On this assumption, however, he showed that the motion of a ship amongst such a system of waves is the same as for still water plus a motion composed of two sine terms. The amplitude of this latter motion depends upon the maximum slope of the waves and the ratio $\frac{T}{T_1}$ (the period of the ship in undisturbed water to the period of the wave). If the ship starts from rest in the upright, θ is the maximum angle of inclination of the ship and θ_1 the maximum wave-slope; then

$$\theta = \theta_1 \frac{1}{1 - \frac{T^2}{T_1^2}}$$

He considered several solutions of the equation of motion:—

(1) $T = T_1$; this is synchronism and the angle of inclination gradually increases. Each wave-impulse adds something to the ship's inclination and without any resistance to rolling the vessel would capsize.

(2) $\frac{T}{T_1} = 0$; this is the case of the ship's period being very small compared with that of the wave. θ will then be positive and equal to θ_1. In other words, the ship will place herself normally to the wave-slope. The maximum amplitude will only be the maximum wave-slope.

(3) $\frac{T}{T_1} < 1$. In this case the wave-period is greater than that of the ship and θ is always positive and greater than θ_1. The vessel always inclines away from the wave-slope. If

$$\frac{T}{T} = \tfrac{1}{4},\ \theta = \frac{16}{15}\theta_1. \quad \text{If } \frac{T}{T_1} = \tfrac{1}{2},\ \theta = \frac{4}{3}\theta_1. \quad \text{If } \frac{T}{T_1} = \tfrac{3}{4},\ \theta = \frac{16}{7}\theta_1$$

The nearer $\frac{T}{T_1}$ is to unity the larger is the maximum amplitude.

(4) $\frac{T}{T_1} > 1$. In this case the wave-period is less than that of the ship, and θ is always negative. The vessel inclines towards the wave-slope.

$$\text{If } \frac{T}{T_1} = 1{\cdot}1, \text{ then } \theta = -4{\cdot}76\,\theta_1;$$
$$\frac{T}{T_1} = 1{\cdot}26, \text{ then } \theta = -\theta_1;$$
$$\frac{T}{T_1} = 2{\cdot}0, \text{ then } \theta = \frac{1}{3}\theta_1;$$
$$\frac{T}{T_1} = 2{\cdot}235, \text{ then } \theta = \tfrac{1}{4}\,\theta_1.$$

This shows the advantage of having T greater than T_1.

He showed that the ship goes through a cycle of changes and considered the effect of variations of $\frac{T}{T_1}$ upon these cycles. He showed that $\frac{T}{T_1} = \frac{5}{4}$ is better than $\frac{T}{T_1} = \frac{4}{5}$, so that it is better to lengthen T rather than to shorten it. Similar results for $\frac{T}{T_1} = 2$ and $\frac{1}{2}$ respectively gave better results by lengthening than shortening T. In each of the cases $\frac{T}{T_1} = \frac{5}{9}$ and $\frac{T}{T_1} = \frac{9}{5}$ the results show baulked oscillations in which, while the vessel swings towards the vertical, she does not reach it but swings back again. The lengthened value of T here also gave better results than for shortening it. The results given above are greater than would be obtained in practice, because resistance has been neglected. Later he determined the effect of resistance upon rolling in still water free from waves. He determined the law of resistance and found it to vary partly as the angular velocity and partly as the square of it. He rolled a ship, and after she was allowed to roll free from disturbance he measured the angle of inclination at the end of each roll. These showed the rate of extinction of the rolling due to the resistance. The loss of extreme angle of roll between one roll and the next represented the work done by the ship in rolling. It is possible to calculate the work done in inclining the vessel to any angle, and the difference between the amount of work thus done in two different angles represents the difference in work necessary, and therefore work done in resistance to bring the ship to these angles of inclination. Hence the work done by resistance between the two consecutive rolls can be actually measured by measuring the extreme angle of inclination in successive rolls.

Having determined the resistance in terms of angles of roll and time, it was easy to determine the law which represented the resistance in terms of the angular velocity.

In applying this to waves, all that is necessary is to take account of the fact that the position of equilibrium about which the ship oscillates is the normal to the effective wave-slope. This normal has a definite oscillation about a fixed vertical. It is, therefore, possible to determine the angle of inclination in terms of time.

As these angles of roll may be considerable, the assumption upon which the general solutions for unresisted rolling, already given, were based will not hold. The actual moments of stability depend upon the form of the ship and the position of its centre of gravity, and as these vary in different ships it is only possible to obtain the relation between inclination and time by a special investigation in each case. A solution by a method of graphic integration was devised by Mr. W. Froude and has been applied to a very small number of cases. The information necessary to obtain a solution in any one case is as follows:—

(1) A curve of righting levers in terms of angle of inclination. This is called a curve of statical stability.

(2) The form and period of the wave on which the ship is supposed to be placed broadside on.

(3) The constants which determine the actual value of the resistance moment in terms of the angular velocity. These can be obtained by rolling the ship in still water and observing the rate of extinction of rolling when that extinction is due to resistance only. The form of the curve of extinction can be obtained by rolling a model of the ship, but the actual ordinates of the curve for an actual ship can only be obtained by experiment on the ship herself, or by inference from a similar ship of approximately the same size, form, and arrangements.

A consideration of these three necessities for the solution of one particular case shows that a considerable amount of work is necessary for determining the angle of inclination in terms of time. Even this solution can only be made for one assumed maximum angle of inclination as a starting condition. For instance, in any case where a ship is assumed to start with a maximum inclination of 20° it is only possible to obtain one solution of angles of inclination in terms of time. If we take another maximum angle of inclination, another complete solution is necessary. The work of each solution is considerable.

For ships which vary much in draught and condition of loading it is evident that for each ship the work of complete investigation for all the conditions of loading of different waves and different angles of maximum inclination is very great. For this reason the investigation of rolling by the Froude graphic method has only been made for a very small number of cases, and our knowledge of the actual angles of inclination of ships obtained by this method is very small.

The curve of statical stability is worked out for many ships in a few conditions of draught and position of centre of gravity. These curves are of little practical value, because they only serve as comparisons between ships. It is assumed that if a ship has a fair range of statical stability, *i.e.*, that the angle of vanishing statical stability is not less than, say, 60°, and the maximum righting lever is not unlike some previous ship which "has been to sea and come home again" safely, this ship will be safe. This assumption is based on the belief that only what has happened to previous ships will happen to the one in question; that is, that the contingencies of waves will be the same in all cases. But when we find that occasionally ships are missing we are compelled to ask ourselves the question—is it possible that some occasional contingencies of sea or ship, or both, may exist which will produce a dangerous and perhaps fatal roll?

Mr. W. Froude's investigations were made for a uniform system of waves. He showed that in unresisted rolling a ship initially at rest and in the upright position is acted upon by a uniform series of waves such that $\frac{T}{T_1} \, \frac{p}{q}$ where p and q are the smallest whole numbers which express this ratio, then the rolling of the ship will be in cycles, the maximum inclination in each roll gradually increasing, and again gradually diminishing, and so on. The period of occurrence of the maximum of maxima will be $2q$T. The number of times the ship passes through the upright in each complete cycle is $2p$ or $2q$, whichever is the smaller. The ship is upright at the middle of the cycle, and on either side of this middle there is an equal maximum which is approximately $\theta_1 \frac{q}{q-p}$, and never exceeds this value (where θ_1 is maximum wave-slope). If T is much larger than T_1, and therefore p is much larger than q, then the value of $\theta_1 \frac{q}{q-p}$ approaches $\theta_1 \frac{q}{p}$ and is less than the wave-slope. If T is much smaller than T_1, then the value of $\theta_1 \frac{q}{q-p}$ approaches θ_1. If T is nearly equal to T_1, then $\theta_1 \frac{q}{q-p}$ approaches a high value.

From this it is seen that our investigations in unresisted rolling may be over a very wide field, but would produce no definite result in the matter of finding cases of large angles of roll in practice. We can only obtain valuable results when resistance is included.

Mr. R. E. Froude in 1896 was led to deal with the subject of non-uniform rolling of ships in an assumed uniform system of waves which did not synchronise with the ship, such as is dealt with above for unresisted rolling, and he dealt with the effect of resistance in such a case. He pointed out that there is a particular phase-relation between the ship and the wave which will produce uniform rolling, just as there is in the case of a synchronous system of waves. If at any stage for any reason the rolling is of the cyclic character considered in non-resisted rolling, then the resistance must gradually introduce uniformity, because the rolling is made up of two seas of oscillations—

(1) That due to the rolling relatively to the water-surface, such as would occur in undisturbed water.

(2) That due to the oscillation of the water-surface itself, caused by the passage of the wave.

We have already seen that the resisted oscillation in undisturbed water gradually decreases when the vessel is left free to oscillate, but takes place in practically uniform time T. The oscillation of the water-surface is forced on the ship and causes a simple harmonic oscillation of the ship in time T_1, in algebraic addition to that due to the free resisted oscillation. When the maximum angle of a roll due to the free oscillation coincides with the maximum angle due to the forced oscillation of the wave, we shall have a maximum extreme inclination which is the sum of that due to the free and the forced. When they are in opposition we shall have a minimum extreme oscillation which is the difference of these two. At stages between coincidence and opposition we shall have extreme angles varying between maximum and minimum. As time goes on the extreme angle due to the free oscillation gradually decreases under resistance, and the sum and the difference referred to above approximate to each other, and the rolling becomes that due to the wave alone. We have seen that in the case of unresisted rolling where the wave and the ship synchronise there is an addition to the angle of inclination for each passage of the wave, and were it not for resistance these accumulated increases would cause the vessel to upset. But in the case of resisted rolling each increase of extreme angle of roll causes an increase in the work done upon the resistance of the ship, and when the increase in work done in increasing the angle of heel by each passage of the wave equals the work done in increasing the resistance incurred in swinging through this greater angle, then we shall have a balance of condition and a uniform angle of roll. The angle at which this balance takes place depends on the period and maximum slope of the wave and the coefficients of resistance between the ship and the water. For instance, with a maximum wave-slope of 3° and with a ratio of ship to wave-period of 1·1 the value of the angle of ultimate uniform rolling in the case of H.M.S. *Revenge* was found to be 13·0° without bilge-keels and 10·8° with them. In the case of synchronism of the ship and the wave, the rolling is uniform always and reaches a maximum of 41·1° without and 14·85° with bilge-keels. The nearer the wave and ship are to synchronism, the larger is maximum inclination reached before uniform rolling sets in and during uniform rolling. Resistance is of much more importance in the case of synchronism. If the ratio of ship to wave-period be 1·3, the maximum angle before uniform rolling is reached is 8·25° without and 6·6° with bilge-keels, while that due to uniform rolling is 4·35° without and 4·24° with. We see, therefore, the important part that the near approach to synchronism plays in creating large angles of roll and the value of bilge-keels in reducing the rolling in conditions approaching synchronism. When on waves of smaller period, when small angles of roll may be expected, the bilge-keels give but small advantage. The assumption in these cases is that the vessel starts from rest in the upright in the mid-height of the wave, and that the rolling is caused by the assumed uniform swell. The vessel will go through the cyclic change already described and will reach a maximum inclination of not more than double that which she reaches when uniform rolling has set in.

A later investigator, Colonel Russo, of the Italian Navy, found by experiment that by varying the assumption as to starting condition of the ship, by letting the wave-action begin to operate first when the vessel is upright and at rest on the crest of the wave, the maximum angle before uniform rolling sets in can be more than four times that due to uniform rolling if the time of the ship is greater than that of the swell. There is an infinite number of solutions of rolling amongst waves because there is an infinite number of initial circumstances, but, whatever these may be, the rolling in a uniform swell will always soon degenerate into a series of uniform forced oscillations in the wave-period.

From this discovery of Colonel Russo's, we see that the region of investigation of possible causes of upsetting is removed from that of uniform rolling even in a non-synchronous sea. The following table shows for the *Revenge* with bilge-keels the variation in maximum angle of inclination before and during uniform rolling in terms of the period and length of the swell:—

Period of swell in seconds...	8	10	12	13·3	15	17	19
Length of swell in feet ...	328	512	738	910	1153	1481	1850
Maximum angle in degrees before uniform rolling ...	6·3	8·0	14·7	21·4	17·1	13·0	11·0
Maximum angle in degress during uniform rolling ...	2·5	4·2	12·6	21·4	15·4	11·0	8·7

The period of free rolling of the *Revenge* through small angles for a double roll was about 16 seconds. The foregoing shows that the maximum rolling (which occurs at synchronism) took place at a period of swell of 13·3 seconds. The period of roll was less at large than small oscillations. The above figures are for waves varying from $\frac{1}{37}$th to $\frac{1}{64}$th of their length in height. The length of wave which corresponds to maximum inclination is 910 feet and height is about one-fiftieth. The maximum wave-slope for such waves is 3·6°. We are in the habit of dealing with waves of one-twentieth of their length in height for strength calculations. Observers have recorded waves in the open ocean of 600 to 800 feet in length and of 30 to 45 feet in height, so that we know that the slope of the waves assumed by Colonel Russo is much less than may be encountered at sea. A wave the length of which is twenty times its height has a maximum slope of 9°. Records of waves having a ratio of height to length of as great as one-thirteenth have been published. The maximum slope of wave corresponding to these proportions is 14°. If it is admissible to take much larger angles of wave-slope we may expect to get much larger angles of maximum inclination both before uniform rolling sets in and when it does. In a case given by Mr. Froude in which the maximum inclination in the *Revenge* before uniform rolling was 12·0°, he showed by calculation that the corresponding maximum wave-slope must have been 5·09°. For 20° maximum inclination the wave-slope was 10·3°. Both these cases were for periods of ship and wave of 16 and 13 seconds respectively. For similar periods of 16 and 14·6 seconds the wave-slope to produce 20° maximum before uniform rolling is only 7°. These figures give some idea of the effect of the wave-slope on the maximum inclination. It is to be remembered that these are the maximum angles obtained by Mr. Froude; but if we take Colonel Russo's maximum angles, which in some cases are double those obtained by Mr. Froude, it is easy to see that large wave-slopes may produce very large angles of roll.

Summarising, we see that:—

(1) With wave-slopes of 3·6° the angles of maximum roll obtained by them in the *Revenge* with bilge-keels may be taken at 22°.

(2) This roll takes place when synchronism exists between the wave and the ship, when the wave is 910 feet long and 18½ feet high and has a wave-slope of 3·6°.

(3) Waves exist which are of this length, but which may have a height of 50 feet, and possibly more, and a wave-slope of 10°.

(4) In such steeper waves we should expect to get much larger angles of roll.

(5) Each ship has peculiarities of rolling due to its form as well as to its lading and bilge-keels, &c.

(6) These peculiarities and the effect they have upon rolling, and the effect different waves will have upon the rolling of the ship, can best be studied experimentally.

It was my intention when you appointed me as your President to have placed before you the results of an experimental study made on lines somewhat similar to those carried out by Colonel Russo, but extended to a wide range of types of ship, waves, and resistance.

The machine for carrying out these experiments is practically complete, but having met with an accident at the end of April last which incapacitated me for some time, I was prevented from being able to do anything to this subject since then. I am, therefore, obliged to ask you to be content with the general *résumé* of the subject which has been given.

I think enough has been said to show what a field of investigation is open to the experimenter. The little that has been done and published by Colonel Russo is only for three battleships of about the same size. For the great bulk of the ocean wayfarers nothing has been done. If it is possible to determine the kind of rolling which is likely to take place under stated conditions it seems to be desirable to do so.

In all that has been said it will be seen that it is possible to determine experimentally the kind of rolling which will take place in a ship which is snug and seaworthy. But it is also possible to study the effect of loose water in a ship under the same set of conditions as to waves, lading, and form of ship. This part of the subject has not received any experimental treatment except in a very limited number of full-sized ships. It is quite conceivable that some conditions of loose water associated with some conditions of sea may produce large angles of inclination.

The subject has been treated as one in which it is probable that the kind of waves met with at sea will be uniform in size and period. That this is not so is a fact with which we are all more or less familiar. The effect of a uniform system of waves is to rapidly induce a condition of uniform rolling. But any deviation from uniformity of sea immediately introduces non-uniformity of rolling, and generally greater extreme angles of roll. Any experimental study of the action of waves upon a ship must include a variation in the character of the waves. The field of investigation is thereby widened and the search for large angles of inclination made more laborious. But the work is of a kind which can be done by many people, and can be done fairly rapidly, so that there seems to be no insuperable objection to doing it. The details of the apparatus need not be described, but the study of the objects attained may be of interest.

(1) Wave-motion is simulated by the revolution about parallel axes of two parallel cranks of different lengths. The line joining the ends of the arms of the cranks is always in the line of the normal to the wave-surface, and a line perpendicular to it is therefore parallel to the wave-surface.

(2) From the form of the ship are determined curves which are the shape of rollers which roll on a straight line parallel to the wave-surface. The form of these rollers is such that the model of the ship in rolling maintains the position in relation to the wave-surface (*a*) which cuts off constant volume of displacement at any angle of inclination; (*b*) in which the perpendicular to the straight line parallel to the wave-surface through the point of contact is the line of the resultant of the water-pressures acting on the vessel.

(3) The resistance to rolling is obtained by (*a*) electro-magnets, the current to which is generated by the motion of the model, (*b*) secondary electro-magnet, the current for which is in the first magnet. (*a*) represents the resistance due to the angular velocity, (*b*) represents the square of that velocity.

The variations in the lengths of the cranks and the speed of revolution give the variation in the wave-form assumed. The variation in the electric current by resistances in the circuit gives the variation in the resistances to rolling of the ship. For instance, the current necessary to represent the resistance of a ship with bilge-keels is very different from that for one without.

It is hoped that sufficient has been said to direct attention to the possibility of extended study of the rolling of ships at sea, so that some valuable work may be done in this important subject.

SECTION H.

ANTHROPOLOGY.

OPENING ADDRESS BY W. H. R. RIVERS, M.D., F.R.S., PRESIDENT OF THE SECTION.

The Ethnological Analysis of Culture.

DURING the last few years great additions have been made to our store of the facts of anthropology—we have learnt much about different peoples scattered over the earth, and we understand better how they act and think. At the same time we have, I hope, made a very decided advance in our knowledge of the methods by means of which these facts are to be collected, so that they may rank in clearness and trustworthiness with the facts of other sciences. When, however, we turn to the theoretical side of our subject, it is difficult to see any corresponding advance. The main problems of the history of human society are little if at all nearer their solution, and there are even matters which a few years ago were regarded as settled which are to-day as uncertain as ever. The reason for this is not far to seek; it is that we have no general agreement about the fundamental principles upon which the theoretical work of our science is to be conducted.

In surveying the different schools of thought which guide theoretical work on human culture, a very striking fact at once presents itself. In other and more advanced sciences the guiding principles of the workers of different nations are the same. The zoologists or botanists of France, Germany, America, our own and other countries, are on common ground. They have, in general, the same principles and the same methods, and the work of all falls into a common scheme. Unfortunately, this is not so in anthropology. At the present time there is so great a degree of divergence between the methods of work of the leading schools of different countries that any common scheme is impossible, and the members of one school wholly distrust the work of others, whose conclusions they believe to be founded on a radically unsound basis.

I propose to consider in this address one of the most striking of these divergencies, but, before doing so, I will put as briefly as possible what seem to me to be the chief characters of the leading schools of different countries. To begin with that dominant among ourselves. The theoretical anthropology of this country is inspired primarily by the idea of evolution founded on a psychology common to mankind as a whole, and further, a psychology differing in no way from that of civilised man. The efforts of British anthropologists are devoted to tracing out the evolution of custom and institution. Where similarities are found in different parts of the world it is assumed, almost as an axiom, that they are due to independent origin and development, and this in its turn is ascribed to the fundamental similarity of the workings of the human mind all over the world, so that, given similar conditions, similar customs and institutions will come into existence and develop on the same lines.

In France we find that, as among ourselves, the chief interest is in evolution, and the difference is in the principles upon which this evolution is to be studied. It is to the psychological basis of the work of British anthropologists that objection is chiefly made. It is held that the psychology of the individual cannot be used as a guide to the collective actions of men in early stages of social evolution, still less the psychology of the individual whose social ideas have been moulded by the long ages of evolution which have made our own society what it is. It is urged that the study of sociology requires the application of principles and methods of investigation peculiar to itself.[1]

About America it is less easy to speak, because it is unusual in that country to deal to any great extent with general theoretical problems. The anthropologists of America are so fully engaged in the attempt to record what is left of the ancient cultures of their own country that they devote little attention to those general questions to which we, more unfortunately situated with no ancient culture at our doors, devote so much attention. There seems, however, to be a distinct movement in progress in America which puts evolution on one side, and is inclined to study social problems from the purely psychological point of view, the psychological standpoint, however, approaching that of the British school more nearly than that of the French.[2]

It is when we come to Germany that we find the most fundamental difference in standpoint and method. It is true that in Adolf Bastian Germany produced one who was thoroughly imbued with the evolutionary spirit, and the *Elementargedanke* of that worker forms a most convenient expression for the psychological means whereby evolution is supposed to have proceeded. In recent years, however, there has been a very decided movement opposed to Bastian and the whole evolutionary school. In some cases this has formed part of that general revolt, not merely against Darwinism, which is so prominent in Germany, but it seems even against the whole idea of evolution. In other cases the objection is less fundamental, and has been not so much to the idea of evolution itself as to the lines upon which it has been customary to endeavour to study this evolution.

This movement, which by those who follow it is called the geographical movement, but which, I think, may be more fitly styled "ethnological," was originated by Ratzel, who was first led definitely in this direction by a study of the armour made of rods, plates, or laths which is found in North America, northern Asia, including Japan, and in a less developed form in some of the islands of the Pacific Ocean.[3] Ratzel believed that the resemblances he found could only be explained by direct transmission from one people to another, and was led by further study to become an untiring opponent of the *Elementargedanke* of Bastian and of the idea of independent evolution based on a community of thought.[4] He has even suggested that the idea of independent origin is the anthropological equivalent of the spontaneous generation of the biologist, and that anthropology is now going through a phase of development from which biology has long emerged.

The movement initiated by Ratzel has made great progress, especially through the work of Graebner[5] and of P. W. Schmidt.[6] It has resulted in an important series of works in which the whole field of anthropological research is approached in a manner wholly different from that customary in this country.[7] I must content myself with

[1] I refer here especially to the work of the "sociological" school of Durkheim and his followers. For an account of their principles and methods see "L'Année sociologique," which began to appear in 1898; Durkheim, "Les Règles de la Méthode Sociologique," Paris; and Lévy-Bruhl, "Les fonctions mentales daos les sociétés inférieures," Paris, 1910.

[2] See especially A. L. Kroeber, "Classificatory Systems of Relationship," Journ. Roy. Anthr. Inst., 1909, xxxix., 77; and Goldenweiser, "Totemism: An Analytical Study." Journ. Amer. Folk-lore, 1910, xxiii.

[3] *Sitzber. d. Akad. d. Wiss. München*, Hist. Cl., 1886, p. 181.

[4] See especially "Anthropogeographie," 1891, Th. ii., 795, and "Die geographische Methode in der Ethnographie," *Geograph. Zeitsch.*, 1897, iii., 268.

[5] See especially "Methode der Ethnologie," Heidelberg, 1911, and "Die melanesische Bogenkultur und ihre Verwandten," *Anthropos*, 1909, iv., 726. The annual "Ethnologica," edited by W. Foy, is devoted to the illustrations of this school of thought.

[6] See especially "L'origine de l'Idée de Dieu." *Anthropos*, iii.–v., 1908–10, and "Grundlinien einer Vergleichung der Religion u. Mythologie der austronesischen Völker," *Denksch. d. Akad. d. Wiss. Wien*, Phil.-hist. Kl., 1910, liii. Schmidt differs from Graebner in limiting the application of the ethnological method to regions with general affinities of culture. Otherwise he remains an adherent of the doctrine of independent origin. (See 'Panbabylonismus und ethnologischer Elementargedanke," *Mitt. d. anthrop. Gesellsch. in Wien*, 1008, xxxviii., 73.)

[7] It must not be understood from this account that all German anthropologists are adherents to the ethnological school. There are still those who follow the doctrines of Bastian, which have undergone an interesting modification through the adoption of the biological principle of Convergence.

one example to illustrate the difference of standpoint which separates the two schools. Few subjects have attracted more interest in this and other countries than the study of primitive decoration. In the decorative art of all lands there are found transitions from designs representing the human form or those of animals and plants to patterns of a purely geometrical nature. In this country it has been held, I think I may say universally, that in these transitions we have evidence for an evolutionary process which in all parts of the world has led mankind to what may be called the degradation and conventionalisation of human, animal, or plant designs, so that in course of time they become mere geometrical forms.

To the modern German school, on the other hand, these transitions are due to the blending of two peoples, one possessing the practice of decorating its objects with human, animal, or plant designs, while the art of the other is based on the use of geometrical forms. The transitions which have been taken to be evidence of independent processes of evolution based on psychological tendencies common to mankind are by the modern German school ascribed to the mixture of cultures and of peoples. Further, similar patterns, even one so simple as the spiral, when found in widely separated regions of the earth, are held to have been due to the influence of one and the same culture.

I have chosen this example because it illustrates the immense divergence in thought and method between the two schools; but the difference runs through the whole range of the subject. In every case where British anthropologists see evolution, either in the form of material objects or in social and religious institutions, the modern German school sees only the evidence of mixture of cultures, either with or without an accompanying mixture of the races to which these cultures belonged.

It will, I think, be evident that this difference of attitude of British and German workers is one of fundamental and vital importance. When we find the chief workers of two nations thus approaching their subject from two radically different and, it would seem, incompatible standpoints, it is evident that there must be something very wrong, and it has seemed to me that I cannot better use the opportunity given to me by the present occasion than in devoting my address to this subject.

The situation is one which has an especial interest for me in that I have been led quite independently to much the same general position as that of the German school by the results of my own work in Oceania with the Percy Sladen Trust Expedition. With no knowledge of the work of this school, I was led by my facts to see how much, in the past, I had myself ignored considerations arising from racial mixture and the blending of cultures, and it will perhaps interest you if I sketch briefly the history of my own conversion.

Much of my time in Oceania was devoted to survey work, in which I collected especially the systems of relationship of every place I visited, together with such other facts concerning social organisation as I was able to gather. I began my theoretical study by a comparison of the various forms of these systems of relationship, disregarding at first the linguistic nature of the terms. From the study of these systems I was able to demonstrate the existence, either in the present or the past, of a number of extraordinary and anomalous forms of marriage, such as marriage with the daughter's daughter and with the wife of the father's father,[1] all of which become explicable if there once existed widely throughout Melanesia a state which is known as the dual organisation of society with matrilineal descent, accompanied by a condition of dominance of the old men which enabled them to monopolise all the young women of the community. Taking this as my starting-point, I was then able to trace out a consistent and definite scheme of the history of marriage in Melanesia from a condition in which persons normally and naturally married certain relatives to one in which wives are purchased with whom no relationship whatever can be traced, and I was able to fit many other features of the social structure of Melanesia into this scheme. So far my work was of a purely evolutionary character, and only served to strengthen me in my previous standpoint.

[1] These terms are used in the classificatory sense.

I then turned my attention to the linguistic side of the systems of relationship, and a study of the terms themselves showed that these fell into two main classes: one class generally diffused throughout Oceania, while the terms of the other class differed very considerably in different cultural regions. Further, it became clear that the terms of the first class denoted relationships which my comparative study of the forms of the systems had shown to have suffered change, while the terms which varied greatly in different parts of Oceania denoted relationships, such as those of the mother and mother's brother, which there was no reason to believe had suffered any great change in status. From these facts I inferred that at the time of the most primitive stage of Melanesian society of which I had evidence there had been great linguistic diversity which had been transformed into the relative uniformity now found in Melanesia by the incoming of a people from without, through whose influence the change I had traced had taken place, and from whose language the generally diffused terms of relationship had been borrowed. It was through the combined study of social forms and of language that I was led to see that the change I had traced was not a spontaneous evolution, but one which had taken place under the influence of the blending of peoples. The combined morphological and linguistic study of systems of relationship had led me to recognise that a definite course of social development had taken place in an aboriginal society under the influence of an immigrant people.

I turned next to a Melanesian institution, that of secret societies, concerning which I had been able to gather much new material, and it soon became probable that these societies belonged properly neither to the aboriginal culture nor to that of the immigrants, but had arisen as the result of the interaction of the two; that, in fact, these secret societies had had their source in the need felt by the immigrants for the secret practice of the rites they had brought with them from their former home. A comparison of the ritual of the secret societies with the institutions of other parts of Oceania then made it appear that the main features of the culture of these immigrants had been patrilineal descent, or at any rate definite recognition of the relation between father and child, a cult of the dead, the institution of taboo, and, lastly, certain relations with animals and plants, which were probably allied to totemism, if they were not totemism itself in a fully developed form.

Further study made it clear that those I have called the immigrant people, though possessing these features in common, had reached Melanesia at different times and with several decided differences of culture, but that probably there had been two main streams: one which peopled Polynesia and became widely diffused throughout Melanesia, which was characterised by the use of kava; another which came later and penetrated much less widely, which brought with it the practice of chewing betel-mixture. Traces of a third stream, the earliest of all, are probably to be found here and there throughout Melanesia, while still another element is provided by recent Polynesian influence. It became evident that the present condition of Melanesian society has come into being through the blending of an aboriginal population with various peoples from without, and it therefore became necessary to ascertain to which of the cultures possessed by these peoples the present-day customs and institutions of Melanesia belong, always keeping in mind the possibility that some of these institutions may not have belonged to any one of the cultures, but may have arisen as the result of the interaction of two or more of the blending peoples.

I must be content with this brief sketch of my scheme of the history of Melanesian society, for my object to-day is to point out that if Melanesian society possesses the complexity and the heterogeneous character I have indicated, and is the resultant of the mixture of three or four main cultures, it cannot be right to take out of the complex any institution or belief and regard it as primitive merely because Melanesian culture on the whole possesses a more or less primitive character. It is probable that some of the immigrants into Melanesia had a relatively advanced culture, possibly even that the institutions and ideas they brought with them had been taken from a culture higher still, and, therefore, when we bring forward any Melanesian institution or belief as an example of primitive thinking or acting, our first duty should be to inquire to which stratum of Melanesian culture it belongs.

To illustrate my meaning, I have time for only one example. No concept of Melanesian culture has bulked more largely in recent speculation than that of *mana*, the mysterious virtue to which the magico-religious rites of Melanesia are believed to owe their efficacy. This word now seems on its way to enter the English language as a term for that power or virtue which induces the emotions of awe and wonder, and thus provides a most important element, not only in the specific mental states which underlie religion, but also plays much the same part in the early history of magic. In recent speculation the idea of *mana* is coming to be regarded as having been the basis of religious ideas and practices preceding the animism which, following Prof. Tylor, we have for long regarded as the earliest form of religion, and *mana* is thus held to be not only the foundation of pre-animistic religion, but also the basis of that primitive element of human culture which can hardly be called either religion or magic, but is the common source from which both have been derived. If I am right in my analysis of Oceanic culture, the Melanesian concept of *mana* is not a suitable basis for these speculations. It is certain that the word *mana* belongs to the culture of the immigrants into Melanesia, and not to that of the aborigines. It is, of course, possible that though the word belongs to the immigrant culture, the ideas which it connotes may belong to a more primitive stratum; but this is a pure assumption, and one which I believe to be contrary to all probability. At any rate, we can be confident that even if the ideas connoted by the term *mana* belong to or were shared by the primitive stratum of Melanesian society, they must have been largely modified by the influence of the alien, but superior, culture from which the word itself has been taken. I believe that the Melanesian evidence can legitimately be used in favour of the view that the power or virtue denoted by *mana* is a fundamental element of religion. The analysis of culture, however, indicates that it is not legitimate to use the Melanesian evidence to support the primitiveness of the concept of *mana*. This evidence certainly does not support the view that the concept of *mana* is more primitive than animism, for the immigrants were already in a very advanced stage of animistic religion, a cult of the dead being certainly one of the most definite of their religious institutions.

Further, I believe that the use of the term *mana* in Melanesia in connection with magic, as a term for that attribute of objects used in magic to which they owe their efficacy, is due to an extension of the original meaning of the term, and that it would only be misleading to use the Melanesian facts as evidence in favour of the concept of *mana* as underlying primitive magic. Here, again, I do not wish to deny that a concept such as that denoted by *mana* may be a primitive element of magic; all that I wish to point out is that the Melanesian evidence cannot properly be used to support this view, for the use of the term in connection with magic in Melanesia is not primitive, but secondary and relatively late.

The point, then, on which I wish to insist is that if cultures are complex, their analysis is a preliminary step which is necessary if speculations concerning the evolution of human society, its beliefs and practices, are to rest on a firm foundation.

I have so far dealt only with Melanesia. It is obvious that the same principle that analysis of culture must precede speculations concerning the evolution of institutions is of wider application; but I have time only to deal, and that very briefly, with one other region.

No part of the world has attracted more attention in recent anthropological speculation than Australia, and at the bottom of these speculations, at any rate in this country, there has usually been the idea, openly expressed or implicitly understood, that, in the culture of this region, we have a homogeneous example of primitive human society. From the time that I first became acquainted with Australian sociology, I have wondered at the complacency with which certain features of Australian social organisation have been regarded, and especially the combination of the dual organisation and matrimonial classes with groups closely resembling the totemic clans of other parts of the world. This co-existence of two different forms of social organisation side by side has seemed to me the fundamental problem of Australian society, and I confess that till lately, obsessed as I see now I have been by a crude evolutionary point of view, the condition has seemed an absolute mystery.[1] A comparison, however, of Australia and Melanesia has now led me to see that probably we have in Australia, not merely another example of mixture of cultures, but even another resultant of mixture of the same or closely similar components as those which have peopled Melanesia, viz. a mixture of a people possessing the dual organisation and matrilineal descent with one organised in totemic clans, possessing either patrilineal descent, or at any rate clear recognition of the relation between father and child. This is no new view, having been already advanced, though in a different form, by Graebner[2] and P. W. Schmidt.[3] If further research should show Australian society to possess such complexity, it will at once become obvious that here also ethnological analysis must precede any theoretical use of the facts of Australian society in support of evolutionary speculations.

It may be objected that we all recognise the complexity of culture, and, indeed, in the study of regions such as the Mediterranean, where we possess historical evidence, it is this complexity which forms the chief subject of discussion. Further, where we possess historical evidence, as in the cases of the Hindu and Mohammedan invasions into the Malay Archipelago, all anthropologists are fully alive to the complexities and difficulties introduced thereby into the study of culture; but where we have no such historical evidence, the complexity of culture is almost wholly ignored by those who use these cultures in their attempts to demonstrate the origin and course of development of human institutions.

I have now fulfilled the first purpose of this address. I have tried to indicate that evolutionary speculations can have no firm basis unless there has been a preceding analysis of the cultures and civilisations now spread over the earth's surface. Without such analysis it is impossible to say whether an institution or belief possessed by a people who seem simple and primitive may not really be the product of a relatively advanced culture forming but one element of a complexity which at first sight seems simple and homogeneous.

Before proceeding further I should like to guard against a possible misconception. Some of those who are interested in the ethnological analysis of culture regard it not only as the first, but as the only, task of the anthropology of to-day. I cannot too strongly express my disagreement with this view. Because I have insisted on the importance of ethnological analysis, I hope you will not for a moment suppose that I underrate the need for the psychological study of customs and institutions. If the necessity for the ethnological analysis of culture be recognised, this psychological study becomes more complicated and difficult than it has seemed to be in the past, but that makes it none the less essential. Side by side with ethnological analysis there must go the attempt to fathom the modes of thought of different peoples, to understand their ways of regarding and classifying the facts of the universe. It is only by the combination of ethnological and psychological analysis that we shall make any real advance. To-day, however, time will not allow me to say more about this psychological analysis, and I must continue the subject from which I have for a moment turned aside.

Having shown the importance of ethnological analysis, I now propose to consider the process of analysis itself and the principles on which it should and must be based if it in its turn is to have any firm foundation. In the analysis of any culture a difficulty which soon meets the investigator is that he has to determine what is due to mere contact and what is due to intimate intermixture, such intermixture, for instance, as is produced by the permanent

[1] I may note here that Mr. Lang, after having considered this problem from the purely evolutionary standpoint ("Anthropological Essays presented to E. B. Tylor" p. 203), concludes with the words, "We seem lost in a wilderness of difficulties."

[3] See especially *Zeitsch. f. Ethnol.*, 1909, xli., 340.

blending of one people with another either through warlike invasion or peaceful settlement. The fundamental weakness of most of the attempts hitherto made to analyse existing cultures is that they have had their starting-point in the study of material objects, and the reason for this is obvious. Owing to the fact that material objects can be collected by anyone and subjected at leisure to prolonged study by experts, our knowledge of the distribution of material objects and of the technique of their manufacture has very far outrun that of the less material elements. What I wish now to point out is that in distinguishing between the effects of mere contact and the intermixture of peoples, material objects are the least trustworthy of all the constituents of culture. Thus in Melanesia we have the clearest evidence that material objects and processes can spread by mere contact, without any true admixture of peoples and without influence on other features of the culture. While the distribution of material objects is of the utmost importance in suggesting at the outset community of culture, and while it is of equal importance in the final process of determining points of contact and in filling in the details of the mixture of cultures, it is the least satisfactory guide to the actual blending of peoples which must form the solid foundation of the ethnological analysis of culture. The case for the value of magico-religious institutions is not much stronger. Here, again, in Melanesia there is little doubt that whole cults can pass from one people to another without any real intermixture of peoples. I do not wish to imply that such religious institutions can pass from people to people with the ease of material objects, but to point out that there is evidence that they can and do so pass with very little, if any, admixture of peoples or of the deeper and more fundamental elements of the culture. Much more important is language; and if you will think over the actual conditions when one people either visit or settle among another, this greater importance will be obvious. Let us imagine a party of Melanesians visiting a Polynesian island, staying there for a few weeks, and then returning home (and here I am not taking a fictitious occurrence, but one which really happens). We can readily understand that the visitors may take with them their betel-mixture, and thereby introduce the custom of betel-chewing into a new home; we can readily understand that they may introduce an ornament to be worn in the nose and another to be worn on the chest; that tales that they tell will be remembered, and dances they perform will be imitated. A few Melanesian words may pass into the language of the Polynesian island, especially as names for the objects or processes which the strangers have introduced; but it is incredible that the strangers should thus in a short visit produce any extensive change in the vocabulary, and still more that they should modify the structure of the language. Such changes can never be the result of mere contact or transient settlement, but must always indicate a far more deeply seated and fundamental process of blending of peoples and cultures.

Few will perhaps hesitate to accept this position; but I expect my next proposition to meet with more scepticism, and yet I believe it to be widely, though not universally, true.[1] This proposition is that the social structure, the framework of society, is still more fundamentally important and still less easily changed except as the result of the intimate blending of peoples, and for that reason furnishes by far the firmest foundation on which to base the process of analysis of culture. I cannot hope to establish the truth of this proposition in the course of a brief address, and I propose to draw your attention to one line of evidence only.

At the present moment we have before our eyes an object-lesson in the spread of our own people over the earth's surface, and we are thus able to study how external influence affects different elements of culture. What we find is that mere contact is able to transmit much in the way of material culture. A passing vessel, which does not even anchor, may be able to transmit iron, while European weapons may be used by people who have never even seen a white man. Again, missionaries introduce the Christian religion among people who cannot speak a word of English or any language but their own, or only use such European words as have been found necessary to express ideas or objects connected with the new religion. There is evidence how readily language may be affected, and here again the present day suggests a mechanism by which such a change takes place. English is now becoming the language of the Pacific and of other parts of the world through its use as a *lingua franca*, which enables natives who speak different languages to converse not only with Europeans, but with one another, and I believe that this has often been the mechanism in the past; that, for instance, the introduction of what we now call the Melanesian structure of language was due to the fact that the language of an immigrant people who settled in a region of great linguistic diversity came to be used as a *lingua franca*, and thus gradually became the basis of the languages of the whole people.

But now let us turn to social structure. We find in Oceania islands where Europeans have been settled as missionaries or traders perhaps for fifty or a hundred years; we find the people wearing European clothes and European ornaments, using European utensils, and even European weapons when they fight; we find them holding the beliefs and practising the ritual of a European religion; we find them speaking a European language, often even among themselves, and yet investigation shows that much of their social structure remains thoroughly native and uninfluenced, not only in its general form, but often even in its minute details. The external influence has swept away the whole material culture, so that objects of native origin are manufactured only to sell to tourists; it has substituted a wholly new religion and destroyed every material, if not every moral, vestige of the old; it has caused great modification and degeneration of the old language; and yet it may have left the social structure in the main untouched. And the reasons for this are clear. Most of the essential social structure of a people lies so below the surface; it is so literally the foundation of the whole life of the people that it is not seen; it is not obvious, but can only be reached by patient and laborious exploration. I will give a few specific instances. In several islands of the Pacific, some of which have had European settlers on them for more than a century, a most important position in the community is occupied by the father's sister.[1] If any native of these islands were asked who is the most important person in the determination of his life-history, he would answer, "My father's sister"; and yet the place of this relative in the social structure has remained absolutely unrecorded, and, I believe, absolutely unknown, to the European settlers in these islands. Again, Europeans have settled in Fiji for more than a century, and yet it is only during this summer that I have heard from Mr. A. M. Hocart, who is working there at present, that there is the clearest evidence of what is known as the dual organisation of society as a working social institution at the present time. How unobtrusive such a fundamental fact of social structure may be comes home to me in this case very strongly, for it wholly eluded my own observation during a visit three years ago.

Lastly, the most striking example of the permanence of social structure which I have met is in the Hawaiian Islands. There the original native culture is reduced to the merest wreckage. So far as material objects are concerned, the people are like ourselves; the old religion has gone, though there probably still persists some of the ancient magic. The people themselves have so dwindled in number, and the political conditions are so altered, that the social structure has also necessarily been greatly modified, and yet I was able to ascertain that one of its elements, an element which I believe to form the deepest layer of the foundation, the very bedrock of social structure, the system of relationship, is still in use unchanged. I was able to obtain a full account of the system as actually used at the present time, and found it to be exactly the same as that recorded forty years ago by Morgan and Hyde, and I obtained evidence that the system is still deeply interwoven with the intimate mental life of the people.

If, then, social structure has this fundamental and deeply seated character, if it is the least easily changed, and only changed as the result either of actual blending of

[1] There are definite exceptions in Melanesia; places where the social structure has been transformed, though the ancient language persists.

[1] See "Folk-Lore," 1910, xxi., 42.

peoples or of the most profound political changes, the obvious inference is that it is with social structure that we must begin the attempt to analyse culture and to ascertain how far community of culture is due to the blending of peoples, how far to transmission through mere contact or transient settlement.

The considerations I have brought forward have, however, in my opinion, an importance still more fundamental. If social institutions have this relatively great degree of permanence, if they are so deeply seated and so closely interwoven with the deepest instincts and sentiments of a people that they can only gradually suffer change, will not the study of this change give us our surest criterion of what is early and what is late in any given culture, and thereby furnish a guide for the analysis of culture? Such criteria of early and late are necessary if we are to arrange the cultural elements reached by our analysis in order of time, and it is very doubtful whether mere geographical distribution itself will ever furnish a sufficient basis for this purpose. I may remind you here that before the importance of the complexity of Melanesian culture had forced itself on my mind, I had already succeeded in tracing out a course for the development of the structure of Melanesian society, and after the complexity of the culture had been established, I did not find it necessary to alter anything of essential importance in this scheme. I suggest, therefore, that while the ethnological analysis of cultures must furnish a necessary preliminary to any general evolutionary speculations, there is one element of culture which has so relatively high a degree of permanence that its course of development may furnish a guide to the order in time of the different elements into which it is possible to analyse a given complex.

If the development of social structure is thus to be taken as a guide to assist the process of analysis, it is evident that there will be involved a logical process of considerable complexity in which there will be the danger of arguing in a circle. If, however, the analysis of culture is to be the primary task of the anthropologist, it is evident that the logical methods of the science will attain a complexity far exceeding those hitherto in vogue. I believe that the only logical process which will in general be found possible will be the formulation of hypothetical working schemes into which the facts can be fitted, and that the test of such schemes will be their capacity to fit in with themselves, or, as we generally express it, "explain" new facts as they come to our knowledge. This is the method of other sciences which deal with conditions as complex as those of human society. In many other sciences these new facts are discovered by experiment. In our science they must be found by exploration, not only of the cultures still existent in living form, but also of the buried cultures of past ages.

And here is the hopeful aspect of our subject. I believe our present store of facts, at any rate on the less material sides of culture, to form but a very small part of that which is yet to be obtained, and will be obtained, unless we very wilfully neglect our opportunities. Waiting to be collected there is a vast body of knowledge by means of which to test the truth of schemes of the history of mankind, not only of his migrations and settlements, but of the institutions and objects which have arisen at different stages of his history and developed into various forms throughout the world.

And this brings me to my concluding topic. I have tried to show that any speculations concerning the history of human institutions can only have a sound basis if cultures have first been analysed into their component elements, but I do not wish for one moment to depreciate the importance of attempts to seek for the origin and early history of human institutions. To me the analysis of culture is merely the means to an end, which would have little interest if it did not show us the way to the proper understanding of the history of human institutions. The importance of the facts of ethnology in the study of civilised culture is now generally recognised. You can hardly take up a modern work dealing with any aspect of human thought and activity without finding reference to the customs and institutions of savage or barbarous peoples. It is becoming recognised that a study of these helps us to understand much that is obscure in our own institutions or in those of other great civilisations of the present or the past. Further, there can be no doubt that we are only at the threshold of a new movement in learning which is being opened by this comparative study.

It is a cruel irony that just as the importance of the facts and conclusions of ethnological research is thus becoming recognised, and just as we are beginning to learn sound principles and methods for use both in the field and in the study, the material of our science is vanishing. Not only is the march of our own civilisation into the hitherto undisturbed places of the earth more rapid than it has ever been before, but this advance has made more easy the spread of other destroying agencies. In many parts of such a region as Melanesia, it is even now only from the old men that any trustworthy information can be obtained, and it is no exaggeration to say that with the death of every old man there and in many other places there goes, and goes for ever, knowledge the loss of which the scholars of the future will regret as the scholars of the past regretted such an event as the disappearance of the library of Alexandria. There is no other science in the same position. The nervous system of an animal, the metabolism of a plant, the condition of the South Pole, for instance, will a hundred, or even a thousand, years hence be essentially what they are to-day, but long before the shorter of those times has passed, most, if not all, of the lower cultures now found on different parts of the earth will have wholly disappeared or have suffered such change that little will be learnt from them. Fortunately, the need for ethnographical research is now forcing itself on the attention of those who have to deal with savage or barbarous peoples. Statesmen have begun to recognise the practical importance of knowledge of the institutions of those they have to govern, and missionary societies are beginning to see, what every wise missionary has long known, that it is necessary to understand the ideas and customs of those whose lives they are trying to reform. Still, we must not be content with these more or less official movements. There is ample scope, indeed urgent need, for individual effort and for non-official enterprise. It is not all who can go into the field and do the needed work themselves, but there are none who cannot in some way help to promote ethnographical research. We have before us one of those critical occasions which must be seized at once if they are to be seized at all: the occasion of a need which to future generations will seem to have been so obvious that its neglect will be held an enduring reproach to the science of our time.

SECTION I.

PHYSIOLOGY.

OPENING ADDRESS BY PROF. J. S. MACDONALD, B.A., PRESIDENT OF THE SECTION.

THE special difficulties of physiology are well known to a large section of my audience, but it may be permissible to illustrate them by reference to an individual case. Take for example those small capsules which are found in the kidneys at the very summit, so to speak, of the problem of renal secretion. These small bodies each occupy a space of less than two thousandths of a cubic millimetre. Within their interior they contain several different kinds of blood-vessels that represent the structures of greatest mechanical interest when dealing with the circulatory system, omitting, of course, the heart. This almost complete sample of the circulatory mechanism, itself formed of a congeries of parts and unitary mechanisms, is enclosed by two or three thousand cells of specific glandular function. Every one of these cells again is a complex of mechanisms about which we cannot rightly think until we reduce our conceptions to the level of molecular dimensions. Enclosed then in this minute space, within a mass that weighs two thousandths of a milligramme, lie quite a series of the problems in which physiology is interested.

The difficulties occasioned by this minuteness of parts, and by the manner in which they are complexly mixed together, render direct investigation of single problems possible only in the very simplest cases, as, for instance, the red blood corpuscle and the nerve-fibre.

A consideration of the dynamic properties of the red blood corpuscle is perhaps the simplest task in physiology. By the aid of the centrifuge these bodies can be obtained free from the embarrassing presence of other cells, may even be washed and immersed in definite solutions of known value. In addition, these compressed discs—the study of the forces normally compressing them open to research by variations in the quality of the surrounding solutions—contain no nuclear reactions, and but the one material of primary dynamic importance.

Everyone knows, however, that even in this case the dynamic conditions are being investigated largely in an indirect fashion. The material of primary importance, hæmoglobin, is stable except with regard to the one well-defined reaction with oxygen to which it owes its utility. This material may readily be obtained pure and its properties examined in homogeneous solutions, and these properties may again be studied after adding to this solution such secondary substances, lipoids and inorganic salts, as are also present in the red blood corpuscle. In the hands of members of this section such studies are not only increasing our knowledge of the properties of hæmoglobin, but are also rapidly leading to a knowledge of those very dynamic conditions with which it is surrounded when present within its microscopical site in the red blood corpuscle. In this very simple instance, the parts of the mechanism being known, it is possible to arrange them in such a fashion as to limit our conceptions of the way in which they are actually arranged within the body.

In cases of greater complexity, where no doubt in course of time the same method of indirect attack will be adopted, in preparation for this event, the necessities of the moment largely confine our attention to a discovery of the various parts present in these mechanisms. In fact, the first requirement is a knowledge of the micro-chemistry of these more complex structures, that is to say, a precise knowledge of the chemical materials distributed in minute spaces of microscopical dimensions. It is well known that my predecessor in this honourable post, Prof. Macallum, of Toronto, has contributed largely to our knowledge of these matters, and that he further assisted us to a right conception of the forces in action between these minute masses of material by his excellent Presidential Address to this Section.

Thinking of the body as no more than a collection of chemical reactions, this elaborate separation of parts in a multiplicity of extremely small spaces protects the individuality of a certain large number of reactions, whilst at the same time securing a rich maintenance of contact with supplies of raw material and a ready means for separating the end-products of reactions from the materials in reaction at each point. Every nucleus, surrounded by its constellation of secondary chemical reactions, is thus given certain limits of size, surface, territory, and environment. These are physical necessities of arrangement possible within the conditions of solution met with in the body, and no doubt largely due to physical states developed by each reaction—that is to say, that the products of each reaction exert a physical influence and produce characteristic physical arrangements. It is not without interest to realise that cell-growth, and the increase in nuclear surface with which it is attended in cell-division, is apparently initiated at every centre by what is doubtless a physical process, and what, as Loeb has shown us, may be accelerated by definite physical change. Such effects of growth are best studied in those early days of enormous expansion when the ovum increases to one thousand million times its original weight, and it is at this time that these separative physical consequences of chemical reactions are most apparent.

During this primary expansion not only have the reactions of nuclear matter been extended to occupy some hundred million times more mass, but it is also true that they have been modified in a very large number of ways, and doubtless this as the consequence of special conditions, extrinsic conditions, existing at the time of formation of each separate part. These modifications are largely shown by differences in appearance and structure, and are each attended by some difference in the function of typical groups of cells. A singular persistence in the similarity of structure and function exhibited by successive generations of similarly placed cells is no doubt sometimes due to the maintenance of those special extrinsic conditions which occasioned their initial modification. In these cases reversion to an original type may occur on immersion in formerly pre-existent conditions, and indeed a whole series of different structures make their appearance as the conditions are further variously modified, as is sometimes seen in the regeneration of parts.

There is, however, seen in some cases a greater degree of persistence, studied, for example, in malignant growths, which is largely retained even when the extrinsic conditions are greatly modified; and in such cases there has doubtless occurred some elimination and refinement—that is to say, rather an abstraction than an addition of character—as the consequence of the initial modification.

In certain places in the adult, physical conditions due to the modification and acceleration of chemical reactions are still frequently provocative of nuclear growth and subdivision: thus in the tonsils, follicles, patches, and lymphatic structures generally, that are embedded in the surface of the alimentary canal. These structures, characterised by their great wealth of nuclear material, experience great nuclear change, to which they are largely stimulated by chemical substances derived from foreign organisms. Specifically affected by each chemical substance, they are probably the site of manufacture of specific neutralising substances that are driven from these sites of activity into the portal system almost as soon as the substances exciting their appearance are driven in from the absorbent surface of the alimentary canal.

In other places in the adult, however, such conditions never recur after a certain date in development. In these places the nuclear material has been so refined as to be irresponsive to conditions that accelerate and modify the reactions of nuclear material in other parts. Permanent sites of monotonous nuclear activity are formed and maintained in such places until the moment when some unusually extreme condition still further limits their activity and terminates their existence. It is significant, too, that this may happen when the condition is not sufficiently extreme similarly to cut short the reactions of other parts.

Now the latter case is typically illustrated by reference to the nervous system, which is thus seen as the site of a severely limited quality of chemical activity. That it is also restricted in amount may be further emphasised by reference to the relatively minute quantity of nuclear material which is present in this system. Thus it is probable that if a direct comparison between the cells of the nervous system and the lymphoid cells to which I have alluded were possible, the essential difference found would be a difference between the stability of certain chemical material in the one case, and a frequently modified wealth of chemical reaction in the other; so that of the two, the nervous system would be the more comparable with the red blood corpuscle.

Thus, if when reviewing the wide array of function in which the nervous system participates, we are led to foresee for each of its cells a great variety of chemical change, or, if when surveying the great differences in function of the organs of the body we are led to expect typical chemical differences between those several parts of the central nervous system with which they are individually associated, we are arrested by this clear evidence of a universally distributed monotony of simple chemical state.

It is true that certain drugs affect some groups of cells within this system more readily than others. None of these instances are, however, of such a kind as to demand the inference that there was any essential difference between different groups of cells. In most cases, indeed, it is probable that differences in relative quantity, and in such simple factors as relative state of solution, are responsible for these effects. Thus there is nothing to refute the statement that all the cells of the nervous system contain chemical materials of an exactly similar kind. Just as every liver-cell is like every other liver-cell in its general chemical character, so in the nervous system are all the cells chemically alike.

Glancing from the liver-cell to the nerve-cell, however, there is at once seen a marked difference of a kind we have not yet considered. The chemical experiences of the liver-cell are multifold, but in the main alike for each cell, and it is thus not surprising that the chemical reactions are in the main the same in every cell, no matter how multifold they may be. The physical experiences of the liver-cells are similarly the same for each cell, and we are not surprised that in physical appearance there is as monotonous a similarity between all the cells in the liver as there is a monotonous chemical similarity between all the cells in the nervous system. In the nervous system, however, there is no monotony in the physical character of the cells. It is a notable physical fact that the cells of the nervous system have diverse shapes and sizes, and still more so that these are such as to bring them into a kind of physical relationship observed in no other epithelial organ. It is a notable physical fact that cells originally separated by considerable distances are brought into close contact by a growth of processes, and that they are in this way arranged into chains forming definite paths for the transmission of physical influence through this system.

Before attempting to explain the manner in which physical conditions give rise to this arrangement, I must briefly sketch the differences in physical state which may be met with in these cells. Thus there are the states of excitation, of rest, and of inhibition. I may simplify matters by saying that there are reasons for considering excitation as associated with an increase in pressure, either due to a temporary increase of particles in motion within the solutions of the cell or to some acceleration in the motion of particles initially present. In rest these particles are in their normal quantity and have their normal motion. During inhibition the particles are decreased in number, or have a retarded motion. Associating excitation with an increase, inhibition with a diminution, and rest with normal degrees of molecular activity, we shall not be far away from the facts.

Everyone is aware that increased molecular activity is associated with a tendency to break bounds, or when taking place behind resistant but distensible bounds with a tendency to expand the region of activity. Thus it happens that the excited cell tends to grow in size, whereas, on the other hand, the inhibited cell tends to diminish, and the resting cell to remain unaltered. These several proceedings are possible so long as the surface membranes of the cells, or of structures within them, which form bounds resistant to the pressure of molecular activity, are at the same time porous to water molecules; and this we know is within limits true—namely, that the cell is enclosed by such semi-permeable membranes. Thus when the excited nerve-cell grows in size, and the region of molecular activity is thus increased, the materials within the cell are diluted by an admission of water.

Attention is now directed to the probability that there is some kind of material in solution within the cell which takes no part in this increase of molecular activity; is, on the other hand, retarded in its motion by agglutination into colloidal clusters, and may finally be precipitated. I, for my part, have no hesitation in saying that there is every probability that this is indeed the primary phenomenon of excitation, this precipitation. Leaving that point, however, alone, it is probable that this tendency towards precipitation occurs. This material, precipitated and diluted, thus loses some of that mass-action formerly holding in check its formation by the particular chemical reaction that is always tending to produce still more of it. More of this material is thus produced within the excited cell, and is in turn precipitated, and still more and more. We may therefore think of these excited cells as laying down a structure which I will ask your permission to describe as a cuticle. The nerve-fibre is the cuticle of the nerve-cell. Once give it such a name, as is in part justifiable, and no one will be surprised that these structures are pushed out to an extraordinary distance from their parent cells, and that their length is measured not like other details of cell-structure in thousandths of millimetres, but sometimes in metres, and therefore on a scale with units one million times larger than usual.

If we entertain this idea, that nerve-fibre growth is proportional to excitation, we are prepared for the statement that the physical characters of the cells within the nervous system and their relations to one another are all due to their relative experience of incidents of excitation. We face the fact that their chemical work is of a universally monotonous type, a drearily slow and respectable type, and that their physical features and arrangements are capable of very simple explanation.

Now structure is everywhere the outcome of function, and those functional developments that lead to the growth and differentiation of structure contain the most interesting and most fundamental problems of physiology. If it is thought that the main relationships of parts within the nervous system are fixed from an early date of development, it would then seem that to the physiologist the nervous system is a place of very limited interest. But this is by no means the case, the relationship of parts is by no means a fixture within the nervous system. In so far as it is fixed, it is the sign of the orderly action of circumstance upon the structures of the body, and the result rather than the cause of the monotony of existence. There is, however, no need to labour this point or to debate our interest in this system. One portion of the nervous system is the seat of the mind, a fact to which I will return later. The whole of it is the very essence of the unity of the organism containing it. It is the rapid transmission of physical states through its individual nerve-fibres, and the modifications in transmission determined by passage into its constituent cells, which serve to weld the actions of the several parts of the body into that phase of common action which is suited to the necessities of the moment.

That there is no moment during life when there are not many paths through the central nervous system engaged in this business of transmission is a statement of commonplace realised by all. There are not, however, in my opinion, a sufficiently large number of persons sufficiently impressed by that greater truth, discovered and analysed by Sherrington: that no path is thus busy without there being at the same time some other path maintained in a condition of enforced rest. Whenever the system is excited at one part it is also inhibited at another, and it is this phenomenon that lies at the root of the harmonious effects produced by this system, and forms the means whereby action suspends antagonistic action.

When considering the influence of states of excitation upon the growth and arrangement of structures within this system, it follows then that I cannot afford to omit some proper consideration of the manner in which this phenomenon of simultaneous inhibition may be explained, and of its influence on the growth and arrangements of structures. To get a clearer view of this process we must think in detail of the probable nature of the structures involved in the simplest case of transmission through the system. It is indeed a simple thing to form a picture of the track entering the system, the structure called the afferent neurone. Here we have a long length of cuticle, or nerve-fibre, stretching right from the surface where it is liable to stimulation by change in circumstance, or—more complicated case, but very usual one—by the maintenance of circumstance. This afferent neurone is mainly cuticle. It is true that its cell-body is placed like a hump somewhere on its back, but this is no more than an index that it is never inhibited. Thus from the site of change of circumstance right into the nervous system transmission is of the simplest kind, since all we know of this nerve-fibre is that it transmits most of the excitations it receives at a rapid pace and without loss from one end to the other. We can therefore see the excitation planted by it into every cell with which it comes in contact within the system. By some of its branches it plants this excitation into nerve-cells, whose nerve-fibres pass out to reach the site of action. It is a simple matter again to picture this first set of efferent neurones as receiving an excitation which they then transmit. That there is a certain complexity in the process is a fact with which we are not at present concerned.

But now, what about the site of antagonistic action, the parts that are held in a state of enforced rest? To them also lead perfectly similar efferent neurones, incapable of producing any other effect in the site of antagonistic action than that of exciting it or transmitting excitations towards it. We must therefore conclude that it is this second set of efferent neurones that are inhibited and maintained in a condition of enforced rest. How then does the change transmitted into the several branches of the afferent neurone, having the same character as it invades every branch, succeed in causing diametrically opposite conditions in two groups of perfectly similar efferent neurones? There is but one answer to this question, namely, that transmission into the second group must be through some intermediate mechanism which reverses the character of the change. Now I have no hesitation in naming definite structures in the nervous system as being alone those to which we can impute this reversal, namely, certain intermediate neurones which have a way of being interpolated between afferent and efferent neurones. Such neurones are seen in the cord sometimes sending their main nerve-fibre towards efferent neurones placed on the other side of the cord, and in the cerebellum the large cells of Purkinje are seen to be approached by afferent nerve-fibres in this double fashion; one set reaching them directly, the other set indirectly through intermediate neurones. We shall then picture neurones with short nerve-fibre processes as placed in these paths that are inhibited, and as sometimes responsible for this singular reversal of the transmitted excitation.

In this connection, too, we must deal briefly with another fact observed by Sherrington, that certain drugs, tetanotoxin and strychnine, affect these intermediate mechanisms in such a way that they lose their power of reversing the character of change transmitted through them. When these drugs are applied to any part of the nervous system action and antagonistic action are simultaneous consequences, and the stronger wins. Of the greatest interest, too, is the fact that this disturbance of the process of reversal may be obtained in a graduated manner by the application of such drugs in varied strengths of solution. It is thus clear that there is nothing peculiar about the nerve-fibre portion of these intermediate neurones, since when given excitations to transmit they transmit them, although it is so frequently their normal business to transmit inhibitions. Clear, too, that their cell-bodies frequently inhibited like those of the efferent neurones may also with a slight modification of condition tend towards excitation, or, as a matter of fact, be excited, again like the efferent neurones. There is no difference discoverable here between these two sets of cells other than a difference of degree. The one salient fact demanding explanation is this difference under normal conditions in which the efferent neurones are seen as excited by identically the same character of transmitted change that inhibits the intermediate neurones.

Now it would be a simple matter to show that all these points might be dealt with adequately on the assumption that nerve-cells invariably contained a mixture of two materials, existing in different proportions in different cells, each of which was forced into a diametrically opposite physical state to the other as the result of changes in physical conditions of the kind transmitted by nerve-fibres.

It is of interest then that there is definite reason to suppose that within nerve-cells there are always two substances which seem to have their states diversely affected by different conditions. One of them is the characteristic constituent of what I have been irreverently terming the cuticle, the nerve-fibre; and the other a complex material which apparently represents the primary product of nuclear activity, and is spoken of as the material of Nissl. It may seem a weak point in my use of the term that this cuticle-stuff is found within the cell-body. Perhaps so, but perhaps also not so; the point is not worth discussing.

The point really worth discussion is as to whether it is true that these substances are affected in diametrically opposite ways by the same change, just as if, for example, one of them was possessed of acid and the other of basic characters; so that the basic was precipitated, and the acid dissolved by the addition of an alkali: since if they exhibit any opposite behaviour in the presence of the transmitted excitation, then it is indeed probable that their admixture is responsible for many of the orderly vagaries of transmission through nerve-cells. I am proceeding as if this is really true to a consideration of its influence on the development of nerve-cells.

Imagine a developing afferent neurone in contact with two other neurones, but by different extents of its surface, so that it transmits a larger quantity of change to the one than to the other. In both cases it affects an algebraical sum of opposing properties, and we might think of it as effecting a compression and an expansion. Now let there be the slightest difference in the forces required to compress and to expand, and it might readily happen that the effect of a minimal dose might be to produce an algebraical sum in favour of compression, whilst a maximal created a general effect of expansion. One of these cells then might be habitually excited and grow a cuticle traversing considerable distances in the central nervous system; whereas the other is inhibited until the accumulation of charges previously received add up to the dose required to tip the algebraical sum in favour of excitation, and then first commences the growth of a short nerve-fibre.

This, however, involves the assumption that these cells of both classes store up all the transmitted energy they receive, that they do not leak, do not transmit, and thus grow their nerve-fibres from the effects of accumulation. Within certain limits this supposition is sound, since we are familiar with that summation which is a leading feature in nerve-cell conduction. Below a certain definite quantity of charge they do not leak, and are found by a second impulse arriving some little time after an apparently ineffectual predecessor in a new state, so that the new-comer is effectual. Now if no new-comer arrives in time we must suppose the energy due to the first as having affected the growth of the cell in one direction or another—that is to say, in one direction if it produced the change characteristic of excitation, and the other if producing to a minimal degree the change characteristic of inhibition. It is legitimate, too, to suppose these limits as set by the capacity and extent of excitable contacts. The larger the extent of contact the sooner and the more effectual must be the leakage. Thus we may readily picture the excited neurone as growing more and more cuticle until this growth is checked by the number, extent, and capacity of the excitable contacts made in course of growth. When a certain measure of growth has occurred we may suppose that residual charges below the margin of leakage are now only just sufficient to maintain the district of cuticle that has been laid down. We have therefore encountered the limits of growth of the nerve-fibre.

As for the second cell, which we have considered as mainly inhibited. In it the mass-action of the products of nuclear change is diminished and we must think of it as enlarging its cell-body by an increased nuclear activity; possessed of a short cuticle but an extending cell-body, possessed of no more than a short nerve-fibre and an extensive set of dendritic processes. As each new dendritic process makes contact with a new branch of the excited afferent neurone its growth will be more and more limited. We have here, then, encountered the limits of growth of the nerve-cell.

There is no difficulty other than that due to the short time at my disposal in compounding these statements so as to cover the whole scale of differential cell-growth, and within each cell of the relative growth of its several parts, that is observed within the nervous system. I may perhaps be permitted this abrupt closure to a development of the probabilities underlying the following expression of opinion.

I hold it as probable that all the individual structures of the nervous system, and so in the brain, have just so much difference from one another in size, in shape, and in function, as is the outcome of that measure of purely physical experience to which each one of them has been subjected; and that the physiological function of each one of them is of the simplest kind. The magnificent utility of the whole system, where the individual units have such simplicity, is due to the physically developed peculiarities of their arrangement in relation to one another, and to the receptive surfaces and motor-organs of the body.

To relieve the monotony of this discussion, let us turn away for a moment to the consideration of certain physical mechanisms found in the body, external to the central nervous system; mechanisms that are placed, so to speak, upon the front of that system so that they are capable rather of affecting it than of being affected by it, and this to such a degree that we must suppose them as rather assisting in the development of the central nervous system than as being assisted to their development by the central nervous system. There are, for example, the lens systems of the eyeball and the sound-conducting and resonant systems of the ear. Now, in dealing with the central nervous system, the suggestion was made that it was developed by just such physical conditions as are transmitted through it in its adult form. In dealing with the eyeball, it is clear that an admission of this sort is not easy. During the evolution associated with natural selection the eyeball is formed by light. It must be so. The eye is as perfect an optical instrument as could be made with a full knowledge of the part played by matter and special arrangements of matter in reflecting, refracting, and absorbing light. Long prior to the development of man, who at a later date acquired sufficient knowledge of these properties to aid him in the formation of crude lenses, there was to be found upon the general surface of the animal world lenses of very great perfection, in fact, complete cameras. Had the first optician then known what was in him he would have been saved infinite pains. Had he indeed known even the lens systems formed on the leaves of plants. Surely there is no escape from the statement that either external agency cognisant of light, or light itself, has formed and developed to such a state of perfection this purely optical mechanism, and that natural selection can have done no more than assist in this process. The influence of natural selection depends upon the frequency of variations, and it is important that there is no variation that has not behind it some cause. In this special case of variation in physical arrangements, it is indeed probable that the most frequent cause of variation would be exerted by physical conditions, since in this case the factors that are thus introduced by variation are not distinguished by any chemical peculiarity. Thinking of the few possible physical causes of variation, there can be little doubt that light itself would produce some change in this optical instrument, and that the variations produced by light would be just those more likely to be adapted to the subsequent traverse of light than such as were accidentally produced by some other physical cause. Accepting such a statement, we may say that in the course of development light formed the eye by its action upon such tissues as those of which the general surface of the body is composed. Now in just the same way there can be little doubt but that sound formed the sound-conducting and resonant portions of the ear. We may perhaps go further than this statement, and say that not only has this mechanism placed in front of the central nervous system been formed in this fashion, but that the parts of the central nervous system behind it have been formed by physical effects transmitted from the ear through this keyboard where sound is transformed into nervous impulses. Thus also, when thinking of the semicircular canals, representing as they do the portion of the surface of the body that is still normally excited by just such changes as affected the whole surface of the animal when its habitat was the sea, there is no need to doubt the view that the structures found there were formed by fluid friction; and that the cerebellum was formed as a consequence of the stimuli which have been transformed by these surface organs into nervous impulses.

But if this was the case during the evolution which led up to man, what occurs in the development of the individual? We can afford to admit the possibility that sound may approach the embryo and that fluid friction is responsible for effects observed, but light is obviously no factor in this process. Here there is no doubt that the eyeball is developed into a very perfect optical instrument in the absence of light, and we must ask: What is the force that in this case imitates the action of light? Some force must be held as arranging the several parts of the eyeball in front of the developing retina, and it is probable that before discovering it we should have to refer to the properties of the retina for an answer. We might indeed say that since the retina is a portion of the central nervous system generally characterised by the undoubted possession of electrically charged surfaces, it is always possible that this cause is of an electrical nature. Leave the statement general and it takes the form that the optical mechanisms of the eyeball are formed in the absence of light by some other definite physical cause or series of causes. Place it temporarily in the form where I would like to leave it, both on general grounds and on the evidence that its development is modified by the addition or subtraction of electrolytes: in the absence of light it is probable that orderly electrical forces arrange the developing parts of the eyeball. Now this is really not a surprising statement, since light may probably, even in the first case, be transformed into some other form of energy such as electrical energy when primarily shaping these surfaces. In any case, however, this is the view, that the individual eyeball is an instrument formed probably by some simple set of physical conditions from which light is absent, and that it is used, after a certain abruptly occurring date, by light, a force that has, up to this time, had no access to it, and yet finds it most beautifully formed for its special use.

Now development after all is rather a retrograde affair. Consider the fertilised ovum and its possibilities. A physical condition determines an increase in the chemical activity of the nucleus. At the same time an addition is made to the chemical material of the nucleus. The nucleus then divides and forms an ever-increasing site of modified chemical activity. Each new portion of this extending site is surrounded by cell bodies subjected to different sets of physical conditions, and in touch with different qualities and quantities of states. We may take it as certain that not any of the many extraordinary events which take place happen without definite cause. For example, this must be true of every single cell division. Any particular cause bearing similarly on successive generations of cells, or, as we may say, allowed to prolong its action upon a special mass of changing nuclear reaction, must finally produce states of an almost irreversible kind, eliminating possibilities of variation. Thus we might describe the ovum as a possible source of countless variations, whereas it is probable the cells of formed tissues are greatly limited in this possibility. Early in these processes, it is true, a portion of still fairly aboriginal material is shut off, and through some cause protected from changes leading to violent modification; and to this share there still appertains much of the variable character of the original ovum. Part of the remainder, perhaps the whole of the remainder, is under the heavy grip of circumstances which differ widely in different cases, and is step by step slowly driven into something of that deadly monotony of condition which is so evident in the red corpuscle, in the nerve-fibre, and in a somewhat less degree in the nerve-cell. Knowing this, then, we shall only with difficulty be induced to credit any particular kind of subordinate cell with any special character. When, for example, it is stated that the mind is, so far as the evidence will permit the statement, associated with the brain, and with no other part of the central nervous system, we can hardly get behind this statement. Mind, in man, is associated with the brain. It is conceivable that in animals it may be associated with parts of central nervous systems so simple in arrangement that we single out nothing from them as the brain. It is conceivable that there is something of the kind, indeed, in humble uni-cellular organisms. But in man mind is associated with the brain.

There is also the point that even in the case of the brain, such phenomena as sleep and deep anæsthesia familiarise us with the fact that the mind is not necessarily always associated with the brain, but only with this when in a certain condition.

Now there is no scientific evidence to support or to rebut the statement that the brain is possibly affected by influences other than those which reach it by the definite paths proceeding from the sense-organs and from the different receptive surfaces of the body. It is still possible that the brain is an instrument traversed freely, as the ear, by sound, by an unknown influence which finds resonance within it. Possible, indeed, that the mind is a complex of such resonances; music for which the brain is no more than the instrument, individual because the music of a single harp, rational because of the orderly structure of the harp. Consider such a possibility, and the analogy which I have prepared in dealing with the eyeball is seen to have some meaning, inasmuch as an instrument shaped in the embryo by a certain set of conditions may in due course of time become the play of some new influence which has taken no immediate part in fashioning it. I will not dwell upon the point behind this statement, that I find it difficult to refrain from using the word "soul."

If, however, such a view is considered, it must be said that there is no evidence that any individual physico-chemical phenomenon is developed within the brain that is not developed within other parts of the nervous system, and in a more confused manner, indeed, within the limits of every living cell. It is some special arrangement of dynamic states that must be held to form the special characteristic of the waking brain, and it should be possible in time to define the peculiarities of those special arrangements whereby we are assuming that the mind is, so to speak, caught.

It is true, too, that there are great difficulties offered to the expanded presentation of a statement which suggests a mysterious influence provocative of mind as possessed apparently of something of the nature of a physical force, since it is held to be constrained in certain peculiarities of physical environment to behave in a special way. It is, indeed, almost clear that this influence must be held to affect those physical surroundings, since there is little doubt that mind, *per se*, affects human conduct and animal behaviour, just as it is impossible to conceive mind, where present, as exerting no influence in natural selection. This, although the risks of the environment must always play the greater part in natural selection, and the influence of the mind be conceived as only secondarily affecting the organism through the intervention of the nervous system, or through mechanisms that are substituted for that system. Admitting these facts, we should in this case be obliged to regard mind resonating amongst the distributed dynamic states of the brain as influencing them in a way that might possibly be demonstrable in any physical apparatus closely imitating those states and their distribution.

Then, again, one of the main objections to a suggestion of this kind is that the condition might involve a transformation of energy which should have been discovered as an otherwise unexplainable quantity in the energy equations of the body. There may, however, be no real necessity to conclude that any transference of energy would be involved in such a process. The distribution of dynamic states in the central nervous system which are suggested as playing the part of resonators is, as I have already related, a distribution of opposite states. If we consider how these opposite states, excitation and inhibition, are arranged in any given case, it is seen that the installation of an equal number of excitations where inhibitions were present, and of inhibitions where excitations were present, will give rise to a new pattern of a very different meaning. Now such a change in the distribution of states might entail either no more than the transmission of nervous impulses, a process in which exceedingly small quantities of energy are dissipated, or, indeed, an actual cessation in the transmission of certain nervous impulses, since it is one of the curious features in these states that the one tends to recoil into the other. We might, indeed, make the assumption that an alteration in the setting of the instrument, such as was attended with a change in consciousness, was always attended by this cessation of nervous impulses, so that a brilliant display of mind might be associated with no increase in the transformation of physical energy, but actually with a diminution in the transformation. Under cover of such an assumption it might be held that this mysterious influence of which I have spoken absorbed instead of contributing energy to the system, or that it diverted energy without loss from one part of the system to another.

Now, in my opinion, there is no one at the present time who is in a position to discuss the energy transformation of the central nervous system. Further, there is certainly no one capable of dealing with such peculiarities as might arise in the energy transformation of that part of it, the brain, which is associated with the mind. There are many points to be cleared up, as, for instance, the extraordinary relationship of the central nervous system to the general muscular system, upon which I might be allowed for a moment to dwell. The fibres of skeletal muscle form the largest site of energy transformation from the oxidation of food or fuel, a site in which apparently no such transformation takes place without a coincident exhibition of characteristic muscle function and the performance of some mechanical work, and are dominated in this transformation by impulses discharged from the ventral portion of the central nervous system. This exhibition of function is invariably the cause of a dispatch of nervous impulses into the central nervous system again, along the nerve-fibres passing into its dorsal portion. Now, since the energy set free in muscle is out of all proportion to the small sum of energy transmitted from the nervous system, it is capable, amongst other things, of dispatching back again to the central nervous system a compensating or even an additional sum of energy. The musculature might then be supposed to reinforce the nervous system. Until such points are given their due importance, it would be ridiculous to dogmatise about the energy equations of the central nervous system, and to discuss the amount of energy expended in the performance of movements, or stored in the absence of movements, within this system.

I will not labour these points, upon which I can throw no light, but put forward this expression of belief rather than opinion to explain an attitude revealed in the remainder of this address, and not as based on evidence or in any way a statement of demonstrated or demonstrable fact. The essential point for the moment is this—that there is some loophole for the view that mind is not directly associated with life or living matter, but only indirectly with certain dispositions of dynamic state that are sometimes present within certain parts of it. It is a point of view not without interest to physiology, since it would leave that science free to consider all phenomena present in such forms of life and living matter as carry no suggestion of an association with mind, as nothing more or less than physico-chemical phenomena, which, when thoroughly investigated, would be completely translatable into scientific terms. Then, too, when there is evidence of mind, the view is that it represents a force acting from without upon what is still no more than matter involved in certain chemical and physical states. Incidents of function would, in such a view, pass straightway into the realms of physical and organic chemistry, requiring special methods of investigation alone, because of the localisation of processes and punctate states in minute microscopical parts not readily removed from their surroundings into selected experimental surroundings of the same value.

We are at liberty, then, to deal with this series of physico-chemical experiments, boldly giving each observed difference in circumstance a possible importance in the determination of observed differences of character, and each difference in character a probable explanation in terms of simple differences in circumstance; we may boldly consider the causation of variations, and use the term "natural selection" as equivalent to the physico-chemical limits to the successful maintenance of each experiment. Let us, for example, begin with the blood.

It is at once legitimate, in the first place, to ask how this blood tissue has arisen from variation in the chemical reactions of nuclear material. The argument runs that some ascertainable cause must have produced a material variation which has been preserved by natural selection, and quite probably, too, by the persistence of the cause over some long period in the history of nuclear material. There is no harm for the moment in surveying causes and temporarily fixing upon one that seems to possess greater appropriateness than any other. Therefore I suggest that we take this main characteristic of nuclear material in the blood tissue, that it is engaged in the production of a pigment, and that the most efficient cause determining pigment production is the action of light. Remembering that we are probably dealing with nuclear matter in general from which this particular material has been split off and set aside by subsequent causes, we can admit this postulate. The pigment-forming propensity of blood is thus taken as probably due to the initial action of light upon nuclear material placed near the surface of the body, and there exposed to the action of light.

Our next step is to discover any probable fact which, favoured by natural selection, might drive into the interior of the body nuclear matter that had been so modified by light that it persisted in the formation of pigment; in other words, Why should any pigment-forming reaction ever be removed from the direct influence of light, and a valuable transformer of radiant energy be thus driven into a position of disadvantage within the interior of the body?

Now let us consider the value of those particular instances of pigment formation which have been allowed by natural selection to persist upon the surface of the body. These successes represent experiments that have not been detrimental to the general mass of chemical reactions which form collectively what we call the organism, and we are entitled to ask, In what way are these successes likely to differ from the failures? If we take the possibility that some pigments convert all the light which they absorb into heat, and receive per unit of surface a share of solar radiation measured as seven thousand horse-power per acre, we have a picture that the body surface might thus be exposed at any one time to the transformation of an excessive amount of energy. The square metre of surface which might in the human body be exposed at one time to the sun would, provided with such pigment, absorb in one hour as much heat as is produced by the whole body in twelve hours, and the temperature of the body might be raised a further 20° C. by this means in one hour. It must, then, be an important matter in which the risks of life maintenance have certainly acted along the lines of natural selection, that such pigments, transforming the total energy they receive into heat, must be driven from any place they have temporarily occupied on the surface of living matter. As in the plant, in successful cases this energy must be largely diverted into chemical work. It would not, then, be surprising that certain modes of pigment formation have been eliminated, and that certain other modes, finding a utility of some other kind, have been retained by natural selection in seclusion within the interior of the body. Let us take it that blood-pigment represents such a mode of reaction, and that its influence is mainly to convert light into heat, and, secondarily, in some degree to determine the separation of oxygen from certain compounds, thus also performing some chemical work when under the influence of light.

Now since it is also part of the general line of argument that it was inefficient in this chemical aspect, and on that account driven from the surface of the body, it must be held as incapable of separating oxygen from more stable compounds; and we find an explanation for the fact that it is engaged upon unstable compounds of oxygen, not absorbing much energy in the process of reduction nor liberating much on oxidation.

Since, in regard to all such chemically dynamic pigments, with a utility dependent upon their constant association with some molecular group in which a corresponding reduction process can be effected, it will never be surprising to find this group actually forming a constituent part of the molecule. It is, then, not surprising to find these two qualities, pigment and unstable oxygen compound, present in hæmoglobin, nor to find in this special case that the secondary process has assumed the position of major importance, and that hæmoglobin is no longer of use as a pigment so much as an unstable compound of oxygen. Following this line of reasoning, there is nothing extraordinary in the discovery that such pigments, utilised as "oxygen carriers" within the interior of the body, are found in other situations than in blood—for instance, in the nerve-cells of certain animals and commonly in skeletal muscle. Blood tissue represents a special set of nuclear reactions possessed of this persistent quality in marked degree.

If it seems strange that the initial formation of blood in the embryo and its maintained formation in the adult persist in the absence of light, let us return to the instance of the eyeball. Of that instrument it was said that, although it was originally formed by light, yet in the mammalian embryo its formation was continued in the absence of light. Here it was necessary to think of some replacement of one cause by another, and not difficult to adopt such a suggestion, since even in the initial process it was probable that light produced its effects subsequent to transformation into some other form of energy, such as electricity. In that particular case this idea of forces, and substituted forces, in action, is capable of being formulated in fashion readily understood, because of the ease with which we can think of arrangements in gross parts being determined by such forces. Here in this new case we are, however, thinking of parts of a different order of magnitude, a fact which I can best illustrate by reference to a single red blood corpuscle occupying a one-tenth millionth of a cubic millimetre, and containing in a one-hundredth part of that space as many molecules of hæmoglobin as there are present red blood corpuscles in one cubic millimetre of blood—that is to say, five millions.

Now there is, in reality, no difficulty in considering some electrical agency as limited in its action to the minute dimensions in which each pigment-forming reaction is in process; some electrical machine such as, for example, might be energised by electrons derived from the dissolved molecules of a pigment-salt; such a machine as might be capable of transforming both light and heat into electrical energy, and which would maintain a process in the absence of light at the cost of energy obtained in the form of heat.

When thinking of the persistence of such reactions as this, initiated in this way by the action of certain primary causes that are then subsequently removed without any cessation of the reaction, we are concerned with one of the fundamental properties of living matter. Everywhere in living matter numerous instances of this property are being discovered, as in the study of immunity and of protection from infection. Nor is there reason to believe that this persistent quality of such variations will not finally be explained in terms of physical chemistry. The main characteristic of living matter is that it contains machines formed by electrolytes distributed upon the complex surfaces of matter in a state of colloidal solution and in the presence of competitive solvents, and that such machines are multiplied within it. Some of these mechanisms are arranged and perfected by the action of physical conditions operative on the surface of living matter, as, for instance, light. Some by energy derived from internal sources, but in a form that embodies conditions originally derived from the surface. Some are primarily due to internal disturbances in the equilibrium of these complex solutions produced by those chemical reactions which take place there.

Now, returning to the grosser characteristics of blood, we find it possessed of other characters curiously reminiscent of the surface of the body, and especially of glandular invaginations from the surface. Thus it is everywhere confined by cells spread upon its surface, the endothelium, which limit its relationship to the general mass of the interior. Its new-formed cells are again passed into an internal core covered by these surface cells, and from this situation, except as a result of violence, they do not pass. We might, in fact, compare the blood to a gland in which the red blood corpuscles were seen as a secretion occupying a lumen which represents the original external surface of the body. I do not wish to lay any emphasis on this point except in so far as it renders clearer this thought: that blood covered by its endothelium represents a single tissue which tends, like any gland, to grow into every interstice of the body, where the conditions of mechanical pressure permit. I shall render the point clearer by saying that the blood capillaries are no more and no less than blood-tissue.

In its early days this blood-tissue, or, if you will, this capillary network, is pushed into each portion of the body by pressure due to its growth. In its later stage the tissues surrounding it, which form the muscular coat of the heart and the walls of the blood-vessels, are arranged into an external mechanical system providing a new pressure, which still further tends to push the blood-tissue into every available space, a process such as, for example, takes place in tumour development and in the granulation tissue present in wounds.

It is a general postulate that cells long exposed to constant conditions may come to be stamped by those conditions. Special change takes place from the time when the blood grew onward by pressure of its own growth to the time when this movement is more clearly determined by the mechanism of the circulatory system, and divergent results occur in different localities of the blood-tissues which can be attributed to the differences in these causes of onward motion. Thus where growth is the leading cause of this progressive motion, as, for example, in the development of bone, the blood-tissue is later found occupying spaces that are cut off from the general mass except by lines of communication too small to transfer a full share of pressure from the circulatory mechanism. In this isolated space the blood-tissue preserves to a greater degree powers of intrinsic growth than in those places where the tissue bears the brunt of new forces. It is true that other factors induced by the new motion given to the fluid core of this tissue complicate this matter. This notwithstanding, it is, however, clear that certain definite differences in circumstance, and those principally of a purely mechanical kind, leave the blood-tissue in one district possessed of aboriginal properties which are in a large degree lost elsewhere.

As to that other tissue, which forms the circulatory system and embraces the blood-tissue, there is here little room for doubt that the structures found are the result of special local conditions acting upon originally similar cells, and little room for the suggestion that samples of several different kinds of special formative cells are driven into these positions by destiny and not by mechanics. This is an old theme, well extended and illustrated by exact observation, especially by Thoma; that in every blood-vessel the arrangement of structures is an almost immediate guide to the conditions of pressure met with in that vessel. Let us proceed through the structures in the walls of a small artery, giving a definite mechanical origin to each tissue. The elastic tissue first met with in the inner coat of the vessel is the result of periodical or intermittent pressure. In the large arteries, where intermittent pressure is the main phenomenon, and where its influence is felt right through the thickness of the wall, this elastic tissue has the major share in forming the structure of the wall. In the small artery, where the total quantity of the causative phenomenon is small, the innermost structures are affected most. This inner zone, formed under the influence of intermittent pressure, protects from intermittency the tissue formed by constant pressure, involuntary muscle. Both with regard to this tissue and with regard to the elastic tissue, it is to be remembered that the conformation of the material embracing the cylindrical mass of blood-tissue is such as to convert incidents of internal pressure into tension as well as pressure. Thus we may say that elastic tissue varies in quantity with the value of intermittent, involuntary muscle with the value of constant, pressure, and tension. On the outer surface of this case, still more protected by the mechanical value of the structures internal to it, but submitted to the traction and friction of surrounding tissues, comes white fibrous tissue. Again, when windows have been cut in the outermost case of large vessels, leaving the inner case intact, and thus destroying the tensile character of the mechanical conditions and permitting the internal pressure to hammer through these windows, they have been found closed in by plaques of cartilage, and even by true bone. It is true that the explanation offered for such results has been different from that here inferred, it being held that cells specially formative of cartilage and bone have been admitted to this new situation by the brusque strokes of operating instruments. True, too, that the complete ligature of vessels has been followed by developments of bone in unexpected places beyond the walls of the blood-vessels, as in the pelvis of the kidney; but how can you make a better internal hammer and better provide for its constant use than, for example, by tying the renal artery? Let me state it as probable that white fibrous tissue, involuntary muscle, and elastic tissue are produced by tension, whereas bone and cartilage are formed by pressure. If we credit the main statement that they are first formed from originally similar cells by circumstances special to each case, and that the difference lies in the circumstances and not in the cells, together with the statement illustrated in former paragraphs that modifications tend to persist when once introduced, we shall probably get near to the truth of the matter. Now it is impossible to leave this special case of the circulatory system—special because here there is no doubt that mechanical conditions are operative from the earliest days of development and from the first beat of the heart—without touching upon two points: the origination of the heart itself and the formation of valves.

Picture the blood-tissue in its earliest form as a lacery of networks distributed in a layer throughout the embryo, protected better by the greater thickness of material covering the central longitudinal axis than at the edges. In the absence of this protection the peripheral parts are subjected to incidents of compression which set pressure-waves travelling along the meshes of this blood-tissue in all directions from the point primarily affected. Since these waves will tend to be reflected within the tissue, we can think of the disturbance caused by them as possessed of a certain periodic recurrence of rhythm determined in its time-relations by the dimensions of the tissue, and as undergoing a tendency to modification as these dimensions are increased. In the earliest stages, whilst the distance from edge to edge is less than one millimetre, giving these waves the very slow rate of one metre per second, we can imagine these periodic changes in pressure exerting their influence upon the tissues enveloping the blood with a frequency of one thousand per second. It is again not difficult to imagine that the protection afforded to the central axial portion, through which each wave must pass in transit from edge to edge, allows us to think of the tissue there as more pressed upon than pressing, so that in this place our attention is directed to the enveloping tissue-cells receiving this rapidly recurring stimulation and being especially affected in the process into a formation of cardiac muscle. Since cardiac muscle resembles so closely in many minute particulars skeletal muscle, which is developed mainly under the influence of electrical discharge from the central nervous system, we must, if consistent, suppose that here, too, the same force is in action. In this, however, there is no difficulty, since it is a simple matter to explain how mechanical pressure may give rise to electrical change, as, for instance, when a nerve is excited by mechanical pressure. There is, however, probably this distinction between skeletal and cardiac muscle, namely, that the electrical stimulus provocative of the latter is of a high frequency and approximates nearer to what I might describe as a constant electrical current. The heart is not by any means the only site of formation of rhythmical contractile tissues, and in these other cases, so far as I am acquainted with them, a similar state of formative conditions may be described. Thus at those points where the conical apices of that second network, the lymphatic system, are forced by pressure of external parts to flow towards certain points in this blood-tissue, rhythmical lymph-hearts are described as developed in these protected sites prior to the final penetration of the blood-tissues, and the forced commingling of lymph with the fluid core of the blood.

Now give the agency that I have described a certain direction, crediting it with a graduated qualitative influence in different parts in correspondence with the date of their formation and with the altering dimensions of the blood-tissue as a whole, and the peristaltic character of the movement subsequently performed by the contractile tissue may be completely explained. Let us, then, suppose that such a peristaltic contractile mass is formed in these enveloping tissues, and consider how it will affect the blood, again enveloped by its own endothelial cells. When driven forward away through this site, the endothelial covering, which at first will slip upon the enclosing heart, later will acquire some attachment by the precipitation of fibrous tissue due to repeated friction. The movement of the endothelial cells is now only partial. They have become describable no longer completely as the surface cells of blood-tissue, and are in a measure the internal covering of the heart, its "tunica intima." With each pulsation this intima is dragged onwards to some slight degree behind the blood column to which it originally belonged. There is no difficulty whatever in thinking that valves are necessarily formed at every point where the conditions are such as tend to break up the blood column into separate parts. Indeed, we may look particularly at every place where valves are found in the blood-vessels and see similar factors at work. In the arterial system there is no projection forwards of interrupted columns of blood, nor is this the case in any of those veins in which no valves are found, as notably in those veins that are protected from partially distributed results of external pressure by the rigidity or by some other incident in the conformation of the framework in which they are found.

And now let us turn to the main function of this developing system, which is to drive the blood in continual sequence past tissues that contribute to it and tissues that abstract from it certain chemical materials, and let us select the main incident, namely, the carriage of oxygen from the lungs to other parts. That this is a main incident is clearly shown by the fact that the red corpuscles which form so important a feature in the structure of blood are formed in a number directly equivalent to this demand, that the blood should be capable of transferring a certain quantity of oxygen. Thus if these structures are lost by hæmorrhage, or rendered less efficient by the presence of carbon monoxide, or when circumstances for the acquisition of oxygen are peculiarly difficult, as on high altitudes, their formation is proportionally accelerated. That negative pressure of oxygen governs blood-production is a statement which will bear some inspection.

Now here we have a function which for its perfect performance is dependent upon another machine, the respiratory mechanism, which in its turn is governed by a different but correlated factor, namely, the carbonic-acid pressure in the blood. In this case we may say that the positive pressure of carbonic acid dominates the quantity of the respiratory activity. It is well known now that this statement has been set on firm ground.

It is interesting, then, to observe how these two mechanisms are brought into exact correlation by the simple fact that the lung surface, a portion of the respiratory mechanism, is formed accurately to a measure provided by the volume of blood dispatched from the heart, and therefore probably by that second growth of blood-tissue which I have spoken of as due to pressure from the heart. The surface of the lungs is some eighty square metres. The heart at each stroke sends into the lungs somewhere about 100 cubic centimetres of blood containing red corpuscles within a total surface also of eighty square metres. Here, then, we have a mechanical link connecting these mechanisms that is obviously forged by an incident of use.

Within the central nervous system, where development mainly affects the shape and distribution of structures rather than their chemical quality, affecting thus what we might call the geography of the system, interesting geographical facts attest to the same forged linkage of mechanisms. Thus, for example, we have the so-called "sympathetic system," offering at first view a curious anomaly to the more usual, somewhat segmental, distribution of nerve-fibres, since from the region of the cord related to the trunk of the body nerves pass through this system to control tissues placed in the head and in the limbs. This anomalous geographical fact is, however, at once explained when we regard the part played by this sympathetic control in the several parts of the body as merely subservient to the interests of locomotion. Under its influence the eye is set for out-of-door, or, if I might say it, for out-of-cave, vision. The heart is accelerated. The glandular organs, with the exception of those useful in times of much exertion and heat production, like the sweat glands, are set at rest, or else the motor organs of special importance in their sphere of influence are quietened. Regarding the matter in this light, there is an obvious convenience of geographical fact in the situation of this instrument midway between those parts of the central nervous system that are swept at this very time by nervous impulses dominating the movements of the limbs, just as there is some convenience in the chemical linkage which has been discovered between the different parts of this sympathetic system that further tends to permit their unison of activity.

On the other hand, when the muscles are at rest and the condition of the body is of the indoor description, the eye is set for close vision, and various glandular organs are allowed to conduct their functions under the influence of nervous mechanisms placed at some distance from the disturbing centres of nervous activities that are used in locomotion.

Doubtless this useful distribution of parts within the nervous system must find an explanation in the same terms as must the dynamic anatomical relation to which I have drawn attention as linking up the respiratory and circulatory systems, namely, the fact that the heart sweeps past the surface of the lungs at each stroke red corpuscles that have the same extent of surface as the lungs. In both cases it is true that the right adjustment of the several parts of this machine has been arrived at as a consequence of use, and that these mechanical linkages are due to circumstances of a purely physical and chemical nature.

In conclusion, I might say that these instances have been selected to illustrate my opinion that some of the experiments of greatest interest to physiology are in process of conduction within the normal body, and are to be observed by records imprinted on its structures. In feeling for the keys whereby each set of records may be interpreted, it is necessary that someone should frankly attempt to assign a definite meaning to every incident of structure. That this attempt should be limited by precise thinking goes without saying, and I may be allowed the hope that my transgression outside the realms of precision have not been beyond the tolerance of this section of the British Association for the Advancement of Science.

NOTES.

A DEPARTMENTAL committee (consisting of Mr. Angus Sutherland, C.B., chairman, Mr. J. E. Sutherland, M.P., Mr. H. M. Conacher, Dr. T. Wemyss Fulton, and Mr. J. Moffatt) has been appointed by the Secretary for Scotland to inquire into and report upon the character and national importance of the inshore and deep-sea fisheries of Norway and other countries engaged in the North Sea fisheries, and the efforts made for the development of the fishing and fish-curing industry in all its branches, including (1) the systems of fishery administration, including the constitution and function of the local committees formed for this purpose in Norway and of any similar organisations in the other countries; (2) the facilities provided for research and for educating and training those engaged in these industries, by the establishment of technical schools, museums, laboratories, classes, or other special facilities; (3) the nature of the various means of capture employed and the methods (including any use of State credit) by which fishermen obtain the necessary capital to maintain the efficiency of their vessels and equipment; and to report in regard to each of the foregoing matters whether it would be advisable for similar action to be taken, with or without modifications, in the case of the Scottish fishing industry, and, if so, what means should be adopted.

REUTER messages from Catania state that frequent earthquake shocks, some of which were fairly severe, have been recorded at the Etna Observatory. The records in the seismic apparatus are reported to be almost continuous and very distinct. The volcano is throwing up dense clouds of smoke, and a rain of cinders is falling as far as Catania. There is also a broad stream of lava, which is destroying the vineyards in its path.

ON Saturday, September 9, the aërial post was inaugurated by Mr. Gustav Hamel, one of our most brilliant flyers, who carried a sack of letters in a Blériot monoplane from Hendon to Windsor in thirteen minutes. Starting at five minutes to five in the afternoon, he arrived at his destination, nineteen miles distant, at 5.8, so that his speed, the wind being behind him, was about 105 miles an hour. The other aviators who should have started were prevented by the thirty-mile wind, and no further deliveries took place until Monday, when Messrs. Greswell and Driver carried six mail-bags over in the early morning. M. Hubert, in an effort to follow, had a bad fall, damaging his machine and severely injuring himself. The affair has aroused great interest, so much so that it is as well to sound a word of warning and say that the aëroplane post is neither practical, useful, nor economical. Letters can be sent far more cheaply, trustworthily, and conveniently by train or motor-van, and it is to be expected that these conditions will continue for the next half-century at least. From a philanthropic point of view the post has been a success, large sums having been received by the sale of letters and postcards, which are to be devoted to charity; but from the aëronautical point of view it proves nothing and promises nothing. Besides, it is unthinkable for very many years to come that we should put good aviators to the menial task of carrying mails regularly.

The Zeppelin airship *Schwaben* made a successful non-stop flight on September 6 from Baden Baden to Gotha by way of Frankfurt-on-the-Main. It left Baden at 6.10, and descended at Gotha at 12.30, covering a distance of about 200 miles. It carried seven passengers in addition to the pilot. On September 9 it flew from Gotha to Berlin, and on September 12 it carried eight passengers from Gotha to Düsseldorf.

Particulars are given in *The Times* of the anthropological research expedition to the islands of Normanby, Fergusson, and Goodenough, in British New Guinea, funds for which are being provided out of the Oxford University common fund and by several of the colleges. The work has been undertaken by Mr. David Jenness, of Balliol College, who proposes, unaccompanied, to spend a year amongst people who are admittedly cannibals. Mr. Jenness started on his journey last week. It is stipulated by the University, in contributing to the expedition, that the University museum shall have the first offer of articles of interest which may be obtained. Assistance has been promised by the missionaries on Goodenough Island, including the use of a boat and native oarsmen. The first few weeks will be spent in cruising around the islands endeavouring to get on friendly terms with the people and in studying the trade relations, after which Mr. Jenness hopes to settle down for some time; later he will proceed on a mission boat to Rossell Island, at the eastern end of the Louisiade Archipelago, to study some ethnological problems concerning the relationships of Oceanic peoples. Mr. Jenness has been provided with the latest scientific instruments, including a phonograph for recording native songs and speech.

A preliminary announcement with reference to the eighth International Congress of Applied Chemistry, which is to be held in Washington, D.C., U.S.A., on September 4, 1912, and in New York on September 6 to 13, 1912, has been sent to us. We learn from it that the sections will be devoted to the following subjects:—(1) analytical chemistry; (2) inorganic chemistry; (3*a*) metallurgy and mining; (3*b*) explosives; (3*c*) silicate industries; (4) organic chemistry; (4*a*) coal-tar colours and dyestuffs; (5*a*) industry and chemistry of sugar; (5*b*) indiarubber and other plastics; (5*c*) fuels and asphalt; (5*d*) fats, fatty oils, and soaps; (5*e*) paints, drying oils, and varnishes; (6*a*) starch, cellulose, and paper; (6*b*) fermentation; (7) agricultural chemistry; (8*a*) hygiene; (8*b*) pharmaceutical chemistry; (8*c*) bromatology; (8*d*) physiological chemistry and pharmacology; (9) photochemistry; (10*a*) electrochemistry; (10*b*) physical chemistry; (11*a*) law and legislation affecting chemical industry; (11*b*) political economy and conservation of natural resources. Further particulars of the prospective arrangements of the congress may be obtained from the secretary, 25 Broad Street, New York City, U.S.A.

The autumn meeting of the Institute of Metals will take place at Newcastle-on-Tyne on September 20 to 22, and the reading of the undermentioned papers has been arranged for:—the corrosion of brass, with special reference to condenser tubes, by Mr. P. T. Brühl; further note on the nature of solid solutions, by Mr. C. A. Edwards; the electrical conductivity and constitution of alloys, by Dr. W. M. Guertler; volume changes in the alloys of copper with tin, by Mr. J. L. Haughton and Prof. T. Turner; non-ferrous metals in railway work, by Mr. G. Hughes; the failure of a brazed joint, by Prof. H. Louis; the mechanical properties of hard drawn copper, by Mr. D. R. Pye; the alloys of aluminium and zinc, by Dr. W. Rosenhain and Mr. S. L. Archbutt.

We learn from *Science* that the third National Conservation Congress will be held in Kansas City on September 25 to 27. It will be remembered that the general objects of the congress are to provide for the discussion of the resources of the United States as the foundation for the prosperity of the people; to furnish definite information concerning the resources, and their development, use, and preservation; to afford an agency through which the people of the country may frame policies and principles affecting the conservation and utilisation of their resources, to be put into effect by their representatives in State and federal Governments.

The third congress of the International Society of Surgery will take place in Brussels on September 25 to 29, and a lengthy programme of papers to be read and discussed has just been issued.

At the meeting of the Astronomical and Astrophysical Society of America, held at the Dominion Observatory, Ottawa, on August 23 to 25, Prof. E. C. Pickering was re-elected to the presidency and Prof. Hussey to the secretaryship. The next annual meeting is to take place in August next at the Allegheny Observatory, Pittsburg.

It is announced in *Science* that Mr. Arthur A. Allen, instructor in neurology and vertebrate zoology in Cornell University, is to spend next year in South America as chief of an expedition organised by the American Museum of Natural History. The expedition will go to Colombia, its immediate object being to explore ruins and collect antiquities.

The New South Wales Government, in consequence of the efforts of Prof. Edgeworth David, F.R.S., has granted the sum of 7000*l.* towards the cost of Dr. Mawson's Antarctic expedition. The amount subscribed locally has now reached 19,100*l.*

The sum of 500*l.* a year for two years has been given to the Sheffield City Council by Mr. Douglas Vickers to cover the cost of a trial of the tuberculin treatment for consumptives, and Dr. Chapman, formerly of the Sheffield Infirmary, has been appointed to superintend the treatment.

The twenty-sixth annual congress of the Incorporated Sanitary Inspectors' Association met at Yarmouth last week under the presidency of Sir James Crichton-Browne, F.R.S., who in his opening address made the following remarks on the subject of tuberculosis:—For all practical purposes the identity of human and bovine tuberculosis is established, and we can hold fast to the faith which had been unquestioned until Koch launched his thunderbolt—the explanation of which was afforded by the Royal Commission report. It was the difficulty he experienced in communicating human tuberculosis to calves, cattle, and pigs, whether by injection or feeding, that led Koch to conclude, too hurriedly, that human and bovine tuberculosis were specifically different. The fact of the comparative immunity of calves, cattle, and pigs to human tubercle bacillus enabled them to realise how much they were indebted to the labours of the Royal Commission. It misled Koch; it would have misled many less experienced investigators; and but for the appointment of the commission there would have been a series of repetitions of Koch's experiments under restricted conditions and an accumulation of testimony that he was quite right in declaring that bovine and human tuberculosis were distinct diseases, followed by a mischievous relaxation of the measures directed to prevent the communication of bovine tuberculosis to human beings and the loss of innumerable lives. The commission fulfilled its mission, and there is now irrefragable evidence that mammals and man can be reciprocally infected with tuberculosis, with the prospect of the introduction of stringent administrative measures for preventing the propagation of tuberculosis among human beings by means of food. Bovine animals are only comparatively, not completely, immune to the human tubercle bacillus, and human beings are notably susceptible to the bovine tubercle bacillus, which produces in them even the pulmonary forms of the disease. He went on to emphasise the necessity of general legislation, applicable to the whole country, to cope with the evil of tuberculous milk supply.

SEPTEMBER this year is proving exceptionally warm, and the record summer is extending its influence into the early autumn. On seven days out of the first twelve in September the shade temperature at Greenwich has exceeded 80°, which brings the total days with 80° and above to forty-four for the summer so far, which is four more than any previous record during the last seventy years. The average maximum temperature for the first eight days of the month is 2° higher than any previous record for the same period. The maximum temperature at Greenwich on September 7 was 92°, and on September 8 94°; the latter is 2° higher than any previous temperature so late in September. There have already been seven days during the summer with the temperature above 90°, and 1868 is the only other summer in the past seventy years with an equal number of hot days. The aggregate rainfall at Greenwich from July 1 to September 12 is 1·62 inches, which is 30 per cent. of the average, and rain has only fallen on twelve days. When a complete discussion is made of the very remarkable summer, it will be full of interest.

THE Parliamentary report of the Meteorological Committee for the year ended March 31 shows that the business has been exceptionally important; the office was transferred to South Kensington, where a museum of instruments and objects of interest, and a small physical laboratory, have been provided. The transfer to the committee of the administration of the Kew Physical Observatory and of the magnetic observatory at Eskdalemuir (to which we have before referred) was carried out. In addition to many useful official publications, we note that Dr. Shaw has completed a book (more particularly for the use of aëronauts) on "Forecasting Weather," which embodies the results of the work of the office in connection with dynamical meteorology during the last ten years. The reports of the operations of all the various departments exhibit great activity. Upwards of 3000 registers of various classes relating to the meteorology of the ocean were received. The information has been utilised in the preparation, *inter alia*, of the monthly meteorological charts of the North Atlantic and Indian Oceans (to which we have frequently referred). Considerable improvements have been made in the maps and tables of the Daily Weather Report; several stations in or near London are now included in a separate table. The usual forecasts have been supplemented by a "further outlook" giving the prospects for a longer period when practicable. The success of these and of the usual forecasts and storm warnings during the year was very satisfactory; wireless telegrams from the mercantile marine were generally received too late for the chart of the current day, but were nevertheless frequently of great assistance to the forecaster. The investigation of the upper air by kites and balloons has been regularly carried on; a systematic attempt was made to ascertain the effect of solar radiation on the instruments, &c. The result, so far as it goes, is said to show that distinctly higher temperatures are recorded while the sun is shining.

To the first part of the *Bergens Museums Aarbok* for 1911 Captain H. Negaard contributes a paper on the earliest population of the Hardanger Field district of south-western Norway, with descriptions and illustrations of their works, weapons, and implements. Among the former, the abundance of remains of Megalithic structures of the Stone age is specially noticeable. In a second paper Mr. J. A. Grieg records the vertebrate remains found among these "boplader," which include those of trout, ptarmigan, willow-grouse, plover, reindeer, and lemming.

DR. FLORENTINO AMEGHINO emphasises his views on early human development in South America in a paper entitled "La antigüedad del hombre en la República Argentina" (Atlántida, tomo iii., 1911). The stratigraphical studies of Wilckens are quaintly described as formed in the cabinet during "un acceso de ameghinofobia aguda." The paper is mainly an answer to the work of A. Mochi in the *Archivio per l'antropologia*, in which the age of the beds containing human remains is held to be in accord with what is known in Europe, while doubt is thrown upon the materials brought as evidence from underlying strata. Ameghino claims certain diminutive eoliths from the South American Eocene as having been fashioned by the precursors of man. His general position is that Argentina may be able to show what European stratigraphy fails to prove, and this, of course, no scientific geologist can overlook.

IN an article on the adaptation of the Primates, published in *The American Naturalist* for August, Prof. F. B. Loomis expresses the opinion that the group, of which the earliest known representatives are the Lower (Wasatch) Eocene Anaptomorphidæ and Notharctidæ, originated in the forest tract north of Hudson Bay, which then enjoyed a tropical climate. "From this ancestral centre the first Primates, along with other groups, migrated in all directions possible. . . . This opened three paths, one south into America, a second south-easterly into England and France, and a third south-westerly into Asia, thence ever southerly across China and India and along the Indo-Madagascar isthmus (or chain of islands) to Madagascar and Africa." At an early date the group became differentiated into fruit-eaters (Anaptomorphidæ, followed by the modern Tarsiidæ) and general feeders (Notharctidæ—giving rise to the tropical American Cebidæ—and the European Adapidæ, from which are derived modern Old World apes and monkeys, while a side-branch gave rise to lemurs). The Cebidæ probably reached their present home from the north during the Eocene, while the Old World Primates travelled from America *via* Bering Strait, and made their way south through eastern Asia to Madagascar and

Africa, reaching England in the Upper Eocene. "With the close of the Eocene the first adaptive radiation of the Primates was complete, and they had achieved an almost world-wide distribution. At the end of the period the North American contingent was extinct, the South American group was isolated, the Asiatic and African forms were scattered on islands and on the African continent, and the European contingent was located in central and southern Europe . . . and it is among these that the next act in the great primate drama took place." To follow the views of the author on this point would take too much space, but it may be mentioned that he adopts the opinion as to the Asiatic origin of the man-like apes and man, considering the Fayum forms described by Schlosser as being probably referable to the Cercopithecidæ. In conclusion, it may be observed that the views of Mr. Loomis differ essentially from those of Dr. Standing (Trans. Zool. Soc., 1908), who believes American monkeys and lemurs to have been differentiated in an equatorial continent connecting Africa with South America.

Vol. vi., No. 15, of the University of California Publications in Zoology contains a contribution (pp. 353–468, pls. 33–48), by Edna Earl Watson, on the unsegmented cestode Gyrocotyle, which is parasitic in the spiral valve of certain chimæroid fishes. The history, occurrence, and gross anatomy of the genus are considered, the distinctive characters of the four known species are pointed out, and the morphology and histology of the systems of organs described. The intermediate host and life-cycle of Gyrocotyle are still unknown. Interesting observations are presented on the functional orientation of this parasite. The acetabulum is directed anteriorly, and its exploratory function is strongly in evidence; it never acts as an organ of fixation. The rosette is posterior, and functions strictly as an organ of attachment. Near the acetabulum is a pair each of sensory pits and papillæ abundantly innervated from the neighbouring portion of the central nervous system, which the author regards as corresponding to the "brain" of a turbellarian. The rosette portion of the nervous system, developed in connection with the powerful posterior organ of attachment, is comparable with the posterior ring commissure in the posterior sucker of a heterocotylean trematode. The rosette of Gyrocotyle is a true scolex, in structure and function, and corresponds to that organ in the segmented tape-worms. On the basis of this and other evidence, the scolex of a cestode is regarded as a posteriorly situated organ of attachment, the "neck" or growing region as the ante-penultimate region, corresponding to the growing zone in annelids, and the proglottis as the intermediate region of the body. According to this view, the anterior end in the tape-worms has disappeared.

Part i. of vol. ii. of the entomological series of Indian Forest Memoirs, by Mr. E. P. Stebbing, contains a detailed account of the pests of the Deodar, and some sketches of the insects that have been observed to prey upon some of these pests, which should be extremely useful to forest officers of every grade. The number of pests, mostly from the Deodar forests of the N.W. Himalaya, which the author discusses, include fourteen species of beetles, six species of lepidopterous caterpillars, and two saw-fly caterpillars, the majority of which are specifically identified, those that are not named being sufficiently described and figured for recognition by the forest conservator. Among the injurious beetles, three species of Scolytus, which are regarded as destructive above all others in the area specified, are said to be quite peculiar to the Deodar. Of insects that attack some of the commoner of the pests, four parasitic Hymenoptera and three predaceous beetles are mentioned, and are duly extolled according to the modern optimistic fashion. The plan of the memoir is good. Each species, so far as the present state of knowledge allows, is described and figured in the several stages of its existence, in the more important phases of its activity, and in its local and constitutional effects upon the tree. Damages also are adjudged, and treatment is suggested.

In addition to giving an account of the work and progress of the society for the year 1910–11, the seventy-eighth annual report of the Royal Cornwall Polytechnic Society contains a short but excellent life, by Mr. F. H. Davey, of the later C. W. Peach, accompanied by a portrait. Peach, who did so much for the geology and natural history of Cornwall, as well as for other parts of the United Kingdom, was born in 1800 and died in 1886. Occupying an ordinary post in the coast guard service, and entirely self-educated, he is credited with having made during the first half of the nineteenth century probably more additions to the Cornish marine fauna than any naturalist except W. P. Cocks.

Pursuing Prof. Brandt's argument that the distribution of plankton is correlated with the activity of denitrifying bacteria, Mr. B. Issatschenko reports in the *Bulletin du Jardin Impérial Botanique*, St. Petersburg (vol. xi., part iii.), the results of cultivating bacteria from samples of water taken from the Black Sea. Two new species of Bacterium were thus obtained, the one an active denitrifying organism, the other only capable of decomposing nitrites. Similarly, Dr. Parlandt describes the action of three denitrifying species cultivated in water from the Baltic Sea.

A brief summary of the leading facts connected with graft hybrids is contributed by Mr. R. P. Gregory to *The Gardener's Chronicle* (September 2 and 9). Although the subject is discussed by Charles Darwin in "Animals and Plants under Domestication," the nature of these vegetative hybrids has remained obscure, and systematic attempts to produce other specimens failed until Prof. H. Winkler managed to raise composite forms from grafts of tomato and black nightshade. A striking feature of the hybrids thus obtained was the development, side by side on the stem, of the stiff hairs and divided leaves of the tomato with the smooth exterior and simple leaves of the nightshade, a phenomenon to which Winkler gave the name of "chimæra"; the explanation is found in the juxtaposition of meristematic tissues derived from each plant. Generally it has been observed that tissue development proceeds in parallel lines, *i.e.* periclinally; thus in *Crataego-mespilus Asnierii*—as illustrated—the epidermis is that of the medlar, while the internal tissue is that of Cratægus, and *Cytisus Adami* presents the appearance of *Laburnum vulgare* clothed in an epidermis of *Cytisus purpureus*.

Mr. E. F. Smith directs attention to the striking resemblances between "crown-gall," an affection of plants, and malignant animal tumours, especially sarcoma. It is inoculable on to healthy plants, reproducing the disease. In the "tumours," both primary and those obtained by artificial inoculation, a bacterial organism (*Bacterium tumefaciens*) is present, which can be isolated and cultivated, and the pure cultures reproduce the disease on inoculation (Circular No. 85, 1911, Bureau of Plant Industry, U.S. Department of Agriculture).

In *The Museums Journal* (vol. x., No. 12, June) Mr. E. E. Lowe, of Leicester, continues a description of models to show the optical properties of rock-forming minerals.

We should prefer to place the models illustrating the crystal-systems on a lower shelf, rather than to tilt some of them in order to show their lateral axes. The features of the optical indicatrix are well illustrated by hoops and wires. The explanations of the models serve as an introduction to the examination of mineral-slices with the polarising microscope; but we may prefer the generalised diagrams of Groth to those here given for a special case. There seems an arrow-head too many in one of the figures; and we doubt if Mr. Lowe's model has, as he states, the short diagonal of the analysing nicol "inclined towards the observer at an angle of 45° with the horizontal plane."

For several years past the Aire and Calder Navigation Company has been improving the navigation along the system of canals between Goole and Leeds by deepening and widening the water-way; and in consequence the traffic has been very largely increased, rendering Leeds an inland port on a small scale. Recently a steamer 80 feet long reached Leeds from the docks at Hull in nineteen hours.

An automatic stabilisator, recently invented by M. Doutre, has been used with partial success on a Farman biplane in France, where it has aroused considerable interest. It is designed solely for preserving fore-and-aft equilibrium, and one of its most interesting results is to give the machine to which it is fitted its best angle of glide independently of the pilot's control. The apparatus consists of two parts, an anemometer and what is termed an "accelerometer." The former is a plate placed normally to the air-flow, and backed by two springs of such a strength that the pressure on the plate, when the machine attains its mean speed, entirely compresses them. The forward motion of the plate resulting from any diminution of the wind-pressure depresses the elevator through the agency of a piston operating by compressed air. The "accelerometer" consists of two movable and relatively heavy cylinder-heads, each sliding on a rod placed end on to the flight-path, which move under inertia whenever the speed of the machine diminishes or increases, and operate the elevator in a similar way to the anemometer. These cylinder-heads are held at each end by springs, which return them to their initial position when the aëroplane progresses at a uniform speed, and also check their movement when the machine pitches without speed variation. Both the accelerometer and the anemometer have been combined in one instrument by the inventor, and experiments in calm weather proved that the machine could safely fly for several seconds uncontrolled.

An interesting article on engineering problems in Nicaragua, by Mr. T. Lane Carter, appears in *The Engineering Magazine* for August. As few countries have such a rainfall as one finds in Nicaragua, irrigation is not one of these problems. At Greytown, at the mouth of the San Juan River, the rainfall is about 300 inches per annum; in the mountains, where the gold mines are situated, the rainfall varies from 100 to 125 inches per annum. With rainfall and soil such as they have in Central America, it is not surprising that the vegetable growth is rapid. Two and a half crops of corn can be raised per year. Sugar-cane will produce there for seven or eight years, and does not need an annual planting, as in Louisiana. But the agricultural engineer will find a great deal to occupy his attention in Nicaragua. In the eastern part of the country agriculture is in as backward a condition as in the days of Columbus. Take, for instance, the usual method there of planting corn. A patch is selected in the forest, and the trees and bushes felled. No attempt is made to clear away the rubbish. A man goes round with a sharp, pointed stick, pokes holes in the ground wherever he can find a place amongst the débris, drops in a few seeds, and leaves the crop to nature's care. There is no hoeing or cultivating done. The corn must fight out its battle unaided by man. Strange to say, the crop is gathered in about eight weeks.

A leading article in *Engineering* for September 1 deals with the recent investigation on the stress distribution in a plate pierced with a hole and subjected to pull, which has been ably carried out by Dr. K. Suyehiro, of the Department of Naval Architecture, Tokio University. Strictly speaking, the solution appertains only to the ideal case of a plate pierced at the centre and extending to infinity in all directions; this is assumed to be subjected, in one direction only, to tension, the distribution of which is uniform at an infinite distance from the origin. Dr. Suyehiro then works out what the distribution of stress is in the immediate neighbourhood of the hole, and finds that the maximum value of the stress is no fewer than three times that of the average value. If there were any real analogy between stream-lines and stress-lines, the maximum stress, he points out, would be double the mean. Dr. Suyehiro also shows that local concentrations of stress have practically vanished at points distant from the centre of the hole by $1\frac{1}{2}$ radii; hence his result is applicable to quite narrow plates. He has also compared the results of his calculations with direct experiments on a strip of india-rubber, and finds remarkably close agreement. In view of the importance of the fact that a ship's deck is under push and pull alternately, a useful investigation might be made on the elastic breakdown and final rupture of a wide bar pierced with a hole and subjected to alternating stresses of push and pull. The original paper is reprinted in full in the issue of *Engineering* already quoted.

OUR ASTRONOMICAL COLUMN.

Kiess's Comet, 1911*b*.—No. 4522 of the *Astronomische Nachrichten* contains a new set of elements calculated by Dr. H. Kobold for comet 1911*b*, also a number of observations of the comet. The observations, made about the middle of August, are somewhat uncertain, owing to the difficulty of the object, and Senor Marisonza reports from Rio de Janeiro that during August 18–20 the brightness had rapidly decreased; he states that it could not be observed there after August 24. The ephemeris computed by Herr A. Kobold shows that the present magnitude should be about 8·6, and the position for September 14 is 18h. 15·3m., -45° 24·1′; the comet is now nearly stationary in Corolla, immediately north of α Telescopium.

Meridian Circle Observations.—From the Harvard College Observatory we have received vols. lxv. and lxvi. of the Annals, embodying the journal of the zones observed with the 8-inch meridian circle during the years 1888–90 and 1890–8 respectively. The observations were made and the volumes prepared by Prof. Searle in the preparation of a catalogue which is to appear in vol. lxvii. of the Annals; a previous publication, vol. lxii., part i., dealt with the fundamental stars employed in the same zone, viz. -9° 50′ to -14° 10′.

Brooks's Comet, 1911*c*.—The brightness of Brooks's comet, 1911*c*, continues to increase, and during the fine nights recently experienced at Portsmouth many British Association visitors who are not astronomers found no difficulty in distinguishing the comet from the surrounding stars merely by naked-eye observations. According to the supplement to No. 4522 of the *Astronomische Nachrichten*, Dr. Schiller reports that on August 29 the comet was about half a magnitude fainter than the Andromeda nebula. Its nucleus, formerly sharply stellar, had become diffuse, and in a bright red field was well seen. Dr. Ebell found that on August 26 the brightness of the comet was comparable with that of two 5·9-magnitude stars near to it, and on September 11 Mr. Rolston found that it was as conspicuous as ν Draconis.

From later observations, August 19, 21, and 24, Dr. Kobold has calculated improved elements and an ephemeris, which he publishes in the supplement named, and from which we take the following:—

Elements.

T = 1911 October 27·76235 (M.T. Berlin)

$$\left.\begin{array}{l}\omega = 152^{\circ}\ 44'\ 17.7'' \\ \Omega = 293^{\circ}\ 10'\ 6.1'' \\ i = 34^{\circ}\ 0'\ 2.8''\end{array}\right\} 1911.0$$

$\log q = 9.690358$.

Ephemeris 12h. Berlin M.T.

1911	α (true) h. m.	δ (true)	log r	log Δ	mag.
Sept. 13	17 14·2	+57 9·7	0·0396	9·7171	5·1
,, 15	16 48·1	+56 40·5			
,, 17	16 22·6	+55 50·5	0·0113	9·7136	4·9
,, 19	15 58·5	+54 42·1			
,, 21	15 35·8	+53 16·8	9·9808	9·7152	4·8
,, 23	15 14·6	+51 37·1			
,, 25	14 55·6	+49 44·7	9·9482	9·7214	4·7
,, 27	14 37·9	+47 41·9			
,, 29	14 21·8	+45 30·0	9·9132	9·7321	4·5

On the accompanying chart we show the approximate apparent path of the comet among the stars for the next month.

Apparent Path of Brooks's Comet, 1911*c*, September 13 to October 15, 1911.

From the ephemeris it will be seen that the comet is nearest to the earth about September 17, when its distance will be about 48 million miles. In calculating the magnitude, Dr. Kobold has taken 6·0 on August 26 as his fiducial point, and from opera-glass observations made on that date we believe that his figure probably errs in the direction of making the comet too faint, so that we may expect to see a fourth-magnitude object at the beginning of October.

VARIABILITY OF POLARIS.—Numerous observers have suspected α Ursæ Minoris to be a variable star, and several periods have been found for its variation, but a lack of agreement has left the question somewhat undecided. As a result of a very large piece of observational work, however, Dr. Ejnar Hertzsprung finds that the pole star is a variable of the δ Cephei type having an amplitude of 0.171 ± 0.012, and a period of 3·9681 days. The grating method described in *Astronomische Nachrichten* No. 4452 was employed, the first- and second-order images of Polaris being compared for density with the image of a neighbouring star. Observations were made on fifty nights, 418 plates being secured with four exposures on each, and the results are tabulated in the paper in No. 4518 of the *Astronomische Nachrichten*. Dr. Hertzsprung also shows that Polaris has other attributes of a Cepheid variable.

OBSERVATIONS OF MARS.—A telegram from Prof. Lowell, published in No. 4521 of the *Astronomische Nachrichten*, announces that photographs of the Martian canals were secured on August 30.

In the same journal M. Jarry Desloges makes some preliminary remarks concerning his observations of the planet during the present opposition. The seeing generally has not been good, although latterly he has been able to use a power of 500, and has had moments of absolute calm. The Mare Cimmerium, among other features, is still very pale and difficult to see during Martian morning. The gulf which formed on Zephyria in 1909 is still visible, and a bright area has been detected on its interior. Aonius Sinus is sharply outlined, but the whole region of the Solis Lacus, although well placed for observation, is lacking in colour; the lake itself is double, or greatly constricted across its median line, as in 1907 and 1909. A number of "canals" appear as broad bands with indefinite edges, and are quite easy to see despite the great distance of the planet; Cyclops, Cerberus, Læstrygon, Titan, Araxes, Coprates, and Bathys are among these, and the last named is more easily seen than in 1907, although the planet was much nearer then. Many bright spots, *e.g.* Elysium, Æolis, Zephyria, Memnonia, Tharsis, &c., are visible, but the southern polar cap is very small and at times difficult to distinguish, appearing as though it were veiled.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

THE University of Edinburgh has just instituted two degrees in veterinary science, viz. bachelor and doctor.

A STATE college of forestry has been established at Syracuse University, and the sum of 55,000 dollars has been appropriated for it.

DR. FRASER HARRIS, at present lecturer on physiology in the University of Birmingham, has been appointed professor of physiology in the Dalhousie University, Halifax, Nova Scotia.

MR. E. D. SANDERSON, dean of the college of agriculture at West Virginia University, has been appointed to succeed Mr. J. H. Stewart in January next as director of the experiment station. He will continue to fulfil the duties of dean.

ELEMENTARY courses of medical study, both theoretical and practical, have been arranged by the authorities of Livingstone College, Leyton, E., for those about to engage in missionary work. Particulars of the course, and the "Mrs. Bishop exhibition," can be obtained from the principal of the college. The session begins on October 2.

AT the jubilee celebration of the University of Christiania, the honorary degree of doctor was conferred upon the following British representatives:—Prof. Alfred Marshall; Sir Thomas Barlow, Bart., K.C.V.O., F.R.S.; Sir J. Rose Bradford, K.C.M.G.; Prof. Sir W. Osler, Bart., F.R.S.; Rev. Prof. A. H. Sayce; Dr. H. Sweet; Prof. Sir James Dewar, F.R.S.; Dr. H. A. Miers, F.R.S.; Sir John Murray, K.C.B., F.R.S.; Prof. Sir William Ramsay, K.C.B., F.R.S.; Prof. W. J. Sollas, F.R.S.; and Prof. Sir J. J. Thomson, F.R.S.

THE Board of Education has issued its regulations for scholarships, exhibitions, &c., in science for the year 1912. The awards for science to be made by the Board under these regulations are identical with those formerly made by the Board under the regulations for technical schools, 1909–10. The conditions for these awards in 1913 will be modified. The subjects of the competitive examination will remain the same, but the papers set will be of not more than two standards corresponding with those of the new scheme of general science examinations. The Board of Education is of opinion that further changes in the conditions of award of Royal scholarships, free studentships, and of Whitworth scholarships and exhibitions, may with advantage be made later, but such alterations will not be brought into operation without due notice being given.

IN the case of the Merchant Venturers' Technical College, Bristol, in which the faculty of engineering of the University of Bristol is provided and maintained, the new calendar shows that the complete arrangements made last year are to govern the work next session, and that the educational needs of every important industry of the city have been borne in mind. It is interesting to notice that several local firms have notified their willingness, other things being equal, to give a preference to students who have completed a course of work in the engineering department; and some firms are prepared to take students into their works at reduced premiums, or, in others, without premiums. Some firms, too, have agreed to allow their apprentices to present themselves at their works at 7 o'clock in place of at 6 o'clock on not more than two mornings a week during the college evening-class session provided they can produce a certificate from the college at the end of the session stating that they have attended a number of evenings equal to the number of cases on which they have availed themselves of the concession.

THE new calendar of the Battersea Polytechnic shows that in the Day Technical College full-time courses are arranged in mechanical, civil, electrical, and motor engineering, architecture and building, and chemical engineering. The courses cover a period of three years, at the end of which time students passing the necessary examinations are awarded the polytechnic diploma. Concurrently with the diploma courses, students can take the degree courses in science and engineering of the University of London. Several new developments have been arranged; in the mechanical engineering department a course of lectures on illuminating engineering will be held; in the electrical engineering department special attention will be given to electric traction, and new machinery and apparatus are being purchased so that the subject may be more thoroughly taught. Attention may also be directed to the chemistry course for sanitary inspectors, and to the arrangements which have been made for the provision of special lectures by trade experts in connection with the paper-making course.

AMONG the college calendars, providing information respecting the arrangements made for the forthcoming session, which have been received during the past week may be mentioned that of the Edinburgh and East of Scotland College of Agriculture, which affords evidence of the greatly increased activity in this branch of technical education. Particulars are given of the courses which may be taken at the central institution in the departments of agriculture, horticulture, and forestry. In horticulture, during the coming session a commencement will be made with the newly instituted two years' course leading up to a special certificate. It is hoped that this course, which has been established at the instance of the Scottish horticultural societies, will be taken advantage of by intending nurserymen, market and estate gardeners, and others. Under the new arrangements with the University of Edinburgh, the teaching in forestry subjects is to be shared between the University and the College, and details are given of the courses offered in the combined forestry school. Various experiments in the growing of field crops and in other branches of agriculture and horticulture are conducted under the advice of local committees of practical men, and are directed towards the solution of problems of importance in the business of the farmer and gardener.

THE celebration of the 500th anniversary of the foundation of St. Andrews University is now in progress, and the influx of distinguished visitors into the ancient city far exceeds anything of the kind in former years. The presence of Royalty alone is necessary to complete the scene. Almost all the visitors are the guests of the University staff, of the St. Andrews School for Girls, of the citizens of St. Andrews and Dundee, or of country houses in Fife and Forfarshire—within easy reach of the city by motor carriages. The cordiality with which all responded to the call for accommodation was a source of gratification to the executive. For the carrying out of the programme various committees dealing with the several departments have been at work about a year. Thus the publications committee has issued several memorial volumes, literary, scientific, and historical, and there is also a small quincentenary handbook of the city and the University of St. Andrews by the librarian. In the memorial volumes the zoological department and the Gatty Marine Laboratory do not bulk so largely as, for example, chemistry, since the history of the laboratory, with the list of publications up to date, forms an independent publication. A large temporary hall about 90 yards in length and 30 yards in breadth has been fitted with a spacious platform at one end and an orchestra at the other, the whole structure occupying the old archery butts to the north of the United College. This hall accommodates between three and four thousand people. Covered ways lead to several cloak-rooms, to the museum, and to the United College buildings generally. In the upper hall of the library in South Street is an exhibition of early and rare printed books and manuscripts. Everything has been done in the way of facilitating transit by railway from a distance and to Dundee, as well as arranging for local conveyances. Clubs for men and for women, a camp in the University park for students, a special post-office and a refreshment-room in the Town Hall are other features which have received attention. Never did the old grey and sea-girt city, with its parallel streets leading to the cathedral, look more charming, or its finely planted promenades and walks (under the fostering care of the Town Council) more enticing. To every graduate and student, as of old, the place appeals with an irresistible charm, and it is to be hoped that the distinguished visitors will be no less fascinated by their unique surroundings. Next week we hope to have an account of the celebration, which began with a reception by the Chancellor on Tuesday evening. Besides the men of science mentioned in NATURE of last week, the following will receive the honorary degree of LL.D.:—Dr. Berry, Dr. Byron Bramwell, Sir H. Butlin, Sir Hector Cameron, Prof. Caullery, Prof. Goebel, Prof. Gotch, Prof. Ludwig Graff von Paucsova, Prof. Holst, Dr. Horne, Prof. Keen, Sir J. Larmor, Prof. Leboucq, Prof. Sedgwick Minot, Prof. Nathorst, Prof. Nijland, Prof. E. E. Prince, Prof. Reddingius, Prof. Schaefer, Dr. Anthony Traill, Prof. Veit, Prof. Watts, and Dr. Smith Woodward.

CONTENTS.

THURSDAY, SEPTEMBER 21, 1911.

THE PROGRESS OF PHYSICS.

The Progress of Physics during Thirty-three Years (1875–1908). Four lectures delivered to the University of Calcutta during March, 1908. By Arthur Schuster, F.R.S. Pp. x+164. (Cambridge: University Press, 1911.) Price 3*s*. 6*d*. net.

IN the year 1908 Prof. Schuster during his visit to India gave to the University of Calcutta four lectures, which he has now incorporated into a book, dealing with the progress which had been made in his subject during his own active lifetime, namely from the year 1875 onward.

The scope of the book he thus explains:—

"It is my aim to trace the changes in our point of view, rather than to give an historical account of the sequence of the discoveries which make this period memorable. . . . I prefer to be frankly subjective, and warn you beforehand that my account will be fragmentary, and to a great extent reminiscent of those aspects which have come under my own personal view."

In his preliminary survey of the state of the science before 1875 he contrasts the endeavour at that time prevalent to get a clear idea of the mechanism underlying the various processes, with the "blinkers" which are in some quarters willingly accepted now, not only as inevitable but as praiseworthy instruments conducive to a rational philosophy. The one idea of Energy is now sometimes upheld as dominating the field, and rendering unnecessary all more picturesque inquiry into forces and motions and coordinates in detail.

It is true that ignorance of detail may often be a dominant feature in both methods of dealing with phenomena; but the modern treatment, as he says—"glorifies our ignorance, while the other accepted it as a regrettable necessity." . . . The "vagueness which used to be recognised as our great enemy is now being enshrined as an idol to be worshipped."

At the beginning of the period dealt with by the author this tendency hardly existed:—

"The tendency to hide ignorance under the cover of a mathematical formula had already appeared, but was not openly advocted; hence students were still taught to form definite ideas of the processes of nature."

So far an advantage seems to him to lie with the past; but then, on the other hand, he recollects a less excellent tendency which then existed to regard the scope of physics as already fairly complete, with all the main avenues explored, and only side tracks and subsidiary paths awaiting the would-be discoverer—whose aim sometimes was to get hold of some neglected residual effect, by employing extremely sensitive instruments and applying power enough to bring it within the compass of observation; and whose other and highly estimable aim was to measure with careful accuracy effects already known.

This condition of things Prof. Schuster thus describes:—

"In many cases the student was led to believe that the main facts of nature were all known, that the chances of any great discovery being made by experiment were vanishingly small, and that therefore the experimentalist's work consisted in deciding between rival theories, or in finding some small residual effect which might add a more or less important detail to the theory."

It is perhaps singular that such an outlook should have so closely preceded an outburst of novelties such as have of late years aroused the enthusiasm of the worker, as well as the occasional derision of the sceptical critic.

"Looking back now on this period, when Röntgen rays and radio-activity were undreamt of, we may well learn to be cautious in our own predictions of the future."

Nevertheless, some of the discoveries were made in what may be called the old-fashioned way, one example being of the first magnitude:—

"A typical example of a great discovery brought about by the method indicated by Maxwell is furnished by Rayleigh's measurements which culminated in the discovery of argon, through a research undertaken to determine with accuracy the density of gases. . . . It is nevertheless indisputable that the greatest discoveries, both formerly and in recent years, have not originated in the hunt of residuals."

No; they have sometimes been begun accidentally, but they have been followed up by those who have been guided by a clue of theory; and some of the most splendid have been made by mathematical physicists who were clearly conscious all the time of what their aim was and what was the meaning of the phenomena they observed.

"Altogether I am doubtful," says Prof. Schuster, "whether any great discovery has ever been made by anyone who has only aimed at recording a number of facts."

Those who contemn theory, and who affect to disbelieve the explanation which physicists give of recently observed phenomena, would do well perhaps to realise that ultra-scepticism has often been a drag on scientific progress, as well as occasionally a safeguard and a help.

As an example tending in this cautionary direction we may quote from the author as follows:—

"The frame of mind with which the academic physicist [or, we might add, the academic chemist] looked upon investigations of the passage of electricity through gases, might be made the subject of instructive comment. The facts, so far as they had been ascertained, did not fit in with recognised views: hence they were ignored, and students were warned off the subject. There was a feeling that perhaps in a century or so the question might be attacked, but that in the meantime it had better be left to be played with by cranks and visionaries. No criticism was more frequent, at that time, than that of characterising as premature any new idea or fresh line of investigation in this direction; as if any advance of science has ever been made which was not premature a fortnight before it was made."

The extreme usefulness of a working hypothesis or theoretical clue can scarcely be emphasised better than by the following:—

M

"If we look back upon these experiments now, they may be used to point the moral that experiments conducted in what is sometimes considered to be the true philosophic spirit, where the investigator without any preconceived theories or notions simply wishes to classify facts, seldom lead to any valuable results.

"Progress began when the subject was attacked with some definite object in view, either some theory however crude which had to be supported, or some numerical connection which had to be investigated."

It has been one of the features of Sir J. J. Thomson's work, for instance, that theory and experiment have gone hand in hand and have been published together. The reviewer has heard this feature objected to, but it is more than justified. The publication of the great discovery which is being here specially referred to is thus mentioned by Prof. Schuster:—

"The lecture in which the above experiments were described, was delivered to the British Association [at Dover] on the occasion of the visit of members of the French Association, which met concurrently at Boulogne.[1] It at once carried conviction, and, though to those who had followed the gradual development of the subject it only rendered more certain what previous experiments had already plainly indicated, the scientific world seemed suddenly to awake to the fact that their fundamental conceptions had been revolutionised. A new era of science begins at this point."

Prof. Schuster had himself made experiments which would have received their quantitative explanation had the idea of a separate atom of electricity detached from matter been at that time fairly conceivable. But, as he says—in full accordance with the attitude of most others at the time—

"The separate existence of a detached atom of electricity never occurred to me as possible, and if it had, and I had openly expressed such heterodox opinions, I should hardly have been considered a serious physicist, for the limits to allowable heterodoxy in science are soon reached."

There were not wanting critics to emphasise the heterodoxy of the idea, even when the discovery had been made; and chemical scepticism concerning *ions* exerted a retarding effect in Britain:—

"This ionic theory of gas discharges, while ignored in England, made good progress abroad; Arrhenius adopted it, as well as Elster and Geitel."

But it is in connection with the subject of terrestrial magnetism and its explanation that the author makes the most biting comment:—

"There can only be one solution of the problem, and if we can explain any magnetic effect on the earth's surface by outside forces, it follows that it cannot at the same time be explained by internal forces. This remark disposes of a good deal of the criticism lavished on pioneer attempts to open out this region of science. Though this criticism is often confined to a judicious shrugging of the shoulders, it stops scientific progress more effectually than active opposition, and is apt to become a constitutional habit with those who give way to its undoubted temptations."

Of course, caution is necessary; but on the whole, says the author—

[1] The title originally was "On the Existence of Masses Smaller than the Atoms," but was changed when the paper was published in the *Philosophical Magazine*, xlviii., p. 565 (1899), to "On the Masses of Ions in Gases at Low Pressure."

"The state of plasticity and flux—a healthy state, in my opinion—in which scientific thought of the present age adapts itself to almost any novelty, is illustrated by the complacency with which the most cherished tenets of our fathers are being abandoned."

For instance,

"Nowadays the student finds little to disturb him, perhaps too little, in the idea that mass changes with velocity; and he does not always realise the full meaning of the consequences which are involved."

This part of the treatise is so important, and the usefulness of theory as a guide to discovery is so vital, that we must dwell on the author's treatment of the more philosophical aspect of physics with special interest.

First of all he admits that we must allow something for intuition:—

"When we consider two rival theories in any branch of human knowledge, we are sometimes drawn towards one or towards the other, not by any process of reasoning, but by an instinctive feeling which may be so strong that we unhesitatingly reject one of the alternatives. . . . The strongest of our scientific 'instincts' is our ultimate belief in the simplicity of nature. If both light and electrical attractions are transmitted through a medium, it would revolt our feelings—that is to say, our non-reasoning faculties—to assume, without strong evidence to the contrary, that two different media exist for the two manifestations."

But it is not to be supposed that the intuition is always right. The example which the author takes—in order to illustrate the useful consequences of even an erroneous theory—is not one with which the reviewer sympathises, for he is one of those who desire dogmatically to deny the possibility of physical action except through a medium; whereas Prof. Schuster says:—

"To me it seems that the dogmatical denial of action at a distance is a survival of the ancient anthropomorphic explanation of natural phenomena."

He admits, however, with cordiality that the search for the medium has resulted in many discoveries, and, like many other theoretical clues—whether correct or not—has been justified by results. From this, he says:—

"Two lessons may here be learned. One is, that the temporary success of a doctrine does not necessarily justify the grounds of its foundation; and the other, that progress in science is more often achieved by a definite hypothesis, which may be followed up and tested, than by a wider and perhaps more philosophic doctrine, which cannot be disproved because it does not endeavour to go deeper than the mere descriptive classification of phenomena."

In the same spirit as that in which he maintains the possibility or conceivability of physical action at a distance, the author is not frightened away from any hypothesis because of its excessive strain upon ordinary common sense. For instance, he is able to contemplate the view that an atom or an electron may be a source or a sink of fluid, continually appearing out of nothing at some points and continually going out of existence at others.

"The universe must have begun by a process which lies outside physical laws, and it seems to me no easier to grasp the conception of a creation which took place at one single time than a creation which continues throughout all ages. Indeed, if we come to think of it, the continuance of a physical law like that of gravitation is as much a miracle as the continuous uniform creation of matter would be."

In this, as in a few other matters, the reviewer is unable to follow him completely.

Coming to another subject, the lecturer has some wise things to say regarding laboratory teaching in physics; some of which—like much else of school teaching—is calculated rather to promote dislike and dulness than to arouse any enthusiasm for science; and whatever may be the merit of college courses in physics, he cannot refrain from noticing how little of that sort of training was available for, or was needed by, the great discoverers.

"The cardinal fact to bear in mind is that previous to 1870, when laboratory instruction, if given at all, was sporadic, the experimental skill of investigators was as great as it is now. We need only mention the names of Faraday, Joule, Helmholtz, and Regnault, in support of that contention. The conclusion is irresistible that an intelligent student, possessing a sufficient theoretical knowledge, is capable of starting research work in physics without previous special training. It is not for him that complicated laboratory courses have been designed, but for the ordinary student."

It is very desirable in all cases that the stimulation of interest shall not be subordinate to the acquisition of mere technical skill. Without enthusiasm, the mere ability to measure all sorts of uninteresting quantities is of comparatively little use.

"The future investigator will no doubt ultimately save time if at an early stage he acquires a certain technical skill and becomes acquainted with physical methods, but otherwise the efforts of the teacher should be directed to stimulating his scientific activity rather than sending him through all manipulations which he might possibly have to perform."

That the author is a great authority in the subjects of terrestrial magnetism and atmospheric electricity is well known, and in his last lecture he enters into these rather fully, compared with his rapid survey of other subjects. Hence these portions have a value of their own, and a few *obiter dicta* may be extracted.

Concerning the view which has been held about the annual and diurnal variations in terrestrial magnetism, he says:—

"A better agreement may be obtained by making the plausible hypothesis that the electric conductivity of the higher regions of the atmosphere is due to solar radiation, and is therefore greater in summer than in winter, and also greater in daytime than at night."

On the subject of atmospheric electricity:—

"The earth as a whole is charged negatively, and on the average we find that there must be nearly a million electrons on every centimetre of its surface. . . . Lenard, in an important research, has shown that a drop of water as it falls never reaches a velocity greater than 8 metres per second, however large the drop, while drops having a diameter of 1·5 millimetres fall with a velocity of about half that amount. . . . The larger drops break up in the air, and doing so become positively electrified, according to Dr. Simpson. If the ascending current spreads out laterally near the top of the cloud, the vertical velocity is diminished, the drops will grow and fall, but only to break up and be carried upwards again. A quantity of electricity large enough to account for the lightning discharge can thus accumulate in a cloud."

We have thus taken a rapid survey of this interesting book and given a sample of its contents.

The only fault we have to find with it is a minor one, that ought not however to pass unnoticed,—the punctuation is of a systematically irritating kind. In the extracts here made it has in most places been corrected, so that the defect will not be noticed in them, but before concluding we must quote without correcting. There is evidently some one among the printers or readers for the press who has a theory about commas; one rule apparently being that a comma must always precede a relative pronoun.

To illustrate the nonsense which is often thus made, it will suffice to quote a few sentences at random:—

P. 158: "To put the result in a form, which is readily appreciated, I will compare different molecules," &c.

P. 98: "Energy cannot be expressed entirely by quantities, which merely depend on change of position (kinematical factors), but must involve," &c.

P. 139: "Nothing has been said as yet on the explanation of the secular variation of terrestrial magnetism, and in our ignorance of the causes, which make the earth behave like a magnet, it is perhaps wisest to put the question aside for the present."

P. 130: "The discussion of the problem [of diurnal variation of terrestrial magnetism] . . . shewed that there is a substantial remnant which comes to us from the inside of the earth, and this is, as it should be, because the earth being a conductor, any change of the magnetic forces must give rise to induced internal currents."

The main part of the cause of diurnal variation, however, lies above the surface of the earth, and is due to electric currents in the upper atmosphere,—says the author; who thereby seems to contravene a more general pronouncement, quoted above, as to the uniqueness of a given explanation. It is probably the more general pronouncement that he would wish to modify.

The immediately preceding extract is of interest for its own sake, and not merely as an illustration of seriocomic punctuation. So is the following:—

P. 156: "It is always satisfactory when we find that different lines of reasoning lead to the same result, and at present there is hardly one, in the domain of Geo-Physics which stands on so firm a basis as that giving to the earth an extremely high rigidity."

In the selected quotations we have done less than justice to the author's treatment of the many problems which have coincided with his active life, and to the solution of which he has so often contributed; but the book is accessible and very readable. We may be grateful to the University of Calcutta for having stimulated the production of these lectures, and to the author for writing them out and publishing them. They constitute another link in the chain which is binding together East and West.

Oliver Lodge.

CHEMICAL STRUCTURE AND PHYSIOLOGICAL ACTION.

The Chemistry of Synthetic Drugs. By P. May. Pp. xiii+229. (London: Longmans, Green and Co., 1911.) Price 7s. 6d. net.

IT is the expressed aim of the author of this volume to bring to the notice of chemists a branch of their subject affording scope for commercial application, and at the same time to interest medical men who may desire information concerning the chemical nature of the synthetic remedies presented to them. It is obvious that but little can safely be assumed as common ground of previous knowledge, in appealing to so wide a constituency of readers, and it was a good thought to begin with a glossary of technical terms: although it seems a little difficult to believe in the existence of the chemist who needs "antipyretic" or "narcotic" defined for him.

The author is to be congratulated on having presented a readable account of a difficult subject in 220 pages of text, not a few of which, moreover, are of necessity occupied by structural formulæ.

A selection of the more interesting and instructive classes of synthetic drugs for discussion probably afforded the only possibility of dealing, within such limits, with a subject in which recorded observations are overwhelmingly abundant and sound generalisations but few. The gain in interest for the non-specialist is well worth the loss in comprehensiveness. It is no disparagement of such a volume to say that it owes much to Fränkel's "Arzneimittelsynthese," as the author duly acknowledges. It could be wished, however, that he had leaned a little less heavily on that authority, particularly in some matters of pharmacological detail. For example, he follows Fränkel in stating that "pilocarpine closely resembles nicotine in many of its pharmacological effects" (p. 31), and accordingly regards as significant the possession by both of a five-membered ring. Of a writer on this subject for English readers one might expect such slight acquaintance with the work of the Cambridge school of physiology as would have sufficed to save him from accepting this statement. That the real pharmacological affinities of pilocarpine are with muscarine, with which it has no obvious community of structure, is one of the anomalies with which the subject bristles. The statement that "atropine and cocaine are closely related . . . in their physiological action, both of them causing dilatation of the pupil" (p. 86), is another instance of a tendency to attach importance to superficial resemblances, in the interests of a preconceived correspondence between structure and action. Mr. May's direct contact with the subject is obviously on the chemical side, but the description of the action of apomorphine as "quite opposite to that of morphine," is again a little crude, even for pharmacology at second hand.

The introductory chapter, dealing with the general theories of the physiological action of drugs, follows Fränkel closely, and would have gained by more attention to the development of theories since 1906. It is rather for its chapters dealing with special groups than as a general theoretical survey that the book should prove of value. Atropine and the tropeines, cocaine and the local anæsthetics, the morphine and isoquinoline groups of alkaloids, are all dealt with in a manner which should enable even the medical practitioner, with mere remnants of his student chemistry as a basis, to follow intelligently the aims of those engaged in producing new synthetic compounds in the different series. The citation of trade names provides a useful link with practical therapeutics. In treating of the isoquinoline alkaloids and the adrenaline series of bases, much space is devoted to recent, and particularly to English, publications: and if some of these seem thus to acquire more prominence in the general scheme than their intrinsic importance warrants, the fault is in the right direction; for, as the author points out, much of this work, as well as that on the organic arsenic and antimony compounds, has not before been collected into one volume.

On the whole, by what it omits as well as by the presentation of what it includes, the book succeeds in giving a more readable, if a slighter, account of the subject than its predecessors in the same field. A high degree of originality is excluded by the nature of the subject. The book would gain much by comparatively slight revision at the hands of someone directly acquainted with the physiological side of the subject, and the author may be recommended to seek such aid before publishing a new edition.

MECHANISM IN CRUCIFEROUS FLOWERS.

Prinzipien der Physikalisch-Kausalen Blütenbiologie. In ihrer Anwendung auf Bau und Entstehung des Blütenapparates der Cruciferen. Von Dr. A. Günthart. Pp. ix+172. (Jena: Gustav Fischer, 1910.) Price 4.50 marks.

THE floral construction of the Crucifer, repeated in so many familiar wild and cultivated plants, is at first sight so remarkably simple that the type is utilised possibly more than any other for the purposes of elementary botany, as presenting a handy symmetrical blossom with few parts and apparently little complication in relation to pollination. More careful observation, however, shows that this is by no means the case; the biological construction is definitely transversely zygomorphic, involving a duplicate mechanism; while morphological considerations show that the apparent simplicity has been attained by extreme reduction-specialisation from anthostrobiloid forms of which phylogenetic suggestions can only be traced in the allied families of the Capparidaceæ and Resedaceæ.

Dr. Günthart's volume constitues an extremely valuable and interesting contribution to the detailed investigation of the floral biology of these flowers. Representative types of twenty-five genera, arranged in thirteen groups, have been worked out by sectional methods, and are copiously illustrated by 136 schematic figures and diagrams. As the title indicates, the special point at issue is the determination of the extent to which any definite purpose or intention can be traced in the elaboration of complex floral mechanism devoted to cross-pollination by insect agency. The reading in of ideas involving purpose or forethought on the part of the plant has been so extremely general in œcological description of flowers, is so pleasing to the imagination, and proves so popular and difficult to escape from in elementary teaching, that a detailed analysis of such well-known Crucifer types as Matthiola, Raphanus, Alyssum, Aubrietia, &c., is particularly welcome.

Thus, among Crucifers generally, (1) the claws of the petals bend away from the lateral stamens as if to leave definite "entrance-slits" to the assumed nectar-containing pouches of the lateral sepals; (2) the anthers of the longer stamens are commonly twisted on their filaments so as to face round towards the adjacent lateral ones, as if with the intention of rubbing the entering proboscis of an insect; (3) the edges of the filaments are frequently extended into elaborate appendage-growths which are apparently intended to guide the proboscis of the insect-visitor exactly to the secreting surface. Such details are so obviously included under the heading of special adaptations to secure insect-pollination that the question of their actual origin demands most careful investigation.

The object of Dr. Günthart's work is to show that practically all subsidiary details of special mechanism and final adjustment may be traced back to a few fundamental tendencies in the floral construction, which, being given by phylogeny, work out on simple mechanical lines the construction details which are at first sight so purposeful. Such "active-factors" in the case of the Cruciferous flower are distinguished as:—

1. The tendency of the floral receptacle to extend in the transverse plane of the floral diagram, this factor controlling the dorsiventral insertion of the petals, the lateral apertures of the flower-tube, &c.

2. A tendency for the median sepals and adjacent parts to be "elevated" by a peculiar growth-extension in the median plane of the receptacle, which is responsible for "true" (primary) calyx-pouches and the increasing restriction of the secreting surface to lateral hollows.

3. The transverse and longitudinal extension of the ovuliferous region: the former phenomenon (Siliculoseæ) still further exaggerating characters induced by the original transverse construction.

4. The mutual pressures between a closed calyx and central ovary exerted on "passive" petals and stamens leading to the production of rotated anthers and marginal extensions of the filaments.

In tracing the elaborate mechanical connections of these phenomena, however, the problem of their meaning is admittedly only removed one step further back. We still remain ignorant of the reasons for the initiation of these "active" characters. Nor is there any reason to believe that continued research will ever satisfactorily solve all problems which stretch back into the distant phylogeny of the group. Still, every step cleared up is one gained, and the vague conception of intention is gradually replaced by the view that from an initial tendency, itself probably induced by some physical cause, certain mechanical results will necessarily follow, which will in turn determine the subsequent possibilities of the evolution of the race. Further, the fundamental factors thus deduced should give the key to the systematic arrangement of the family.

FACT AND FANCY IN DIETETICS.

"*What Shall I Eat?*": *a Manual of Rational Feeding.* By Dr. F. X. Gouraud. With a Preface by Prof. A. Gautier. Authorised English translation by F. J. Rebman. Pp. xvi+379. (London: Rebman, Ltd.; New York: Rebman Co., n.d.) Price 6*s.* net.

THERE appears to be a plethora of books on diet just now, but the present volume does not reach the same standard of excellence which is noticeable in several other books on the subject recently reviewed in these columns.

Dr. Gouraud's work contains a certain amount of useful information, it is true, but it is so interwoven with speculations and contradictions that it is not likely to prove useful either to specialists or to the public at large.

The preface tells us it is intended for the business man and the educated housewife among others, but we wonder what the average man of business would make out of the following sentences:—

"Endogenetic purin is produced by the rejection of nuclein by the organism; its percentage, though variable in each individual, is a fixed quantity in each individual. Exogenetic purin of alimentary origin varies considerably according to diet, and may be reduced to zero by a regimen entirely free of all xanthic bodies."

"Beef is a powerful factor in membral hyperacidity. Its alimentary value, which depends almost wholly on the percentage of fats present in it, is rather slight. It takes only second place to butter, sugar, and rice. Its sole merit from the alimentary standpoint can only be that it supplies within a small compass a comparatively large amount of assimilable nitrogen."

"The third nutritive element in milk is the carbohydrates, *i.e.* lactose or milk sugar. This is a bihexose well known for its diuretic properties which makes the sugar in diabetics. Phosphorus is also abundant, and is present chiefly in the shape of physiological values well differentiated."

Quotations such as the preceding could be multiplied indefinitely. A physiologist will at once detect the gross misstatements of fact; but the man in the street, so far as he can make head or tail out of technical language, will at any rate detect the want of logic and of a knowledge of English composition. The glossary at the end of the book will not help him much, for we learn there that purins are unclean or poisonous substances, that xanthin is a yellow colouring matter, that steapsin is a diastasic ferment, that inosite is a saccharine substance, that casein is a derived albumin, that galactose is lactose, that ammonia contains hydrogen atones, &c., &c.

The translator does not in the greater number of instances know the English equivalents for French technical terms, or for the names of pathological conditions. We select only one gem for special mention; we are told that milk is curdled by the *pressure* of the stomach. This is a very free translation of *présure*, which really means rennet. Not having seen the book in the original French, it is a little difficult to apportion the blame between Dr. Gouraud and his translator. Internal evidence leads one, however, to conclude that both are at fault.

The book is a curious and muddled medley of fact and fancy; the translation has evidently been carried out by someone unfamiliar with physiology, and deficient in his knowledge of both French and English.

W. D. H.

OUR BOOK SHELF.

Lilies. By A. Grove. Pp. xi + 116 + 8 coloured plates. *Apples and Pears.* By G. Bunyard. Pp. xi + 116 + 8 coloured plates. (Present-day Gardening Series.) (London and Edinburgh: T. C. and E. C. Jack, n.d.) Price 1*s.* 6*d.* each.

MR. GROVE's book on lilies is one of the most welcome that have appeared in this series. Among popular flowers the genus is, perhaps, the most trying with which English gardeners have to deal, and the presence of many species in our gardens is due more to the efficiency and rapidity of ocean transit than to a proved capability of our cultivators to grow them in gardens. It is probably to the facility with which stocks can be renewed that the present unsatisfactory state of lily cultivation is largely due. The incentive to conquer the problems of keeping them alive and propagating them are, to a great extent, lacking when a new and vigorous stock can be easily obtained from the salerooms. Mr. Grove is, however, an enthusiast, and we have it on the authority of Mr. Elwes—himself the author of a classical work on the genus—that he knows more about their cultivation than anyone else living. There is no botany in the work; it is purely a gardening book cleverly and pleasantly written by a master of his subject. Mr. Elwes contributes an interesting preface.

Mr. Grove's study of lilies has been carried on unostentatiously in his garden on the Berkshire hills, and his name is comparatively unknown except to the *élite.* It is otherwise with Mr. Bunyard. As the head of one of the first fruit-tree nurseries, and an experienced author on hardy fruits, he has long filled a high place in the esteem of those occupied in the same pursuits. The present little volume is certainly one of the best that has ever appeared on the subject of apples and pears. Although concise it is comprehensive, and deals efficiently with every phase of their treatment. The author gives lists of the best sorts for various purposes and different districts, all the better because they are comparatively short. He deals with their cultivation from the propagation and planting of the trees, and the way to combat insect pests, to the storing of the fruit. The state of many orchards of this country impels one to hope that this book may be widely read.

Each of these volumes is illustrated by eight coloured plates, and makes a very creditable addition to the useful series to which it belongs.

The Animal World. By Prof. F. W. Gamble, F.R.S. With an Introduction by Sir Oliver Lodge, F.R.S. (Home University Library of Modern Knowledge.) Pp. 255. (London: Williams and Norgate; New York: Henry Holt and Co., n.d.) Price 1*s.* net.

PROF. GAMBLE'S account of the animal world is written from the point of view of function. Its chief aim is to direct attention to the adaptations of structure to the performance of movement, breathing, and other vital functions. An introductory chapter, which contains a general survey of the structure and classification of animals, is rather condensed, and will probably be more useful to the reader who has already a little knowledge of animal life than to the beginner. The description of the movements, and of the succession and distribution of animals, provides opportunity for pointing out the great advantages possessed by birds and mammals in consequence of their warm blood. The quest for food, modes of breathing, the colours and senses of animals, societies and associations, symbiosis, the care of the young, and short accounts of the life-history of a few animals, form the subjects of successive chapters. The concluding chapter on heredity and variation might well have been a little more extended: the subject-matter is too briefly explained to be of full value to the reader for whom the book is intended.

Several of the figures are crude, especially that of Vorticella. The statement on p. 28 that the buds of cœlenterates may remain in connection with the parent tissues "by strings of mesenchyme" requires modification. On p. 37 the spaces between the mesenteries of a sea-anemone are designated the cœlom, and immediately below are referred to as increasing the capacity of the digestive cavity.

The book, which is written in a fresh clear style, is characterised throughout by breadth of view, and is also noteworthy for the aptness of the illustrative examples cited. The thoughtful reader, with an interest in biology, will find in this volume food for thought in abundant measure.

Orthochromatic Filters. Pp. 55. (Croydon: Wratten and Wainwright, Ltd., n.d.) Price 6*d.*

THE title of this little book does not include its contents, for there is a chapter on "contrast filters," with some very striking examples of their use. A photograph of an engineers' blue print taken through a strong red filter that needs the exposure to be increased twenty-four times with a Wratten's panchromatic plate, renders the blue as a full black, instead of the rather feeble grey given by an ordinary plate with no filter. The great improvement obtainable in the rendering of the grain of dark-coloured woods, as well as in other cases, is well illustrated. We learn that the sensitiveness to green and red of ordinary orthochromatic plates is generally from 2 to 5 per cent. of the total sensitiveness, while in a panchromatic plate this rises to as much as 18 per cent. From these and other figures of a like nature the necessary increase of exposure when using certain colour filters with various specially sensitised plates is calculated in a simple way. The chapter that will be of most interest to those who are fairly familiar with the use of colour filters and sensitised plates, deals with the optical properties of filters. It gives clear examples of the degradation of defining power of the lens by the use of a filter strained by being too tightly screwed up in its cell, and also of filters which introduce various degrees of astigmatism. Many other matters are dealt with which are of prime importance to those who use colour screens.

Studies of Trees and Flowers. By M. Wrigley. With descriptions by Annie L. Smith. Pp. 129 + viii + 129 plates. (London: Methuen and Co., Ltd., n.d.) Price 15*s.* net.

THE photographs that form the chief feature of this weighty volume reflect considerable credit on the skill of the author as a manipulator with the camera. Undoubtedly the most impressive are the photographs of plants *in situ*; the picture of the foxglove is good, except that it fails to show the lower portion of the plant; those of the birches, especially of the silver birch and of the Burnham beeches, are instructive, but the best are the illustrations of two groups of Scotch firs at Kincraig that betoken group as well as individual habit. Many of the sprays, notably of the blossoming myrtle and hawthorn, and of the fruiting broom, are attractive, but it is not apparent that any useful purpose is served by these or the general collection, since it is not difficult and more advisable to obtain natural specimens in season. Miss Lorrain Smith has carried out satisfactorily the task of supplying appropriate brief notes, and doubtless appreciated the Peziza and Usnea that appear at the end.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Ooze of the Thames.

Some time ago I directed attention to the part played by annelids in making the ooze of rivers, such as the Nile, fertile. Aided by a Government grant, research has been continued during the year, and in August a special visit was paid to Kew Gardens and the Thames. The river was very low, and I was able to collect specimens which are not always available, and bring away a sample of the ooze for careful examination. I found the mud teeming with *Helodrilus oculatus*, Hoffm., a new record for the south of England; *Paranais naidina*, Bretscher, new to Britain; *Monopylephorus elegans*, Friend, new to science; and other things, showing how much work still remains to be done by London naturalists. There were also many living nematodes, all apparently belonging to one species, half an inch or more in length. I have not yet been able to work out its history or discover its host, but the thing which seems to me to be of special interest relates to this parasitic creature. In examining the ooze from time to time the thing that struck one was the presence of numberless white threads of considerable length and great tenuity. These proved to be the integuments of vast numbers of dead nematodes. In the case of annelids, the process of decay is so rapid that dead worms are rarely found, and only by means of the most careful microscopic examination or chemical analysis can one discover how numerous they have been. But the evidence goes to show that the ooze of rivers is immensely enriched in nitrogenous matter year by year through the death of annelids, as well as oxygenated by their tireless movements.

While much has been done in the analysis of soils, little if anything seems to have been undertaken in relation to ooze. My own researches are at present largely restricted to the systematic study of the living species of annelids; but it would be of immense advantage to science, and especially to agriculture, if some expert like Dr. Russell could give us careful analyses of river oozes. I have appealed many times for samples of ooze from estuaries and rivers in order that something might be done, but hitherto the response has been very heartless, and there has been no alternative but to make special journeys to interesting localities, at great cost of time and money. The importance of the subject, however, is such that I venture again to bring it to the notice of students and investigators in the hope that it may receive the attention it deserves.

Swadlincote, September 16. HILDERIC FRIEND.

Ancient Forests in Scotland.

Referring to your correspondent's letters which appeared in Nature of June 1 and August 24 last in regard to the contemplated cutting down of the fir trees at Auchnacarry, in south Inverness-shire, permit me to state that, though very old (say two to three hundred years), these cannot properly be said to have formed part of the ancient Caledonian Forest. The fir was very probably found in the latter, and in certain places it may have been the prevailing description; unquestionably it is the most prominent survivor, and during the last few centuries has been one of the most important economical products of the Highlands of Scotland.

The cause of the disappearance of the Caledonian Forest has hitherto seemed obscure, if not inexplicable. Some light, however, is perhaps afforded by the fact that over the entire area which it covered, say all the counties north of the Firths of Forth and Clyde, except perhaps the Isle of Bute, Fife, Caithness, and the Orkney and Shetland Islands, the surface is frequently bestrewn with iron slags. So numerous are these latter in some districts that a hundred heaps of slag may be found almost within the confines of a single parish. From an examination of the pieces of charcoal found amongst these slags it has been ascertained that when these were formed the principal trees in the neighbourhood were birch and oak, but in some instances traces have been found of beech, ash, elm, fir, and holly.

Evidently in the more ancient times, namely, before the use of water-power was introduced in Scotland for the extraction of iron from the ore, two processes were successively employed for the purpose. In the earliest, the natural wind was taken advantage of, and the seat of operations was determined by the favourable physical configuration of the land to guide and concentrate the blast on the materials of combustion. From one document, at least, we learn that this method seems to have been employed down to 900 years ago. The sites associated with the later or succeeding process, and at which, presumably, bellows were used, are all in sheltered positions where the remaining forests were located; a few of the very last of these in operation can be dated as belonging to the fourteenth and fifteenth centuries. There is reason to believe that the bellows were in use in this connection as early as, if not earlier than, the Roman occupation.

When water-power for iron-making was introduced into Scotland at the beginning of the seventeenth century, the sites chosen were not only in protected situations also, but on low ground, on the banks of rivers, and preferably with suitable wood for fuel in the vicinity; but some of the latter seems to have been rolled down from the heights above, or floated by water from considerable distances. This class of works continued in operation generally until about 1760, and in the case of those near Inverary and Buname until much more recent years. Charcoal made from pine wood was very largely used at all of this series of works.

From the foregoing it may be gathered that as the iron slag heaps of Scotland form the memorials of her ancient forests, our knowledge of the latter may be much restricted by a neglect of the study of the metallurgical industries there in former times. GEORGE TURNER.

30n Langside Road, Glasgow, September 4.

"The Polynesian Wanderings."

Your review of my book, "The Polynesian Wanderings" (August 10), is warmly appreciated as performing the service of an introduction to scholars interested in the philology of the Pacific. In order to prevent a misconception of the work, I ask leave to note an exception to one or two statements in the review which might produce a wrong impression.

Mr. Ray comments upon the incommensurability of the several languages of Polynesia and Melanesia. What he puts in a few lines I had discussed in pages, and had announced that it was impracticable, in our present knowledge of Melanesian speech, to essay a quantitative comparison. On pp. 142 and 143 of the volume I have been at pains to establish my method of comparison by computing a coefficient of recognisability of the Proto-Samoan borrowed element in some ninety Melanesian languages. This is a figure which may be reached independently of the quantity of the loan material; it rests upon each borrowed word by itself in comparison with the same word as found in the present speech of Nuclear Polynesia; it expresses the extent of the deviation from the norm. The determination of quantity lying beyond our reach at present, I have utilised the only element of comparison which in years of research I have been able to discover, that of quality. When Mr. Ray has read again my detailed statement of method he will be the first to thank me for having introduced some principle of comparison where none has hitherto existed. I am convinced that this coefficient of quality amounts to more than a makeshift; its value will exist in its applicability as a constant factor. Mr. Ray cites my determination of coefficient 93 for Nguna and 76 for Sesake, "the same language, Sesake being a colony from Nguna." The lower coefficient of Sesake is not a matter of mere opinion; it is the mathematical product of the presence in that language of several consonant mutations expressive of a wider divarication from the Proto-Samoan stem. If we were in possession of practically complete dictionaries of Nguna and Sesake, this coefficient of quality would, in my best judgment, still be applicable. Suppose that such dictionaries should exhibit Nguna as having Proto-Samoan loan material quantitatively to the extent of 100 words to the thousand, and Sesake 125; of course, it is understood that I am using figures symbolically. We should err in assigning to Nguna a 10 per cent. Proto-Samoan element and to Sesake $12\frac{1}{2}$ per cent. We should have to regard quality as well as quantity; we should have to employ my quality coefficient (subject to such recomputation as a better supply of data would make possible) as an essential factor. Thus Nguna, as a result of the combination of the two elements, would be indicated by 9·3 per cent. and Sesake by 9·5 per cent. Then and thus only will it be possible to state positively that Nguna and Sesake have received the same influence from the Proto-Samoan, the question of whether *qua* Melanesian they are the same language being a matter wholly distinct.

It was of set purpose that I have omitted the discussion of the syntax of the grammar of Oceanic languages. Our present material is all stated most inaccurately; our authorities, without exception, have stated their considerations of grammar in terms of the grammatical categories of inflected speech. The grammar of these isolating languages must be newly written. It will form a large part of the Samoan dictionary of Polynesian philology upon which I am now engaged. In various publications I have made preliminary announcement of some of the principles of this grammar—*e.g.* in my monograph on the Beach-la-mar jargon, just published, I have dealt with the evolution of the verb in the diffuse attributive; but in the present incomplete stage of the study it did not seem advisable in the volume under review to seek to exceed the phonetic examination of the material there assembled.

WILLIAM CHURCHILL.

New York, August 28.

In my review of Mr. Churchill's book, "The Polynesian Wanderings," I certainly intended my remark as to the liability of error arising from deficient and imperfect material to apply both to quantitative and qualitative comparisons. With regard to the former, there can be no dispute, and the impracticability of quantitative comparison was recognised by Mr. Churchill on p. 143 of his book. But a qualitative comparison as given by Mr. Churchill in his tables, and referred to in the letter, seems to be equally liable to error through inaccuracy in the material. Referring again to the tables for Nguna and Sesake, which I took as typical cases, Mr. Churchill finds that the lower coefficient of Sesake—*i.e.* 76 as opposed to Nguna 93 (implying that Sesake was less like Polynesian than Nguna)—was due to the presence in Sesake "of several consonant mutations expressive of a wider divarication from the Proto-Samoan stem." Mr. Churchill's Sesake words were taken from the lists of Codrington and Gabelentz. The source of his much shorter list in Nguna is not stated. Using a longer list by Bp. Patteson (from which those of Codrington and Gabelentz were derived) and a very long (MS.) vocabulary of Nguna, I find that all Mr. Churchill's examples in Sesake are identical with Nguna, and all the Nguna are identical with Sesake. The consonant mutations are the same. Thus the quality of the likeness to Polynesian is the same for both languages, and the great difference in Mr. Churchill's results is entirely due to the lists being defective and appearing under different names. For the *accurate* application of Mr. Churchill's comparisons the vocabularies used *must* be equal in extent and signification.

My desire in the note on Mr. Churchill's omission to discuss grammar was to direct attention to the fact that he had not shown that any distinctively Polynesian particles (as, *e.g.*, the article *te*, the verbal signs *kua*, *na*, the so-called possessive words *loku*, *toku*, &c.) were used in Melanesian languages.

SIDNEY H. RAY.

Habits of Dogs.

I HAVE read with interest the letter of Miss Everett in your issue of August 31 on dogs eating wasps, as I have a poodle which also eats them, with evident satisfaction. He generally catches them alive, but will also pick them up from the floor when recently killed; he evidently suffers somewhat from the sting, but only for ten or fifteen seconds.

I have always attributed this liking for wasps to some stimulating action of the poison similar to that produced by formic acid on man; this idea was suggested by the following plan, learned in Switzerland.

If a freshly peeled wand be plunged into an ants' nest, so as to be bitten by the infuriated ants, and is then passed between the lips, a sensation of refreshment is experienced which appears to be out of proportion to the effect which one would expect from the mere acidity.

I believe that I have read somewhere that formic acid is a stimulant.

ROBERT VENABLES.

8 rue du Sundgau, Mulhouse, Alsace, September 8.

ON p. 348 Dr. Kidd asks if it is known to be a common thing for dogs to carry hedgehogs in their mouths. I can only answer for my own dog, a fox-terrier. Last season a hedgehog strayed into our garden, and appeared anxious to stay; but the dog carried it in his mouth repeatedly, and so teased it in various ways, that we were not surprised when the hedgehog beat a permanent retreat by absconding. The curious circumstance in the affair was that the dog appeared to carry the hedgehog, rolled in a ball, without causing his lips to bleed; in this particular, Carlo seems to be cleverer than Dr. Kidd's dog!

R. HOOPER PEARSON.

A Gilbert White Manuscript.

MENTION has been made in the Press of the recent sale of a hitherto unpublished manuscript by Gilbert White. It consists of a nature calendar which the author of "The Natural History of Selborne" carefully drew up before he wrote the first of the letters which are the basis of his famous book. To the latter, he tells us, he meant to add an "Annus Historico-Naturalis," and it seems that the MS. in question was intended to be used in this connection. I am pleased to say that the Selborne Society will shortly produce the calendar (which is particularly interesting) in facsimile, and print a limited edition on Italian hand-made paper.

I should be glad to give further particulars to any of the many admirers of Gilbert White who would care to have them.

WILFRED MARK WEBB.
(*Honorary Secretary*.)

Miniature Rainbows.

THE recent letters on miniature rainbows recalled to my mind a rather interesting case which I observed some years ago at Inversnaid, on Loch Lomond. Here a small stream makes a pretty waterfall; and while standing beside the pool at the base of the fall, and directly opposite the fall itself, I noticed first a brilliant rainbow reflected in the pool. The actual bow was formed in the spray above the pool, and, unless my recollection is greatly at fault, it appeared less brilliant than its reflection. But the bow and its reflected image, viewed together across the pool, formed an almost complete circle, broken only where the extremities of the real bow in the spray appeared to come down towards the surface of the pool.

ARGENTINA AND THE ANDES.[1]

THE author has gathered his Argentine experience from two prolonged sojourns at the estancia of his brother, a settler dating back to 1868. He stayed in the country for more than a year, and since his notes were submitted to English estancieros of experience, the present book may reasonably be assumed to contain no errors of importance; it gives us a very fair idea of the actual life, and also of the conditions, which prevailed in earlier times.

FIG. 1.—The Pampas sown with Alfalfa. From "Argentine Plains and Andine Glaciers."

The homesteads, built like forts, the boundless cattle runs, encounters with Indians, the hunting trips in the wilds, have all cnanged for a better and much duller state of things. The Indians have retreated or vanished before the rapidly advancing civilisation; the runs are all fenced in, and to visit some lagoon, where alone interesting bird life might be watched, is likely to mean trespass!

The influence of the industrious Italians is steadily transforming the Pampas into interminable agricultural fields, a change which is spreading further and further to the West. The process is as follows. The owner of undeveloped blocks of land of his domain of, say, fifty square miles, accepts a number of Italian time-squatters, who after having raised crops of Indian corn, wheat, or linseed for several years, are moved on to another block, whilst the former is then permanently sown with alfalfa, *i.e.* lucerne. These pioneering or preparatory cultivators are North Italians; the Southerners stick to the towns. A family takes up from 700 to 800 acres; they find themselves in everything, and pay a quarter of the produce as rent. This is a better plan than their taking land "on halves," the owner supplying them in this case with everything, an arrangement which necessitates capital and produces friction. The author has carefully gone into these and kindred economic questions.

However, the best description of such a land, with scenery none and the natives gone, cannot rise above the level of a stockfarm, in spite of accounts of ensilage, the lassoing, branding, and counting of stock, and the invasion by locusts. There are some interesting observations. The native-born cattle and sheep have learned to avoid eating the poisonous weed *romerilla* (unfortunately animals and plants are scarcely ever mentioned except by their vernacular names, and our author does not profess to be a naturalist), but the imported horses, bulls, and rams have to be taught not to eat this plant. They are tied up, and the collected weeds are burned to the windward of them, so that they are well smoked, after which they dislike the green plant.

The pampas grass is said to be dying out where it comes into contact with this dreary civilisation, and this shrinking seems to take place in a round-about way. Formerly, when all the pasture was native and coarse, the cattle did not touch the still coarser pampas grass; now, when the pasture consists nearly everywhere of lucerne, the cattle go for the grass as a change of diet, or tonic, and thus keep the tussocks stunted, which ultimately succumb to the repeated cropping. The pampas are a land of promise for the energetic young man; if he begins early, and is prepared to work hard, he may, without capital, force

FIG. 2.—Penitentes, with rubble concealing the connecting ice base. From "Argentine Plains and Andine Glaciers."

[1] "Argentine Plains and Andine Glaciers: Life on an Estancia, and an Expedition into the Andes." By Walter Larden. Pp. 320. (London: T. Fisher Unwin, 1911.) Price 14*s.* net.

his way up to a managership, and finally become a wealthy estanciero on his own account. But the author gives the emphatic warning that "Argentina is not a country suitable for the English of the usual emigrant class."

A relief from the monotonous ranch life was the crossing of the Andes into Chile by way of Mendoza, with excursions of several weeks towards Aconcagua and the glaciers of the headwaters of the Tupungato valley, in company of an enthusiastic exploring engineer, who finds his recreation in the climbing of difficult peaks.

The ninety-one original photographs (two of which are here reproduced by the courtesy of the publishers) are excellent representations of a multitude of scenes from lassoing gauchos, sheep-shearing, and locust-plagues, to shifting dunes amongst lagoons, glaciers, and *nieves penitentes*.

THE ERUPTION OF ETNA.

IN the last issue of NATURE (p. 368), a brief reference was made to what has proved to be a somewhat important eruption of Etna. Our knowledge of the successive phenomena is still scanty, the telegrams inserted in English newspapers being short; but, from the more lengthy accounts given in the *Corriere* of Catania, some further details may be gleaned.

The eruption was, as usual, preceded by a series of tremors interspersed with stronger shocks. At Mineo, which lies about 35 miles S.S.W. of Etna, the first movement was recorded on September 10, at 0.58 a.m., followed for more than fifteen hours by almost incessant tremors. After 4.28 p.m., however, a period of calm ensued, which for at least twenty-four hours was interrupted by only one disturbance; and, even at Linguaglossa (about ten miles north-east of the central crater), the shocks had become so infrequent and so slight that the inhabitants were no longer awakened by them.

Almost concurrently with the first tremors, black clouds of vapour and ashes were seen to rise from Etna. The first new vent was opened at 4.30 a.m. on September 10 on the northern flank of the mountain to the north-west of M. Frumento,[1] and at a height of about 9200 feet; the second, at 9.40 a.m., in the neighbourhood of M. Nero; in both cases an hour or more after pronounced shocks. From both openings there issued dense clouds, with lapilli, sand and ashes, but no lava. Later in the day, at 12.15, a third vent appeared, near M. Crozza, and a little later a fourth, near Castiglione Sicilia. After this, new vents opened in rapid succession. On September 11 there were sixteen in action, of which fourteen ejected vapour and dust, and the other two, lower down, lava. On September 13 Prof. Riccò reported that as many as 54 vents had opened in the region between M. Rosso and the craters formed in 1879. The central crater also ejected an immense quantity of ashes, which have covered the surrounding country to the depth of several inches.

During the first day there seems to have been no outflow of lava. At 1.30 a.m. on September 11, however, during a period of comparative seismic calm, a new vent opened between M. Rosso and M. Nero, at a height of about 5250 feet, with enormous emission of dust, &c., followed by a stream of lava. Five hours later another vent appeared in the same district, from which a copious stream of lava issued. The streams rapidly descended the steep slope, passed round M. Rosso and then between the lavas of 1646 and 1809, thus assuring the safety of Linguaglossa. The main stream presented a front from 12 to 15 yards high, and from 500 to 600 yards wide, and advanced rapidly, sometimes at the rate of a quarter of a mile an hour. During the next two or three days, its velocity was reduced. On September 13, it had crossed the carriage road and circum-Etnean railway; the next day it had approached to within two miles of the Alcantara River, which forms the northern boundary of the volcano. On the 15th the main stream split into four subsidiary streams, and the violence of the eruption perceptibly abated. At the time of writing (September 18) the lava stream, the flow of which appeared to be checked, had made another onward movement.

C. DAVISON.

[1] It should be remembered that some of the names given above are duplicated on Mount Etna. The height of the mountain in 1900 was 10,758 feet.

THE CENTENARY CELEBRATION OF THE UNIVERSITY OF CHRISTIANIA.

THE delegates of the foreign and national universities and of many academies of science met an enthusiastic reception at the centenary festival. The organisation was admirable throughout, and much useful assistance was given by a number of students, who acted as marshals, and by ladies who had been asked by the University authorities to help in the entertainment. The majority of the professors and students spoke English well, so that if any foreign delegate met with a difficulty—which is improbable—at least the way was made smooth for all who spoke English.

The Prime Minister, Mr. Konow, and many of the other high officials of the State associated themselves throughout with the University, so that the festival was regarded not merely as academic but also as national.

On the afternoon of Monday, September 4, a short reception was held at the University by the rector, Dr. Brögger, to welcome the delegates, who numbered about 130, and to explain the expediency of dividing us into twelve groups, according to the geographical positions of our several countries. Each group was requested to choose a spokesman, and I had the honour of being chosen to represent the British Empire.

On the evening of Monday the doctors and professors of the University invited their foreign and Norwegian guests, to the number of three or four hundred, to supper at the Grand Hotel. Before supper Prof. Morgenstjerne gave us a cordial welcome in a speech delivered in French, and afterwards we went to the dining-rooms, of which there were several, and supped in groups of skilfully chosen parties of congenial spirits.

The more formal part of the festival took place the following morning (Tuesday, September 5) at the National Theatre. Dr. Brögger presided on the stage, to which access was given by two gangways on each side of the orchestra. The King and Queen honoured the meeting with their presence; and the spectacle was brilliant with the dresses of the ladies, the academic robes, and bright uniforms.

The proceedings began with a cantata composed by Mr. Winter Hjelm, of which the words are by Björnson, entitled "Lyset" (the Light), sung by the students, both men and women, with a full orchestra. After two parts of the cantata had been given Dr. Brögger addressed the audience in German on the history of the University. The groups of delegates then presented their several addresses of congratulation, and each spokesman delivered a speech of a few minutes in length. The rest of the cantata was then given, and this brought the meeting to an end.

In the evening the King and Queen received all the delegates at the castle, and said a few gracious words to each guest.

On Wednesday (September 6) the second formal meeting took place in the handsome new Aula of the University. This hall is not so large as the National Theatre, where the meeting had taken place on the previous day, so that it was only possible to admit national and foreign delegates, but other entertainments were provided by the committee of ladies.

The proceedings on this occasion consisted of instrumental and vocal music, and of a short address by Prof. Stang on the work of the University. The rector then explained that in the honorary degrees which were to be conferred, the claims of mathematics and astronomy were purposely excluded, because degrees in these branches of science had been conferred only a few years ago, on the occasion of the Abel Festival, I myself having then received a degree.

The heads of faculties then presented the names of the several doctors in the various departments of learning to the rector. It may be interesting to note that of the five speeches two were in English, two in German, and one in French. The degrees were then conferred by the rector on the new doctors, of whom but few were actually present. It may here suffice to say that the new British doctors were Prof. Sanday, Prof. Alfred Marshall, Sir Frederick Pollock, Sir Thomas Barlow, Sir John Bradford, Sir William Osler, Prof. Sayce, Dr. Henry Sweet, Sir James Dewar, Principal Miers, Sir John Murray, Sir William Ramsay, Prof. Sollas, and Sir Joseph Thomson.

In the evening the Municipality of Christiania entertained the delegates at dinner in the municipal buildings.

On the following morning a number of parties were taken round the museums, and the two old Viking ships naturally attracted much attention. In the afternoon the Videnskabs Selskabet—the national academy of science—gave a party in the garden attached to their fine house. This home of science was presented to the society not long ago by two Norwegian ladies, whose names, unfortunately, I omitted to take down. As the weather was glorious, this was one of the pleasantest of our many entertainments.

In the afternoon Prof. Birkeland gave a lecture in French on the phenomena attending the discharge of electricity through rarefied gas, with the application of his ideas to cosmogony on the largest scale. The lecture was of great interest; but it contained so much that was new, at least to me, that I will not venture to give a detailed account of his results. I understand that he is now sending a paper on the subject to the *Comptes rendus*.

The festival at Christiania terminated with a brilliant gala performance at the theatre of three acts of Björnson's "Mary Stuart," in the presence of the King and Queen.

On the following morning (Friday, September 8) a large number of the delegates, accompanied by ladies and their Norwegian hosts, left Christiania for Bergen in a special train put at their disposal by the Government. The line affords scenery of great beauty, and is a monument of the triumph of the engineers over enormous difficulties, for we climbed to the height of 4000 feet, and reached the region of snow and glaciers. The weather had been magnificent on the eastern side of the mountains, but we were in heavy rain as we descended the wonderful gorges of the western side. It had been supposed by most of us that the arrival at Bergen would be the real end to the hospitality shown to us; but in this we were mistaken. Every house in Bergen was illuminated in our honour, so that we ran into a city of light, and, notwithstanding the heavy rain, the streets were densely crowded in the neighbourhood of the station. On Saturday and Sunday it was fine again, and thus we learned that Bergen is not a city of eternal rain.

On Saturday a visit to the museum and to the marine biological station had been organised, followed by a drive through the romantic hills which surround the town. In the late afternoon the municipality, as represented by the President and by the first Burgomaster (for in Norway there are two Mayors for each city), invited us to a dinner, at which there were many excellent speeches. Finally, we were invited to the theatre, where a comedy by Björnson was admirably acted. This play, entitled "Geography and Love," was perhaps chosen to teach men of science that they ought not to become intolerable nuisances to their wives.

On Sunday morning the special train returned to Christiania, somewhat emptied by the departure by sea of some delegates, who were bound for St. Andrews.

It is notoriously difficult to judge of places and institutions in their holiday dress, but I am sure that all the visitors must have carried away an impression of great activity in the study of literature and science on the part both of the professors and students; and what I have written will have shown how great was the hospitality extended to us during this crowded week.

G. H. DARWIN.

CELEBRATION OF THE FIVE-HUNDREDTH ANNIVERSARY OF THE FOUNDATION OF THE UNIVERSITY OF ST. ANDREWS.

CELEBRATIONS there have been in St. Andrews from very early times, more especially when its ancient chapels and monasteries were in full activity, and still more when its splendid cathedral, the largest and finest in Scotland (yet so ruthlessly destroyed by the Reformers) lent its countenance to the ceremonies. The present, however, surpasses them all save in the absence of the King, who so often favoured the city and the University up to the time of Charles II. Thus, to confine the remarks to academic life, great were the rejoicings on February 14, 1413, when Henry Ogilvie, M.A., the bearer of the papal Bull of the cultured Benedict III. endowing the young University with its important privileges, entered the city. Bells sounded from the steeples, a solemn convocation of the clergy was held in the refectory of the Priory, and a procession to the high altar of the cathedral was made by the whole assembly in rich canonicals, "whilst 400 clerks, besides novices and lay brothers and an immense number of spectators, bowed down before the high altar in gratitude and adoration."[1] After high mass the day was devoted to mirth and festivity. Such was a fitting baptism to a university which owed its beginning more to the impulse of learned men to teach than to public or private endowments. No special buildings at first existed, the masters opening pedagogies in various parts of the town, the larger meetings in churches or in the refectory of the Priory so recently and so judiciously restored by the late Lord Bute.

Now, after the lapse of five centuries of an almost unbroken continuity in academic life, the University again engages in festivity and rejoicing. During its long and chequered career it has surmounted numerous trials and difficulties—such as the turmoil of revo-

[1] Tytler, "Hist. Scot."

lutions, the asperities of reformations, and the paralysing spoliations—and to-day is not lacking in vitality, vigour, and eagerness to fit a university of the olden time to every modern improvement. Formerly it had seen the burning of martyrs in front of its gates or in its vicinity, had endorsed the law on the unfortunate witches, and rigidly excluded women even from its quadrangle, on one hand; and, on the other, it had reared or fostered many men of note who spread its fame throughout other lands, or sent its best and wisest to preside over the sister-universities or to teach within their walls. Science, literature, and divinity have been enriched by the labours of its staff throughout this long period, its students have increased in number, women have entered its gates on the same footing as men, and its interests have been widened by the union with the college of the enterprising and prosperous city of Dundee.

With its long, chequered, and honourable career behind it, and imbued with high purpose for the future, the University held the first function of the celebration on Tuesday afternoon, September 12, in the presentation of his portrait to Mr. Carnegie. This was a gift of the students, Senate, and University Court in recognition of their former rector's munificence to the University, for to him it owes, amongst other things, its fine Carnegie Park, pavilions, library, and gymnasium. The picture represents Dr. Carnegie in his robes as rector. Principal Sir James Donaldson made the presentation on behalf of the subscribers, and Dr. Carnegie made a notable acknowledgment.

In the evening there was a reception by the chancellor, Lord Balfour of Burleigh, who, with Lady Balfour, graciously received the great concourse of visitors and others in the North Hall at the United College of St. Salvator and St. Leonards. No more brilliant scene could have been imagined. Not even the great array of silver ornaments and statues, of gorgeously arrayed Churchmen of every rank at the celebration of the endowment of the young University in 1413 to grant degrees by the papal Bull, could have exceeded the varied and striking array of the representatives of science, of medicine, of arts, divinity, law, and other distinguished men and women from almost every civilised country in lines from New Zealand to Australia and radiating through the old world and through the new to the old grey city on the Scottish coast. The bright colours and ornamentation of the robes and hoods, the gold chains of office—academic and civil—the brilliant orders and medals, and the still more varied colours and graceful drapery of the ladies, mingled with the sheen of spurs and the full-dress uniforms of military men, both highland and lowland, of representatives of the navy and groups of civic dignitaries, made a scene never to be forgotten. One thing more only can be alluded to, and it is that the welcome given by Lord and Lady Balfour to every one of the 3500 was of such a kind that from first to last the proceedings were of a most pleasant and harmonious kind. The band of the Scots Guards at the eastern end of the hall enlivened the proceedings, which were further enhanced by the chaste decoration of the interior, from the platform to the opposite end.

Moreover, a torch-light procession of the students starting from the Carnegie Park, clad in the most varied and fantastic costumes, made a striking and most fascinating scene throughout the city, as the long, snake-like line of fire wound its way along crescent, street, and promenade. Whether man or woman held the torch it was sometimes difficult to say; so that if the women students were not present, their places were sympathetically filled. To add to the charm of the proceedings the old tower of the United College of St. Salvator and St. Leonards was outlined each evening at every angle by rows of electric lamps—white, blue, and red.

Finally, a symposium was held in the Volunteer Hall under the auspices of the Students' Representative Council, at which all graduates and students of the University met. Many old friends thus had an opportunity of seeing each other and of contrasting the old *régime* with the new, and there was no happier assembly during the celebration than this.

Under bright sunshine the morning of Wednesday, September 13, was occupied by marshalling in the United College quadrangle the assembled University Court, Senate, lecturers, graduates—both ordinary and honorary—students, including members of the Officers Training Corps, delegates and distinguished men from the colonies, India, from foreign universities and societies, Lords of Session, sheriffs, the Provost and Town Council, and others to form a procession to the town church (Holy Trinity), so recently and so finely restored under the auspices of Dr. P. M. Playfair. In the church an impressive commemoration service was performed, chapters were read by the chancellor and vice-chancellor, the "Te Deum Laudamus" was sung, and an appropriate and eloquent sermon was given by the Moderator of the General Assembly (Principal Stewart, of St. Mary's College). Prayers were said by Dr. Playfair and the Very Rev. Archibald Henderson, D.D., clerk of the United Free Church, and it is noteworthy that the first prayer was a translation by the late Marquis of Bute, a former rector of the University, of the prayer given in 1413 on the arrival of the papal Bulls establishing the University. The whole tone of the procession and its surroundings and of the service in the Church of the Holy Trinity was in keeping with old academic tradition, and the same feeling pervaded the great assemblage. In no other Scotch city could the combination of past and present render the scene more purely academic.

In the afternoon the presentation of congratulatory addresses took place in the North Hall, the chancellor, rector, and the staff occupying the platform. About 166 addresses were handed in by the distinguished delegates of universities, learned societies, university general councils, town councils, churches, and other important bodies; and as each was as a rule arrayed in official robes, with gold chains and orders, the scene was one of the most interesting in the celebration. As the representatives of each country were announced, the band played a brief but appropriate piece of music. The chancellor (Lord Balfour of Burleigh), after reading a letter from the King, then delivered an eloquent and masterly address, in which he welcomed the delegates from all parts of the world, alluded to the founders of the University, its continental character, its modern modifications, the effect of its training on the national life, and finally he sketched a picture of the future of the University. Principal Sir James Donaldson then welcomed the delegates and guests on behalf of the senate.

A delightful entertainment, consisting of historical tableaux connected with the University, was given by the students in the evening. Moreover, students of the 'eighties (1880–9) had a special symposium.

Equally favourable was the weather of Thursday morning, when the rector of the University, the chosen representative of the students, was installed. The popularity of the Earl of Rosebery, who now has held the rectorship in every Scottish university, was sufficient to have filled the vast hall several times over, and, as it was, every available space was packed, little short of 4000 people being present. Before the entrance of the procession of the chancellor, rector, principals, senate, and staff in general, the students beguiled the time with songs, and as the procession entered the band played "Gaudeamus Igitur." The president of the Students' Representative Council then intimated the result of the rectorial election; Lord Rosebery took the oath, was robed, amidst the cheers of the students and audience, and then delivered his address, which was marked throughout as the production of a finished orator and man of affairs, as the experience of a man of letters, and as the counsel of a statesman. He lightly touched on the early history of the University (much of which recent writers have necessarily borrowed from Lyon, biassed though he was, and others), the troubled times following its foundation, the tenacity of its hold on learning (science for the time being forgotten) amidst the vicissitudes of its centuries, and in a fascinating manner drew a picture of the first rector as a Struldbrug of Swift doomed to perpetual life, who, from a point of vantage, surveyed the progress of the University century after century, and, though shocked at and severely critical in regard to many of the changes, concluded by affirming that, after all, substantial advances had been made all along the line. In his final words the rector counselled the students to hold fast to the simple and temperate life, the dogged perseverance, and the pure and high aims of those who had gone before them. Especially did he warn them of the dangers of losing that self-reliance, that frugality, that resolute application to work, and that masterful surmounting of difficulties which have made their countrymen thrive even under neglect, and have won for them the respect of the world. Above all, should they avoid being a "spoon-fed" nation.

After the conclusion of the rectorial address, congratulations from the Senate were conveyed by Principal Stewart to Sir James Donaldson on the completion of his twenty-fifth year of office, and in recognition of the skill and ability with which he had guided the affairs of the University. The principal feelingly replied. Then the graduation ceremony proceeded. The first (about ninety) were those receiving the honorary degree of LL.D., and as each distinguished graduate stepped on the platform to be capped by the chancellor, he or she was cheered by the students and audience; and so with the fourteen men who received the D.D. degree. Amongst those on whom the degree of LL.D. was conferred were many eminent men of science, as mentioned in the last issue of NATURE (p. 374), some of whom had been students in the old university, or had carried out researches in its marine laboratory.

In the afternoon garden-parties on a large scale were given by the mistress and council of St. Leonards' School in their fine grounds, the band of the Scots Guards playing at intervals; whilst another large party was entertained at Mount-Melville, the seat of Mr. J. Younger. Both had endless beautiful and interesting pictures in scenery and landscape gardening, in fine trees and shrubs, to entertain them, especially at Mount-Melville, where arboriculture has long been prominent.

The banquet in the Bell-Pettigrew Museum in the evening was on a large scale, the chair being occupied by the chancellor, and he was supported by the rector and principals, by Lord Reay, Lord Elgin, Lord Stair, Lord Ailsa, Lord Pentland, Lord Kinnoull, Lord Tullibardine, Lord Haddo, Lord Southesk, Lord Kinnaird, Lord Glenconner, Lord Shaw, the principals of Edinburgh, Glasgow, and Aberdeen, Dr. Andrew Carnegie, Mr. Whitelaw Reid, Mr. A. J. Balfour, the Maharajah Gaekwar of Baroda, and a long list of distinguished men. After the loyal toast the chancellor declared the museum open, and alluded to the munificent gift of Mrs. Bell-Pettigrew. Speeches were given by the rector, principals, Mr. Balfour, Sir William Turner, Sir Donald Macalister, Lord Reay, Lord Elgin, Lord Pentland, Mr. Munro-Ferguson, President Butler (New York), and many others, and the dinner was throughout of the most agreeable and successful character.

In order to entertain those whom the limited capacities (550) of the hall had of necessity excluded, a ladies' "at home" was held in the large North Hall, under the auspices of the Ladies' Celebration Committee. Lady Balfour, Lady Leconfield, Lady Helen Munro-Ferguson, and the ladies of the executive committee received the guests, who spent a most enjoyable evening. Moreover, a similar reception was held in the Victoria Art Galleries, Dundee, where Lady Baxter of Invereighty and Mrs. Urquhart, the wife of the Lord Provost of Dundee, received the guests, and the evening was spent in the same happy and memorable way.

The close of the quincentenary celebrations occurred on Friday, September 15, which was chiefly spent in Dundee in connection with University College (formerly the Baxter College), which is now an integral part of the University of St. Andrews. A special train conveyed the Court, Senate, staff and guests from St. Andrews to Dundee at 10 a.m., and all the visitors assembled at University College Library, signed the visitors' book, and proceeded to the gymnasium, where, on behalf of the council of the college, Lord Camperdown gave them a cordial welcome. Remarks were then made by the chancellor and by the rector, who, in a humorous yet suggestive speech, held that universities of the future would always be founded in great centres of population. The buildings, especially the new Carnegie Physics Laboratory, the medical buildings, the engineering laboratory, the college museum of natural history, the various class-rooms, and the city museum, were then inspected, and a tribute paid to the wonderfully complete arrangements for the teaching of medicine, engineering, physics, and other departments.

A luncheon was given by the University in the drill-hall, where the guests were received by Lord Provost Urquhart and the magistrates. The chancellor occupied the chair, and many distinguished men supported him, viz. Lord Reay, Lord Rosebery, Lord Camperdown, Lord Stair, Lord Shaw, the principals, senate, and staff of the University, and others. Between 600 and 700 persons were present. The usual toasts were given, and the company broke up about half-past two to proceed to view various large mills in the city, to join the excursions to Glamis, Rossie Priory, and a sail by steamer to Perth—all under most favourable auspices.

Another function was a graduates' and students' dinner in the Bell-Pettigrew Museum at St. Andrews, presided over by the chancellor, at 7.20 p.m. More than 500 were present, and amongst the guests was Sir Dyce Duckworth, who has so frequently visited St. Andrews, and he, in his speech, took his hearers back to the days of Principal Tulloch, on whose grave that afternoon a procession of old graduates and alumni had placed a wreath. The same would have been done if the grave of Sir David Brewster, of world-wide renown, had been in St. Andrews, for the University cherishes the memory of her, and subsequently Edinburgh's, great scientific principal.

Lastly, a students' ball at 10 p.m. brought the proceedings to a termination. This was one of the brightest and gayest of the social gatherings, under the auspices of the Students' Representative Council and its president, Mr. Dickey. The uniforms of the officers of the warships at present in St. Andrews Bay, the bright robes of the foreign and British graduates, the varied hues of the ladies' attire, and the gowns of the students themselves lent a charming novelty to the picture.

Thus ended the stately celebration of the five-hundredth anniversary of the foundation of St. Andrews University, under the most cheerful of sunny skies, pure (but not "piercing" air), and amidst the unique academic surroundings of the place, which usually, and unfortunately, are wholly absent in those great populous centres where the universities spoken of by the rector will in future be. But the great stretches of pure sand, the expanse of the blue waters of the bay (on which the warships proudly ride), and the long lines of tidal rocks remind us that nowhere within the British dominions can the sciences of geology, botany, and zoology be studied under more inspiring or more favourable auspices than in the little city by "the cold North Sea." Be that as it may, one thing is certain, viz. that both guests and hosts vied with each other in making this celebration one of the most delightful and memorable gatherings it is possible to conceive. W. C. M.

EDWARD WHYMPER.

IN Edward Whymper, who died suddenly at Chamonix on Saturday last, September 16, we have lost one who was more than a most undaunted and successful climber of mountains. Born on April 27, 1840, the son of an artist and engraver on wood, he was brought up to the work and carried it to great perfection. He went to the Alps on a professional errand in 1860 and began his career as a climber. Next year he made the first ascent of the Pelvoux, and in 1864 vanquished its neighbour, the Ecrins, the highest summit of Dauphiné. Before that he had attacked the Matterhorn. How this was at last conquered, in 1865, and of the tragedy of the return, when four lives were lost, it is needless to tell. In 1867 he visited Greenland and attempted to penetrate the inland ice. It was a failure, though not from his fault. In 1872 he returned to do some surveying on the coast. In 1879–80 he undertook his notable journey to the Ecuadorian Andes, during which he successfully ascended ten volcanic mountains, ranging from 15,000 feet to above 20,000 feet, most of them hitherto unclimbed, spent a night on the summit of Cotopaxi, and twice reached that of Chimborazo.

In later years Whymper made four or five exploratory expeditions in the Canadian Rockies and Selkirks. But he was more than a successful mountaineer: he was a keen observer of all natural phenomena. His two great and beautifully illustrated books, "Scrambles amongst the Alps" and "Travels amongst the Great Andes of the Equator," contain much of scientific value. He was a student of glaciers, and a keen critic of those who claimed for them great powers of erosion; a close observer of volcanic and other geological phenomena, and a collector who knew what was worth bringing. While at Disco Bay he obtained a fine series of fossil plants and of Eskimo relics. From the Andes he brought many specimens of rocks and other material, descriptions of which have been published, and himself wrote a paper on the aneroid barometer, besides devising a modification of the mercurial instrument for use on high mountains.

Whymper's latest books, "Chamonix and Mont Blanc," published in 1896, and "Zermatt and the Matterhorn," which appeared in the following year, are admirable of their kind, and have met with great success. He was a fellow of the Royal Society of Edinburgh, had received the Patron's medal of the Royal Geographical Society, and been decorated with the Order of St. Maurice and St. Lazare, besides being an honorary member of foreign geographical societies and Alpine clubs. T. G. BONNEY.

NOTES.

THE Government of the Commonwealth of Australia has promised to contribute 5000*l.* towards the expenses of the Mawson Antarctic Expedition, and the Victorian Government 6000*l.* This amount brings the contributions of the various Australian Governments to the sum of 22,000*l.*

THE friends of the late Christian A. Herter have contributed to a memorial fund in recognition of his labours in promoting medical science. The fund, which amounts to 8000*l.*, has been confided to the directors of *The Journal of Biological Chemistry*. The chief aim of the trust is to further the interests of that journal, which was founded by Herter.

ACCORDING to the *Revue Pratique de l'Électricité*, a bronze statue has been erected at Poleymeux, in the Rhone Department, France, in memory of Ampère. The inventor is represented standing in an attitude of meditation, the right hand raised to the forehead, the left clenched. On the side is inscribed "La Science," suggestive of the subject of his meditation.

AN International Engineering Exhibition is to be held in April next at Baku, Russia, and will be open for six weeks. The exhibits will comprise internal-combustion engines, air-compressors, electrical apparatus, motor-cars, &c. Particulars of the prospective arrangements may be obtained from the sole honorary representative in this country—Dr. P. Dvorkovitz, 1 Broad Street Place, E.C.

DR. R. KARSTEN, lecturer in comparative religion in the University of Helsingfors, has started on an expedition to Gran Chaco and Bolivia for the purpose of making investigations on the sociology and religion of various tribes of natives, some of whom are little known, while others have never been visited. He will be accompanied by his cousin, O. Lindholm.

M. G. FAYET, of the Paris Observatory, has been appointed astronomer at the Nice Observatory, in succession to M. Simonin.

MR. MARCONI has been elected president of the Junior Institution of Engineers in succession to Sir J. J. Thomson, F.R.S.

MR. J. J. NOCK has been appointed by the Secretary of State for the Colonies, on the recommendation of the Kew authorities, curator of the Hakgala Gardens, Ceylon.

THE meeting of the International Sanitary Conference to revise the provisions of the convention of 1903 for the prevention of the invasion and propagation of plague and cholera, is to take place in Paris on October 10 next.

A CONFERENCE of members of the Museums Association and others interested is to take place in the Free Public Museums, Liverpool, on Wednesday, October 18, the object being to discuss subjects of interest to those concerned in the work of museums.

PROF. LUIGI CARNERA, hitherto the director of the International Latitude stations at Carloforte and Oncativo, has been appointed professor of astronomy and geodesy in the Istituto Idrografico della R. Marina at Genoa, to which address he desires all communications to him to be sent.

THE new session (the seventieth) of the Pharmaceutical Society's School of Pharmacy is to be opened on October 4, when the inaugural address will be delivered by Dr. J. Macdonald Brown. The Hanbury gold medal will be presented on the occasion to M. Eugène Léger, of the Hôpital St. Louis, Paris.

A REUTER message from Adelaide states that Mr. Brown, the South Australian Government geologist, reports that the uranium ores recently discovered in the northern portion of South Australia possess great importance, owing to the limited extent of the world's supply of radium-producing ore. He also reports the existence of extensive deposits of corundum in the same district, and recommends prospecting there for rare gems.

THE third exhibition of small power engineering appliances, models, and scientific apparatus will be held at the Royal Horticultural Hall, Vincent Square, Westminster, on October 13 to 21. It will comprise working and stationary engineering models of all kinds, small power steam, gas, and oil engines, lathes and light machine tools, electrical appliances, &c. There will also be a completely equipped model engineering workshop, in which demonstrations of metal-working processes and small engine building will be given daily.

AN agreement has been signed by the representatives of the United Kingdom and Germany, the carrying into effect of which will mean a thorough investigation into the extent of sleeping sickness in the Gold Coast Colony, the Ashanti and Northern Territory Protectorates, and Togoland. Each Government will keep the other informed of the incidence, extent, and possible spread of the disease in its territory, and will treat the other's native subjects free of charge; but each may impose restrictions on the frontier traffic and may prevent suspected sufferers from crossing its border. The agreement is for three years certain from December 1, 1911, and continues thereafter for yearly periods, unless denounced at least six months before the close of a year.

IT is reported in *The Lancet* that the chief medical officer of one of the Austrian army corps has recently ordered the use of Calmette's serum against serpent-bites, and a fairly large stock of it has now been issued to each regiment in the south of the Empire. The men and the medical officers are instructed in the use of it, and regular inspections of the stock, as well as lectures on the natural history of the poisonous kinds of serpents, are provided for. In addition to the serum, the various appliances necessary for its proper application have been supplied to the army hospitals. Hitherto much dependence has been placed on the treatment of such injuries by alcohol and the application of permanganate of potash.

IN May last great excitement was created in Turkey and throughout the Mohammedan world by the rumour that a party of English archæologists had profaned the Mosque of Omar at Jerusalem in search of the regalia of Solomon, the Ark of the Covenant, and the Tables of the Law. A full account of the results of this expedition appear in *The Field* of September 16, of which a summary is given by *The Times* of the previous day. The excavations were chiefly devoted to what is known as the Virgin's Well and the maze of tunnels and chambers connected with it. Many fragments of Jewish and Hellenistic pottery were found. While some of it may be attributed to Canaanitish potters, none can be safely dated so late as the ninth century B.C. One Israelitish lamp, in almost perfect condition, is certainly as old as the eleventh century B.C. The Hellenistic pottery betrays indubitable evidence of that school of pottery which was transformed in the eighth and ninth centuries B.C. by Cypriote or Rhodian influence.

THE mediæval belief that the neuro-hystero-psychic manifestations known as Tarantism, because they were attributed to the bite of the Tarantula spider (*Lycosa tarantula*), has again appeared in the Troad, according to an interesting account given by a correspondent of *The Times* in its issue of September 9. The ecstatic dances, now said to be due to the promptings of the spirit of St. George, are similar to those which prevailed in Europe from 1374 to the beginning of the sixteenth century, the only difference being that in the present case the excitement is shared by men as well as women. The correspondent quotes two instances, which may probably be attributed to automatic suggestion, in which spider bites were said to be the cause of similar phenomena in one of the Troad villages. Similar manifestations are said to have occurred recently in the small island of Marmora, and at Balouki, a suburb of Constantinople. It is suggested that the investigation of these phenomena should be undertaken by medical experts and by the societies devoted to psychical research.

DR. MAX OHNEFALSCH-RICHTER publishes in *The Times* of September 11 an interesting letter on the discoveries of the Prussian Academy's archæological expedition to Paphos, in Cyprus. We appear to allow the Germans to excavate as they please in one of our colonies. That is very good of us, and it is all to the good of science; but it is a pity that our archæologists cannot be digging in the kingdom of Cyprus too. That little island-realm, which owns the sway of George V. (in succession to Richard Lionheart, who was the first English King of Cyprus) is full of archæological treasures which only await the spade. Witness the fine collections of Minoan antiquities from Enkomi in the British Museum. Dr. Ohnefalsch-Richter describes antiquities of a later period, chiefly Greek inscriptions, written in the peculiar Cypriote syllabic script, from Paphos. A discovery of his own at Rantidi last year gave the impetus to the Prussian work which has resulted in so great an addition to our knowledge of Cypriote inscriptions. The site on which they have been found by Dr. Zahn is that of the ancient high-place of Aphrodite at Paphos.

INFORMATION has been received of the arrival of the magnetic survey vessel, the *Carnegie*, at Mauritius on August 6, having been thirty-one days out from Colombo, Ceylon. The exceptionally large chart errors (approximating in magnetic declination to four degrees for one extensively used chart and for another even to six degrees) which were shown on the portion of the cruise from Cape Town to Colombo, *via* St. Paul I., April–June, have been confirmed by the cruise from Colombo to Mauritius. The *Carnegie* also arranged her route so as to intersect the tracks of the *Gauss* (1901–3), and thus has been able to secure valuable secular variation data. A fuller account is published in the September issue of *Terrestrial Magnetism and Atmospheric Electricity*. Dr. Bauer, during his visit to Australian institutions, was able to set afoot a general magnetic survey of Australia, one of the largest land areas remaining to be explored in this respect. The survey is to be conducted under the joint auspices of local organisations and of the Carnegie Institution of Washington, the observer-in-charge for the latter being Mr. E. Kidson, formerly of the Christchurch Magnetic Observatory, and more recently observer on board the *Carnegie*. Cooperation has also been effected between the Mawson Antarctic expedition and Dr. Bauer's department.

In the obituary notice of the Rev. F. J. Jervis-Smith, F.R.S., which appeared in Nature of September 7, the writer, who was an old friend, remarked:—"Trained as a mechanical engineer, he gave up the calling of his choice, went to Oxford, and entered the Church for family reasons." Mr. E. J. Jervis-Smith writes to say that this is not correct, as his father's education was entirely classical. Also, he says, "My father intended from his earliest childhood to enter Holy Orders, as it was his father's greatest wish that he should do so." The Rev. F. J. Jervis-Smith certainly knew all the tricks of the engineer's workshop, and prided himself upon so doing; and this led the writer of the notice to believe that he had been trained in mechanical engineering, instead of receiving the usual classical education with the intention of entering Holy Orders. His interests were, however, scientific and engineering, whatever was his educational course, for his son says:—"As a child my father saw a great deal of Mr. William Ellis Metford, who imbued him with a love of mechanics and scientific apparatus. He had a small scientific and mechanical laboratory of his own at Taunton, where he carried on research work before going to Oxford as Millard lecturer."

We learn from *The Lancet* that a society for the prevention of diseases and epidemics (Gesellschaft zur Bekämpfung von Volksseuchen) has been founded in Austria which will act in concert with the Public Board of Health and the Sanitary Department of the Ministry of the Interior. Its aims are to supplement the endeavours of the public authorities in combating diseases, to improve the general circumstances of patients and their families belonging to the poorer classes, to provide adequately trained attendants for the care and nursing of patients during epidemics, and to organise medical help and hospital accommodation in non-epidemic times. The society will also encourage investigations relative to the spread of diseases, as well as their prophylaxis and treatment, and will, so far as possible, make the general public acquainted with the results of these scientific researches. The society will endeavour to improve the knowledge, not only of the so-called epidemics, but also of all diseases which prevail extensively. The present intention is that the scientific part of the work shall be divided amongst all practitioners in the country through the instrumentality of the local medical unions and councils. It is thought possible that an international society for the study of epidemic diseases may in the course of time be called into existence.

Man for September contains an important report by Mr. C. L. Woolley on the great collection of pottery brought by Dr. M. A. Stein from Chinese Turkestan and western China, which dates from the first century B.C. onwards. Much of it consists of hand-made pots fired in an open hearth, as is still the custom in modern India, and showing in the section the uneven bands of colour usually resulting from this process. An important advance is illustrated by the moulded ware, in which the moulds employed show distinct Gandhara influence. The wheel-made pots are usually of finely levigated clay, kiln-fired, sometimes smothered, sometimes of a clear terra-cotta red. It is not necessary to suppose that the glazed specimens were imported, because similar glazes, though on a different body, were certainly locally produced.

Recent reports announce numerous important prehistoric finds in this country. In a sepulchral barrow of the Bronze age at Eye, near Peterborough, a pot containing food offerings to the dead was unearthed in 1910. But it was only in the present year that the actual interment was discovered, the skeleton being that of a tall man, whose corpse had been laid on the right side with the head to the south-west, and the arms and legs flexed, a disposition typical of this period. The absence of articles accompanying the interment makes it difficult to fix the date more closely than in the second millennium B.C. During the visit of the Cambrian Association to Promontory Hill Fort, which overlooks the Vale of Clwyd, near which some fine bronze trappings were found some forty years ago, the accidental discovery by a member of the party of some fragments of pottery at the mouth of a rabbit burrow enabled Prof. Boyd Dawkins to conclude that this site had been occupied from the later Bronze and Iron age down to the end of the second or third century of the Roman occupation.

The Times of September 6, in its second article describing the excavations made by Commendatore Boni at the Roman Forum, throws some light on the problems connected with the famous Niger lapis, or black stone, which was unearthed in 1890, and has since supplied the material for a vigorous controversy. It is a slab of black marble covering remains which are certainly of great antiquity, including a broken rectangular stele bearing an inscription, which has hitherto remained undeciphered. These remains bear marks of intentional demolition; and close to the place were found a series of dedicatory gifts, such as small idols of clay, bone, or bronze, with some river sand, which was obviously brought here from a distance to serve some special religious purpose. It thus appears to mark the site of a ruined sanctuary, hitherto assumed to be an unlucky spot—the grave of Romulus, or of his foster-father Faustulus, or Hostus Hostilius. Commendatore Boni now believes that this was the site of the rostra destroyed by the patricians at the beginning of the civil war, about 124 B.C. The present remains, he supposes, mark an expiatory rite performed in obedience to an oracle procured from the shrine of Demeter at Enna, in Sicily, from which advice was sought how best to expiate the contamination of the Forum by the slaughter of so many Roman citizens. It thus represented a popular monument intended to be a lasting memorial of plebeian resentment against this outrage on the part of the aristocratic faction.

The contents of Nos. 3 and 4 of the second volume of the Economic Proceedings of the Royal Dublin Society include an article by Prof. G. H. Carpenter on insects, &c., injurious to crops and trees observed in Ireland in 1910.

We have received a copy of the report of the museum of the county borough of Warrington for the year ending June 30. It may be noticed that the museum accepts such miscellaneous objects as a Rhone beaver and a portion of tree-trunk gnawed by the Canadian representative of the same.

In the September number of *British Birds* Miss E. L. Turner records the breeding of the bittern in Norfolk during the past summer. It appears that three adult birds were observed in the latter part of December, 1910; booming commenced at the end of the following January, and continued, with the exception of February, until June 4, when it ceased. A half-fledged young bird was taken on July 8 (and subsequently liberated) which appeared to be four or five weeks old; and it is suggested that this was the latest of the brood, the other members of which had dispersed. The empty nest was observed. If, as appears to be the case, the cock ceases to boom immediately after the young are hatched, it may be inferred that both parents share in the task of feeding their offspring. Although the bittern is doubtless a night-feeder, it appears to tend its young at intervals throughout the day, as one at least of the old birds was observed to visit the nest several times a day.

A FEW weeks ago reference was made in this journal (August 10, p. 200) to the discovery of a breeding colony of fulmar petrels at Berriedale Head, Caithness. In the September number of *The Irish Naturalist* Mr. R. J. Ussher announces the existence of a colony of these birds on a high, perpendicular cliff on the coast of Mayo, this being the first instance of the breeding of the species in Ireland. According to the local boatmen, these white "cawnoges" made their appearance on the cliff, which is about 700 feet high, four years ago, and have been steadily increasing in numbers since that date. On July 10 Mr. Ussher scaled the cliff, and, with the aid of binoculars, counted eighteen sitting fulmars on a ledge about 400 feet above the water, the specific identity of the bird being rendered certain by individuals which flew close overhead. It is also stated that a colony of about twenty fulmars was observed on a cliff in Ulster in May, the birds, according to local report, having made their appearance in 1910, and remained through the breeding season. Mr. Ussher does not believe that the fulmars have been attracted by the whaling stations on the west coast of Ireland, but that their appearance is part of the extension of the breeding area of the species now in progress. Of this extension Mr. R. M. Barrington gives a summary in a separate paper in the same serial.

IN an article on the purpose and some principles of systematic zoology, published in *The Popular Science Monthly* for September, Mr. Hubert Lyman enunciates the following five propositions, which he regards as of prime importance in regard to the present condition of the science and the lines on which it is studied:—(1) Naming and describing new species and correcting nomenclatural errors, while valuable, and indeed essential, is frankly the most elementary, and hence the lowest, form of zoology. (2) To be of real worth and permanent value, the systematic study of any group of animals must take into account, so far as they are known, the pre- and post-natal development, the geological history, and the geographical distribution of the species which compose it. (3) While genera and larger groups in our systems of classification ought to be based on relationship, their delimitation is often of necessity artificial, and is purely a matter of expediency and convenience. (4) The value of a character for distinguishing species or higher groups depends chiefly on its constancy, and for indicating relationships within a group on its significance; in neither case is its conspicuousness anything more than a matter of convenience. (5) In all systematic work, the line between facts of nature and opinions of the worker should be sharply drawn; the value of the work often depends on the clearness of this line. The article is certainly opportune, as there is a decided tendency at the present day to regard systematic work as the end and final aim of zoology instead of the foundation.

A NOTE by Prof. A. C. Seward in *The Geological Magazine* (July) describes a fossil bipinnate leaf, taken from the Molteno beds at the base of the Stormberg series in Cape Colony, that supplies the type of a new genus, Stormbergia. The stalked pinnules furnish the chief distinctive feature of what is regarded as a probable fern frond; in some respects it resembles *Bernoullia helvetica*, a fossil fern of Rhætic age.

IT is obvious that the task of exhibiting alpine plants on tables in April calls for considerable enterprise and previous calculation. A prize offered by the Royal Horticultural Society of Ireland has inspired an article on the subject, contributed by Mr. W. H. Paine to *Irish Gardening* (September). The cultural directions refer to species of Primula, Androsace, Viola, Aubrietia, Saxifraga, Shortia, and Anemone. With regard to methods, while the various plants have their special soil requirements, it is recommended that the plants should be panned in autumn to get established, then plunged in sand and covered with a depth of leaves, sand, or bracken through the winter. Preparations for bringing the plants into exhibiting condition must be started several weeks before the show takes place.

WITH the object of estimating the aperture of stomata, Dr. Francis Darwin, assisted by Miss D. F. M. Pertz, has devised an ingenious apparatus that he calls a porometer. It consists of a small campanulate glass vessel attached to an air chamber. The glass vessel is fixed to a leaf, and pressure in the chamber is reduced, whereby air is drawn through the stomata. The rate of flow of the air into the chamber is measured, and supplies a comparative indicator of changes in the apertures of the stomata. The porometer provides a continuous method; it indicates the movements of a group of living cells, and possesses a great advantage over the horn hygroscope and cobalt paper, inasmuch as the readings of the instrument are independent of transpiration. The experiments described in the Proceedings of the Royal Society (vol. lxxxiv.) are designed to show how illumination and water supply influences stomatal aperture.

THE main features of an address, delivered by Mr. R. R. Gates before the National Academy of Sciences at St. Louis, on the mode of chromosome reduction, is published in *The Botanical Gazette* (May). With regard to general facts, it is noted that there are two ordinary methods of chromosome reduction in organisms, the one involving an end-to-end arrangement, the other a side-by-side pairing; the difference is not of phylogenetic or hereditary value, but is a matter of cell mechanics. Consequent upon the important point first demonstrated by Strasburger, that the chromosomes are in homologous pairs throughout the tissues of the sporophyte, it is argued that the reduction process consists in a segregation of the paired somatic chromosomes in the heterotypic mitosis, and a split of these chromosomes in the homotypic, and that the supposed function of synapsis to bring about a pairing of the chromosomes is not justified.

A MEMORANDUM on the monsoon conditions prevailing during June and July, with a forecast for August and September, issued by the officiating director-general of Indian observatories on July 30, states that an almost complete break in the rains began between June 18 and 26. On July 5 a fresh advance of the Arabian Sea current occurred, and extended rapidly into the interior; but by July 15 the monsoon had again begun to weaken, and a second break set in, which lasted until about July 27. The total rainfall of this month fell short of the normal by about 34 per cent., the defect being almost general. From a consideration of the various extra-Indian conditions which usually influence the behaviour of the monsoon, the inference is drawn that although the latter may be expected to continue unsteady and weak, the drought is likely to become less general as the season progresses. The combined rainfall of August and September, however, will probably fall short of the normal, particularly in parts of central and north-west India. Reports subsequently received by telegraph seem to show that this forecast is, in the main, likely to be fulfilled.

The Scientific American of August 19 publishes a most interesting article entitled "The Head of the Official Meteorological World," accompanied by an excellent photograph of Dr. W. N. Shaw, taken by Mrs. Shaw (who, in addition to her skill as an amateur photographer, takes an active interest in educational matters). The presidency of the International Meteorological Committee, comprising the principal directors of the national weather services of the world, is by no means an easy position. Great tact is required at meetings in reconciling opinions which are sometimes quite opposed to each other, in introducing new subjects for discussion, and in referring difficult matters to the consideration of carefully selected subcommittees. The writer of the article (Mr. C. F. Talman) points out that the committee was singularly fortunate in having among its members a man ideally fitted to occupy this post, vacated by Prof. Mascart (head of the French Meteorological Service) shortly before his death in 1907. He reviews with much ability the varied and useful work of the present holder of the position, from the beginning of his academic career, the marks of his "directive genius" as shown in the operations of the Meteorological Office, and briefly sketches some of the evidences of the "advanced position that he has come to occupy in the general campaign of meteorological research." To mention one important matter only, the British meteorological year-books and their appendices now appear so punctually that they set the pace for similar publications throughout the world.

In *The Cairo Scientific Journal* for August Dr. W. F. Hume gives an account of the finding of a meteorite which fell in the delta of the Nile on June 28, in the village lands of El Nakhla, some 44 kilometres E.S.E. of Alexandria. Fragments were reported as having fallen at five separate localities, and several pieces were secured for examination. The specific gravity was 3·4, and the interior of the specimen showed prismatic crystals, probably of enstatite, and yellow grains of olivine or peridot; the outer surface was covered with a black, glistening skin rich in iron. Specimens were exhibited in Section C at the British Association, where Dr. Hume gave further details.

In the same number Mr. J. I. Craig describes a fragment of a sundial which was found at the temple of Basa in the Sudan, in lat. 16° 42′ and long. 33° 53′ E. It is constructed from a block of marble which is not of local origin, but must have been imported, probably from Europe. It contains portions of seven converging lines, and two curved lines on a conoidal surface, and much resembles two sundials which are now in the museum at Alexandria. Since the worked surface is not complete, and what is left is not a true geometrical surface, computation of the locality for which the dial was constructed is impossible; but it is suggested that the block was carved after an Alexandrian model, and the hour lines were adjusted for a place in the Sudan. Illustrations of the dial are given, but the article does not mention where it is preserved.

Mr. H. Grindell Matthews recently succeeded in establishing communication by means of his wireless telephone over a distance of five and a half miles by speaking from Beachley, near Chepstow, to New Passage, on the opposite bank of the Severn. The system will now be tried by the War Office at Aldershot, which will be given the option of purchasing Mr. Matthews's invention. Meanwhile further experiments are being carried out, and attempts to communicate from Chepstow to Cardiff, a distance of twenty-five miles, are being made. Cody man-lifting kites play a prominent part in the necessary arrangements, and apparently Mr. Matthews recently received a bad electric shock from the wire attached to the kite, although no power was being used at the time. Mr. Matthews was also able to obtain sparks when the kite wire was touched by another coil of wire. This apparently has convinced Mr. Matthews that, given a sufficient length of insulated wire, it is possible to collect energy from the atmosphere. We shall wait to see the results of further experiments in this direction, which doubtless Mr. Matthews will make shortly.

The researches of Pictet have made it probable that most of the plant alkaloids are to be regarded as degradation products of vegetable proteins, since they are formed by the union of these simple substances with formaldehyde. The ring compounds synthesised in this manner are subjected to further minor changes in the plant, such as oxidation, reduction, replacement of hydroxyl, &c., and converted into the natural alkaloids. Pictet showed how in this way the majority of the alkaloids could be supposed to be formed, but specially excluded the isoquinoline alkaloids, which comprise such important representatives as morphine and the alkaloids of opium, berberine, &c., from his hypothesis. In the current number of the *Berichte* he shows how tyrosine or phenylalanine condense with formaldehyde to tetrahydroisoquinoline derivatives, and is able to effect the complete synthesis of hydroxyberberine starting from homopiperonylamine and formaldehyde. The conception that alkaloids are derived from proteins is therefore to be extended also to the isoquinoline alkaloids.

The September issue of *The Central*, the magazine of the City and Guilds of London Central Technical College Old Students' Association, is of special interest. It opens with an appreciative account, by Mr. G. C. Turner, of the career and work of Prof. Henrici, F.R.S., who retired from his professorship at the college at the end of last term. A full report follows of the banquet to Prof. H. E. Armstrong, F.R.S., in May last, which was duly noted in Nature at the time. Important articles by old students of the college deal with lifeboat launching slipways, the training of alluvial rivers by the guide-bank system, modern simple span truss-bridge construction, and the electro-technical commission.

OUR ASTRONOMICAL COLUMN.

The Expected Return of Comet 1905 II. (Borrelly).—From a number of observations made in 1905, M. Fayet has calculated a definite orbit for Borrelly's comet of that year, and finds that perihelion passage should take place on 1911 December 18·601 (Paris M.T.). Ephemerides based on these elements are published in No. 4523 of the *Astronomische Nachrichten*, and the complete discussion is to appear shortly in vol. xxx. of the Annals of the Paris Observatory.

Until the end of November the southern declination of the comet will make observations impossible in our northern observatories, although the general conditions of this apparition are more favourable than those of 1905.

The Discovery of Eclipsing Variables; β Aurigæ a Variable Star.—In an interesting paper appearing in

No. 2, vol. xxxiv., of *The Astrophysical Journal*, Dr. Joel Stebbins discusses the probability of there being a number of readily detectable eclipsing variables among those stars known to be short-period spectroscopic binaries. Such stars must offer the phenomena of mutual eclipse to some parts of the universe, and Dr. Stebbins establishes the probability that a very fair proportion will present more or less partial eclipses to the earth; as a class, that is, they offer greater probability of the discovery of eclipsing variables than do the bulk of the stars. Not only that, but their periods can be more or less determined from their spectroscopic elements, and so the times of maximum light-variations suggested. Such periods would be the most favourable for observation, and with the selenium photometer Dr. Stebbins considers that for stars of magnitude 2·0 and brighter a 0·10 magnitude variation may be considered conspicuous, so that very small eclipses might become evident in properly timed observations.

To test his proposition, Dr. Stebbins made observations of β Aurigæ and δ Orionis, and found that both were eclipsing variables. The work on the latter is not yet complete, but its extreme light-range is not far from 0·10 magnitude.

In the case of β Aurigæ, a number of consecutive observations indicated no change, but on October 23, 1910, the selenium photometer showed the magnitude to be 0·07 fainter than before. From a number of observations, fully discussed in the same number of the journal, Dr. Stebbins finds that the total range is 0·087 magnitude, of which 0·076 is due to eclipses and 0·011 is due to ellipticity of figure of the two components. The times of light-minimum are apparently in exact accordance with the times predicted from Baker's spectroscopic elements. It would also appear that the surface-intensities of the components are many times greater than that of the sun.

Cometary Phenomena.—From Dr. K. Bohlin we have received an abstract from the *Naturwissenschaftlichen Rundschau* in which he reviews our present knowledge of cometary phenomena. In the first part systems of comets are dealt with, and in the last of five well-defined systems, we find comet 1910*a* classed with 1890 IV. and 1907 I. In dealing with the light, extent, and structure of comets, there is little that is new to record; and in the chapter on spectra the latest results are not mentioned, although they replace much that preceded them. The section discussing the tails of comets, and the strange fluctuations in the streams of matter forming them, is interesting, and is illustrated by some reproductions from photographs.

Observations and Catalogues of Nebulæ.—Now that the subject of the classification and distribution of nebulæ is to the fore, Dr. Bauschinger's publication in vol. iv., part i., of the *Annalen der Kaiserlichen Universitäts-Sternwarte in Strassburg*, of the Strassburg observations and catalogue, will prove a welcome addition to the literature dealing with the subject.

The publication consists of three parts, in the first of which Dr. Wirtz discusses his observations of nebulæ made with the 49-cm. refractor during the period April, 1902, to March, 1910. The general methods of observation are described, and then the results tabulated; special micrometer measures of the stars in the Omega and Dumbell nebulæ were made, and the results are shown on two charts.

The second part of the present publication contains a general catalogue of the nebulæ observed at Strassburg from 1881 until 1910, and gives the various designations, the positions (1900·0), and brief descriptions of the physical features of 1257 nebulæ; the catalogue has been compiled by Dr. Wirtz, who writes the introduction, wherein he points out that it is the outcome of the work initiated by Winnecke in 1872. The final part of the publication consists of a most interesting comparison, by Dr. Wirtz, of the Strassburg results with those of other nebulæ observers.

A New Observatory in Africa.—From No. 4519 of the *Astronomische Nachrichten* we learn that the French Geographical Society charged M. Jarry Desloges with the erection of a more or less temporary observatory on the "Hautes Plateaux" of northern Africa. Extensive and arduous researches as to the "seeing" at various places over a wide region at an altitude of 1100 metres or more have been made, and now an observatory is in course of erection.

RECENT SOIL INVESTIGATIONS.

It is well known that the United States Bureau of Soils does not attach the same importance to a chemical analysis of the soil as is usual elsewhere. The argument adopted is that all soils contain the same rock minerals, and therefore the soil solution from which plants derive their nourishment must be identical in composition, so far as mineral plant food is concerned, in all cases. But inasmuch as the aqueous extracts of different soils show the same kind of differences towards plants as the soils themselves, it follows, if the original hypothesis is true, that the infertility of the poor soils must be due to some toxic organic substance. Search is therefore being made for substances of this nature, and during the progress of the experiments numerous interesting fields are opening up. Evidence has, for example, been obtained which is considered to prove that the roots of growing plants, and particularly the root hairs, possess an extracellular oxidising power; this power is greatest in fertile soils, and is diminished in certain infertile soils. The oxidation is attributed mainly, if not entirely, to the activity of a peroxidase produced by the roots. Messrs. Schreiner and Reed, the authors of this paper, also consider that soil itself can effect oxidations closely analogous to those of an oxidase, although, in their view, the process is mainly non-enzymotic.

Another publication, also from the Bureau of Soils, gives the results of Messrs. Robinson and McCaughey's investigations on the colours of soils, which they trace to organic matter and to ferric oxide. All varieties of colour, from white to yellow, red, brown, and black, are thus derived, the darker colours indicating, as a rule, the better agricultural conditions.

In addition to the research work going on, the Bureau of Soils is also engaged in a soil survey of the States, the results of which are issued in the form of circulars dealing with particular soil types. The basis of the survey is the mechanical analysis of the soil; but the officer in charge makes full local investigations, so that the report always takes account of the agricultural conditions. Among the reports issued, so far, are those dealing with the Portsmouth sandy loam, the Sassafras silt loam, the Norfolk fine sandy loam, and the Norfolk fine sand. In a general introductory circular Dr. Whitney describes in non-technical language the kind of examination that is made in the laboratory, and the limitations to which soil analysis is subjected. The account is very interesting, and will be found useful to others engaged in this work.

Messrs. Hart and Peterson, of the Wisconsin Agricultural Experiment Station, have recently published their work on the sulphur requirements of farm crops. Some years ago Mr. Dymond directed attention to the problem here, and showed that the supply of sulphates was not always adequate to the needs of the crop. A similar conclusion is reached by Messrs. Hart and Peterson, and they suggest that, in order to meet the losses due to drainage and cropping, it will be necessary for permanent fertility to supply sulphates to the soil.

The biochemical significance of phosphorus is discussed by Miss Caird in a paper read before the Royal Society of Victoria, a reprint of which was recently to hand. The low phosphorus content of the Australian soils is well known; it appears, also, that Australian native grasses have a markedly lower phosphorus content than European, and that the wood of Australian trees is lower in phosphates than European trees. Acclimatised European grasses contain more phosphorus than the native sorts, but less than the same kinds grown in Europe. Finally, it is pointed out that the loss of phosphorus from Victorian grass lands by export of their products is considerable, and must be made good.

THE ASTRONOMICAL AND ASTROPHYSICAL SOCIETY OF AMERICA.[1]

ORIGINATING on the occasion of the formal opening of the Yerkes Observatory in October, 1897, the Astronomical and Astrophysical Society of America now includes in its membership most of the workers in astronomy and allied subjects throughout the Western Continent, and many from other countries. Inaugurated for the purpose of advancing astronomy and astrophysics, its system has been to hold an annual meeting of the nature of a conference, lasting for several days, generally at a different location each year. Accounts of the meetings, with abstracts of the various papers presented, have been published from year to year either in *The Astrophysical Journal* or in *Science*. At the tenth annual meeting, held at Yerkes, August, 1907, the publication of the present volume of proceedings was authorised, and its preparation entrusted to Prof. W. J. Hussey, of the Detroit Observatory at Ann Arbor, Michigan. It contains full particulars of the organisation of the society, and abstracts of the papers presented at all the meetings; the majority of these are now well known, and being only short summaries are not suitable for further abstraction.

The society undertakes the organisation of special branches of astronomical investigation, in a similar manner to the various sections of the British Astronomical Association. One of the most important of these deals with the collection of data referring to meteors, and it has strongly recommended the establishment of a network of photographic stations about one hundred miles apart for the purpose of obtaining a record as complete as possible of all the meteors appearing within the network. Automatic instruments of as simple and inexpensive type as can be obtained are recommended.

Another section deals with cometary phenomena, and the society financed a special expedition to Honolulu for the photographic recording of Halley's Comet in May, 1910, in charge of F. Ellerman, of the Mount Wilson Observatory.

In a report of progress on the radial velocity determinations at the Lick Observatory, W. W. Campbell mentions that the programmes of observation for the Mills spectrograph attached to the 36-inch equatorial, and for the D. O. Mills expedition to Santiago, Chile, have aimed to secure at least four spectrograms of every star down to 5·0 visual magnitude, with three-prism dispersion if possible, and of fainter stars with two-prism dispersion. Up to June 1, 1907, three-prism spectrograms of 882 stars had been obtained at Mount Hamilton. It was expected that the programme would be completed by June, 1910. On the D. O. Mills expeditions Messrs. Wright and Curtis have obtained 530 stars brighter than 5·01 visual magnitude, and 150 stars fainter than 5·00 magnitude. The total number of separate stars the spectra of which have been photographed is 1368. Many new spectroscopic binaries have been discovered during the progress of the reductions, but it has only been possible to investigate fully the orbits of a few of the total number now known.

CHARLES P. BUTLER.

COAST-SURVEYING.[2]

IN surveying, uniformity of method may be carried to a point at which it militates against maximum efficiency, which demands that each region should be surveyed by the method most suited to its character and the object in view. While a uniform method of operations facilitates the compilation of results, a reasonable adaptation of method to the case in hand distinguishes a scientific survey from a mechanical process of measurement.

Dr. Ball has been engaged for several seasons in surveying the eastern desert of Egypt, including both the mining area and the Red Sea coast, carrying on a triangulation of approximately second-order and a plane-table topographical survey at the same time. In aiming at the greatest economy of time, together with adequate accuracy, he has employed the method described in this paper along the coast of the Red Sea. Having fixed by triangulation a series of points on moderately high ground overlooking the coastal plain, he determines a series of points on the sea-margin by observing their directions and the depression-angles with a theodolite. Thus the azimuths of the lines are obtained from that of a side of the triangulation, and the determined altitude of the observation point furnishes, with the depression-angle, the distance of the sea-margin. So far the method is not new; but the computations involved are troublesome, and this has prevented the more general use of it.

To surmount this difficulty Dr. Ball uses a scale, to be specially constructed by the surveyor for each station occupied, such that when the apparent angle of depression to a point on the coast is observed the scale will enable the true distance of the point from the station to be at once laid down on the chart. The height of the station being accurately known from the triangulation, the distances corresponding to the different depression-angles can be computed for each 5′ and laid off to scale without any great expenditure of time. When a large extent of coastline is to be mapped on a single scale, and numerous stations will be occupied, it will be more economical to construct a single-scale diagram, from which any desired scale can be taken; instances of such a diagram for both metric and British units are given.

This method should greatly facilitate the work of a surveyor engaged on a coast survey who thoroughly understands the use of his theodolite and is possessed of adequate neatness and accuracy in drawing. The accuracy of the method is fully discussed, and the limits of distance for which it can be employed are investigated on the assumption that distances shall be correct to within 100 metres, while the altitude of the station is not more than 1 metre in error, the error of depression-angle does not exceed 10″, and the coefficient of refraction is liable to a variation not exceeding 20 per cent. of itself. This study was undertaken by Mr. H. E. Hurst, of the Survey Department, and the whole memoir forms a very thorough piece of work and an instructive addition to field-surveying.

H. G. L.

WORK OF A LONDON NATURAL HISTORY SOCIETY.[1]

THE South London Entomological and Natural History Society has existed since 1872, and now numbers 169 members, many of whom are among the most prominent entomologists of the day. The volume of publications before us is well printed and illustrated, and as it is not likely to be so widely circulated as it deserves, it may be well to give a detailed list of the various interesting papers included in it.

Robert Adkin, "On the Lepidoptera of a London Garden." Discusses the conversion of the country village of Lewisham into a suburban district, and the results of thirty years' experience of what was, entomologically, an actually barren plot of ground when laid out as a garden. During this time, about 180 species of butterflies and moths, out of the British list of about 2000, were obtained, of which eleven were butterflies. Among these is *Celastrina argiolus*, which appears to have been common at Lewisham in Stainton's time, and is still a common garden insect at Chiswick, in quite a different part of London. No great rarities are enumerated, but this was perhaps hardly to be expected; on the other hand, a large number of species are mentioned as having been only taken or observed *once*.

Robert Adkin, "Notes on *Hepialus humuli* and its Shetland forms." The writer considers that the form *thulensis* is restricted to Shetland. Alfred Sich, "Larval Legs." Deals with their development in certain Lepidoptera. H. J. Turner, "A few days with the butterflies of Zermatt." Account of a collecting tour. Alfred Sich, "The Middlesex home of *Clausilia biplicata*." Notes on the former occurrence of this and other land-shells in a locality

[2] "A New Method of Coast-surveying." By Dr. J. Ball. Survey Department Paper, No. 21. (Cairo, 1911.)

[1] Proceedings of the South London Entomological and Natural History Society, 1910–11. With nine plates. Pp. xvi+175. (London: The Society, Hibernia Chambers, London Bridge, S.E., n.d.) Price 4s. 6d.

(now destroyed) at Chiswick. J. Platt Barrett, "The Butterflies of Sicily." Includes "sixty-five Sicilian butterflies out of the ninety-seven given by Ragusa." Dr. T. A. Chapman, "On insect teratology" (remarks to introduce discussion on teratological specimens). W. J. Kaye, "An entomological trip to South Brazil" (Lepidoptera). W. J. Lucas, "The natural order of insects Neuroptera." A general sketch of the families, with illustrations of examples. R. A. S. Priske and H. Main, "Notes on the glow-worm, *Lampyris noctiluca*." W. J. Kaye, annual address, read June 26, 1911. The address is chiefly devoted to the neuration of Lepidoptera, but also contains obituary notices, &c., that of J. W. Tutt being specially noteworthy.

The volume also includes a list of members at the beginning, and an abstract of proceedings at the end.

TRANSMISSION OF TRYPANOSOMES.

IT will be most unwelcome news to many that, according to a recent number of the Bulletin of the Sleeping Sickness Bureau (No. 29, August 17), Dr. Taute, at Tanganyika, has succeeded in transmitting a human trypanosome to monkeys by means of *Glossina morsitans*. So long as it was believed that *G. palpalis* alone was capable of transmitting the trypanosomes of human beings, it was hoped that the range of sleeping sickness would be coterminous with the distribution of this species of fly; but if other tsetses also can transmit the disease, there seems to be no reason why it should not spread over practically the whole African continent. Too much weight must not be laid, however, on laboratory experiments, the success of which, as the editor of the bulletin remarks, does not prove that the like is of common occurrence in nature.

Quite recently, however, a disease of human beings has been found to occur in northern Rhodesia and Nyasaland in regions where only *G. morsitans*, and no *G. palpalis*, is stated to occur, caused by a trypanosome which has been named *Trypanosoma rhodesiense*, since it shows certain peculiarities distinguishing it from the typical *T. gambiense* of sleeping sickness.

In the same number of the bulletin a summary is given of further researches by Chagas on the human trypanosome of Brazil, of which an account was published in NATURE (August 4, 1910, p. 142). Chagas has found that the parasite multiplies in other tissues besides the lungs, namely, the cardiac muscle, the central nervous system, and the striated muscles more especially; he believes that in the lungs a multiplication of sexual forms takes place, and that the multiplication in the tissues is asexual. The infection caused by this trypanosome, transmitted by a bug (Conorhinus sp.), attacks the whole population in the districts in which it occurs, so that children probably all sicken in their first year, and either die or pass over to the chronic stage. The chronic disease shows various forms, but two more especially, those in which heart-symptoms occur and others in which nervous symptoms preponderate. The goitre frequently seen in the province of Minas Geraes is believed to be attributable to the same infection.

THE BRITISH ASSOCIATION AT PORTSMOUTH.

SECTION K.

BOTANY.

OPENING ADDRESS BY PROF. F. E. WEISS, D.Sc., PRESIDENT OF THE SECTION.

GREATLY as I prize the honour done me by the Council of the British Association in electing me to the office of President of the Botanical Section, my gratification has been heightened by the knowledge that the meetings of this section would be graced by the presence of the distinguished group of Continental and American botanists who have just taken part in the International Phytogeographical Excursion to the British Isles.

I am sure that I am voicing the unanimous feeling of the section in offering them a hearty welcome to our deliberations, and, in conveying to them our sense of the honour they have done us by their acceptance of the invitation of this Association, I should like to express our hope that by their participation in our proceedings they will help us to promote the advancement of botanical science, for which purpose we are met together.

In view of these special circumstances in which we forgather, it may seem inappropriate if I deal, as I shall be doing, in my Presidential Address mainly with fossil plants, with the study of which I have been for some time occupied; but I need hardly assure our visitors that, while we entertain some feelings of satisfaction at the contributions made during the past half-century towards our knowledge of extinct flora of Britain, yet, as the later sittings of this section will show, and as they have no doubt realised during their peregrinations through this country, our botanical sympathies and energies are by no means limited to this branch of botanical study. Moreover, I hope during the course of my address to point out the ecological interest which is afforded by certain aspects of Palæobotany.

On the sure foundations laid by my revered predecessor, the late Prof. Williamson, so vast a superstructure has been erected by the active work of numerous investigators that I must limit myself in this address to exploring only certain of its recesses, and I shall consequently confine myself to some aspects of Palæobotany which have either not been dealt with in those able expositions of the subject given to this section by previous occupants of this presidential chair, or which may be said to have passed since then into a period of mutation.

The great attractiveness of Palæobotany, and the very general interest which has been evinced in botanical circles in the progress of recent investigations into the structure of fossil plants, are due to the light they have thrown upon the relationship and the evolution of various groups of existing plants. It was the lasting achievement of Williamson to have shown, with the active cooperation of many working-men naturalists from the Lancashire and Yorkshire coalfields, that the structure of the coal-measure plants from these districts can be studied in microscopic preparations as effectively as has been the case with recent plants since the days of Grew and Malpighi. Indeed, had Sachs lived to continue his marvellous historical account of the rise of botanical knowledge up to the year 1880 or 1890, he would undoubtedly have directed attention to the remarkable growth of our knowledge of extinct plants gained by Binney and Williamson from the plant remains in the calcareous nodules of English coal-seams, and by Renault from the siliceous pebbles of Autun. We are not likely to forget the pioneer work of these veterans, though since then investigations of similar concretions from the coal deposits of this and other countries have been undertaken by numerous workers, and have revealed further secrets from that vast store of information which lies buried at our feet.

The possibilities of impression material had indeed been practically exhausted in 1870, and further advance could only come from new methods of attacking the problems that still remained to be solved. The most striking recent instance of the insufficiency of the evidence of external features alone was Prof. Oliver's demonstration of the seed-bearing nature of certain fern-like plants, based on microscopical comparison of the structure of the cupule of Lagenostoma, with the fronds of Lyginodendron, after which discovery confirmatory evidence speedily came to hand from numerous plant impressions examined by Kidston, Zeiller, and other observers.

Undoubtedly in the hands of a less competent and far-sighted observer than Williamson the new means of investigation might have proved as misleading as the old method had been in many instances. Indeed, as is well known, the recognition in the sections of Calamites and Sigillarias of the presence of secondary wood had caused Brongniart to place these plants among conifers, owing to his belief that no Vascular Cryptogams exhibited exogenous growth in thickness. It required all Williamson's eloquence and pugnacity to convert both British and French Palæobotanists to his views, ultimately accepted with such handsome acknowledgment by Grand' Eury, one of his antagonists, in his "Géologie et Palæontologie du Bassin Houiller du Gard."

It is curious that Grand' Eury refers in his introduction to the discovery of traces of secondary growth in Ophioglossum, and not to that of Isoëtes, a plant much more nearly related, as we now believe, to the Lepidodendraceæ, and the structure of which had been so thoroughly investigated by Hofmeister. Williamson, it is true, refers to the secondary growth in the stem of Isoëtes in his memoir on Stigmaria, but compares it with the periderm-forming cambium of that plant, and does not, therefore, recognise any agreement in the secondary growth of these two plants.

Adopting Von Mohl's interpretation of the root-bearing base of the Isoëtes plant as a "caudex descendens," Williamson instituted a morphological comparison between the latter and the branching Stigmaria, and came to the conclusion that they were homologous structures, a view which, as we heard at Sheffield, is supported by Dr. Lang on the strength of a re-examination of the anatomy of the stock of Isoëtes. If we do not accept Williamson's interpretation of the Stigmarian axis as a downward prolongation of caulome nature, the question remains open whether this underground structure represented a leafless modification of a normal leaf-bearing axis such as is known in the leafless rhizoms of Neottia and other saprophytic plants, or whether the Stigmarian axes were morphological entities of peculiar character. Grand' Eury, in comparing them with the rhizoms of Psilotum, accepted the former alternative, and, apart from morphological considerations, was led to this view by the fact that he had observed aërial stems arising in many instances as buds on the horizontal branches of Stigmaria. Confirmation of this mode of growth is still required, but it is quite conceivable that there may have been a mode of vegetative reproduction in the Stigmariæ analogous to that of Ophioglossum.[1]

The alternative interpretation of the Stigmarian axes as special morphological entities has received weighty support from Scott and Bower, who consider them comparable to the rhizophores of Selaginella, which, as is well known, may either be root-bearers, or in certain circumstances become transformed into leafy shoots. This peculiarity has led Goebel to regard them as special members, somewhat intermediate between stems and roots. But though they might therefore be regarded as of a primitive nature, the rhizophores of the Selaginellaceæ seem such specialised structures that I incline to agree with Bower that, so far as their correspondence with Selaginella is concerned, the Stigmarian axes would agree most closely with the basal knot formed on the hypocotyl of *Selaginella spinulosa*. Seeing, however, that the nearest living representative of the Lepidodendraceæ is in all probability Isoëtes, which Bower has aptly summarised as like "a partially differentiated Lepidostrobus seated upon a Lepidodendroid base," we must inevitably consider the root-bearing base of Isoëtes as homologous with the branching axes of Stigmaria, whatever their morphological nature may have been, and perhaps we shall be on the safest ground if we consider them both as different expressions of the continued growth of the lower region of the plant, which appears to have been a primary feature in the morphology of both these members of the Lycopodiales.

The somewhat considerable difference in external appearance between the homologous organs of these two plants may be considered bridged over by the somewhat reduced axes of Stigmariopsis and by the still more contracted base of the Mesozoic Pleuromoia, which, in spite of its very different fructification, we may unhesitatingly compare with Isoëtes so far as its root-bearing axis is concerned.

I was inclined at one time to seek an analogy for the Stigmarian axis in that interesting primitive structure, the protocorm of Phylloglossum, and of embryo Lycopods; but I now consider that the resemblances are largely superficial, and do not rest upon any satisfactory anatomical correspondence.

One of the features which has caused some divergence of opinion in the past as to the morphology of the Stigmarian axis has been the definite quincuncial arrangement and the apparent exogenous origin of the roots borne on these underground organs. Schimper, indeed, considered these two features so characteristic of foliar organs that he suggested that these so-called "appendices" might possibly be metamorphosed leaves. Not quite satisfied with this view, Renault endeavoured to establish the existence of two types of lateral organs on the Stigmarian axis, true roots with a triarch arrangement of wood and root-like leaves of monarch type. Williamson, however, clearly showed that the apparent triarch arrangement was really due to the presence at two angles of the metaxylem of the first tracheids of secondary wood, and reasserted the existence of only one type of appendicular organs, agreeing so closely, both in structure and in their orientation to the axis, on which they were borne, with the roots of Isoëtes that it would be impossible to deny the root nature of the Stigmarian "appendices" without applying the same treatment to the roots of Isoëtes.

Still, so distinguished a Palæobotanist as Solms Laubach, after a careful weighing of all the available evidence, continued to uphold Schimper's view of the foliar nature of these outgrowths, both in his "Palæophytologie" and in his memoir on Stigmariopsis, in which he stated that he was in complete agreement with Grand' Eury's conclusion: "Que ces organes sont indistinctement des rhizomes et que les Sigillaires n'avaient pas de racines réelles, ainsi que Psilotum." Indeed, in reviewing the account I gave of the occurrence of a special system of spiral tracheids in the outer cortex of the Stigmarian rootlets, Count Solms directed attention to their similarity to the transfusion tissue of Lepidodendroid leaves, and asserted that we have here a further indication of the former foliar nature of these rootlets. Personally, I still adhere to the belief, expressed at the time, that these peripheral cortical tracheids represent a special development required by a plant with an aquatic monarch root of the Isoëtes type and a large development of aërial evaporating surface. The fact that the lateral outgrowths from the Stigmarian axis have been generally considered to be exogenous is not a valid argument against their root nature, as the same origin is ascribed to the roots of Phylloglossum and to those produced on the rhizophores of Selaginella. Probably, indeed, as Bower points out in his masterly exposition of the "Origin of a Land Flora," in dealing with the Lycopodiales, "the root in its inception would, like the stem of these plants, be exogenous." According to the "recapitulation theory," indeed, the exogenous formation of the roots in the embryo of certain Lycopods, as well as of the first roots of Isoëtes and the first root of the Filicales, might be regarded as the retention of a more primitive character in these particular organs. The roots of Stigmaria, even if exogenous, might therefore merely represent a more ancestral stage. This difference between the roots of Isoëtes and the rootlets of Stigmaria may, however, be more apparent than real, for my colleague, Dr. Lang, has directed my attention to the fact that there appear to be in Stigmaria remnants of a small-celled tissue on the outside of what has generally been taken to be the superficial layer of the Stigmarian axis, and a careful investigation of this point inclines me to agree with him that very probably the Stigmarian rootlets were actually formed like those of Isoëtes, somewhat below the surface layer, which, after the emergence of the rootlets, became partially disorganised. Should this surmise prove correct, when apices of Stigmaria showing structure come to light, the last real difference between the rootlets of Isoëtes and the rootlets of Stigmaria will have disappeared, and the view for which Prof. Williamson so strongly contended will be finally established.

While a careful comparison of Isoëtes with the extinct Lycopodiaceous plants may be taken to settle finally its systematic position, the Psilotaceæ have been somewhat disturbed by such comparisons. Placed formerly without much hesitation in the phylum Lycopodiales, certain features in their organisation, such as the dichotomy of their sporophylls and the structure of their fructification generally, have suggested affinity with that interesting group of extinct plants, the Sphenophyllales. Their actual inclusion in this group by Thomas and by Bower may

[1] It is of interest in this connection to note that Potonié has recently put forward the suggestion that many of these vertical outgrowths from the more or less horizontal Stigmarian axes, some of which, as figured and described by Goldenberg, taper off rapidly to a point, without any trace of ramification, may be comparable with the conical "knees" of Taxodium, and represent woody pneumatophores so common in the Swamp Cypress and other swamp-inhabiting trees.

seem, perhaps, somewhat hazardous, considering the differences existing between the Psilotaceæ and Sphenophyllum; and the more cautious attitude of Seward, in setting up a separate group for these forms, seems, on the whole, more satisfactory than forcing these aberrant relatives of the Lycopods into the somewhat Procrustean bed of Sphenophyllales, which necessitates the minimising of such important differences as the dichotomous branching of the axis and the alternate arrangement of their leaves, though the latter character allows, it is true, of some bridging over. But, even adopting this more cautious attitude, the study of the Sphenophyllales has been of great help in coming to a clearer understanding of certain morphological peculiarities of the Psilotaceæ, quite apart from the flood of light which this synthetic group of Sphenophyllales has thrown upon the relationship of the Lycopodiales to the Equisetales.

More far-reaching in its bearing on the relationships of existing plants has been the study of those interesting fern-like plants which seem to show in their vegetative organs a structure possessing both fern-like and Cycadian affinities. Full of interest as these so-called Cycadofilices were in their vegetative organisation, they were destined to rivet on themselves the attention of all botanists by the discovery of their fructifications. No chapter in the recent history of Palæobotany is more thrilling than the discovery, by the patient and thorough researches of Prof. Oliver, of the connection between Lyginodendron and the well-known palæozoic seed, Lagenostoma. With Dr. Scott as sponsor, this new and startling revelation met with ready acceptance, and, thanks to the indefatigable energies of Palæobotanists, no fossil fern seemed at one time safe from possible inclusion among the Pteridospermæ.

The infectious enthusiasm with which the discovery of the seed-bearing habit of the Lyginodendreæ and the Medullosæ was greeted carried all before it, and we in England, particularly, have perhaps not looked carefully enough into the foundations upon which rested the theory that these groups form the "missing links" between the Ferns and Cycads. A criticism against the wholesale acceptance of this view has been put forward by Prof. Chodat,[1] of Geneva, that distinguished and versatile botanist whom we have on several occasions had the pleasure of welcoming among us. Couched throughout in friendly and courteous language, and full of admiration for the work of those who were concerned in the establishment of the group of Cycadofilices, now termed Pteridospermæ, Prof. Chodat suggests that English Palæobotanists have not sufficiently appreciated the work of Bertrand and Corneille[2] on the fibro-vascular system of existing ferns, and have not revised, in the light of the researches of these French investigators, the interpretation given to the arrangement of the primary vascular tissues of Lyginodendron. In Chodat's opinion the structure of the primary groups of wood found in the stem and in the double leaf-trace of this plant is not directly comparable with the arrangement found in the petiole of existing Cycads. In the latter the bulk of the metaxylem is centripetal, while we have, in addition, a varying amount of small-celled centrifugal wood towards the outside of the protoxylem, and, though separated from it by a group of parenchymatous cells, the bundle may be conveniently described as mesarch. In Lyginodendron, and the same applies to Heterangium, the primary bundles of the stem appear at first sight to be mesarch too, but in Chodat's opinion, if I understand him correctly, the metaxylem is exclusively centrifugal in its development, but, widening out and bending inwards again, in form of the Greek letter ω, the two extremities of the metaxylem are united on the inside of the protoxylem, forming an arrangement described by Bertrand and Corneille in the case of several fern petioles under the name of "un divergeant fermé."

Several details of structure, such as the type of pitting of the metaxylem elements and the separation of the protoxylem from the adaxial elements of metaxylem by parenchymatous cells, confirm Chodat in his view that the primary bundles of Lyginodendron are not really mesarch, and that the stem of Lyginodendron is essentially Filicinean in nature. Chodat cites other characters, such as the presence of sclerised elements in the pith, and the absence of mucilage ducts, in support of his view of the purely filicinean affinities of the Lyginodendreæ. The presence of secondary thickening in Lyginodendron, he regards not as indicative of Cycadian affinity, but merely as another instance of secondary growth in an extinct Cryptogam, taking up very much the position of Williamson in his earlier controversy with French botanists with regard to the secondary thickening of Calamites and Lepidodendreæ. Chodat is also at variance with Kidston and Miss Benson as to the nature of the microspores borne on the fronds of Lyginodendron or Lyginopteris, as he prefers to call this plant. He certainly figures some very fern-like sporangia, attached to the fronds of Lyginodendron, but anyone who has worked with the very fragmentary and somewhat disorganised material contained in our nodules knows how difficult it is to be absolutely certain of structural continuity. Nevertheless a re-investigation of the whole question of the microsporangia of Lyginodendron seems to me clearly called for by the publication of Chodat's figures.

As regards the seed-bearing habit of Lyginodendron, Chodat adopts wholeheartedly Oliver's correlation of Lagenostoma with the fronds of Lyginodendron, but would regard the seed, apparently devoid of endosperm at the time of pollination, as a somewhat specialised macrosporic development, of more complex structure, but analogous in its nature to the seed-like organ exhibited by Lepidocarpon in another phylum of the Pteridophyta. "In any case," he concludes, "the origin and the biology of this kind of seed must have been very different from those of the seeds of the Gymnosperms."

This contention, based mainly on the tardy development of the endosperm in Lagenostoma, is the least weighty part of Chodat's criticism, for it has never been asserted that the seeds were identical with those of existing Cycads. We know that the seed-habit was adopted by various groups of Vascular Cryptogams, and it is revealed in fossil plants in various stages of evolution, so that it may be readily presented to us at a special stage of its evolution in Lyginodendron. Moreover, we must remember that in so highly organised a Gymnosperm as Pinus, the macrospore itself is not fully developed at the time of pollination. Though not suggesting this as a primitive feature in the case of the pine, we can well imagine how, by a gradual process of "anticipation," the prothallus might become established before pollination in any group of primitive seed-bearing plants. There are other more specialised rather than primitive features in the complex structure of Lagenostoma which might with much more reason be invoked, to show that the seed of Lyginodendron does not form a step in the series of forms leading to the Cycadian ovule.

But leaving this point out of consideration, Chodat brings forward some strong reasons for his conclusions that the Lyginodendreæ were plants possessing stems of purely fern-like structure, increasing in thickness by means of a cambium, that their foliage was of filicinean structure, but provided with two kinds of sporangia, microsporangia similar to those of Leptosporangiate ferns, and macrosporangia of specialised type, containing a single macrospore. This group, therefore, Chodat regards as a highly specialised group of ferns, which, he considers, shows no particular connection with the Cycads, and may have formed the end in a series of highly differentiated members of the Filicineæ.

Of the Medullosæ, on the other hand, Chodat takes a very different view. Both in the structure of their primary and secondary growth, as well as in their polystely, he sees close affinity of these forms to the Cycads, borne out by smaller secondary features, such as the presence of mucilage ducts and the simple form of pollen-chamber. Chodat considers the agreement of the Medullosæ with the Cycadaceæ to be so close that he regards them as Protocycadeæ, the fern-like habit being restricted to the position of the sporangia on the vegetative fronds. Medullosa, therefore, would be only one link in the chain connecting the Cycads with the Filicales, and a link very

[1] Chodat, R.: "Les Ptéropsides des temps paléozoïques," *Archives des Sciences physiques et naturelles*, Genève, tome xvi, 1903.

near the Cycadian end of that chain. Other forms more closely connected with the Filicinean phylum are still to be sought.

In bringing Prof. Chodat's views to your notice, I do not wish to urge their acceptance, but his criticism seems to me sufficiently weighty to demand a careful reconsideration of the structure and affinities of the Lyginodendreæ, which, whatever may be their ultimate position in our scheme of classification, will continue in the future, as they have done in the past, to command the attention of all botanists interested in the evolution of plant life.

If the wholeheartedness with which we in England received the theory of the Cycadian affinity of Lyginodendron has laid us open to friendly criticism, I am afraid some of us may be accused of exceeding the speed-limit in our rapid acceptance of the Cycadoidean ancestry of the Angiosperms. Ever since Wieland put forth the suggestion in his elaborate monograph of the "American Fossil Cycads" that "further reduction and specialisation of parts in some such generalised type, like the bisporangiate strobilus of Cycadoidea, could result in a bisexual angiospermous flower," speculation as to the steps by which the evolution might have been brought about has been rife, and Hallier in Germany and Arber and Parkin in England have put forward definite schemes giving probable lines of descent. Arber and Parkin in their criticism and detailed suggestions connect phylogenetically with the Bennettitales, the Ranales, as primitive Angiosperms, and displace from this position the Amentales and Piperales, which were regarded by Engler as probably more closely related to the Proangiosperms. Of course, the resemblance between the amphisporangiate, or, as I should prefer to call it, the heterosporangiate "strobilus" of Cycadoidea, and the flower, say, of Magnolia is very striking, and the knowledge we have gained of the structure and organisation of the Bennettitales certainly invites the belief in a possible descent of the Angiosperms from this branch of the great Cycadian plexus; but the ease with which the flower of the Ranales can in some respects be fitted on to the "flower" of Cycadoidea raises suspicion. Critics of the Arber-Parkin hypothesis may possibly incline to the view that "truth is often stranger than fiction," and that the real descent of the Angiosperms may have been much less direct than that put forward in these recent hypotheses. The particular view of the morphology of the intraseminal scales and seed pedicles adopted by Arber and Parkin is, as they admit, not the only interpretation that can be put upon these structures, and the views on this point will probably remain as various as are those of the female cone of Pinus. Even if we regard the ovulate portion of the Cycadoidean "flower" as a gynæcium, and not as an inflorescence, we are bound to admit, as do Arber and Parkin, that it is highly modified from the pro-anthostrobilus type with a series of carpels bearing marginal ovules. Cycadoidea was evidently a highly specialised form, and may well have been the last stage in a series of extinct plants.

Arber's very sharp separation of mono- and amphisporangiate Pteridosperms does not seem to me quite justified. Amphisporangiate forms may have been preserved, or may have arisen anew in various groups of Pteridosperms or in their descendants. Heterospory, we know, originated independently in at least three of the great phyla of vascular Cryptogams, and originally, no doubt, the same strobilus contained both macro- and microsporangia, as was the case in Calamostachys Casheana, in the strobili of most Lepidodendraceæ, and as is still the case in the strobili of Selaginella and in Isoëtes. Even in the existing heterosporous Filicineæ, micro- and macrospores are found on the same leaf and on the same sorus; and though in the higher Cryptogamia and the lower Phanerogamia there may have been a tendency to an iso-sporangiate condition, yet, as the two kinds of spores are obviously homologous in origin, nothing is more natural than an occasional reversion to a heterosporangiate fructification. Thus, in the group of Gymnosperms, we have many instances of the occurrence of so-called androgynous cones. In 1891, at the meeting of the British Association at Leeds, I described such amphisporangiate cones which occurred regularly on a *Pinus Thunbergii* in the Royal Gardens of Kew, and only this spring I was able to gather several hermaphrodite cones of *Larix europea*. They have, of course, been observed and described by many authors for a variety of Gymnosperms. What more likely than that many extinct Gymnosperms may have developed heterosporangiate fructifications? It is not necessary, therefore, to fix on one group of ancestors for the origin of all existing Angiosperms. Indeed, the great variety of forms, both of vegetative and reproductive organs, which we meet with in the Angiosperms, not only to-day, but even in the Cretaceous period, in which they first made their appearance, warrants, I think, the belief in a polyphyletic origin of this highest order of plants. It is no doubt true, as Wieland points out, "that the plexus to which Cycadoidea belonged, as is the case in every highly organised plant type, presented members of infinite variety," and, indeed, so far as the vegetative organisation goes, we knew already, through the labours of Nathorst, of such a remarkable form as *Wielandiella angustifolia*, while Wieland has shown us a further type in his Mexican Williamsonia. Nevertheless, these diverse forms all agree in the structure of their gynæcium, the particular organ which is not so easy to bring into line with that of the Angiosperms.

I am quite alive to, though somewhat sceptical of, the possibility of a direct descent of the Ranales from the Cycadoideæ, but my hesitation in accepting Arber and Parkin's view of the ancestry of the Angiosperms is enhanced by the consideration that it seems almost more difficult to derive some of the apparently primitive Angiosperms from the Ranales, than the latter from Cycadoidea. Indeed, this common origin of Angiosperms from the Ranalian plexus will, I feel sure, prove the stumbling-block to any general acceptance of the Arber-Parkin theory. It is easy enough to assume that all Angiosperms with the unisexual flowers have been derived by degeneration or specialisation from forms with hermaphrodite flowers of the primitive Ranalian type, but unfortunately some of these degenerate forms possess certain characters which appear to me to be undoubtedly primitive.

It is difficult for those who accept Bower's view of the gradual sterilisation of sporogenous tissue not to regard the many-celled archesporium in the ovules of Casuarina and of the Amentales as a primitive character, and though, as Coulter and Chamberlain point out, this feature is manifested by several members of the Ranunculaceæ and Rosaceæ, as well as by a few isolated Gamopetalæ, its very widespread occurrence in the Amentales seems to indicate its more general retention in this group of plants, and does not agree readily with the theory that these unisexual orders are highly specialised plants, with much-reduced flowers. The possession of a multicellular archesporium is, however, not the only primitive character exhibited by some of the unisexual orders of the Archichlamydeæ. Miss Kershaw[1] has shown, in her investigation of the structure and development of the ovule of Myrica, that in this genus, which possesses a single erect ovule, the integument is entirely free from the nucellus, and is provided with well-developed vascular bundles, in both of which features it resembles very closely the palæozoic seed Trigonocarpus. The same features were shown, moreover, by Dr. Benson[2] and Miss Welsford to occur in the ovules of *Juglans regia*, and in a few allied genera, such as Morus and Urtica. Also in a large number of Amentales with anatropous ovules (Quercus, Corylus, Castanea, &c.), Miss Kershaw has demonstrated the occurrence of a well-developed integumentary vascular supply. No doubt a further search may reveal the occurrence of this feature in some other dicotyledonous ovules, but in the meantime it seems difficult to believe that such a primitive vascular system, which the Amentales share with the older Gymnosperms, would have been retained in the catkin-bearing group, if it had undergone far-reaching floral differentiation, while it had disappeared from the plants which in other respects remained primitive. It would be still more difficult to imagine that it had arisen in the Amentales subsequently to their specialisation.

There are other structural characters and general morphological considerations, which I have not time to deal with, which underlie the belief in the primitiveness of the

[1] *Annals of Botany*, vol. xxiii., 1909. [2] *Ibid.*

Amentales and some allied cohorts, and I trust they will be set forth in detail by a better systematist than I can claim to be. My object in bringing the matter forward at all is to point out some of the difficulties which prevent me from accepting a monophyletic origin of the Dicotyledons through the Ranalian plexus.

One of these difficulties lies in the relationship of the Gnetales to the Dicotyledons. Arber and Parkin have recently made the attempt to gain a clearer insight into the affinities of this somewhat puzzling group by applying to it the "strobilus theory[1] of Angiospermous descent." The peculiar structure of the flowers of Welwitschia lends itself particularly well to a comparison with those of Cycadoidea, and a good case can no doubt be made out for a hemiangiospermous ancestry of this member of the Gnetaceæ, and by reduction the other members, in many respects simpler, might be derived from a similar ancestor, though probably, so far as Ephedra and Gnetum are concerned, an equally good, if not better, comparison might be made with Cordaites. But even supposing we admit the possibility of a derivation of the Gnetales from an amphisporangiate Pteridosperm, I think the Amentales merit quite as much as the Gnetales to be considered as having taken their origin separately from the Hemiangiospermæ, and not from the Ranalian plexus. I find this view has been put forward also by Lignier[2] in his attempt to reconstruct the phylogenetic history of the Angiosperms, and I feel strongly that such a polyphyletic descent, whether from the more specialised anthostrobilate Pteridospermæ or from several groups of a more primitive Cycado-Cordaitean plexus, is more in accordance with the early differentiation of the Cretaceous Angiosperms, and with the essential differences existing now in the orders grouped together as Archichlamydeæ.

Attempts at reconstructing the phylogeny of the Angiosperms are bound to be at the present time largely speculative, but we may possibly be on the threshold of the discovery of more certain records of the past history of the higher Spermaphyta, since Dr. Marie Stopes has commenced to publish her investigations of the Cretaceous fossil plants collected in Japan, and Prof. Jeffrey has been fortunate enough to discover cretaceous plant-remains showing structure in America. The former have already provided us with details of an interesting Angiospermic flower, and if the latter have so far only yielded Gymnosperms, we may at all events learn something of the primitive forms of these plants, the origin of which is still as problematical as is that of the Angiosperms.

I trust that the criticisms I have made of the theory put forward by Messrs. Arber and Parkin will not be taken as a want of appreciation on my part of the service they have done in formulating a working hypothesis, but merely as an expression of my desire to walk circumspectly in the very alluring paths by which they have sought to explore the primæval forest, and not to emulate those rapid but hazardous flights which have become so fashionable of late.

While the description of new and often intermediate forms of vegetation has aroused such widespread and general interest in Palæobotany, other and more special aspects of the subject have not been without their devotees, and have proved of considerable importance. Morphological anatomy has gained many new points of view, and our knowledge of the evolution of the stele owes much to a careful comparison of recent and fossil forms, even when these investigations have produced conflicting interpretations and divergent views.

Another promising line of Palæobotanical research lies in the direction of investigations of the plant tissues from the physiological and biological points of view. Happily, the vegetable cell-wall is of much greater toughness than that of animal cells, and in consequence the petrified plant-remains found in the calcareous nodules are often so excellently preserved that we can not only study the lignified and corky tissues, but also the more delicate parenchymatous cells. Even root-tips, endosperm, and germinating fern-spores are often so little altered by fossilisation that their cells can be as easily studied as if the sections had been cut from fresh material. It is this excellence of preservation which has enabled us to gain so complete a knowledge of the anatomy of palæozoic plants, and since the detailed structure of plant organs is often an index of the physical conditions under which the plants grew, we are able to form some opinion as to the habitat of the coal-measure plants. Though a beginning has already been made in this direction by various authors, we have as yet only touched the fringe of the subject, and, as Scott points out in the concluding paragraph of his admirable "Studies," the biology and ecology of fossil plants offer a wide and promising field of research. Such studies are all the more promising, as we now have material from such widely separated localities as the Lancashire coalfield, Westphalia, Moravia, and the Donetz Basin in Russia.

Now that it has been definitely shown by Stopes and Watson that the remains of plants are sometimes continuous through adjacent coal-balls, we may safely accept their conclusion that these calcareous concretions were in the main formed *in situ*, and that the plant-remains they contain represent samples of the vegetable débris of which the coal-seam consists. We have in these petrifactions, therefore, an epitome, more or less fragmentary, of the vegetation existing in palæozoic times on the area occupied by the coal-seam, and the Stigmarian roots in the underclay, as well as other considerations, lead us to believe that the seam more frequently represents the remains of the coal-measure forest carbonised *in situ*. While this seems to be the more usual formation of coal-seams, it is obvious from the microscopic investigations of coal made by Bertrand, and as has recently been so clearly set forth by Arber in his "Manual on the Natural History of Coal," that in the case of bogheads and cannels the seam represents metamorphosed sapropelic deposits of lacustrine origin. In other cases, again, considerations of the nature of the coal and the adjacent rocks may incline us to the belief that some, at any rate, of the deposits of coal may be due to material drifted into large lake-basins by river agency.

Broadly speaking, however, and particularly when dealing with the seams from which most of our petrified plant-remains have been collected, we may consider the coal as the accumulated material of palæozoic forests metamorphosed *in situ*. What, then, were the physical and climatic conditions of these primæval forests? The prevalence of wide air-spaces in the cortical tissues of young Calamitean roots, as indeed their earlier name Myriophylloides indicates, leads us to believe that, as in the case of many of their existing relatives, they were rooted under water or in waterlogged soil. We gather the same from the structure of Stigmaria, while the narrow xerophytic character of the leaves at any rate of the tree-like Calamites and Lepidodendra closely resembles the modifications met with in our marsh plants. It has been suggested by several authors that the xerophytic character of the foliage of many of our coal-measure plants may be due to the fact that they inhabited a salt marsh. A closer examination of the foliage, however, of such plants as Lepidodendron and Sigillaria does not reveal the characteristic succulency associated with the foliage of most Halophytes, and in view of the absence of such water-storing parenchyma, the well-developed transfusion-cells of the Lepidodendreæ can only be taken to be a xerophytic modification such as is met with in recent Conifers.

The specialisation of the tissues indeed is only such as is quite in keeping with the xerophytic nature of marsh plants. Moreover, the particular group of Equisetales are quite typical of fresh water, and we should expect that if their ancestors had been Halophytes, some at any rate at the present day would have retained this mode of life. Nor have we at the present time any halophytic Lycopodiales, while Isoëtes, the nearest relative to the Lepidodendra, is an aquatic or sub-aquatic form associated with fresh water.

Among the Filicales, *Acrostichum aureum* seems to be the only halophytic form, inhabiting as it does the swamps of the Ceylon littoral,[1] and though, as Miss Thomas has

[1] Tansley, A. G., and Fritsch: "The Flora of the Ceylon Littoral," *New Phytologist*, vol. iv., 1905.

pointed out, its root structure is in close agreement with that of many palæozoic plants, its frond shows considerable deviation from that of Lyginodendron or Medullosa, both of which plants, as Pteridosperms, are on a higher plane of evolution, and might therefore be expected to show a more highly differentiated type of leaf. But, on the contrary, these coal-measure plants show a more typically Filicinean character, both as regards the finely dissected lamina, and also in the more delicate texture of the foliage compared with the specialised organisation of the frond of *Acrostichum aureum*, described by Miss Thomas.

Nor is it necessary to call to aid the salinity of the marsh to explain the excellent preservation of the tissues of the plant-remains in the so-called coal-balls, in view of the well-known power of humic compounds to retard the decay of vegetable tissues. In addition to these arguments, I might direct attention to the presence of certain fungi among the petrified débris, as more likely to be found in fresh water than in marine conditions. Peronosporites, so common in the decaying Lepidodendroid wood, and the Urophlyctis-like parasite of Stigmarian rootlets, seem to me to support the fresh-water nature of the swamp; just as the occurrence of the mycorhiza, described by Osborn, in the roots of Cordaites seems to indicate the presence of a peaty substratum for the growth of that plant. Potonié also refers to the occasional occurrence of Myriapoda and fresh-water shells as indicative of the fresh-water origin of at least many of the coal-deposits, and a common feature of the petrified remains of coal-measure plants is the occurrence of the excrements of some wood-boring larvæ in the passages tunnelled by these palæozoic organisms through the wood of various stems.

A strong argument in favour of the brackish nature of these swamps would be supplied by the definite identification of Traquairia or Sporocarpon as Radiolaria, though we must remember that certain marine Cœlenterata find their way up into the Norfolk Broads, and fresh-water Medusæ are by no means unknown in different parts of the tropics. Of course, if the coal-measure swamps were estuarine or originated in fresh-water lagoons near the sea, they may have been liable from time to time to invasions of salt water, sufficient to account for the presence of occasional marine animals, but without constituting a halophytic plant association.

Potonié, who has made so close a study of the formation of coal, and supports the theory of its fresh-water origin, considered for a long time the comparison between the coal-measure swamp and the cypress swamps of North America, as the nearest but at the same time a somewhat remote analogy, more particularly as he believed that the nature of the coal-measure vegetation required a tropical and also a moister climate than obtains in the southern States of North America. Though, in view of the great development of Pteridophytic vegetation in countries like New Zealand, I think Potonié possibly exaggerates the temperature factor, he is probably right in assuming a fairly warm climate for the coal-measure forest. The difficulty, so far, has been to account for the great thickness of humic or peaty deposits which must have accumulated for the formation of our coal-seams, in view of the fact that extensive peat-formation is generally associated with a low temperature. In the tropics, peat may be deposited at high altitudes, where there is low temperature and high rainfall, but it is generally supposed that the rate of decomposition of vegetable remains is so active that lowland peat-formation was out of the question. Dr. Koorders, however, has observed a peat-producing forest in the extensive plain on the east side of Sumatra, about a hundred miles from the coast. This swamp-forest has been recently re-explored at the instance of Prof. Potonié, and he finds it to agree closely with the vegetative peculiarities which he considers must have been presented by the vegetation of the coal-measure forest. A typical "Sumpflachmoor," this highly interesting tropical swamp has produced a deposit of peat amounting in some places to 30 feet in thickness. The peat itself consists mainly of the remains of the Angiospermic vegetation of which the forest is made up, including pollen-grains and occasional fungal filaments; the preservative power, which has enabled this accumulation of débris to take place, being due to the peaty water which is seen above the roots of the bulk of the vegetation. The latter consists mainly of dicotyledonous trees belonging to various natural orders, and they mostly show such special adaptations as breathing roots (pneumatophores) and often buttress roots. With the exception of a tree-fern, Pteridophyta, Liverworts, and Mosses, and, indeed, all herbaceous vegetation, are poorly represented in this swamp, though high up in the branches of the trees there is a fair number of epiphytes, and at the edge of the swamp-forest lianes, belonging particularly to the palms, play an important part in the vegetation. The water, partly on account of its peaty nature, partly owing to the intense shade, is almost devoid of Algæ, and none of these organisms were found in the peat itself. The interesting account given by Potonié of this tropical peat-formation is very suggestive when certain features, as, for example, the absence or relative paucity of certain of the lower groups of plants, such as Algæ and Bryophyta, in the peat, are compared with the plant-remains in some of our coal-seams. Replacing the now dominant Angiosperms by their Pteridophytic representatives in palæozoic times, we have a very close parallel in the two formations.

Another interesting question arises when we consider the great variety of types of vegetation met with among the plant-remains of the coal-seams. For in addition to the limnophilous Calamites and Lepidodendraceæ mentioned above, the coal-balls abound with the remains of representatives of the Filicales, the Pteridospermæ, and the Cordaitaceæ. Were these also members of this swamp vegetation, or have their remains been carried by wind or water from surrounding areas? With regard to some plant-remains, namely, those found exclusively in the roof nodules, the latter was undoubtedly the case; for we have ample evidence, both in their preservation and their mode of occurrence, that they have drifted into the region of the coal-measure swamp after its submergence below the sea. This would apply to such plants as *Tubicaulis Sutcliffii* (Stopes), *Sutcliffa insignis* (Scott), *Cycadoxylon robustum*, and *Poroxylon Sutcliffii*, and other forms, the remains of which have so far not been observed in the coal-seam itself. These plants represent a vegetation of non-aquatic type, and may be taken to have grown on the land areas surrounding the palæozoic swamps. But, on the other hand, we have remains of many non-aquatic plants in the coal-seam itself, closely associated with fragments of typical marsh-plants. How can their juxtaposition be explained?

The advance of our knowledge of ecology points, I think, to a solution of this difficulty. No feature of this fascinating study, which has of late gained so prominent a place in botanical investigation, is more interesting than to trace out the succession of plant associations within the same area, noting the ever-changing conditions which the development of each association brings about. If we follow with Schroeter the gradual development of a lacustrine vegetation from the reed-swamp through the marsh (or Flachmoor) to a peat-moor (Hochmoor), we see how one plant association makes place in its turn for another. May not the mixture of various types of vegetation which we meet with in the petrifactions of our coal-seam represent the transition from the open Calamitean or Lepidodendroid swamp to a fen or marsh with plentiful peat-formation, due to the gradual filling up of the stagnant water with plant-remains? Thus in places, at any rate, a transition from aquatic to more terrestrial types of vegetation would take place, while the tree-like forms rooted in the deeper water would continue to flourish. The coal-measure swamp in this stage would differ from the tropical swamp of Kooders by a more abundant undergrowth of herbaceous and climbing plants, rooted in damp humus and passing off gradually into drier peat. Such an undergrowth of Cryptogamic types, mainly Filicinean or Pteridospermic, would have admirable conditions for luxuriant development, apart from the provision of a suitable substratum for its roots, owing to the narrow xerophytic nature of the foliage on the canopy of the trees under which it grew.

Here, too, we see the explanation of the striking difference between the microphyllous and arborescent Calamites and Lepidodendraceæ, and the large ombrophile foliage of the Filicineæ and Pteridosperms, which spread out their shade-leaves under the cover of marsh xerophytes, in exactly the same way as Prof. Yapp has so admirably depicted for recent plants in his account of the "Stratification in the Vegetation of a Marsh."

The development of a mesophytic vegetation in the shelter of the marsh xerophytes makes it unnecessary to postulate an obscuration of the intense sunlight by vapours, as was done by Unger and Saporta for the Carboniferous period. The assumption of a variety of conditions of plant life within the same area helps materially to clear up the difficulties presented by the somewhat incongruous occurrences met with in the petrified plant-remains. The presence of fragments of Cordaites, mixed with those of Calamites and Lepidodendra, in the coal-balls cannot always be explained either by a drift theory or by conceiving the fragments to be wind-borne; but, given an area of retrogressive peat above the ordinary water-level, even so xerophytic a plant as Cordaites might well establish itself there, its mycorhiza-containing roots being well adapted for growth in drier peat. The curious occurrence of more or less concentric rings in the secondary wood of the stem and roots of Cordaites may represent a response, probably not to annual variations of climate, but to abnormal periods of drought, which would affect the upper-peat layers, but not the water-logged soil in which were rooted the Calamites and Lepidodendra.

If, as I suspect, we had in the peat deposit of the coal-seam a succession of associations, we ought to find its growth and history recorded by the sequence of the plant-remains, very much as Mr. Lewis has discovered with such signal success in our Scottish peat-bogs. That some differences occur in the plant-remains building up a seam can be noted by a microscopic examination of the coal itself, in which, as Mr. Lomax tells me, the spores of Lepidodendra occur in definite bands. But no systematic attempt has as yet been made to investigate from this point of view the seams charged with petrified plant débris. Before the Shore pit, which was reopened last summer through the renewed generosity of Mr. Sutcliffe, was finally closed down, I obtained two series of nodules, ranging from the floor to the roof of the seam, and have had these cut for detailed examination. I should not, however, like to make any generalisation from these isolated series, but intend, during the coming winter, to investigate in the same manner further series taken from large blocks of nodules, which have been removed bodily so as to retain the position they occupied in the seam. Though at present the data are only fragmentary, there seems to be some indication that the plant-remains are not without some relation to their position in the seam. Of course, Stigmarian rootlets are ubiquitous, and in the nodules of the lower part of the seam predominant, but other plant-remains appear to be more frequently found at one level of the seam than another. The problem, however, is very involved, and it has become apparent that it is as important to study the fine débris in which the larger fragments are embedded as the distribution of these latter. Moreover, attention must be paid to the stage of decomposition presented by the particles forming the matrix of the nodule, as this varies in the lower and upper parts of a seam, very much as in a peat-bed we can distinguish the lighter-coloured fibrous peat from the darker layers at the base of a peat-cutting. Mr. Lomax, who has a unique experience of these coal-balls, informs me that he can tell whether a nodule is from the top or bottom of the seam by the lighter or darker colour of the matrix. The importance of applying the methods which have been so successful in elucidating the history of modern peat-deposits to the investigation of the coal-seam will be clearly appreciated both by palæobotanists and ecologists, and this particular problem offers a striking illustration of the interdependence of various branches of botanical investigation. It is fortunate, indeed, that the two fields of work, Palæobotany and Plant Ecology, though they have been subjected to fairly intensive cultivation, have not become exclusively the domain of specialists. The strength and progress of modern Botany have been due to the close collaboration of workers engaged in different branches of botanical science, and the fact that British ecologists have combined to attack a series of the problems from very diverse points of view leads one to hope that, with a continuance of that intimate cooperation which has characterised their work so far, and with the added stimulus of the friendly visit of our distinguished colleagues from abroad, considerable progress may be expected in the future in this branch of botanical study. Privileged as I have been to assist at the deliberations of the British ecologists, without as yet having taken any active part in their work, I feel myself at liberty to point with appreciation to the excellent beginning they have made of a botanical survey of Great Britain and Ireland, as well as to the more detailed investigations of special associations and formations, such as the woodlands, the moorlands, the fens, the broads, salt marshes, and shingle beaches. I am glad to think that our foreign visitors have been able to see these interesting types of vegetation under the guidance of those who have made a special study of these subjects.

The importance to ecologists of an up-to-date critical Flora was dwelt upon by my predecessor in this presidential chair, and this obvious need may be regarded as a further illustration of the inter-relationship of the various aspects of Botanical Science. Though it has been obvious to all that the swing of the pendulum has been for a long time away from pure systematic botany, I am convinced that the great development of plant ecology, of which we have many indications, will not merely lessen the momentum of the swinging pendulum, but will draw the latter back towards a renewed and critical study of the British flora. That a revival of interest in systematic botany will come through the labours of those who are engaged in survey work and other forms of ecological study, is foreshadowed by the fact that Dr. Moss has undertaken to edit a "New British Flora," which will, I believe, largely fulfil the objects put forward by Prof. Trail in his Presidential Address. I trust, however, that in addition to the ecologists, those botanists who are interested in genetics will contribute their share towards the completion of our knowledge of critical species, varieties, and hybrids, all of which offer such intricate problems alike to the systematist and to the student of genetics.

De Vries prefaced his lectures on "Species and Varieties, their Origin by Mutation," with the pregnant sentence: "The origin of species is an object of experimental investigation," and this is equally true of the study of the real and presumptive hybrids of our British flora, which may be investigated either synthetically or, when fertile, also analytically, as in some cases their offspring show striking Mendelian segregation. Some good work has already been accomplished in this direction, but more remains to be done, and we have here an important and useful sphere of work for the energies of many skilled plant-breeders.

I would therefore like to plead for intimate collaboration between all botanists, hopeful that, as progress in the past has come through the labours of men of wide sympathies, so in the future, when studies are bound to become more specialised, there will be no narrowing of interests, but that the various problems which have to be solved will be attacked from all points of view, the morphological, the physiological, the ecological, and the systematic. Thus by united efforts and close cooperation of botanists of all schools and of all countries we shall gain the power to surmount the difficulties with which our science is still confronted.

SUB-SECTION K.

AGRICULTURE.

OPENING ADDRESS BY W. BATESON, M.A., F.R.S., CHAIRMAN OF THE SUB-SECTION.

THE invitation to preside over the Agricultural Sub-section on this occasion naturally gave me great pleasure, but after accepting it I have felt embarrassment in a considerable degree. The motto of the great Society which has been responsible for so much progress in agricultural affairs in this country very clearly expresses the subject of our deliberations in the words "Practice with Science," and to be competent to address you, a man should be well conversant with both. But even if agriculture is allowed to include horticulture, as may perhaps be generally conceded, I am sadly conscious that my special qualifications are much weaker than you have a right to demand of a President.

The aspects of agriculture from which it offers hopeful lines for scientific attack are, in the main, three: Physiological, Pathological, and Genetic. All are closely interrelated, and for successful dealing with the problems of any one of these departments of research, knowledge of the results attained in the others is now almost indispensable. I myself can claim personal acquaintance with the third or genetic group alone, and therefore in considering how science is to be applied to the practical operations of agriculture, I must necessarily choose it as the more special subject of this address. I know very well that wider experience of those other branches of agricultural science or practical agriculture would give to my remarks a weight to which they cannot now pretend.

Before, however, proceeding to these topics of special consideration, I have thought it not unfitting to say something of a more general nature as to the scope of an applied science, such as that to which we here are devoted. We are witnessing a very remarkable outburst of activity in the promotion of science in its application to agriculture. Public bodies distributed throughout this country and our possessions are organising various enterprises with that object. Agricultural research is now everywhere admitted as a proper subject for University support and direction.

With the institution of the Development Grant a national subsidy is provided on a considerable scale in England for the first time.

At such a moment the scope of this applied science and the conditions under which it may most successfully be advanced are prominent matters of consideration in the minds of most of us. We hope great things from these new ventures. We are, however, by no means the first to embark upon them. Many of the other great nations have already made enormous efforts in the same direction. We have their experience for a guide.

Now, it is not in dispute that wherever agricultural science has been properly organised valuable results have been attained, some of very high importance indeed; yet with full appreciation of these achievements, it is possible to ask whether the whole outcome might not have been greater still. In the course of recent years I have come a good deal into contact with those who in various countries are taking part in such work, and I have been struck with the unanimity that they have shown in their comments on the conditions imposed upon them. Those who receive large numbers of agricultural bulletins purporting to give the results of practical trials and researches will, I feel sure, agree with me that with certain notable exceptions they form on the whole dull reading. True they are in many cases written for farmers and growers in special districts, rather than for the general scientific reader, but I have sometimes asked myself whether those farmers get much more out of this literature than I do. I doubt it greatly. Nevertheless, to the production of these things much labour and expense have been devoted. I am sure, and I believe that most of those engaged in these productions themselves feel, that the effort might have been much better applied elsewhere. Work of this unnecessary kind is done, of course, to satisfy a public opinion which is supposed to demand rapid returns for outlay, and to prefer immediate apparent results, however trivial, to the long delay which is the almost inevitable accompaniment of any serious production. For my own part, I much doubt whether in this estimate present public opinion has been rightly gauged. Enlightenment as to the objects, methods, and conditions of scientific research is proceeding at a rapid rate. I am quite sure, for example, that no organisation of agricultural research now to be inaugurated under the Development Commission will be subjected to the conditions laid down in 1887 when the Experimental Stations of the United States were established. For them it is decreed in Sect. 4 of the Act of Establishment:—

"That bulletins or reports of progress shall be published at said stations at least once in three months, one copy of which shall be sent to each newspaper in the States or Territories in which they are respectively located, and to such individuals actually engaged in farming as may request the same and as far as the means of the station will permit."

It would be difficult to draft a condition more unfavourable to the primary purpose of the Act, which was "to conduct original researches or verify experiments on the physiology of plants and animals" with agricultural objects in view. I can scarcely suppose the most prolific discoverer should be invited to deliver himself more than once a year. Not only does such a rule compel premature publication—that nuisance of modern scientific life—but it puts the investigator into a wrong attitude towards his work. He will do best if he forget the public and the newspaper of his State or Territory for long periods, and should only return to them when, after repeated verification, he is quite certain he has something to report.

In this I am sure the best scientific opinion of all countries would be agreed. If it is true that the public really demand continual scraps of results, and cannot trust the investigators to pursue research in a reasonable way, then the public should be plainly given to understand that the time for inaugurating researches in the public's name has not arrived. Men of science have in some degree themselves to blame if the outer world has been in any mistake on these points. It cannot be too widely known that in all sciences, whether pure or applied, research is nearly always a very slow process, uncertain in production and full of disappointments. This is true, even in the new industries, chemical and electrical, for instance, where the whole industry has been built up from the beginning on a basis developed entirely by scientific method and by the accumulation of precise knowledge. Much more must any material advance be slow in the case of an ancient art like agriculture, where practice represents the casual experience of untold ages and accurate investigation is of yesterday. Problems, moreover, relating to unorganised matter are in their nature simpler than those concerned with the properties of living things, a region in which accurate knowledge is more difficult to attain. Here the research of the present day can aspire no higher than to lay the foundation on which the following generations will build. When this is realised it will at once be perceived that both those who are engaged in agricultural research and those who are charged with the supervision and control of these researches must be prepared to exercise a large measure of patience.

The applicable science must be created before it can be applied. It is with the discovery and development of such science that agricultural research will for long enough best occupy its energies. Sometimes, truly, there come moments when a series of obvious improvements in practice can at once be introduced, but this happens only when the penetrative genius of a Pasteur or a Mendel has worked out the way into a new region of knowledge, and returns with a treasure that all can use. Given the knowledge it will soon enough become applied.

I am not advocating work in the clouds. In all that is attempted we must stick near to the facts. Though the methods of research and of thought must be strict and academic, it is in the farm and the garden that they must be applied. If inspiration is to be found anywhere it will be there. The investigator will do well to work

"As if his highest plot
To plant the bergamot."

It is only in the closest familiarity with phenomena that we can attain to that perception of their orderly relations, which is the beginning of discovery.

To the creation of applicable science the very highest gifts and training are well devoted. In a foreign country an eminent man of science was speaking to me of a common friend, and he said that as our friend's qualifications were not of the first rank he would have to join the agricultural side of the university. I have heard remarks of similar disparagement at home. Now, whether from the point of view of agriculture or pure science, I can imagine no policy more stupid and short-sighted.

The man who devotes his life to applied science should be made to feel that he is in the main stream of scientific progress. If he is not, both his work and science at large will suffer. The opportunities of discovery are so few that we cannot afford to miss any, and it is to the man of trained mind who is in contact with the phenomena of a great applied science that such opportunities are most often given. Through his hands pass precious material, the outcome sometimes of years of effort and design. To tell him that he must not pursue that inquiry further because he cannot foresee a direct and immediate application of the knowledge is, I believe almost always, a course detrimental to the real interests of the applied science. I could name specific instances where in other countries thoroughly competent and zealous investigators have by the shortsightedness of superior officials been thus debarred from following to their conclusion researches of great value and novelty.

In this country, where the Development Commission will presumably for many years be the main instigator and controller of agricultural research, the constitution of the Advisory Board, on which Science is largely represented, forms a guarantee that broader counsels will prevail, and it is to be hoped that not merely this inception of the work, but its future administration also, will be guided in the same spirit. So long as a train of inquiry continues to extend, and new knowledge, that most precious commodity, is coming in, the enterprise will not be in vain and it will be usually worth while to pursue it.

The relative value of the different parts of knowledge in their application to industry is almost impossible to estimate, and a line of work should not be abandoned until it leads to a dead end, or is lost in a desert of detail.

We have, not only abroad, but also happily in this country, several private firms engaged in various industries —I may mention especially metallurgy, pharmacy, and brewing—who have set an admirable example in this matter, instituting researches of a costly and elaborate nature, practically unlimited in scope, connected with the subjects of their several activities, conscious that it is only by men in close touch with the operations of the industry that the discoveries can be made, and well assured that they themselves will not go unrewarded.

Let us on our part beware of giving false hopes. We know no hæmony "of sovran use against all enchantments, mildew blast, or damp." Those who are wise among us do not even seek it yet. Why should we not take the farmer and gardener into our fullest confidence and tell them this? I read lately a newspaper interview with a fruit-farmer who was being questioned as to the success of his undertaking, and spoke of the pests and difficulties with which he had had to contend. He was asked whether the Board of Agriculture and the scientific authorities were not able to help him. He replied that they had done what they could, that they had recommended first one thing and then another, and he had formed the opinion that they were only in an experimental stage. He was perfectly right, and he would hardly have been wrong had he said that in these things science is only approaching the experimental stage. This should be notorious. There is nothing to extenuate. To affect otherwise would be unworthy of the dignity of science.

Those who have the means of informing the public mind on the state of agricultural science should make clear that though something can be done to help the practical man already, the chief realisation of the hopes of that science is still very far away, and that it can only be reached by long and strenuous effort, expended in many various directions, most of which must seem to the uninitiated mere profitless wandering. So only will the confidence of the laity be permanently assured towards research.

Nowhere is the need for wide views of our problems more evident than in the study of plant-diseases. Hitherto this side of agriculture and of horticulture, though full of possibilities for the introduction of scientific method, has been examined only in the crudest and most empirical fashion. To name the disease, to burn the affected plants, and to ply the crop with all the sprays and washes in succession ought not to be regarded as the utmost that science can attempt. There is at the present time hardly any comprehensive study of the morbid physiology of plants comparable with that which has been so greatly developed in application to animals. The nature of the resistance to disease characteristic of so many varieties, and the modes by which it may be ensured, offers a most attractive field for research, but it is one in which the advance must be made by the development of pure science, and those who engage in it must be prepared for a long period of labour without ostensible practical results. It has seemed to me that the most likely method of attack is here, as often, an indirect one. We should probably do best if we left the direct and special needs of agriculture for a time out of account, and enlisted the services of pathologists trained in the study of disease as it affects man and animals, a science already developed and far advanced towards success. Such a man, if he were to devote himself to the investigation of the same problems in the case of plants, could, I am convinced, make discoveries which would not merely advance the theory of disease-resistance in general very greatly, but would much promote the invention of rational and successful treatment.

As regards the application of Genetics to practice, the case is not very different. When I go to the Temple Show or to a great exhibition of live stock, my first feeling is one of admiration and deep humility. Where all is so splendidly done and results so imposing are already attained, is it not mere impertinence to suppose that any advice we are able to give is likely to be of value?

But so soon as one enters into conversation with breeders, one finds that almost all have before them some ideal to which they have not yet attained, operations to perform that they would fain do with greater ease and certainty, and that, as a matter of fact, they *are* looking to scientific research as a possible source of the greater knowledge which they require. Can we, without presumption, declare that genetic science is now able to assist these inquirers? In certain selected cases it undoubtedly can—and I will say, moreover, that if the practical men and we students could combine our respective experiences into one head, these cases would already be numerous. On the other hand, it is equally clear that in a great range of examples practice is so far ahead that science can scarcely hope in finite time even to represent what has been done, still less to better the performance. We cannot hope to improve the Southdown sheep for its own districts, to take a second off the trotting record, to increase the flavour of the muscat of Alexandria, or to excel the orange and pink of the rose Juliet. Nothing that we know could have made it easier to produce the Rambler roses, or even to evoke the latest novelties in sweet peas, though it may be claimed that the genetic system of the sweet pea is, as things go, fairly well understood. To do any of these things would require a control of events so lawless and rare that for ages they must probably remain classed as accidents. On the other hand, the modes by which combinations can be made, and by which new forms can be fixed, are through Mendelian analysis and the recent developments of genetic science now reasonably clear, and with that knowledge much of the breeder's work is greatly simplified. This part of the subject is so well understood that I need scarcely do more than allude to it.

A simple and interesting example is furnished by the work which Mr. H. M. Leake is carrying out in the case of cotton in India. The cottons of fine quality grown in India are monopodial in habit, and are consequently late in flowering. In the United Provinces a comparatively early-flowering form is required, as otherwise there is not time for the fruits to ripen. The early varieties are sympodial in habit, and the primary apex does not become a flower. Hitherto no sympodial form with cotton of high quality has existed, but Mr. Leake has now made the combination needed, and has fixed a variety with high-class cotton and the sympodial habit, which is suitable for cultivation in the United Provinces. Until genetic physiology was developed by Mendelian analysis, it is safe to say that a practical achievement of this kind could not have been made with rapidity or certainty. The research was planned on broad lines. In the course of it much light was obtained on the genetics of cotton, and features of interest were discovered which considerably advance our knowledge of heredity in several important respects. This work forms an admirable illustration of that simultaneous progress both towards the solution of a complex physiological problem and also towards the successful attainment of an economic object which should be the constant aim of agricultural research.

Necessarily it follows that such assistance as genetics can at present give is applicable more to the case of plants and animals which can be treated as annuals than to creatures of slower generation. Yet this already is a large area of operations. One of the greatest advances to be claimed for the work is that it should induce raisers of seed crops especially to take more hopeful views of their absolute purification than have hitherto prevailed. It is at present accepted as part of the natural perversity of things that most high-class seed crops must throw "rogues," or that at the best the elimination of these waste plants can only be attained by great labour extended over a vast period of time. Conceivably that view is correct, but no one acquainted with modern genetic science can believe it without most cogent proof. Far more probably we should regard these rogues either as the product of a few definite individuals in the crop, or even as chance impurities brought in by accidental mixture. In either case they can presumably be got rid of. I may even go further and express a doubt whether that degeneration which is vaguely supposed to be attendant on all seed crops is a physiological reality. Degeneration may perhaps affect plants like the potato which are continually multiplied asexually, though the fact has never been proved satisfactorily. Moreover, it is not in question that races of plants taken into unsuitable climates do degenerate rapidly from uncertain causes, but that is quite another matter.

The first question is to determine whether a given rogue has in it any factor which is *dominant* to the corresponding character in the typical plants of the crop. If it has, then we may feel considerable confidence that these rogues have been introduced by accidental mixture. The only alternative, indeed, is cross-fertilisation with some distinct variety possessing the dominant, or crossing within the limits of the typical plants themselves occurring in such a way that complementary factors have been brought together. This last is a comparatively infrequent phenomenon, and need not be considered till more probable hypotheses have been disposed of. If the rogues are first crosses the fact can be immediately proved by sowing their seeds, for segregation will then be evident. For example, a truly round seed is occasionally, though very rarely, found on varieties of pea which have wrinkled seeds. I have three times seen such seeds on my own plants. A few more were kindly given me by Mr. Arthur Sutton, and I have also received a few from M. Philippe de Vilmorin—to both of whom I am indebted for most helpful assistance and advice. Of these abnormal or unexpected seeds some died without germinating, but all which did germinate in due course produced the normal mixture of round and wrinkled, proving that a cross had occurred. Cross-fertilisation in culinary peas is excessively rare, but it is certainly sometimes effected, doubtless by the leaf-cutter bee (Megachile) or a humble-bee visiting flowers in which for some reason the pollen has been inoperative. But in peas crossing is assuredly not the source of the ordinary rogues. These plants have a very peculiar conformation, being tall and straggling, with long internodes, small leaves, and small flowers, which together give them a curious wild look. When one compares them with the typical cultivated plants which have a more luxuriant habit, it seems difficult to suppose that the rogue can really be recessive to such a type. True, we cannot say definitely *a priori* that any one character is dominant to another, but old preconceptions are so strong that without actual evidence we always incline to think of the wilder and more primitive characteristics as dominants. Nevertheless, from such observations as I have been able to make, I cannot find any valid reason for doubting that the rogues are really recessives to the type. One feature in particular is quite inconsistent with the belief that these rogues are in any proper sense degenerative returns to a wild type, for in several examples the rogues have *pointed* pods like the cultivated sorts from which they have presumably been derived. All the more primitive kinds have the dominant stump-ended pod. If the rogues had the stump pods they would fall into the class of dominants, but they have no single quality which can be declared to be certainly dominant to the type, and I see no reason why they may not be actually recessives to it after all. Whether this is the true account or not we shall know for certain next year. Mr. Sutton has given me a quantity of material which we are now investigating at the John Innes Horticultural Institution, and by sowing the seed of a great number of individual plants separately I anticipate that we shall prove the rogue-throwers to be a class apart. The pure types then separately saved should, according to expectation, remain rogue-free, unless further sporting or fresh contamination occurs. If it prove that the long and attenuated rogues are really recessive to the shorter and more robust type, the case will be one of much physiological significance, but I believe a parallel already exists in the case of wheats, for among certain crosses bred by Prof. Biffen, some curious spelt-like plants occurred among the derivatives from such robust wheats as Rivet and Red Fife.

There is another large and important class of cases to which similar considerations apply. I refer to the bolting or running to seed of crops grown as biennials, especially root crops. It has hitherto been universally supposed that the loss due to this cause, amounting in Sugar Beet as it frequently does to five, or even more, *per cent.*, is not preventable. This may prove to be the truth, but I think it is not impossible that the bolters can be wholly, or almost wholly, eliminated by the application of proper breeding methods. In this particular example I know that season and conditions of cultivation count for a good deal in promoting or checking the tendency to run to seed; nevertheless one can scarcely witness the sharp distinction between the annual and biennial forms without suspecting that genetic composition is largely responsible. If it proves to be so, we shall have another remarkable illustration of the direct applicability of knowledge gained from a purely academic source. "Let not him that girdeth on his harness boast himself as he that putteth it off," and I am quite alive to the many obstacles which may lie between the conception of an idea and its realisation. One thing, however, is certain, that we have now the power to formulate rightly the question which the breeder is to put to nature; and this power and the whole apparatus by which he can obtain an answer to his question—in whatever sense that answer may be given—has been derived from experiments designed with the immediate object of investigating that scholastic and seemingly barren problem, "What is a species?" If Mendel's eight years' work had been done in an agricultural school supported by public money, I can imagine much shaking of heads on the County Council governing that institution, and yet it is no longer in dispute that he provided the one bit of solid discovery upon which all breeding practice will henceforth be based.

Everywhere the same need for accurate knowledge is apparent. I suppose horse-breeding is an art which has by the application of common sense and great experience been carried to about as high a point of perfection as any. Yet even here I have seen a mistake made which is obvious to anyone accustomed to analytical breeding. Among a number of stallions provided at great expense to improve the breed of horses in a certain district was one which was shown me as something of a curiosity. This particular animal had been bred by one of the provided stallions out of an indifferent country mare. It had been kept as an unusually good-looking colt, and was now travelling the country as a breeding stallion, under the highest auspices. I thought to myself that if such a practice is sanctioned by breeding acumen and common sense, Science is not, after all, so very ambitious if she aspires to do rather better. The breeder has continually to remind himself that it is not what the animal or plant *looks* that matters, but what it *is*. Analysis has taught us to realise, first, that each animal and plant is a double structure, and next that the appearance may show only half its composition.

With respect to the inheritance of many physiological qualities of divers kinds we have made at least a beginning of knowledge, but there is one class of phenomena as yet almost untouched. This is the miscellaneous group of attributes which are usually measured in terms of size, fertility, yield, and the like. This group of characters has more than common significance to the practical man. Analysis of them can nevertheless only become possible when pure science has progressed far beyond the point yet reached.

I know few lines of pure research more attractive and at the same time more likely to lead to economic results than an investigation of the nature of variation in size of the whole organism or of its parts. By what factors is it caused? By what steps does it proceed? By what limitations is it beset? In illustration of the application of these questions I may refer to a variety of topics that have been lately brought to my notice. In the case of merino sheep

I have been asked by an Australian breeder whether it is possible to combine the optimum length of wool with the optimum fineness and the right degree of crimping. I have to reply that absolutely nothing is yet known for certain as to the physiological factors determining the length or the fineness of wool. The crimping of the fibres is an expression of the fact that each particular hair is curved, and if free and untwisted would form a corkscrew spiral, but as to the genetics of curly hair even in man very little is yet known. But leaving the question of curl on one side, we have, in regard to the length and fineness of wool, a problem which genetic experiment ought to be able to solve. Note that in it, as in almost all problems of the "yield" of any product of farm or garden, two distinct elements are concerned—the one is *size*, and the other is *number*. The length of the hair is determined by the rate of excretion and length of the period of activity of the hair follicles, but the fineness is determined by the number of follicles in unit area. Now analogy is never a safe guide, but I think if we had before us the results of really critical experiments on the genetics of size and number of multiple organs in any animal or even any plant, we might not wholly be at a loss in dealing with this important problem.

A somewhat similar question comes from South Africa. Is it possible to combine the qualities of a strain of ostriches which has extra long plumes with those of another strain which has its plumes extra lustrous? I have not been able fully to satisfy myself upon what the lustre depends, but I incline to think it is an expression of fineness of fibre, which again is probably a consequence of the smallness and increased number of the excreting cells, somewhat as the fineness of wool is a consequence of the increased number and smallness of the excreting follicles.

Again the question arises in regard to flax, how should a strain be bred which shall combine the maximum length with maximum fineness of fibre? The element of number comes in here, not merely with regard to the number of fibres in a stem, but also in two other considerations: first, that the plant should not tiller at the base, and, secondly, that the decussation of the flowering branches should be postponed to the highest possible level.

Now in this problem of the flax, and not impossibly in the others I have named, we have questions which can in all likelihood be solved in a form which will be of general, if not of universal, application to a host of other cognate questions. By good luck the required type of flax may be struck at once, in which case it may be fixed by ordinary Mendelian analysis, but if the problem is investigated by accurate methods on a large scale, the results may show the way into some of those general problems of size and number which make a great part of the fundamental mystery of growth.

I see no reason why these things should remain inscrutable. There is indeed a little light already. We are well acquainted with a few examples in which the genetic behaviour of these properties is fairly definite. We have examples in which, when two varieties differing in number of divisions are crossed, the lower number dominates—or, in other words, that the increased number is a consequence of the removal of a factor which prevents or inhibits particular divisions, so that they do not take place. It is likely that in so far as the increased productivity of a domesticated form as compared with its wild original depends on more frequent division, the increase is due to loss of inhibiting factors. How far may this reasoning be extended? Again, we know that in several plants—peas, sweet peas, Antirrhinum, and certain wheats—a tall variety differs in that respect from a dwarf in possessing one more factor. It would be an extraordinarily valuable addition to knowledge if we could ascertain exactly how this factor operates, how much of its action is due to linear repetition, and how much to actual extension of individual parts. The analysis of the plants of intermediate size has never been properly attempted, but would be full of interest and have innumerable bearings on other cases in animals and plants, some of much economic importance.

That in all such examples the objective phenomena we see are primarily the consequence of the interaction of genetic factors is almost certain. The lay mind is at first disposed, as always, to attribute such distinctions to anything rather than to a specific cause which is invisible. An appeal to differences in conditions—which a moment's reflection shows to be either imaginary or altogether independent—or to those vague influences invoked under the name of Selection, silently postponing any laborious analysis of the nature of the material selected, repels curiosity for a time, and is lifted as a veil before the actual phenomena; and so even critical intelligences may for an indefinite time be satisfied that there is no specific problem to be investigated, in the same facile way that, till a few years ago, we were all content with the belief that malarial fevers could be referred to any damp exhalations in the atmosphere, or that in suppuration the body was discharging its natural humours. In the economics of breeding, a thousand such phenomena are similarly waiting for analysis and reference to their specific causes. What, for instance, is self-sterility? The phenomenon is very widely spread among plants, and is far commoner than most people suppose who have not specially looked for it. Why is it that the pollen of an individual in these plants fails to fertilise the ova of the same individual? Asexual multiplication seems in no way to affect the case. The American experimenters are doubtless right in attributing the failure of large plantations of a single variety of apples or of pears in a high degree to this cause. Sometimes, as Mr. W. O. Backhouse has found in his work on plums at the John Innes Horticultural Institution, the behaviour of the varieties is most definite and specific. He carefully self-fertilised a number of varieties, excluding casual pollination, and found that while some sorts—for example, Victoria, Czar, and Early Transparent—set practically every fruit self-pollinated, others, including several (perhaps all) Greengages, Early Orleans, and Sultan, do not set a single fruit without pollination from some other variety. Dr. Erwin Baur has found indications that self-sterility in Antirrhinum may be a Mendelian recessive, but whether this important suggestion be confirmed or not, the subject is worth the most minute study in all its bearings. The treatment of this problem well illustrates the proper scope of an applied science. The economic value of an exact determination of the empirical facts is obvious, but it should be the ambition of anyone engaging in such a research to penetrate further. If we can grasp the *rationale* of self-sterility we open a new chapter in the study of life. It may contain the solution of the question What is an individual?—no mere metaphysical conundrum, but a physiological problem of fundamental significance.

What, again, is the meaning of that wonderful increase in size or in "yield" which so often follows on a first cross? We are no longer content, as Victorian teleology was, to call it a "beneficial" effect and pass on. The fact has long been known and made use of in breeding stock for the meat market, and of late years the practice has also been introduced in raising table poultry. Mr. G. N. Collins,[1] of the U.S. Department of Agriculture, has recently proposed with much reason that it might be applied in the case of maize. The cross is easy to make on a commercial scale, and the gain in yield is striking, the increase ranging as high as 95 per cent. These figures sound extravagant, but from what I have frequently seen in peas and sweet peas, I am prepared for even greater increase. But what *is* this increase? How much of it is due to change in number of parts, how much to transference of differentiation or homœosis, as I have called it—leaf-buds becoming flower-buds, for instance—and how much to actual increase in size of parts? To answer these questions would be to make an addition to human knowledge of incalculably great significance.

Then we have the further question, How and why does the increase disappear in subsequent generations? The very uniformity of the cross-breds between pure strains must be taken as an indication that the phenomenon is orderly. Its subsidence is probably orderly also. Shull has advocated the most natural view that heterozygosis is the exciting cause, and that with the gradual return to the homozygous state the effects pass off. I quite think this may be a part of the explanation, but I feel difficulties, which need not here be detailed, in accepting this as a complete account. Some of the effect we may probably also attribute to the combination of complementary factors;

[1] Bureau of Plant Industry, Bulletin No. 191, 1910.

but whether heterozygosis, or complementary action, is at work, our experience of cross-breeding in general makes it practically certain that genetic factors of special classes only can have these properties, and no pains should be spared in identifying them. It is not impossible that such identification would throw light on the nature of cell division and of that meristic process by which the repeated organs of living things are constituted, and I have much confidence that in the course of the analysis discoveries will be made bearing directly both on the general theory of heredity and on the practical industry of breeding.

In the application of science to the arts of agriculture, chemistry, the foundation of sciences, very properly and inevitably came first, while breeding remained under the unchallenged control of simple common sense alone. The science of genetics is so young that when we speak of what it also can do we must still for the most part ask for a long credit; but I think that if there is full cooperation between the practical breeder and the scientific experimenter, we shall be able to redeem our bonds at no remotely distant date. In the mysterious properties of the living bodies of plants and animals there is an engine capable of wonders scarcely yet suspected, waiting only for the constructive government of the human mind. Even in the seemingly rigorous tests and trials which have been applied to living material apparently homogeneous, it is not doubtful that error has often come in by reason of the individual genetic heterogeneity of the plants and animals chosen. A batch of fruit trees may be all of the same variety, but the stocks on which the variety was grafted have hitherto been almost always seminally distinct individuals, each with its own powers of luxuriance or restriction, their own root-systems, and properties so diverse that only in experiments on a colossal scale can this diversity be supposed to be levelled down. Even in a closely bred strain of cattle, though all may agree in their "points," there may still be great genetic diversity in powers of assimilation and rapidity of attaining maturity, by which irregularities by no means negligible are introduced. The range of powers which organic variation and genetic composition can confer is so vast as to override great dissimilarities in the conditions of cultivation. This truth is familiar to every raiser and grower, who knows it in the form that the first necessity is for him to get the right breed and the right variety for his work. If he has a wheat of poor yield, no amount of attention to cultivation or manuring will give him a good crop. An animal that is a bad doer will remain so in the finest pasture. All praise and gratitude to the student of the conditions of life, for he can do, and has done, much for agriculture, but the breeder can do even more.

When more than fifteen years ago the proposal to found a school of agriculture in Cambridge was being debated, much was said of the importance of the chemistry of soils, of researches into the physiological value of foodstuffs, and of other matters then already prominent on the scientific horizon. I remember then interpolating with an appeal for some study of the physiology of breeding, which I urged should find a place in the curriculum, and I pointed out that the improvement in the strains of plants and animals had done at least as much—more, I really meant—to advance agriculture than had been accomplished by other means. My advice found little favour, and I was taken to task afterwards by a prominent advocate of the new school for raising a side issue. Breeding was a purely empirical affair. Common sense and selection comprised the whole business, and physiology flew at higher game. I am, nevertheless, happy now to reflect that of the work which is making the Cambridge School of Agriculture a force for progress in the agricultural world the remarkable researches and results of my former colleague, Prof. Biffen, based as they have been on modern discoveries in the pure sciences of breeding, occupy a high and greatly honoured place.

In conclusion, I would sound once more the note with which I began. If we are to progress fast there must be no separation made between pure and applied science. The practical man with his wide knowledge of specific natural facts, and the scientific student ever seeking to find the hard general truths which the diversity of Nature hides—truths out of which any lasting structure of progress must be built—have everything to gain from free interchange of experience and ideas. To ensure this community of purpose those who are engaged in scientific work should continually strive to make their aims and methods known at large, neither exaggerating their confidence nor concealing their misgivings,

> "Till the world is wrought
> To sympathy with hopes and fears it heeded not."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—Dr. Alex. Findlay, special lecturer in physical chemistry, is resigning his post in consequence of his acceptance of the chair of chemistry in the University of Wales at Aberystwyth.

Dr. Murray has resigned his post as assistant lecturer and demonstrator in chemistry, having been appointed head of the chemical and metallurgical department of Wolverhampton Technical School.

BY the will of Dr. S. J. Gee, late physician to St. Bartholomew's Hospital, the sum of about 20,000*l.* is left to his daughter for life, with contingent remainder to the Royal College of Physicians, London, upon trust, so far as possible, to form a permanent endowment fund for the college.

THE winter session of the London (Royal Free Hospital) School of Medicine for Women will be opened on Monday, October 2, with an introductory address by Sir Henry Butlin, P.R.C.S., upon "Research in Medicine and Women in Medical Research." Mrs. Garrett Anderson, president of the school, will occupy the chair.

MR. T. HARRIS, of the Imperial College of Science and Technology, and the Cavendish Laboratory, Cambridge, has been appointed lecturer and demonstrator in the physical department of the East London College in succession to Mr. E. Marsden. Mr. P. Kemp has been appointed lecturer in the electrical engineering department of the same college.

THE exchange of professors between Harvard University and the Ministry of Public Instruction in France comes into effect this winter for the first time, and the Bulletin of the American Geographical Society announces that Prof. W. M. Davis will go to Paris to lecture until the end of March, after the International Congress at Rome has ended. Prof. Diehl, of the Sorbonne, will go to Harvard University to lecture on Byzantine history.

A SPECIAL course of twelve lectures on illumination is to be given at the Polytechnic, Regent Street, during the present session. The lectures, which will be under the supervision of Mr. L. Gaster, editor of *The Illuminating Engineer*, will deal with all illuminants, including recent advances in electric, gas, oil, and acetylene lighting; the effect of light on the eye; the hygienic aspects of illumination; and the measurement of light and illumination. Practical problems, such as the lighting of schools, streets, and factories, will be treated in the second half of the course, commencing in January, 1912. Until December 5 the lectures will be held on Tuesday evenings at 7.30, and during January and February next on Thursday evenings at the same hour.

THE new session in the faculties of arts, laws, science, engineering, and medical sciences at University College, London, will begin on October 2. The list of public introductory lectures at the college contains the following, among others:—Wednesday, October 4, Prof. H. R. Kenwood on "The Scope of School Hygiene and the Legislative Provisions dealing with the School Child," being the first of a course of lectures on school hygiene specially designed for school teachers; Friday, October 6, Prof. G. Dawes Hicks on "Bergson's Conception of Creative Evolution" (this lecture is designed as an introduction to a course of four public university lectures to be delivered by Prof. Henri Bergson at University College on October 20, 21, 27, and 28). A course of public lectures on heating and ventilating engineering will be given by Mr. A. H. Barker, the introductory lecture on Tuesday, October 17, being on "Problems in Heating and Ventilation awaiting Solution by the Engineer." On the same day Mr. E.

Kilburn Scott, the newly appointed lecturer on electrical design, will begin his course on that subject.

A REVISED scheme of examination for inspectorships of mines has just been issued. The appointments are made after a competitive examination of candidates nominated by the Home Secretary. Each candidate must hold a first-class certificate under the Coal Mines Regulation Act, and must, within five years previous to his application, have been employed for two years as manager or under-manager of a coal mine, or in some other responsible capacity requiring regular attendance underground in a coal mine. Practical knowledge and experience of metalliferous mining and quarrying will also be taken into consideration. Candidates must be between twenty-three and thirty-five years of age at the time of examination. The revised subjects of examination are:—(1) English; (2) elementary mathematics; (3) elementary geology; (4) coal mining; (5) ore and stone mining; (6) electricity in mines; (7) law relating to mines and quarries; (8) oral examination; (9) chemistry; (10) physics. The last two are optional. ... ate for the return of the filled-up nomination ... e to the next appointments is October 15. ... plication and full particulars can be obtained ... ivate Secretary, Home Office, London.

... nteenth volume of reports, for the academic year 1909–10, from the universities and university colleges which participate in the annual grant made by Parliament for "University Colleges in Great Britain," and from the three colleges in Wales which receive a grant, has been published as a Blue-book (Cd. 5872). For the financial year 1909–10 the amount of grant paid by the Treasury to university colleges in England was 96,100*l.*, and for the year 1910–11, 101,250*l.* In the year 1909–10, 15,000*l.* was added to the annual grant in aid of university education in Wales. An introduction to the reports signed by the President of the Board of Education enumerates the private benefactions in aid of university education in this country made during the year under review, which have been announced from time to time in these columns. Apart from the recent munificent gifts to Reading University College, these benefactions were not comparable in magnitude or importance with those recorded in the previous report. The introduction goes on to say:—"The small extent to which university work is endowed by private benefaction in this country is emphasised, if comparison is made with the measure of support in other countries. Thus, within a year of its foundation the Kaiser Wilhelm Society for the promotion of science in Germany had at its disposal a capital of half a million sterling, which is being devoted to the equipment of institutes at which men already eminent in their respective subjects will be installed. In France, M. Auguste Lautreuil left 284,000*l.* towards the promotion of science in that country. In the United States Mr. Rockefeller handed over 764,000*l.* to the Rockefeller Institute for Medical Research, which he had previously endowed with large sums. These three instances are sufficient to show how small is the endowment of research in this country as compared with others, and from what a disadvantage this country inevitably suffers in the advancement of learning and research, now more than ever before essential to the welfare and prosperity of the nation."

THE reports referred to in the above note show that nearly 33 per cent. of the income of the English colleges was derived from fees, about 15 per cent. from endowments, a little more than 14·5 per cent. from grants from local education authorities, and 28 per cent. from the Exchequer. In the case of Welsh colleges, nearly 25 per cent. of their total income was derived from fees, nearly 6 per cent. from endowments, 6 per cent. from local education authorities, and 53·5 per cent. from the Exchequer. As a result of an increased Treasury grant the total annual income of the Welsh university colleges rose from 50,000*l.* to about 65,000*l.* The total number of students of all kinds for 1909–10 was returned as 22,187 in England (of whom 8174 were full-time students) and 1710 for Wales. No students taking courses for matriculation have been included amongst the full-time students. The total numbers of degree students in England rose from under 4400 to nearly 4900. In Wales the numbers increased from 1175 to 1191. The number of post-graduate students in the English universities and colleges concerned grew from 1052 to 1255, while in Wales it fell from 45 to 37. The number of part-time students of all kinds in England reached the figure of more than 13,700. Only about 1200 of these were reading for degrees or attending post-graduate courses.

THE new calendar of Armstrong College, Newcastle-upon-Tyne, directs attention to the fact that the faculty of science in the University of Durham is seated entirely at Armstrong College. In addition to pure science the college gives instruction in engineering (mechanical and civil), electrical engineering, mining, metallurgy, naval architecture, and agricultural science. The agricultural department of the college directs the Northumberland County Agricultural Experimental Station at Cockle Park, and the Durham County Station for Dairy Research at Offerton Hall. For the purpose of forestry instruction the college is in possession of 900 acres of wood at Chopwell, in the county of Durham, and its zoological equipment includes a laboratory of marine biology at Cullercoats, on the Northumbrian coast. Amongst prospectuses of technical institutes which have reached us may be mentioned those of the Sir John Cass Technical Institute, Aldgate, and the Northern Polytechnic Institute, Holloway. At the Sir John Cass Institute several new departures are being made. The curriculum of students in the fermentation industries now includes courses on "Brewing and Malting" and the "Micro-Biology of the Fermentation Industries." In the physics department, lectures and demonstrations will be given on "colloids," which will deal with their relation to technical problems. The special courses on liquid, gaseous, and solid fuel in the metallurgy department have also been extended, and will include laboratory work of fuel analysis and on gas analysis. There are also special features in the work of the Northern Polytechnic, and one of importance is the day school of building, which provides a practical course of training for those about to enter any profession or business connected with the construction of buildings, with surveying, or with municipal engineering. The course of work in the school provides instruction in both the principles and processes of building work, and should be of interest to parents who intend to place their sons in the architectural or surveying professions, and to builders whose sons are destined to take a future share in the management of a business.

THE eighth report of the Commissioners for the Exhibition of 1851 to the Home Secretary has been issued as a Blue-book [Cd. 5723]. The last report was published in 1889. The report proper runs to some twenty-six pages, the remaining part of the volume of 132 pages being given over to appendices, which include copies of leases, the charter of the Imperial College of Science and Technology, general regulations, accounts, and so on. Full details are given of the various steps taken by the commissioners to carry out their object of forming a centre at South Kensington for institutions engaged in the promotion of science and art, and more especially in their application to industry. As regards the consideration of future policy, the commissioners say:—"When we became free from the encumbrance of a heavy mortgage debt we were enabled to devote a considerable portion of our income to scholarships for scientific research. The remainder has been invested from time to time, so that we are now in a position to increase the scope of our activities. We have accordingly considered the uses to which we should apply our funds in the immediate future. It is not contemplated to disturb the existing provision of scholarships for purposes of research; but in our opinion a point has been reached when the capital resources of the commission should no longer be applied to assist in the erection of buildings at South Kensington, and when the balance of the income derived from our present funds should be so used as to give a further impetus to scientific and artistic training consistent with the objects of our charter. We believe that our income can be used to great advantage by the provision of scholarships and bursaries endowed, not for all time, but for limited periods, and directed specially to encourage not only research work, but also the training of 'captains of industry.' We shall, moreover, endeavour to include in any extension that we may hereafter devise for our scheme of scholarships some provision for encouraging the study of the fine arts on lines corresponding to those which have proved so efficacious in relation to science and its applications. In such assistance as we may afford from time to time to the solution of problems affecting the industrial welfare of the nation, we shall have regard principally to schemes which from their nature require support from other than ordinary sources."

THE first part of the Board of Education statistics of public education in England and Wales for the school year 1909–10, dealing with educational statistics, has been published (Cd. 5843). In his preface Sir Robert Morant points out that the Board has not for the year under review been able to make any substantial change in the statistics of technical institutions, evening schools, and allied classes. It is hoped, however, that when the proposed new regulations have come into operation, it will be possible to provide a series of tables relating to "further education," in which the various types of schools will be more clearly differentiated than is at present possible. As regards technical institutions—that is to say, institutions giving an organised course of instruction in day classes, including advanced instruction in science, or in science and in art, and provided with a staff and equipment adequate for the purpose and fulfilling other requirements laid down by the Board—there were 35 recognised during the year; and they provided 124 courses in which 736 teachers were employed. The number of students who attended at any time during the year was 2946, and on 2584 of these grants were paid by the Board. Of these 2946 students, 190 were under 16 years of age, 735 under 18 but over 16, 1284 over 18 but under 21 years of age, and 737 were over 21. In addition to these students of technical institutions there are many other students studying science and technology in day technical classes. In a series of tables the Board provides information of 230 courses held in 109 institutions in which day technical classes were recognised, but points out that "the 'day technical classes' to which the following tables relate constitute merely a small fraction of the whole number of day technical classes in existence in England." In the 230 courses mentioned there were 10,924 students taught by 983 teachers.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 4.—M. Armand Gautier in the chair.—Kr. **Birkeland**: The electrical constitution of the sun. A development of views put forward in two earlier communications. The photosphere is regarded as a sea of electric arcs. The bearing of these views on Laplace's nebular hypothesis is discussed, since, if matter is radiated under the action of electrical forces, it is not necessary to assume that at one time the nebula extended to the orbit of Neptune, and this reduces the force of Moulton's objections to Laplace's theory.—M. **Merlin**: Some theorems of arithmetic and an enunciation which contains them. Henri **Villat**: A mixed problem of the theory of harmonic functions in an annular area.—Ed. **Griffon**: A singular case of variation by budding in the peach tree. A description of the appearance of shoots of almond, bearing blossom, on a peach tree.—Marcel **Baudouin**: Human post-mortem actions on the human bones in the bone caves of the polished stone period.—Stanilas **Meunier**: An Egyptian meteorite recently presented to the museum. This meteorite appears to belong to a new lithological type, and will be described in detail in a later communication.

September 11.—M. Armand Gautier in the chair.—Émile **Picard**: An addition to a theorem relating to integral equations of the third species.—Armand **Gautier**: The mechanism of the variation of race, and the molecular transformations which accompany these variations.—A. **Korn**: An important class of asymmetrical nuclei in the theory of integral equations.—Tr. **Lalesco**: Theorem on characteristic values.—L. E. J. **Brouwer**: The theorem of M. Jordan in space of n dimensions.—A. **Blondel**: The various methods of measuring orientation in wireless telegraphy.—C. **Statescu**: Solutions of heterogeneous magnetic salts in a heterogeneous magnetic field.—P. **Mahler** and E. **Goutal**: The use of combustion under pressure for estimating carbon in steel. A modified calorimetric bomb, not enamelled, and having a capacity of 1 litre, has been used for the direct combustion of iron and steel in oxygen under a pressure of 25 atmospheres. The carbon dioxide produced is absorbed in a standard solution of baryta. The method is shown to compare favourably, as regards accuracy, with the usual methods, and has the advantages of rapidity and ease of execution.—Paul **Vuillemin**: Mutation of a hybrid transmitted to its descendants.—E. **Roubaud**: The Chæromyies, a new Diptera with larvæ sucking the blood of mammals.—H. **de Dorlodot** and Ach. **Salée**: The synchronism of the Carboniferous limestone of the Boulonnais with that of Belgium and England.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part ii. for 1911, contains the following memoirs communicated to the society:—

January 14.—C. **Runge**: The radio-activity of air from the open sea.

February 25.—H. **Weyl**: The asymptotic distribution of particular solutions in integral equations.—G. **Angenheister** and C. **Rohloff**: Meteorological observations in the South Seas, from the Samoa Observatory.

March 11.—R. **Gans**: The electron theory of ferro-magnetism, ii.—G. **Tammann**: The alterations in the properties of metals due to mechanical treatment.

The Business Communications of the society, part i. for 1911, contain the ninth report on the publication of Gauss's works, and the tenth report of the Samoa Observatory for 1910–11.

THE STONE AGE IN NORTH AMERICA.

The Stone Age in North America: an Archaeological Encyclopaedia of the Implements, Ornaments, Weapons, Utensils, &c., of the Prehistoric Tribes of North America, with more than three hundred full-page plates and four hundred figures illustrating over four thousand different objects. By W. K. Moorehead. Vol. i., pp. xii+457; vol. ii., pp. vi+417. (London: Constable and Co., Ltd.; Boston and New York: Houghton Mifflin Co., 1911.) Price, 2 vols., 1*l.* 11*s.* 6*d.* net.

MR. MOOREHEAD has produced two handsome volumes amply illustrated. They deal with a subject that has scarcely ever been treated as a whole. Special aspects of the use of stone by the older inhabitants of the American continent have formed the subject of monographs by Wilson, Abbott, Holmes, and others, but no one has ever ventured to deal with the entire field. Mr. Moorehead is an enthusiast for his subject, a condition of mind that inevitably lends a human interest to his book, while, almost as surely, it leads him into sundry exaggerations. He takes up the position of the strongly convinced advocate rather than that of the impartial judge. This attitude is one by no means uncommon in books produced in the United States on subjects depending upon induction and hypothesis, rather than upon observed facts. Nor is the attitude unknown in Europe; but the conditions differ in an important manner. On this side the literature of our prehistoric periods is already fifty years old; certain facts and a definite terminology have been generally accepted; the main grouping is again an accepted fact, and the result is that, to write intelligibly, the author of a new treatise is compelled to subscribe to these conditions. The common terminology may be right or wrong; it may, and often does, beg the question, but the system is practical, inasmuch as it enables the writer to state his arguments and the reader to understand them, without pausing to disentangle the meaning of the terms in which they are stated. The book can thus be read without impatience, and it may be with profit.

Now one of the perplexing features of the productions of the Stone ages is the marvellous similarity in form of the implements from the most widely separated districts. This is, of course, a commonplace, for everyone knows that, *e.g.*, implements from South Africa, from the laterite beds of Madras, and, say, from Trenton, New Jersey, differ only in the material of which they are made. In the later neolithic times, such similarities are perhaps even more marked, and, in some ways, more astonishing, though, at the same time, each country has its characteristic forms.

This being the case, surely it would be wisdom, and tend to the elucidation of the problems of early man, if the writers of new treatises would endeavour to make their local discoveries fall into line with the scheme already accepted in Europe—if they would master and adopt the classification to be found in the text-books of the subject. It is not claimed for a moment that the scheme or the classification is perfect, or even that it is the last word, but only that it exists, and is generally adopted, while in addition, it is the considered judgment of a great number of men who have given their lives to the study. Mr. Moorehead and his committee, who five years ago undertook the classification on which his book is founded, do not appear to have given any thought to this aspect of the question, and have treated North America as archæologically independent of the rest of the ancient world. From one point of view they are certainly justified. In the United States the Stone age was in existence so recently that both the methods of manufacture and the purpose of many stone implements are matters of fact. Here the field is their own, and they need no external help, but in the main we have no hesitation in saying that conformity with European scholars would have been better.

While we have thought it desirable to formulate this objection to Mr. Moorehead's method, we can commend the matter of his book. It is called an encyclopædia, and the term is not inaccurate, for it comprehends practically all the types of later stone tools found in Northern America. Its intention is to supplement the very remarkable "Handbook of American Indians," published by the Smithsonian Institution in 1907. This work, reasonably enough, did not treat the Stone age as a special subject, and hence the complement now before us was produced. One cannot but regret that no place has been found in these volumes for a complete statement of the evidence as to the discoveries of Mr. Abbott at Trenton, New Jersey. Controversy raged fiercely at the time, and weighty opinions were to be found on both sides. A book with this title should certainly have dealt with the matter.

It may appear surprising to us that the discoveries in the mounds of America, of stone implements, pottery, and the like, are disclaimed by the existing Indians, though a comparison of the relics with those in use by the Indians until late years shows them to be very similar.

Such disclaimers are, however, common enough among primitive peoples. The negroes of West Africa will have nothing to say to the stone implements and images dug up in their plantations. It is probable enough that even if one or the other possessed either history or trustworthy tradition, they would equally disclaim any knowledge of the remains. In Africa the pressure of a superior civilisation from the East and North has produced a constant shifting of the tribes during, say, the last two thousand years. During the same period, or even less, economic and other causes must have created something like a nomadic condition in North America. For these reasons it might well be that the existing tribes on a particular spot would know nothing of the origin of the ancient burial places among which they lived.

One feature in connection with North American stone implements that is clearly brought out in Mr. Moorehead's illustrations is the astonishing likeness between some of them and others from Mexico. On p. 93 of vol. i. may be seen a group from Kentucky showing this similarity very strongly. The likeness would not seem to be due to utilitarian causes, but rather to an artistic tradition. This is interesting in itself, but it also has a bearing on another point, perhaps even more interesting. On p. 162 of vol. i. is a curious group of chipped implements, some of them in the form of human profiles, while others are axes with curved sides expanding to a crescent-shaped cutting edge. It is well known that in passing from the use of stone to that of metal (often copper) the earliest metal axes are accurate copies of the stone type. Experience soon showed that hammering of the copper edge not only sharpened it, but, very naturally, widened it also, so that the natural result of the process was to produce a rounded cutting edge, with a curve from its two sides towards the butt. This resulting form, being at once more practical and more elegant, in turn became the type of copper or bronze axe.

These two facts, the presence of Mexican stone types, as well as types founded on a cast-metal prototype, in American Indian settlements, may well lead one to consider whether both one and the other had an origin further south than the United States. It may be contended that copper implements are common enough in the United States, and that there is no need to look further. But it is not of so much importance that the prototype should be of metal; it is that it should be of *cast* metal.

These are some of the many questions that are raised by the perusal of Mr. Moorehead's elaborate work. We can congratulate him on its encyclopædic character, a useful feature. The amount of material is amazing, and the exquisite implements from Tennessee in the Missouri Historical Society's museum will be a surprise to most people on this side. We could have wished that he had placed his figures somewhat nearer the text relating to them, and that his index had been a little better.

THE VULCANICITY OF OUR EARTH.

Die vulkanischen Erscheinungen der Erde. By Dr. K. Schneider. Pp. viii+272. (Berlin: Gebrüder Borntraeger, 1911.) Price 12 marks.

DR. SCHNEIDER opens his work by reference to what is found in many books on vulcanology and geology, namely, the part played by volcanic activities in the economy of nature. In consequence of volcanic action minerals of high specific gravity are brought to the surface, the contours between land and water may be changed, and new islands may be created. Since Tertiary times 3·96 mill. km.^{2} of land surfaces have been covered by volcanic ejecta. These accumulations have altered relative altitudes, on which climate, plant life, and other things depend. Valleys have been blocked, lakes formed, and river courses have been changed. At the time of an eruption a variety of gases and chemical products are brought to the surface, and many mineral deposits are closely associated with volcanic action. Although in many ways volcanoes have been beneficial to humanity, in their immediate vicinity they have been frequently associated with the loss of life and property. Volcanic explosions have excited the imagination, given rise to myths concerning subterranean deities or monsters, and indirectly have had an effect on literature and art.

At present we are told that on the surface of our world there is one active volcano to 1420475·5km.^{2}

We can regard volcanoes from a geographical, petrographical, chemical, and other points of view, and what has been done in each of these directions is briefly reviewed. The notes relating to the temperatures of lava and the average depth at which a rapid change might be expected in materials similar to those we meet with on the surface of our earth might easily have been extended.

Dr. Schneider's classification of volcanoes depends on their forms, and of these there are seven types. The names given to these types were quite as startling to me as was the word anhydrohepsepterion when I first heard it. It turned out to be a saucepan in which you can cook potatoes without water.

Pedioniten are fissure outflows like the Deccan Traps. *Aspiten* are characterised by the relationship of their height to an extended base, as, for example, Mauna-Loa. *Tholoiden* refer to forms with a gentle sloping base which runs inland from a coast and then suddenly rises with convex flanks to a rounded summit. *Beloniten* are illustrated by the needle-like peak of Mount Pelée. *Koniden*: these are mountains the flanks of which are convex-concave. A slight reference is made to this logarithmic curvature of volcanic profile which was first noticed in connection with Mount Fuji, but the lesson it teaches respecting the height of a mountain and the area of its base in relation to the material out of which it is formed, has apparently escaped notice. The relation of form to the size of ejectamenta, friction, wind, and the character of an eruption has not been overlooked. *Homaten*. In these the slope rises directly from the coast to the summit as in Hverfjell in Iceland. *Maare*. Here the volcanic neck has risen to the surface, clastic material has been spread widecast, and flat hollows have been created similiar to those in the crater lakes in the Eifel. Each of these types can also be found in the moon, and on our earth consists of materials with different physical structures. *Rheumatitische* material is that which flows like lava. The other materials may be clastic like lapilli and ash, gaseous and aqueous. Tertiary volcanoes are characterised by the prevalence of materials first referred to, whilst the materials of recent volcanoes are more clastic.

A chapter of considerable interest to geologists is one which gives an outline of voeanic action in Europe since Tertiary times. This, however, does not entirely overlook the vulcanicity which took place in earlier periods. The number of active volcanoes in the world during the Diluvium-alluvium period is estimated at 1081, whilst during historical times only 201 can be counted. These latter are grouped along great lines of dislocation in the larger features of the earth's crust. They do not occur in rows, but in relatively small zones. These are two out of eight laws formulated in connection with the geographical distribution of volcanoes, which is illustrated by numerous maps. The volume concludes with a catalogue of 367 volcanoes which have been active during historical times. This number, it will be observed, does not correspond with the one just given. Although we observe certain lacunæ in this catalogue, it is a very useful compilation for those interested in vulcanology.

Although geologists may object to Dr. Schneider's new terminology, they must not overlook the fact that they themselves have had many christening parties. Some thirty or forty years ago a distinguished president of the Geological Society, when he first heard of Belenites—a word not unlike Beloniten—interrupted the speaker by the remark, "Tut! tut! Belemnites in volcanic rocks indeed!" If we say nothing about the new language, then Dr. Schneider is to be congratulated on his work. JOHN MILNE.

BIOMETRICAL METHODS FOR PSYCHOLOGISTS.

The Essentials of Mental Measurement. By Dr. Wm. Brown. Pp. vii+154. (Cambridge: University Press, 1911.) Price 3*s*. 6*d*. net.

THIS volume is based on a research "devised for the purpose of determining to what extent correlation exists between certain very simple mental abilities, in cases where the individuals experimented on are, as near as may be, identically situated with respect to previous practice, general training, and environment; and how closely, if at all, these elementary abilities are related to general intellectual ability as measured by teachers' judgments, school marks, &c."

The groups of individuals tested were homogeneous as far as possible, and were selected from a London elementary school, a London higher grade school, from among women students of a training college, and men and women university students. The tests employed were fourteen in number. In two of them the subject was required to cross out as quickly and accurately as possible on a printed page certain letters (e and r in one case, and a, n, o, s in the other), in a third all the letters were to be crossed out. Speed and accuracy in the addition of single digits were measured in a fourth; while in the fifth, sixth, and seventh the ability to estimate the relative lengths of printed lines was tested in different ways, including conditions under which illusions are known to be produced. The power of memorising poetry and strings of nonsense syllables were examined in the eighth and ninth, while the tenth test was the *combinations methode* of Ebbinghaus. In this "the subject is shown a passage of continuous prose with one-third to one-quarter of the words replaced by blanks, and is asked to supply the missing word or words of similar significance." The eleventh and twelfth were marks obtained in the ordinary school curriculum for drawing, and the total school marks; in the thirteenth general intelligence was graded by the independent estimates of two different teachers, which were found to be very closely correlated together. In the fourteenth association time was measured by counting the number of words associated with a given word which the subject could write down in a given time.

The majority, but not all the tests, were applied throughout each of the six groups, and the statistical treatment of the records is very complete and satisfactory. The results for each group were, of course, kept distinct, and correlation coefficients were calculated between the result of each test and the result of each of the others, while to estimate the trustworthiness of each the correlation between the results of two separate applications of the test on each subject was measured. In addition to this, certain groups of tests were taken and the partial correlation coefficients calculated, *i.e.* the correlation between any two members of a group for constant values of the remaining members. As the probable errors are given for all the coefficients calculated, comparisons between them can be satisfactorily made.

Limitations of space forbid us from giving an account of all the conclusions drawn by the author, but two at least can be stated very simply and are worthy of note; firstly, that the *combinations methode* of Ebbinghaus is a good measure of mental ability. It correlates with "general intelligence" almost as clearly as "scholastic intelligence" (school marks) "does"; and secondly, mechanical memory, *i.e.* the power of memorising a number of nonsense syllables, is also fairly closely correlated with general intelligence. This research was published in the British Journal of Psychology for October, 1910. Together with the chapters which appear in this volume on the mathematical theory of correlation and on the history of the use of the theory in psychology, it formed a thesis approved for the degree of doctor of science in the University of London. The thesis, with chapters added on mental measurement, psycho-physical methods, and on the significance of correlation in psychology, constitutes the bulk of the present volume. Its object appears to be not so much to instruct the beginner in psychology on the best way of measuring psychical characters, but to introduce the professed psychologist to the biometrical methods of Prof. Karl Pearson and his school. The author shows a considerable grasp of the subject, and does not perhaps realise the difficulties of less mathematically minded people than himself. Thus the chapter on the mathematical theory of correlation, if intended for an introduction to the subject, could well have been expanded, rendered more elementary, and more amply provided with examples. It is by examples rather than by precept that people who are confused by algebraical symbols are able to learn to use the methods. Those who can readily follow the notation will find the book profitable to read and useful for reference, particularly as a good bibliography is appended. E. H. J. S.

ELECTRIC CRANES.

Electric Crane Construction. By Claude W. Hill. Pp. xx+313. (London: C. Griffin and Co., Ltd., 1911.) Price 25*s*. net.

A LARGE measure of flexibility in the supply of power is an essential feature in all hoisting machinery. Not only must the point from which the load is suspended be capable of movement in different directions, but the whole machine must be able to travel, and these requirements render electricity a particularly well-adapted agent for the working of such machinery. A modern book on cranes becomes thus quite naturally a book on electric cranes.

Mr. Hill's work is a thoroughly practical treatise on electric crane construction. The subject is so complicated and so many-sided that any attempt to treat it in a general way must be unsatisfactory, and the author has wisely decided to represent his subject rather by means of well-chosen examples of successful work than by a general treatise. The importance of scientific principles is, however, not overlooked; interleaved with the descriptive matter we find the necessary calculations as to stresses, stability, power required, action of brakes, and other matters capable of scientific treatment. The examples chosen comprise various forms of overhead travelling cranes, locomotive and portable jib cranes, derricks, sheer legs, transporters, revolving cantilever cranes, and cableways. Then follows a chapter on the power required for crane driving. From tests quoted by the author, it appears that the efficiency in many cases is remarkably high, reaching nearly 70 per cent.

In discussing starting torque and acceleration, the author also quotes from practical experience for hoisting, lowering, travelling, and slewing. Chapter x. deals with the design of crane structures. Here we find discussed the strength of struts, both on the basis of Euler's and Rankine's formulæ, the strength of lattice girders and various types of beams generally, the construction of cantilevers and cognate matters, all exemplified by very full diagrams and working drawings.

The following three chapters deal with design of machinery, frames, bearings, axles, and drums, brakes and toothed gear. Especially the last-named subject is very fully treated, including the question of permissible wear and the use of worm-gearing. Most readers will be surprised at the high efficiency obtained by this mode of driving, when the worm runs in an oil bath. The explanation given by the author is that metallic contact between the teeth does not take place, since the film of oil between the surfaces is not squeezed out even at very heavy pressure. This has also been the experience of motor-car designers who find for worm-drive efficiencies well above 90 per cent.

After a short chapter on hooks, ropes, and chains, we come to the electric and magnetic details beginning with the design of magnets. It is to be regretted that the author has adopted the hybrid system of units where induction is given as so many c.g.s. lines per square inch. In working with such a system one loses completely the connection with first principles, and the solution of any problem becomes simply a matter of blindly applying certain formulæ. As regards motors, the author deals very fully with the question of rating as influenced by the intermittent service, and he shows that crane motors should, as regards mechanical strength and commutation, be designed for the full load, but as regards heating for a very much reduced load. Only D.C. motors are discussed, the author holding that A.C. motors are unsuitable for crane work. This is perhaps too sweeping a condemnation. In many docks on the Continent polyphase motors are used, and with the advent of the A.C. commutator motor there is given every facility for using alternating current where no continuous current is available, and the author's recommendation of installing a converter for the power supply to the cranes becomes a useless complication.

A table on p. 302, giving from practical experience the annual working cost of seven different cranes, is very interesting. It shows that the cost of power taken at 1·5*d.* per unit is negligibly small. It amounts in the worst case to only 1·3 per cent. of the total cost, and in most cases it is about 1 per cent. Thus, with current purchased even at the usual lighting rate of about 4*d.* per unit, the cost of power is quite insignificant. This is due to the fact that the load factor of a crane is exceedingly small. The total energy given off by all the crane motors per annum only represents full output over about twenty to seventy hours per annum. The annual cost is almost entirely made up by interest, depreciation, and repairs, and the problem to be solved by the designer of cranes is not so much the saving of current as the production of a cheap and robust design.

GISBERT KAPP.

MORPHOLOGY OF THE VERTEBRATES.

Éléments de Morphologie des Vertébrés. Anatomie et Embryologie Comparées, Paléontologie et Classification. By Prof. L. Vialleton. Pp. xiv+790. (Paris: Octave Doin et Fils, 1911.) Price 18 francs.

THIS is an interesting and thoughtful introduction to the morphology of the vertebrata, very clearly written, well illustrated, and with several distinctive features. The author thinks, probably with justice, that the vertebrata are better subjects than the invertebrates for the illustration of morphological principles. Their structure is more thoroughly known and its relations to the conditions of life are more certain; the development of the chief types has been worked out in its main features; and we have, on the whole, more information in regard to the past history. Filiation is clearer among vertebrata than among invertebrates. For learning the lessons of morphology it is better to begin with one phylum than with many, and the most educationally profitable phylum is that with which students are likely to be most familiar—the vertebrata.

The plan of the book is as follows. After an introduction dealing with general concepts such as homology, the author devotes the first part to general embryology—the germinal layers, the early primordia, and the fundamental architecture of head and trunk and limbs. The second part deals seriatim with all the systems and organs, from the skin to the gonads, treating everything comparatively and embryologically. It is all very clear and careful, but in a book of the dimensions of this one we look for rather more criticism. To take but a single instance, we think Vialleton's conventional account of the pectoral skeleton of the Monotreme, with its episternum and absence of procoracoids, might have been improved without risk of dogmatism. We may notice here that there is a carefully selected bibliography at the end of each chapter, and that the references are punctiliously accurate.

The third part of the book gives a systematic account of the whole phylum of vertebrates, and takes due notice of the extinct forms. There are many interesting detailed expressions of the author's judgment, *e.g.* his treatment of the Ratitæ as a heterogeneous group derivable from at least three stocks, or his reuniting of Marsupials with Eutheria; but the outstanding feature in this section is to be found in the numerous carefully drawn up schemata showing distribution in time and probable affinities. There are twenty of these, condensing much reflection.

In the concluding section of his book, Prof. Vialleton deals analytically with the problem of the evolution of vertebrates. He discusses the origin of organs, and makes much of Kleinenberg's theory of substitution; he distinguishes between well-established genetic series and morphological series (so often mixed up together, *e.g.* in connection with the evolution of Equidæ); he recognises the importance of paying more attention to the phenomena of convergence; he gives an admirable discussion of correlation and of vestigial organs. Passing to the actual data bearing on the phylogeny of vertebrates, he marshals the palæontological facts in a masterly way, and discusses such points as the successive appearance of classes, the occurrence of generalised types and transitional types, the absence of the latter at phyletic bifurcations, the extinction of types, and the indubitable progress from age to age. Turning to embryological data we find an admirable critical discussion of the recapitulation doctrine, of which there is little left when the author has done. We cannot help feeling, however, that there is sure to be a rebound in a few years to some subtler rehabilitation of Haeckel's famous biogenetic law. The author believes in a good deal of polyphyletism, and he confesses himself a mutationist: *transformist* theories do not please him: "C'est l'évolution avec ses brusqueries et ses divergences qui constitue la réalité."

THE PRINCIPLE OF RELATIVITY.

Das Relativitätsprinzip. By Dr. M. Laue. Pp. x+208. (Braunschweig: F. Vieweg und Sohn, 1911.) Price 6.50 marks.

IT is almost impossible nowadays to glance through a journal containing original papers in physics without coming across something relating to the Principle of Relativity. This principle is an extension of that Newtonian relativity which enables us to treat machines on a moving earth as if they were at rest. The new extension covers the phenomena of optics, heat, and electromagnetism. It is sometimes called the electromagnetic principle of relativity, but as it contains also a mechanical principle it has now become usual to term it simply the Principle of Relativity. It asserts that physical phenomena generally do not depend upon rectilinear uniform translation through space; that, for instance, the optical isotropy of space is not affected by motion through it; that the velocity of light is the same in all directions and independent of displacement; and that it is therefore impossible to discover, say, the earth's motion of translation by any optical, electrical, or mechanical device. In fact, it is based upon the negative result of the Michelson-Morley experiment, and all other attempts to discover "æther-drift."

Einstein, who founded the modern relativity theory in 1905, based his arguments upon the impossibility of establishing an absolute time-scale, either as regards rate or as regards epoch, so long as the utmost limit of rapidity of signalling is imposed by the finite velocity of light. He showed how this limitation affects all measurements of length and time whenever the relative velocity dealt with approaches the velocity of light. The clocks in a moving system, synchronised by light signals, necessarily have a slower rate than those in a system at rest, in the ratio $\sqrt{1-\frac{v^2}{c^2}}:1$, where v is the relative velocity and c the velocity of light, and this applies whichever of two systems is regarded as being at rest. There is, in fact, no "absolute" time-scale.

Many conclusions from this principle appear far-fetched, even fantastic. Thus, not only electrons, but all matter possesses an infinite "mass" when moving with the velocity of light; mass is identical with latent energy; two particles projected in opposite directions with the velocity of light have a "relative" velocity which simply equals the velocity of light, and so on. In spite of such apparent absurdities, the Principle of Relativity has made what is no less than a triumphal march through the world's physical publications.

Dr. Laue's work comes, therefore, as a welcome contribution to what has become a matter of very living interest. He goes fully into the negative results of Michelson, Trouton, Brace, Rayleigh, and others, the positive results of Wilson, Rowland, Eichenwald, Lebedew, Poynting (misspelt "Pointing"), and Fizeau, and the theoretical work of Lorentz, Einstein, and Minkowski. He shows that there is no physical evidence against the principle, and that it has the advantage over other systems of accounting for the absence of æther-drift. In the analytical work, a vector algebra on the basis of Heaviside's notation is used, but it is made, after Minkowski's example, four-dimensional. A brief summary of operations with these "world-vectors" is of great assistance to the reader.

E. E. F.

OUR BOOK SHELF.

The Principles of Electric Wave Telegraphy and Telephony. By Prof. J. A. Fleming, F.R.S. Second edition (revised and extended). Pp. xx+906. (London: Longmans, Green and Co., 1910.) Price 28s. net.

WHEN reviewing the first edition of Prof. Fleming's book five years ago we pointed out that it filled to perfection the want for a thorough and exhaustive treatise on the subject of wireless telegraphy, and was sure of a warm welcome on that account. Since then the volume has been twice reprinted, and now there is issued a new edition largely rewritten and considerably improved. The rapid progress in electric wave signalling is indicated even in the title, which is now so worded as to cover the subject of Hertzian telephony, at the time of the first edition so much in its infancy as not to be worthy of inclusion. To this subject Prof. Fleming now devotes a short final chapter, in which he reviews briefly the special difficulties in transmission and summarises the present position. (In the last paragraph, by an obvious oversight, telegraphy is written in place of telephony.)

Much of the volume has had to be revised on account of the progress which has been made in all directions. The author has acted wisely in curtailing the historical portions and devoting himself mainly to the explanation of the scientific principles on which the art of wireless telegraphy is based, and on which the numerous instruments now used are founded. The purely historical side of wireless telegraphy is now more or less a matter of the past: it has entered into a period of development which if less sensational is of more benefit to mankind. From the more or less crude empirical art of ten years ago wireless telegraphy is now firmly based on a solid scientific foundation, exact methods of measurement have been developed, and steady progress, not less rapid because of its steadiness, is possible. Prof. Fleming's book still deserves to rank as the best existing treatise on the subject, at any rate in the English language, and if the same industry is shown in the future in keeping it up to date it should continue for long to hold this premier position.

M. S.

Die Anwendung der stereographischen Projektion bei kristallographischen Untersuchungen. By Prof. H. E. Boeke. Pp. viii+58+plate. (Berlin: Gebrüder Borntraeger, 1911.) Price 2.60 marks.

THE stereographic is the form of plane projection of the sphere ordinarily in use in crystallographic work, and during recent years it has come much into vogue, not merely for showing the zonal relations subsisting between the poles corresponding to the faces of a crystal, but also as a means of checking the accuracy of the calculations involved in the goniometric measurement of a crystal. Accordingly, various methods by means of nets or protractors have been devised to facilitate the use of the projection, many of which have scarcely yet found their way into the text-books. Penfield provided for English readers in a series of brilliant papers that appeared in *The American Journal of Science* a clear and concise account of the best and most practicable methods, and, moreover, designed various diagrams to aid the student in plotting the positions of the poles.

In the present volume Prof. Boeke aims at providing similar privileges for German readers. He gives a clear account of the properties of the projection, and discusses at some length its use as an aid in computation in the case of the several kinds of systems of crystalline symmetry, both geometrical and graphical proofs being given of the fundamental propositions. The application of the projection to crystal drawing and the determination of the optical characters are also explained. A pocket in the cover contains one of Prof. Wulff's stereographic nets, which are graduated in distance and azimuth referred to a pole in the equatorial zone for every other degree, the size of the sphere being the same as that selected by Penfield, viz. 14 cm.

The book is one that may be commended for the use of students of crystallography, but it might advantageously have included an adequate description of the properties and use of the gnomonic projection which at present is merely alluded to in a brief paragraph, even though some slight alteration of the title would have been involved.

Quaternions as the Result of Algebraic Operations. By Dr. A. L. Baker. Pp. ix+92. (London: Constable and Co., Ltd., 1911.) Price 6s. net.

IN this book the author establishes the principles of quaternions by the use of the six operations addition, subtraction, multiplication, division, reversion, and mean reversion. By the introduction of reversion, we pass from arithmetic to algebra. Complex functions depend on the recognition of mean reversion, the operands still being scalars; and when the operands are scalars and vectors, the method becomes generalised into quaternions.

The key of the argument is the conception of *mean reversion*, that operation which twice repeated reverses the quantity operated on. There is nothing new in this, but Dr. Baker applies the conception in an unusual way to the representation of a scalar as a sphere in space, which, as possessing perfect symmetry and therefore devoid of direction in space, is the only available ideographic symbol for a scalar. He finds that a mean reversed scalar is represented in all its properties by a directed magnitude in space, that is, by a vector. The algebraic representation of mean reversal is, of course, $\sqrt{-1}$, leading to the usual Argand diagram; and the same idea enters into the constitution of any vector. The argument that $ii=-1$ may be accepted as sufficiently sound; but it may be doubted if the rule for the product of perpendicular vectors, viz. $ij=k$, &c., can be rigorously deduced on the assumption that the operation of a vector α upon a perpendicular vector β must be the same in kind, but as far removed in detail from that which would have been used had β been parallel to α. We certainly prefer Hamilton's own somewhat metaphysical argument.

It is clear that Dr. Baker has no regard for the views of those self-styled purists who deny that a vector can have versor properties. Having established the well-known i, j, k rules, he develops in a satisfactory manner the important properties of quaternions, and ends his discussion by a useful account of the linear vector function. Students new to the method will probably find the argument in the earlier chapters difficult to follow; thereafter all is plain sailing.

C. G. K.

Lessons on Soil. By Dr. E. J. Russell. Pp. xv+132. (Cambridge University Press, 1911.) Price 1s. 6d.

A COURSE of lessons on soil provides an essential sequence to the formation of school gardens if it is desired to make the best use of the latter. Teachers contemplating such a course are strongly recommended to consult this excellent primer, in which Dr. Russell presents a series of lessons evolved from practical classes conducted for children in the higher standards at an elementary school and in an intermediate form at a secondary school. The earlier chapters contain simple experiments for observing the properties of clay, sand, and other soil constituents; pot cultures are introduced to compare the food value of soil and subsoil, as also the action of water in soils; methods are described for detecting the presence of soil organisms and for demonstrating the advantages of hoeing. Finally, the practical bearing of the lessons, which it should be noted are confined to soil physics, is indicated, not only with reference to agriculture, but also as they serve to explain the aspects of the countryside and other natural features such as the connection between stream, ford, and village. The primer is not only practical and informative, but is designed to arouse the inquiring instinct. It is the first volume of a new series contemplated by the Syndics of the Cambridge University Press.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The "Earthquake House" at Comrie.

I RECENTLY visited the "Earthquake House" at Comrie, and was sorry to find that, in the matter of repairs, it had been neglected for a long time, and was in a very dilapidated condition.

It may be remembered that this small building was erected in 1872, through the combined efforts of the British Association and Mr. Drummond, for the purpose of carrying on observations on the, then, frequent manifestations of seismic activity experienced in that district, and I believe the investigations made there, with the simple apparatus and methods employed, represent some of the earlier attempts to obtain definite data respecting the direction, duration, and intensity of seismic vibrations. From these and other early observations, I suppose, the modern science of experimental seismology has been evolved, and for this reason the building should always be regarded as of great scientific and historical interest, and its preservation a matter of common desire. Though the original wooden pins which were used have disappeared, some of the white sand that was placed on the floor some forty years ago is still to be seen there.

Mr. J. J. Macdonald, of the Commercial Bank, Comrie, has most kindly associated himself with me in an endeavour to obtain permission to place this property in the hands of a committee, and to raise funds for the purpose of protecting it and putting it in a proper state of repair. We propose to fence it in so that it may be preserved from the depredations of children and others (who now have free access to it) for all time.

Without now entering into the details of the trouble and correspondence our negotiations have entailed, I may say that the owner has kindly given us full permission to take such steps as may be necessary for the restoration and protection of the building, and that we hope to place it, as far as possible, in its original condition without delay.

An estimate has been submitted to us, and the sum required to carry out all the necessary work is about 30*l*.

May I ask those of your readers who are interested in this matter to subscribe towards this sum? Mr. Macdonald has kindly consented to act as treasurer, and all donations should be sent to him without delay. The names of those forming the committee, a list of subscribers, and the details of the work done, will be published later.

CECIL CARUS-WILSON.

Preston Vicarage, Faversham, September 11.

The Upper Trade-winds.

RECENTLY Herr Peppler[1] directed attention to the fact that the air-pressure gradient from the equator towards the subtropical zones, which is positive at the heights at which the anti-trade-winds blow, must be negative in still higher layers (±20 km.).

Owing to the low temperature of the stratosphere above the equator, the mean temperature of the whole air-column up to these heights is lower above the equator than above the subtropical zones, and Herr Peppler accordingly supposes that the air pressure at the top of the column is also lower.

Consequently, we may expect to meet above the anti-trade a wind blowing towards the equator, and it would be reasonable to call this wind the *upper trade-wind (Oberpassat; Vent alizé supérieur)*. The ascents of registering and pilot balloons made during the last two years at Batavia Observatory have given some proof of the existence of this upper trade-wind.

Regarding the air-pressure gradient, I compared the pressures recorded during the balloon ascents made on the *Otario* cruises in the North Atlantic, in ±30° N. latitude, with those found at Batavia in the corresponding southerly season. These mean pressures and differences follow hereunder:—

Height	Air Pressure Batavia 6° S	Air Pressure N. Atlantic ±30° N.	Difference
km.	mm.	mm.	mm.
12	164	157	7
13	139	136	3
14	119	117	2
15	100	99	1
16	86	85	1
17	74	74	0
18	63	65	−2

Though the records are few in number, the decrease and reversal of the gradient are conspicuous.

The numerous balloon-flight observations now made in Batavia (the results of which are just going to the press) have proved that the anti-trade reaches a maximum at a height of 12–15 km. (in the dry season lowest and in the rainy season highest). Higher up its strength decreases, and at heights of ±17 km. feeble southerly and westerly winds blow. Berson was the first to observe these winds in Central Africa.

The height at which I found them above Batavia, viz. ±17 km., corresponds exactly with that in which the pressure gradient passes the zero value.

Still higher up we must expect to meet the upper trade, and the explanation of the occurrence of these southerly and westerly winds simply is that they are feeble winds of variable direction occurring between two great overlying air currents, similar to those which are often observed in the layers between trade and anti-trade, or monsoon and trade.

Recently the ascent of a balloon of 2 kg.,[1] which reached 22 km., gave fair evidence of the existence of the upper trade, as may be seen from the wind directions and velocities given hereunder:—

	Height	Wind blowing from	Velocity in m. p. sec.		Height	Wind blowing from	Velocity in m. p. sec.
	km.				km.		
Anti-Trade	13	E 15 N	12·8	Upper Trade	17·5	E 85 S	4·6
	13·5	E 22 N	15·2		18	E 25 S	8·8
	14	E 32 N	15·2		18·5	E 7 S	13·6
	14·5	E 35 N	20·8		19	E 9 S	15·0
	15	E 34 N	21·2		19·5	E 4 S	21·1
	15·5	E 23 N	28·8		20	E 11 N	28·5
	16	E 4 N	24·0		20·5	E 3 S	27·2
	16·5	E 16 N	26·9		21	E	27·2
	17	E 15 N	7·5		21·5	E 9 S	30·4
					22	E 10 S	30·8

The present dry season is not advantageous for the discrimination of the upper trade from the upper easterly counter-wind, because, according to the difference observed between the dry and wet season, in this season pressure at those heights is lowest probably over Java and not over the equator. Consequently, the southerly components by which the upper trade differs from this counter-wind will be small.

In the rainy season (December-February), however, the contrary will be the case, and accordingly I expect to obtain in those months observations which will give stronger evidence of the existence of the upper trade-winds.

W. VAN BEMMELEN.

Batavia Observatory, August 20.

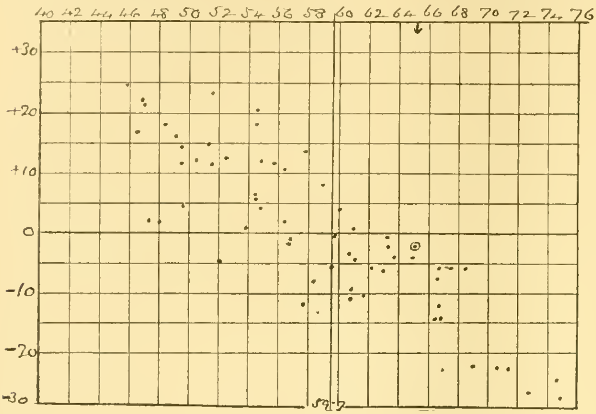
[1] Beiträge zur Physik der freien Atmosphäre. Bd. iv., Heft 1.

[1] This balloon reached as a registering balloon a height of 15·5 km. on July 18; at that height it burst, was found again and brought back, and after being carefully pasted, it was sent up again on August 3 as a pilot balloon, being observed from two points 1·9 km. apart.

Rainfall in the Summer of 1911.

ONE does not hear much of effort on the part of official meteorologists to supply long-range forecasts of months, seasons, &c. It may be said, the thing cannot be done; better to say, it cannot be done infallibly. My own experience leads me to think a beginning might now be made with what will no doubt some day be a familiar institution, like the useful but imperfect daily forecast.

The question may be asked, Could the remarkable qualities of this summer (so hot and dry) be foreseen in any measure? I consider there was reason to expect a very small rainfall (at Greenwich): and I would submit the enclosed rough dot diagram in support of this view.



Rainfall comparison of Greenwich summer.

It is got thus: the rainfall of spring plus summer (March–August) in each year, 1841–1910, is noted, and these values are added in groups of five (1841–5, 1842–6, &c.). Then each sum is compared, by the dot method, with the difference between it and the *fifth* after, a plus value meaning that the later sum is the higher, while a minus value means it is lower. (Each dot signifies one sum by the horizontal scale, and the difference by the vertical.)

Before this summer we had got to comparing the sum for 1903 (*i.e.* the group 1901 to 1905), which is 68·4 inches, with the difference between it and the sum for 1908 (*i.e.* 1906–10), which is 6 inches (68·4–62·4). Next we have the sum for 1904, which is 65·3 inches, and the value for 1909 has to be ascertained (*i.e.* the group 1907–11).

Find 65·3 in the horizontal scale (see arrowhead), and consider where the new dot is likely to go. (The encircled dot shows its actual position.) It will be seen that, wherever the sums have exceeded (say) 62 inches, the fifth sum after has been a lower value hitherto. Let us lessen the sum 65·3 by 1 inch, and see what we get. We have thus 64·3 inches as (say) an extreme upper limit for the group 1907–11. Now, the sum for 1907–10 was known, viz. 54·5; and 64·3 – 54·5 = 9·8 for March–August, 1911. The spring had 5·2 inches, so that we might look for a summer rainfall not over 4·6 inches. (The average is 6·7 inches.) The actual amount appears to have been 3·7 inches. The difference of the sums for 1904 and 1909 is – 1·9 inches; and the previous distribution of dots, indeed, points to a greater diminution than 1 inch.

ALEX. B. MACDOWALL.

Limits of Explosibility in Gaseous Mixtures.

In making experiments recently on the explosion of gases by means of an incandescent wire, I have obtained much wider limits of explosibility than those usually given. The following table shows the numbers obtained:—

	Limits with incandescent platinum wire Per cent.	Limits (Clowes) Per cent.
Marsh gas	2·5 to 24	5 to 13
Coal gas	4 to 28	6 to 29
Hydrogen .	3 to 75	5 to 72

In each case the gas was mixed with air. The explosion was carried out in a glass tube of about 10 c.c. capacity having a stop-cock at each end, and a mercury gauge of small bore attached to the middle of the tube. When the explosion occurs the mercury moves more or less sharply, according to the force of the explosion, but a distinct movement, apart from that due merely to the expansion caused by the heating of the wire, can be seen with the proportions of gases given above. The marsh gas was prepared from zinc methyl, as aluminium carbide, on treating with water, was found to give 33 per cent. hydrogen.

I am not clear as to why the limits should be wider than those usually obtained; possibly it is due to catalytic action of the platinum wire, or possibly the apparatus is more sensitive than that usually employed. The matter seems of interest in connection with colliery explosions. Using the same apparatus, I have obtained explosions with coal-dust and air, and with lycopodium powder and air, no other gas being present.

University College, Cardiff.

Working Hypotheses *v.* Collection of Bare Facts.

PERHAPS it is desirable to explain that my review of Prof. Schuster's book published in NATURE of September 21 was written and sent to you before Prof. H. H. Turner had delivered his address to the British Association as president of Section A. Consequently, nothing in my review is a reply to, or has any reference to, Prof. Turner's excellent address. It would be discourteous to criticise an important pronouncement of a leader in science in any back-handed way. My statement and his are probably not really in opposition, though they to some extent emphasise opposite types of investigating activity.

OLIVER LODGE.

Use of Wind-furnaces in Smelting.

IT may interest your correspondent, Mr. George Turner (p. 381), to be reminded that wind-furnaces (furnaces without any blast but that of the wind) were used, at all events for lead smelting, much less than 900 years ago. Until some time in the seventeenth century the Derbyshire lead-smelters did not employ an artificial blast. They, like their predecessors in Roman times, built their furnaces on the tops of hills and facing the quarter of the prevalent winds. Dr. Percy in his "Metallurgy of Lead" gives extracts from Bishop Watson's "Chemical Essays" and from an earlier writer, Joshua Childrey, describing such wind-furnaces.

H. T. WOOD.

Meteor-showers.

BESIDES the ordinary display of Orionids that occurs near the middle of October, a considerable amount of meteoric activity may be looked for about the beginning of the month. Indeed, the intensity of the earlier meteor-showers promises to be considerably greater than that of any of the subsequent ones in October. The following are computed particulars of two important meteor-showers that become due before October 6.

Epoch September 29, 3h. (G.M.T.), second order of magnitude. Principal maximum September 30, 18h. 25m. Secondary maxima September 29, 16h., and October 2, 16h. 25m.

Epoch October 5, 6h. 30m., third order of magnitude. Principal maximum October 3, 22h. 10m. Secondary maxima October 2, 2h. 45m., and October 4, 11h.

After these there will be meteoric quiescence until October 12.

JOHN R. HENRY.

2 Belgrave Villas, Rathmines, Dublin, September 26.

Habits of Dogs.

In reply to Dr. Kidd's question as to the disposition of dogs to carry hedgehogs in their mouths, I may say that a smooth-haired Irish terrier, "Tim," of which I had charge for some weeks in the early spring of the present year, speedily became an expert hunter of hedgehogs, and carried home five living ones in the course of a month. I am inclined to think that he came upon the first one in its winter quarters quite by chance; but on almost every subsequent occasion, when taken out for a run after dark, he quickly disappeared amongst the gorse and ling, and, eluding my daughters, returned home alone with a hedgehog in his mouth. On one occasion he had cunningly bitten off the ends of a number of the spines on the back of his captive, and on only one occasion did I see blood upon his lips.

H. C. Chadwick.

The Biological Station, Port Erin, Isle of Man, September 16.

With reference to the letter of Mr. Venables in Nature of September 21, it may interest your correspondent to know that the stimulation from formic acid taken by the mouth *is* "out of proportion to the effect which one would expect from the mere acidity."

Formic acid is given in medicine for states of debility, *e.g.* following influenza, and a tincture made from the whole ant (*Formica rufa*) is given in homœopathy for certain nervous and rheumatic states.

"Appledore," Park Drive, Golders Hill, N.W., September 25.

THE TURIN MEETING OF THE INTERNATIONAL ELECTROTECHNICAL COMMISSION.

The fourth meeting of the International Electrotechnical Commission was held at Turin, and came to a close on September 16. For several reasons this meeting has established an international interest, not only for electrical engineers, but for mathematicians, engineers, and all interested in the standardisation of symbols used in mathematical literature and formulæ.

The opening business of the meeting consisted in the election of a new president; Dr. Budde, until recently the head of Messrs. Siemens and Halske, of Berlin, and probably the best known of the electrical engineers of Germany, was unanimously elected to fill the position in place of the retiring president, the eminent American physicist, Prof. Elihu Thomson. Colonel Crompton was re-elected as honorary secretary on the proposal of Prof. Feldmann, of Holland, who, in putting forward his proposal, referred to the St. Louis Congress of 1904, and the part Colonel Crompton took in urging the advisability of international cooperation in matters electrical. He said that Colonel Crompton was, in fact, the father of the International Electrotechnical Commission.

It was extremely satisfactory to note that Dr. Budde's election was proposed by the French delegates, which shows that at any rate any political differences which may exist between France and Germany do not extend to the more serene atmosphere of the scientific world.

The proceedings were formally opened by the reading of a report by the honorary secretary, Colonel Crompton, on the progress of the work since the last formal meeting, and more particularly since the informal meeting which took place at Brussels last year. He pointed out that whereas in 1908 there were only ten countries taking part in the Commission there were now twenty-one countries subscribing, each of which had formed its own local electrotechnical committee, in most cases with the direct aid of their respective Governments, and he thought it practically certain that at least three or four other countries were on the way to join, so that the movement might be called practically universal.

Prof. Elihu Thomson then gave an address as retiring president, and described the work carried out at the Brussels informal conference, and advocated that the work of the central office in London would be much lightened by the formation of a few international subcommittees additional to the one which already existed. He pointed out that the subject which required such continuous treatment by an international subcommittee was that of the standardisation of nomenclature and symbols used by mathematicians, engineers, and others, dealing with electrical questions, and he thought that the same might apply to the question of illumination as it was most desirable that the engineers engaged in illumination, not only by electricity, but by other means, should also standardise the expressions and formulæ they use. He emphasised the need of conducting the work of the Commission so that it may be a material assistance to the electrical industry, and so as not to retard progress or design in any way.

Two days were occupied by unofficial meetings dealing with the business in hand. A report on nomenclature was presented by Dr. Budde, the newly elected president, and after considerable discussion the amended list of terms and definitions drawn up in the two official languages of the Commission—English and French—was provisionally adopted. This list had been prepared by a subcommittee at a conference held at Cologne last May, and was thoroughly discussed and finally adopted at this meeting.

The next and very important matter was that of mathematical symbols. Here again the proposals put forward at the unofficial congress held at Brussels in 1910 were discussed, somewhat modified, and provisionally adopted; and a resolution was proposed by Dr. Budde, and seconded by Mr. Alexander Siemens, the president of the Institution of Civil Engineers of London, that the letters "I," "E," and "R" should be adopted to represent current, electromotive force, and resistance respectively in the simple algebraic expression of Ohm's law. It will be seen that in coming to this decision concessions were made by Germany dropping the letter "W" for resistance, and by Great Britain discontinuing the letter "C" for current. It is evident that this agreement on the symbols employed in Ohm's law will be a great convenience to all electrical students.

The discussion on symbols was a very thorough one, and the difficulties that appear likely to arise, at any rate amongst electrical engineers, are comparatively small compared with the difficulties of selecting suitable signs on account of the limited range of the type letters suitable for the purpose. For magnetic quantities either Gothic, Script, heavy-faced, or any special type was decided upon.

Although the matter was not in any way discussed at the conference, it appears likely that this difficulty could best be met by the substitution of a number of new symbols not necessarily representing letters of any type, but of a form and shape that they could be easily remembered and recognised, and which would be free from the present existing difficulty of causing great trouble to the composer in setting up his type and spacing his lines.

Eventually a subcommittee, consisting of one member each from Belgium, France, Germany, Great Britain, Holland, Spain, Switzerland, and the United States was appointed to continue the study of these international symbols.

The next interesting point dealt with was the vector diagrams in use for alternating-current quantities. It was agreed that in the graphical representation of alternating magnetic quantities advance in phase should always be represented in the counter-clockwise direction; in other words, the rotation of the vector should be to the left.

On the question of rating of electrical machinery and apparatus the proposals of the Brussels conference were adopted without modification as follows:—

1. The output of electrical generators is defined as the electrical power at the terminals.

2. The output of electrical motors is defined as the mechanical power at the shafts.

3. Both the mechanical and the electrical power are to be expressed in international watts.

In this work careful attention had to be given to the exact choice of the equivalent words in the two official languages. The convenient word "output" employed by English-speaking nations has no exact equivalent in French. In this case again a sub-committee, consisting of one member from those international committees interested in the subject was appointed to carry on further this question of the international rating of electrical machinery and apparatus.

It was decided that the next meeting of the Commission should be held in Berlin in 1913, the exact date to be announced later.

Mr. Gano Dunn, the president of the American Institution of Electrical Engineers, invited the Commission to hold an official meeting at San Francisco in 1915, on the occasion of the opening of the Panama Pacific Exhibition. On the motion of Prof. Feldmann, of Holland, seconded by Mr. W. Duddell, of England, the meeting thanked Mr. Dunn for the invitation, and stated its willingness to hold a meeting in San Francisco in 1915, and instructed the Central London Office to cooperate with the American Society in the organisation of an international electrical congress to be held at the same time.

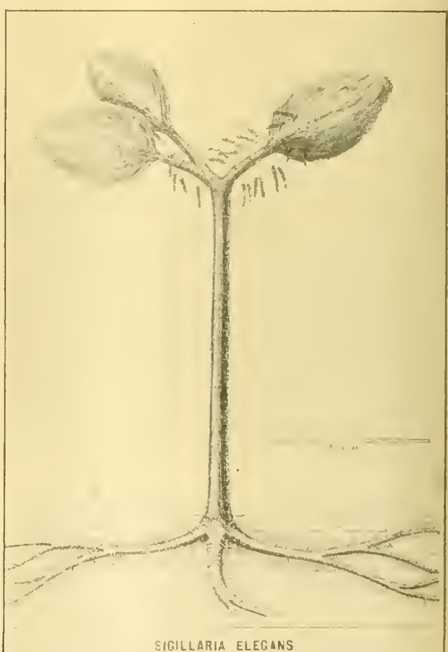
It is interesting to remark that at the meetings of the Electrical Congress, which was sitting at the same time, it was decided that for the future the irregular method of summoning international congresses at the time of the international exhibitions should be discontinued, and that in all cases where such exhibitions were held the International Electrotechnical Commission should be the body which should be invited by the country holding the exhibition to organise the electrical congresses, and in this way avoid much clashing and waste of effort.

Finally, the honorary secretary of the Illuminating Engineering Society of London, Mr. Leon Gaster, who was personally invited to attend this meeting at the invitation of the president, referred at some length to the desirability of standardising the terms and expressions used in connection with illumination. As stated above, this matter was dealt with by Prof. Elihu Thomson in his address. Mr. Gaster gave very cogent reasons why the present loose methods of expressing standards of light and of measuring these same standards should be discontinued, and that it was just as desirable in this kindred science of illumination that all nations should understand one another, as in the case of the electrical art and industry. Mr. Gaster's suggestions were strongly supported by Dr. Kennelly and Dr. Clayton Sharp, who are president and past president respectively of the Illuminating Society of the United States, and the suggestion that the various national committees be requested to put themselves in communication with their respective illuminating societies was unanimously adopted.

There is no doubt that at this full meeting of the International Electrotechnical Commission during the week in which the delegates worked together much international courtesy was shown, a great many pleasant friendships were made, and undoubtedly every additional international meeting of the kind greatly helps on the cause of solidarity between men of science of the world. The meeting room certainly contained a collection of men second to none in the electrical world for intellectual capacity; and that the meeting passed off so smoothly and so much work was done in a comparatively short time showed that the selectors of the delegates had also considered their diplomatic qualities, which had also been carefully studied by the countries which had sent them to the meeting.

PLANTS OF COAL-MEASURES.[1]

THE fossil flora of the Upper Carboniferous rocks of Belgian Hainaut is in many respects similar to that of our British coal measures, though many species occur in Belgium which are unrecorded from Britain and *vice versa*. Those who are interested in the systematic study of British Carboniferous plants



SIGILLARIA ELEGANS
Restauration d'apres MM. Grand'Eury et Kidston 1901.

will therefore find much that is of interest in Dr. Kidston's description of the collections, preserved in the Brussels Museum, from this coalfield. In all, 191 species, included in more than fifty genera, are enumerated. It is scarcely necessary to add that the author's high reputation for the accuracy of his deter-

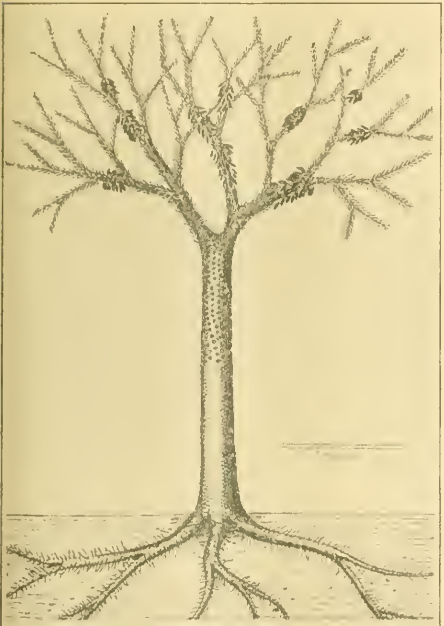
[1] Extrait des Memoires du Musée royal d'Histoire naturelle de Belgique. Tome iv, "Les Vegetaux Houillers recueillis dans le Hainaut Belge et se trouvant dans les Collections du Musée royal d'Histoire naturelle à Bruxelles." By Dr. R. Kidston, F.R.S. Année 1909. Pp. iv+282+xxiv plates. (Bruxelles: Polleunis et Centerick, 1911.)

minations and the completeness of his tables of synonymy is fully maintained in this large memoir.

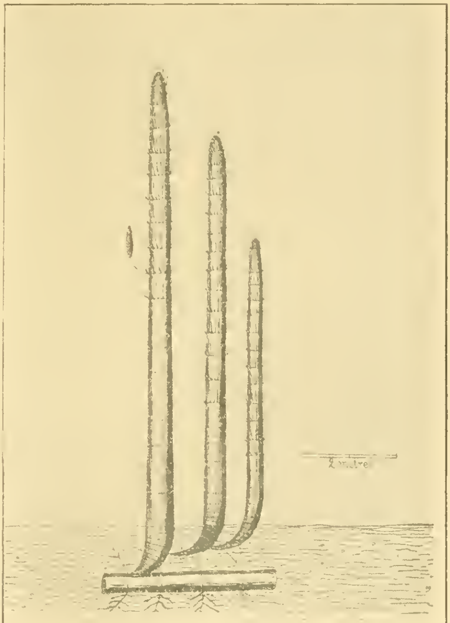
The work is in the main an enumeration of the species represented in the collection, with lists of synonyms. In the case of many of the rarer or more difficult species, the author has added notes of a critical nature which are often of great value. We may, however, regret that he has not seen his way to give a description of each genus and species involved. Such diagnoses would have added very greatly to the value of the work. As it stands it resembles the shell of a nut without the kernel, and in practice one will require to make use of another work containing such descriptions, in conjunction with that now under discussion, whereas one volume might have sufficed. We do not overlook the fact that in the case of a considerable number of genera, including Renaultia, Sphenophyllum, and Asolanus among others, as well as certain species of Sphenopteris, Sigillaria, and the like, none of which are new to science, a full diagnosis has been included. But in the majority of cases the author has apparently thought any description unnecessary, even where no figure of the plant is given.

The number of new genera and species discussed is remarkably small. We notice only one new genus, Boweria, and two new species, both of Lepidodendron and Sigillaria. These with a couple of new seeds complete the list of new plants. The new genus is proposed for the reception of a widely distributed plant formerly known as *Renaultia schatzlarensis*, since its sporangia now prove to be annulate, and the genus Renaultia is reserved for certain plants with exannulate sporangia. Turning to the new Lycopods, *Lepidodendron simile*, of which, however, no diagnosis is given, appears to approach *L. lycopodioides*, Sternb.; and *L. belgicum* sp. nov., a stem in the Ulodendroid condition, which is fully described, has also some points of resemblance to Sternberg's species. The two new Sigillarias are both members of the straight-ribbed section with distant leaf scars, and of the type of *S. laevigata*, Brongn.

These and many other fossils are illustrated by twenty-four large plates from excellent photographs, reproduced with exceptional clearness. In the text there are forty-one smaller illustrations, all of a high average. Among these are twelve careful restorations from the author's own pencil of some of the most characteristic types of Carboniferous vegetation, such as *Sigillaria elegans*, a Lepidophloios, and *Calamites suckowi*, which are here reproduced. These embody the results of the author's lifelong practical experience of Carboniferous plants, and they are also interesting from the fact that in some cases they differ very remarkably from the restorations which are now to be found in most of our text-books. Without expressing any opinion on the accuracy of Dr. Kidston's drawings, we must, however, add that if these are faithful portraits of the plants of the period in question, the Carboniferous vegetation must have been even more weird in aspect than we had imagined.



LEPIDOPHLOIOS
Restauration d'après M. Kidston 1901.



CALAMITES SUCKOWII
Restauration d'après M. Kidston 1901

Turning next to some further points of interest, we notice that the author, after many years' consistent use of the term Calamocladus for one particular type of Calamite foliage, has now apparently abandoned it for the alternative Asterophyllites, which usually commends itself to Continental workers. The point may appear to be a small one, but any change of importance as regards nomenclature at the hands of the leading authority on the systematic study of Carboniferous plants in this country is worthy of note. Among the plants more fully described, on which new contributions to our knowledge are offered, we would particularly direct attention to the stems and cones of *Calamites paleaceus*, Stur., *Selaginellites Gutbieri* (Gœpp.), *Pinakodendron ohmanni*, Weiss, and *Sphenophyllum majus* (Bronn). The memoir concludes with a discussion on the age and horizon of the Hainaut basin.

In conclusion, the Belgian palæobotanists may be congratulated on this noteworthy addition to the literature on their fossil floras, and on their good fortune in having secured such an authority as Dr. Kidston to fulfil the task.

To the author we would add our congratulations on the successful completion of a volume which must have occupied his attention for many years past, and will always rank high in the annals of systematic palæobotany. We may also express the pious hope that some day our own British Carboniferous flora may receive an equally adequate treatment at his hands.

E. A. N. A.

THE ELECTRICAL EXHIBITION AT OLYMPIA.

THE important lesson to be learned from the Electrical Exhibition at Olympia is that rapid strides are being made towards a period of hygiene in our daily lives for which electricity will be wholly responsible. During the last six years a large number of electricity supply companies and corporation electricity departments have reduced their price for energy for heating, cooking, and similar domestic purposes to about one penny per unit, and manufacturers of cooking and heating apparatus have been developing this side of the industry with commendable rapidity. The large percentage of firms exhibiting and demonstrating domestic appliances, together with the comparative absence of heavy electrical machinery at Olympia, sufficiently indicates the aspect of electrical supply which is receiving the most attention. A factor in this important problem has been the development of cheaper wiring systems, a development purposely directed to securing the smaller consumer. In this direction also is to be noted the tendency towards the production of smaller and cheaper meters, cheaper service boxes, main switches, and other auxiliary apparatus.

Another factor which is helping to render the installation of electric light more economical, and therefore further within the reach of the smaller user, is that, owing to small devices, such as lamp-holders, switches and fuses being manufactured in large quantities, and practically to a few standard designs, the cost of these is now far less than it was a few years ago. This brings us to mention what is perhaps the most remarkable sign of the development of the electrical industry to the ordinary thoughtful observer outside the industry itself. Fifty years ago, or even less, electricity, except in so far as its applications to telegraphy were concerned, was practically an abstract science, fascinating no doubt on account of its potential developments, but scarcely a serious factor in engineering. Now, however, not only is electricity a most important agent in practically all branches of engineering, but the manufacture of electrical plant and apparatus has assumed the proportions of a great industry. It is the commercial aspect of this industry which is so very clearly brought home to the visitor at the exhibition, especially in the case of those smaller pieces of electrical apparatus which form the bulk of the exhibits. The manufacture and sale of these has developed into an enormous trade, and one can see that the exhibitors at Olympia are not only engineers and electricians, but are business men and traders, in the widest acceptance of these terms.

To return to the actual exhibits. It will be noticed that one of the most outstanding features of the exhibition is the improvement in electric lamps. Only a few years ago the metal filament lamp was an object of scientific interest, the difficulties of even squirting the filament not then having been overcome to the extent of producing a lamp with any considerable degree of capability to withstand rough usage. Some of the metal filament lamps shown now are exhibited under conditions designed to illustrate that they are as strong mechanically as the carbon filament lamps which they are rapidly superseding. Several manufacturers are now making filaments of drawn tungsten, and the *clou* of the exhibition, from the electrical engineer's point of view, is a 16-c.p. 220-volt Osram lamp, which has a filament only 0·015 mm. diameter, and yet possesses wonderful mechanical strength. Other lamps are shown, fitted on two model tramcars, which are allowed to run down inclines and collide with one another. Before the moment of impact, the lamps are purposely switched off, as it is when the filaments are cold that they are more brittle; yet the lamps withstand this rough usage without any damage, and are again lighted automatically as they are propelled up the inclines to enable the operation to be repeated.

The standardisation to which we have alluded applies to a considerable extent to lamp shades and reflectors, and concurrently with this the old haphazard way of installing lighting systems is giving way to more precise methods. Shades and reflectors of the Holophane type, designed to effect even distribution of light, are exhibited as stock articles by several firms, and much information is available at the exhibition in this hitherto little considered detail of electric lighting. The most careful arts of the glassworker are now employed to give effect to the investigations of the student of optics in the production of diffusing globes and reflectors which, by conservation and redirection of the rays of light, prevent waste and give maximum effect in any desired direction.

The adaptability of electricity to artistic fittings is also well demonstrated in an exceedingly fine show of models to suit almost every style of architecture of the English and Dutch schools. There is also a display of some very dainty French crystal pendants, together with reproductions of the genuine old Dutch lighting fittings of the sixteenth and seventeenth centuries.

A new development that may be mentioned is in connection with the mercury-vapour lamp. A "light transforming reflector" is being introduced, made of a material which becomes fluorescent under the action of the light from the lamp, and increases the number of red rays; although this has not actually solved the problem of converting the light from the mercury-vapour lamp into a pure white light, it is at any rate a step in the desired direction.

The visitor who proposes only to spend a short time at the exhibition in which to form an idea of the numerous domestic applications of electricity to which we have alluded will find a large number of these concentrated in the "Electric Home." This is a suite of rooms consisting of drawing, dining, bed, and bath rooms, together with a kitchen and scullery, efficiently and beautifully lighted. In the kitchen demonstrations of electric cooking are being carried out, and are under the direction of a first-class cook. Electric laundry work is also shown.

A COUNTRY IN THE MAKING.[1]

THE Argentine Republic has recently celebrated the centenary of its existence as an independent State, and, in the national "stocktaking" which inevitably belongs to such an event, considerable attention has been given to education, as a result of which we have two large volumes of statistical records, and a third volume of monographs, on the various grades of educational work that come under the direction of the State.

Prior to its escape from Spanish control, such education as there was in the country was under clerical, and, for the most part, Jesuitical direction. In the ancient (Argentine) city of Cordova, the foundation of which by Peruvian Spaniards dates back to 1573, the Jesuits established a high school (*Colegia maxima*) in 1610, which Pope and King combined to raise to the dignity of a university very few years later. The university was for two hundred years the sole representative of higher studies. It was secularised in 1800, and a sister university was set up at Buenos Aires in 1821 by the recently organised Government.

It is interesting to note how world-wide was the influence of Napoleonic ideas. There was then no Department of Public Instruction, and the new university was entrusted with the duty of educational administration in the city and district. After various experiments in constitution-making, however, the influence of the great republic of the north made itself felt, and in the federal form of government which was completely adopted in 1860, the duty of providing primary schools was put upon the local legislatures, and a central Ministry of Public Instruction was also formed. It was not, however, until Sarmiento's presidency (1868–73) that the country really woke up to its educational needs. Sarmiento had been an exile for some years, and during that time Chile had sent him to Europe and the United States to study educational systems. He had met Humboldt, Guizot, Cobden, and Horace Mann, and entered upon his presidential period full of great projects for the development of national education. His influence led to greatly-increased grants from the central exchequer to the provincial governments, and to the establishment of a great training college for teachers on the model of similar institutions in the United States.

The degree of progress which has been attained in the provision of primary schools, and the vast difficulties of the Government, are best illustrated by the comparative number of children between six and fourteen who could not read or write (*illettrés*) in 1895 and in 1900. There were in the former year 57 per cent., and in the latter 32·6 per cent. Education is compulsory between six and fourteen; we may suppose that the children in school do not learn to read within a year, and so reduce the 32·6 to approximately 28 per cent.—not a bad result if we keep in mind the enormous territory and the sparseness of the population, immediately the precincts of the large towns are left behind. Uruguay is the only other South American State which comes approximately near to such a result; the number of illiterates rises to 80 per cent. in Brazil and 90 per cent. in Venezuela. In spite of what has been accomplished in the sphere of primary education, the cost to the State is very small in comparison with what is paid for the higher schools and universities.

Most of the secondary schools are under the direct control of the Central Government. They follow a five-year course preparatory to the university. As is the case in Austria, it is worthy of note that psychology is a subject of instruction in the last school year. The schools in Buenos Aires are magnificently housed; their equipment is costly, and their staffs are ample. The five schools cost the city more than 100,000*l.* in 1908. But in the smaller towns things do not go so well. The subjects are appropriated to chairs (*catedras*), the holders of which must give at least three hours a week instruction. They are for the most part occupied by local professional men, whose main interests are not, of course, in the school. There are two State high schools for girls, in Buenos Aires and in La Plata, but the majority of girls are educated in conventual institutions. The Jesuitical seminaries also attract many of the sons of the wealthier classes.

There are now three universities in the country, a third having been founded by the State of La Plata in 1906. This last foundation follows the United States model, with a supervising president who brings unity into the system of government by more or less independent faculties such as obtains in Cordova and Buenos Aires. All the universities are handsomely provided with funds. In 1908, Cordova received 55,000*l.*, Buenos Aires 90,000*l.*, and La Plata 86,000*l.* from the national exchequer. Nor is capital expense spared. The State has recently voted 1,200,000*l.* for various university buildings, including a new hospital for the medical school at Buenos Aires, and buildings at Cordova in celebration of the tercentary of its foundation.[1]

Vigorous life and a profound belief in education are obvious everywhere. Technical schools, a new public school on the English pattern, magnificent museums and libraries such as our great provincial cities may long yearn for in vain—all these are pointed to with legitimate pride. Here and there in the record one comes across interesting bits of heterodoxy, which bear witness to a healthy independence of view. "J'estime que l'institution des Kindergarten est une véritable hérésie pédagogique et un crime de lèse-enfance." This is startling, to say the least. Nevertheless, the volumes fill one with admiration for the pride and faith in the future of their country which animates their authors and the administrators whose work they record.

DR. F. W. PAVY, F.R.S.

ON September 19 the death occurred of Dr. Frederick William Pavy, F.R.S., in his eighty-third year. Dr. Pavy was born in Wiltshire in May, 1829, and was educated at Merchant Taylors' School. He subsequently entered Guy's Hospital, where he had a distinguished career, and in the course of his graduation at the London University took the exhibition and gold medal in materia medica, the gold medal in medicine, and honours in other subjects. He became a doctor of medicine in 1853. He studied physiology in the laboratory of Claude Bernard, in Paris, and soon began that prolonged research into the relation of sugar to the animal economy, in reference to the causation and treatment of glycosuria and diabetes, which terminated only with his life.

Dr. Pavy's first communication to the Royal Society was in 1855, and was entitled "An experimental inquiry into the nature of the metamorphosis of saccharine matter as a normal process of the animal economy." In this he gave reasons for believing that the sugar formed in the liver is not entirely destroyed by combustion in the body, but is changed by means of fermentation. This was followed in 1858 and 1860 by accounts of an "Experimental inquiry into the alleged sugar-forming function of the liver." In these he demonstrated that the large amount of sugar found in the blood returning from the liver was not, as Bernard supposed, present during life, but was really the result of a transformation of the glycogen taking place with great rapidity after death.

In subsequent papers he showed the influence upon the formation of sugar in the blood, of the injection of alkalis, and of acids, into the circulation. Claude Bernard had shown that a lesion of a certain part of the fourth ventricle would cause glycosuria; in 1859 Pavy, in a communication "On the lesions of the nervous system producing diabetes," demonstrated that the same change in the urine was brought about by removal of the superior cervical ganglion, or the division of the sympathetic trunk in the neck. He referred this appearance of sugar to an alteration in the vasomotor apparatus of the liver. In 1863 he was led to ask why the gastric secretions did not in health digest the gastric mucous membrane itself; and from a series of ingenious experiments he drew the inference that this was due to the circulation in the stomach walls of an alkaline blood which was sufficient to neutralise the acid gastric juice, coming into contact with the mucous membrane.

In the same year, Dr. Pavy was elected a Fellow of the Royal Society, and so far as communications to this society were concerned he appears to have rested on his oars for several years. Not that he was idle; far from it. He was for a time demonstrator of anatomy at Guy's Hospital. Within two or three years of graduation, he was appointed lecturer on physiology and comparative anatomy, and he continued his lectures on physiology until 1878, for the last five years in conjunction with Dr. Pye-Smith. In 1859 he was appointed assistant physician to Guy's Hospital, and in 1871 he became full physician. In 1862 appeared his work entitled "Researches on the Nature and Treatment of Diabetes," and he soon acquired a large professional practice among sufferers from that complaint.

Dr. Pavy did not, however, confine himself to the subject of diabetes; he did valuable work in connection with the forms of functional albuminuria, and he wrote a "Treatise on the Function of Digestion." This was followed in 1874 by a "Treatise on Food and Dietetics," which was a standard book for many years. In 1890, at the age of sixty-one, he retired from hospital work at Guy's, but he still enjoyed a large private practice, held the offices of censor and Harveian orator at the Royal College of Physicians, and continued unintermittingly and with dogged perseverance his researches upon the destination of sugar and other carbohydrates in the animal system. In 1875 he read a paper before the Royal Society "On the production of glycosuria by the effect of oxygenated blood on the liver," and in the following ten years he read as many papers bearing on the carbohydrates and diabetes. He made many practical additions to the chemistry of the subject, and his introduction of an ammoniated cupric test in the volumetric estimation of sugar was undoubtedly of great value.

Dr. Pavy has made numerous other communications to medical journals on these subjects; he published in 1894 a "Treatise on the Physiology of the Carbohydrates," and in 1908 delivered three lectures "On the pathology and treatment of diabetes viewed by the light of present-day knowledge." In all this later work he insists on the fact that carbohydrates can be both derived from, and converted into, proteid, as one of great importance in relation to diabetes.

Dr. Pavy's work was well known abroad, and he was the recipient of several honours. He was a corresponding member of the Société d'Anatomie of Paris; and in 1908 the Academy of Medicine of Paris awarded the Godard prize to his work on carbohydrate metabolism on diabetes. In 1901 he was awarded the Baly medal by the Royal College of Physicians of London.

FREDERICK TAYLOR.

NOTES.

EXHAUSTIVE tests have been made during the last two weeks by Mr. A. W. Sharman with instruments invented by him for telephoning through water without wires. A small telephone station has been erected in a room in an hotel on the cliffs at Pegwell Bay, and the other station has been fitted up on a motor-boat cruising in various parts of the bay. The microphone used in speaking is connected in series with a battery of four or five dry cells and an impulse coil, the coil being of special construction and giving very short induced currents of high potential, which are communicated to the water by two wires connected to the terminals of the coil and terminating themselves in plates buried in the sand or submerged in the water. Two similar plates, connected direct with a very low resistance telephone receiver, enable the speech to be "picked up" at distances of a mile and more. The speech transmitted through the water has been very distinct, and the system has shown good possibilities of its being used as a means of verbal communication between two ships, such as a battleship and a submarine. The effect is very directional; and another advantage is that, with a small tuned buzzer, telegraphic signals can be transmitted through the earth or water for a distance of several miles; the primary energy required is extremely small, four watts sufficing to telephone over a distance of two miles. Experiments are also being made in combining with the Sharman instruments a sensitive telephone receiver invented by Mr. T. Thorne Baker, with which it is hoped the present range may be increased by 50 per cent. or more.

THE naval dirigible, an experimental airship which has been building at Messrs. Vickers' works, Barrow, for the Admiralty, during the last two years, was wrecked on Sunday, September 24, while being towed out into the centre of Cavendish Dock in preparation for a flight. The vessel, which is of the Zeppelin type, is 510 feet long, 45 feet in diameter, and of a capacity of 20,000 cubic metres. The rigid framework, containing seventeen separate gas-bags, is constructed of a new alloy known as "duralumin." Each of the gondolas, fore and aft, contains a 200 horse-power Wolseley motor, the motor in front driving two propellers on either side, and that in the rear driving one propeller placed behind the gondola. The accident started so soon as the order to begin to veer the bow round towards the centre of the dock was obeyed. The ship bulged and broke by her seventh, eighth, and ninth gas-bags, approximately in the middle. The outer fabric fortunately held, enabling both portions to be secured and eventually returned to the shed, without injury to the crew, though several men were obliged to swim for safety. The exact cause of the accident is unknown, nor is it likely to be made public. Structural weakness would seem to account for it, coupled with the fact that the keel, which originally ran the length of the vessel between the two gondolas, had been removed in order to lighten her.

The Aëronautical Society of Great Britain at a special general meeting held on Monday, September 25, passed resolutions repealing its old constitution, under which it has been governed for forty-five years past, and substituting a new one, which provides for the creation of a technical side in addition to the lay or members' side. Fellowships and associate fellowships are to be granted to those respectively of considerable eminence and of an acknowledged position in the science of aëronautics, and special encouragement is to be given to students, for whom there is a separate grade. The growth of aëronautical engineering as a profession is the chief cause for this change, which, it is hoped, will give a much needed fillip to aëronautical industry, besides protecting and fostering its interests. The new council was also elected at the meeting, and is composed of the following:—A. E. Berriman, Griffith Brewer, Captain A. D. Carden, T. W. K. Clarke, B. G. Cooper, J. W. Dunne, J. Dunville, J. H. Ledeboer, Captain E. M. Maitland, F. K. McClean, Lord Montagu of Beaulieu, A. Ogilvie, M. O'Gorman, F. Handley Page, Colonel H. E. Rawson, and Colonel F. S. Stone.

News has been received at the Royal Geographical Society that the International Geographical Congress, which was to have been held at Rome next month, has been postponed until the spring of 1912.

The Secretary of State for the Colonies has appointed Sir Ronald Ross, K.C.B., F.R.S., professor of tropical medicine in the University of Liverpool, to be a member of the Advisory Medical and Sanitary Committee for Tropical Africa, in succession to the late Sir Rubert Boyce, F.R.S.

Mr. A. P. Trotter informs us that his name has been attached to the Report of the British Association Committee on Practical Standards for Electrical Measurements without his authority, and doubtless as the result of a mistake. But it compels him to state that he withdrew from the committee in July, 1910, because he strongly disagreed with some of its resolutions and with the mode in which the business was conducted.

Circumstances have arisen which have led to the abandonment of the arrangements made to hold the autumn meeting of the Iron and Steel Institute in Turin. The meeting will be held, therefore, at the Institution of Civil Engineers, Great George Street, Westminster, on October 5. Among the papers which have been submitted, a selection of which will be read and discussed, may be mentioned:—Reports on the iron-ore resources of Italy: (*a*) Sardinia, by Ing. L. Testa, (*b*) Brembana Valley, by Cav. G. Calvi, (*c*) central Italy, by Ing. A. Ciampi, (*d*) southern Italy and the island dependencies, by Prof. G. la Valle; on the mechanical influence of carbon on alloys of iron and manganese, by Prof. J. O. Arnold and Mr. F. K. Knowles, of Sheffield; on the autogenous welding of metals, by Dr. Francesco Carnevali, of Turin; on the application of electric energy to the manufacture of iron and steel in Italy, by Cav. Ing. Remo Catani, of Rome; on the present state of the metallurgical industry of Italy, by Signor Comm. Luigi Dompé and Cav. Francesco Saverio Pucci, of Milan. Papers will be submitted also by Mr. E. Adamson, of Sheffield; Mr. L. L. Fermor, of Calcutta; Prof. Federico Giolitti, of Turin; Prof. F. Giolitti and Dr. Francesco Carnevali, of Turin; M. L. Grenet, of Argenteuil, France; and M. V. A. Kroll, of Luxembourg.

Dr. C. H. Wind, professor of theoretical physics at Utrecht University, died on August 7, after a long illness, at the age of forty-three. Prof. E. v. Everdingen, director of the Royal Netherlands Meteorological Institute at de Bilt, sends us the following particulars of Dr. Wind's career and scientific work:—Cornelis Harm Wind was born at Groningen, and studied physics and mathematics there and at Leyden and Berlin (1886–95), and physical chemistry with van 't Hoff at Amsterdam (1895). He was then appointed lector in theoretical physics and physical chemistry at Groningen. In 1902 the Government, desiring to encourage the application of theoretical physics to the solution of meteorological problems, appointed Wind as director of the Meteorological Institute at de Bilt. As such he reorganised the practical work, devised schemes for extensions in terrestrial magnetism, seismology, and kite work, and introduced many improvements in the regular publications. In 1904, however, when the time for theoretical work had scarcely arrived, he was called upon to take the chair of theoretical physics at Utrecht, and accepted the invitation, not without much hesitation. Wind's theoretical work of the Groningen period promised a brilliant career. His work on magneto-optics led him to predict an analogue to Kerr's phenomenon, afterwards verified by Zeeman. Haga and Wind's experimental researches on diffraction of Röntgen rays induced him to investigate the explanation of diffraction phenomena generally. Other researches consider Gibbs's phase rule, the kinetic theory of gases, and the second law of thermodynamics. Also one part of Bosscha's text-book of physics was written by him in this period. Unhappily, at Utrecht his health began to give way and prevented further development in this direction. Nevertheless, he continued to show great interest in geophysical problems as a member of the board of visitors of the Institute for Marine Investigations, afterwards also of that of the Meteorological Institute. Those who met him at the meetings of the Permanent International Council for the Investigation of the Sea will remember his activity in organising the hydrographical work. His many friends and colleagues who remember his keen interest in their affairs and work whenever they asked his advice know that, though his life was too short, it was not in vain.

In his pamphlet, "The Stone Age and Lake Lothing" (Norwich: Norfolk News Co., Ltd.), Mr. J. Chambers says:—"My intention was to write a brief notice of the flint implements I found lately when excavating in the bed of Lake Lothing, at Lowestoft." Beyond a few remarks on various methods of identifying stone implements, the author's intention has not been carried out. His remarks on the history of the lake are interesting, but he leaves the very subjects on which he has some valuable first-hand information to dabble in place-name speculations, the value of which may be estimated by his list of "acknowledged authorities."

In the September issue of *Man* Messrs. W. L. H. Duckworth and L. R. Shore describe a collection of crania derived from the peat deposits, which are now deposited in the Cambridge University Museum. While, as regards the mammalian fauna, the type from the peat deposits is certainly distinctive, there is great diversity in the cranial forms. Two of these crania tend to intrude among those of the prehistoric age; but this association is with examples the Palæolithic origin of which is not universally accepted. It seems at the same time certain that this collection contains examples somewhat unusual when judged by the three standard tests—the calvarial height index, the bregmatic angle, and the lambda angle—when compared with modern European crania. In view of the doubts still expressed by some authorities regarding the crania from Galley Hill and Brünn, the problem of the connection of them with the peat deposit examples must remain somewhat uncertain.

The Museums Journal for September contains an interesting article by Mr. H. Stuart Page on the evolution of English pottery, with valuable suggestions for the preparation of a type collection. He begins his survey with the old English slip-ware made at the end of the seventeenth and the beginning of the eighteenth centuries. He points out that the advent of Oriental porcelain entirely changed the outlook of the English potter. This was introduced by the East India Company when the custom of tea-drinking was becoming established in this country, and we can easily realise how wonderfully beautiful these thin, white, glossy, transparent vessels must have appeared to people who were then daily using the home-made coarse utensils. From a valuable chart appended to this paper we can understand the subsequent course of evolution. In dealing with the preparation of a type collection, Mr. Page warns his fellow-curators that they must not attempt to compete with private collectors in purchasing specimens which from their rarity have acquired a high fictitious value. Only the educational needs of a museum should be kept in view, and a collection of less than a hundred pieces carefully selected, arranged in the position for which they were designed, and fully labelled, would, he suggests, be sufficient for the purpose. As the Board of Education is now prepared to give financial aid in the formation of such type collections, it is the duty of curators to select their examples with discrimination. Such a scheme should commend itself to those museums where space and funds are limited, and in those places where a large number of specimens already exist; the idea could be carried out so as to serve the place of an index to the main collection.

In *Phytopathology* (vol. i., No. 3), Mr. J. R. Johnston states that the *Bacillus coli* (the common microbe present in the intestinal tract of man and most animals), when inoculated into coconut plants, is capable of destroying the soft tissues. The *B. coli*, or a form indistinguishable from it, is also the cause of "bud-rot," a disease of the coconut plant.

Judging from the report for 1910, the Sarawak Museum seems to be doing its work, in the matter of the fauna and flora of Borneo, in a thoroughly efficient manner. In addition to duplicates, the museum contains 40,975 named specimens of Bornean animals, referable to 5852 species and subspecies. Besides these, there are between 4000 and 5000 forms not yet properly named. His Highness the Raja has sanctioned the building of a new wing, which when complete will make the museum two-thirds as large again as at present. Arrangements have been made for the publication of a Sarawak Museum Journal, of which the first part was expected to appear in February last.

Much interesting information with regard to the economic products of India is to be found in the report of the Industrial Section of the Indian Museum for 1910–11, more especially in the part dealing with the work of the laboratory. Among the items, reference may be made to the analysis of a sample of Para rubber, the yield of *Hevea brasiliensis*, grown at Darjiling, this rubber being of good quality. On the other hand, rubber from *Ficus altissima*, grown in Assam, proved unsatisfactory. The tree in question is referred to as *Ficus altissima*, Bl., var. *typica*, King; but such a reference, even if it be generally used in botany, is incorrect, as *Ficus altissima typica* (to use the zoological form of nomenclature) is clearly the original type described by Blanford. Experiments as to the suitability of Indian fish-oils for the dressing of jute are likewise discussed, and it has been found that such oils, which in some cases must be diluted with mineral oil, would be satisfactory for this purpose if they could be produced at a sufficiently low price. An outbreak of beri-beri in Bengal led to the analysis of samples of rice, which showed that while husked rice contained from 0·6 to 0·8 per cent. of phosphoric anhydride, "polished" grain contained an average of only 0·4 per cent., which in some samples was reduced to from 0·26 to 0·22 per cent.

To *The American Naturalist* for September Mr. T. Barbour contributes a translation of an important article, by Dr. P. N. van Kampen, on the zoogeography of the East Indian Archipelago, originally published in Dutch in *Natuurkundig Tijdschrift voor Nederlandsch-Indië* for 1909. By means of maps of the distribution of mammals, amphibians, and fresh-water fishes it is shown that Wallace's line "has no value as a zoogeographic boundary," and that nearly the entire eastern half of the archipelago must be regarded as a transition area between the Oriental and Australian regions, the boundaries of which cannot be defined. After reference to the theory that the Australian fauna came from South America, it is concluded "that in post-Cretacean times there was a broad connection between the three Greater Sunda Islands and Asia on the one hand, and between New Guinea and Australia on the other; that, further, also between the Sunda Islands and New Guinea a connection must have existed, which was really less easy to pass over." Celebes is considered to possess an impoverished Indian fauna, due to the absence of free connection with the larger western isles, this poverty being most noticeable in the case of fishes. Its fauna may be the result of the consolidation of smaller islands, which were supplied by feeding lines from islands to the south, north, and east. "It is peculiar that the truly Indian character of Celebes remained unsuspected so long; while, on the other hand, no one doubted, but rather laid stress upon, the Australian relationship of that vast easterly island, New Guinea, the fauna of which is fully as Indian as that of Celebes is Australian." An African element is supposed to be represented in Celebes by the black ape (Cynopithecus) and the babirusa, the former being considered to be related to the baboons and the latter to the wart-hog. The evidence for this seems, however, inconclusive.

The new regulations for recruitment of the Indian Imperial Forest Service are published in *The Indian Forester* (August), with some cogent criticisms not altogether favourable. The substitution of several recognised training schools in place of a definite establishment at Oxford does not meet with favour, but the appointment of a member, retired or active, of the Indian forest department as a controlling director is regarded as a hopeful arrangement. Coincidently the number contains a communication issued by the Government of India revising the regulations for the training of provincial candidates at the Forest College, Dehra Dun.

A revision of the small liliaceous tribe Nolineæ, intermediate between the Yucceæ and Dracæneæ, has been prepared by Dr. W. Trelease, and is published in the Proceedings of the American Philosophical Society (vol. l., No. 200). The author recognises four genera by the inclusion of the monotypic genus Calibanus, founded on Hooker's *Dasylirion Hartwegianum*. Ovary and fruit furnish characters distinguishing the genera Nolina, Calibanus, Beaucarnea, and Dasylirion. The species are pronounced xerophytes with a succulent caudex; some of them reach tree size, as *Nolina longifolia* and *Beaucarnea gracilis* that are illustrated. The focal centre of the tribe lies on the Mexican tableland, with a distribution southwards to Central America and northwards to California and Colorado. Half the species are assigned to Nolina, and only seven are placed under Beaucarnea.

Among the sixty-eight parts mapped out in connection with the Clare Island Survey, one of the earliest and a most interesting number is the graphic account of the lichens contributed by Miss A. Lorrain Smith. The region of rock, moorland, and sea coast on Clare Island and the adjacent mainland is particularly favourable to their development. The seaward rocks are clothed with black *Verrucaria maura*; *Ramalina scopulorum* and *Ramalina cuspidata* grow within reach of the spray, and *Physica parietina* gives colour to the boulders; proceeding inland, *Lecanora parella* and *Lecanora atra* are first prominent, and then *Lecidea rivulosa*. The peaty soil carries fine growths of Cladonia and Stereocaulon, and in the grass species of Peltigera are abundant. The present list, not regarded as exhaustive, enumerates 280 species, of which only about thirty were previously recorded for the county, while the new records for Ireland approximate to this figure. The rarer species include *Arthopyrenia leptotera*, *A. microspila*, *Arthonia subvarians*, *Microthelia dissepta*, and the alpine *Pertusaria gyrocheila*.

The reopening of the old alluvial goldfield in eastern Sutherland was referred to in Nature of July 13 (p. 51). It was then remarked that gold was being obtained, but whether it occurs in paying quantities had still to be proved. Information recently received from the field shows that the experiment has been a financial failure, but fresh attempts are being made at another locality.

The twelfth half-yearly review of mining operations in South Australia records the further development of the Tanami Goldfield in the Northern Territory, and states that instructions for the provision of a battery have been given by the Minister for Mines. The most important mineral product of South Australia is copper, and owing to its low price during the half-year copper mining had not been active. Further progress is being made in the development of the carnotite lode at Radium Hill, and the manufacture of gas fire-blocks has begun a fresh use of the extensive china-clay deposits of South Australia.

In the September number of *The Scottish Geographical Magazine* there appears a paper on the plant geography of Ardgoil, a public park of the Corporation of Glasgow, comprising some 14,000 acres, bordering on Loch Long and Loch Goil. Maintained in its natural condition of a Highland estate, it offers an excellent field for the study of such problems; and Mr. T. Nisbet's paper, read to the geographical section of the Royal Philosophical Society of Glasgow, is an excellent example of the useful work which can be done in local investigations. The present distribution of trees and plants is compared with the records in early statistical accounts, and the controlling influence of the greater hillside and glen population which existed a century and more ago is pointed out.

In the Proceedings of the Royal Irish Academy Prof. G. A. J. Cole describes the glacial features in Spitsbergen, and compares them with such as are to be seen in Ireland, where we associate with the waning of the Irish Ice age. The general appearance of aridity in the form and manner of weathering in Spitsbergen is very striking, and the action of penetrating water and repeated frosts leads to a rapid destruction of the rock, often forming cirque-like basins on the hill-slopes. Such cirques, illustrations of the arid type of weathering, Boulder-clay, and fluvio-glacial deposits are well shown by photographs taken by the author, who discusses the possibility of somewhat similar conditions having existed over Ireland during the Glacial period.

A correspondent asks what is "teart land," for the investigation of which the Development Commissioners have made a grant. The use of the word "teart" in connection with certain soils was referred to in Nature of November 3, 1910 (p. 25), and of May 11, 1911 (p. 364), both times in reference to Mr. C. T. Gimingham's very promising work on problems presented by such lands. Dr. E. J. Russell informs us that the word is used to denote certain pastures in Somersetshire on which cattle "scour," or get diarrhœa badly, whilst on other pastures round about they remain perfectly healthy. Botanical examination of the pastures reveals nothing that can account for the scouring, nor is there any evidence of disease organisms. Only the Lower Lias formation is affected, alluvial pastures all round a Lias pasture being quite sound. The whole problem is very baffling and extraordinary, but it is typical of many other pasture problems which require investigation.

In the August number of *La Géographie* M. Paul Mougin discusses the snowfall in Savoy. The material available includes many references to the deficiency or excess of snowfall in different years, and by research among the documents preserved in the official centres of the province a large amount of information has been collected which reaches back for many years. But such data are but approximate, and are only available for exceptional years; nevertheless, from 1773 onwards the dates of the earliest and latest snowfalls have been recorded at Annecy. Taking the mean dates for each twenty-five years, there seems to have been a maximum annual duration of snow in the period 1801–25, since when it has decreased. It is pointed out that this corresponds with the maximum extension of the glaciers in 1818–20, and do not contradict their retreat, which commenced after 1863. From 1853 the depth of snow falling in each year has been recorded at Annecy, and since 1900 the Administration des Eaux et Forêts has considerably increased the number of observing stations. From such data M. Mougin discusses the increase of snowfall with altitude, and the marked increase recorded in passing from north to south. There are also localities of exceptionally heavy snowfall which are not on the highest parts of the mountain range.

The interesting weather charts of the North Atlantic for September 7–13, prepared from radio-telegrams and other data, and published in the first issue of the valuable monthly meteorological charts for October by the Meteorological Office, show that the distribution of barometric pressure was subject to considerable variation. The chief features were the movement of high and low systems, generally of small intensity, across America to the Atlantic, and their subsequent tracks across the ocean. At the close of the period the eastern half of the Atlantic was under the influence of a very large high-pressure system extending from Greenland and Iceland southward to the edge of the tropics, and the office was enabled to predict successfully a continuance of these conditions for some days. On the same chart it is notified that the French Meteorological Office has commenced the dispatch of wireless messages from the Eiffel Tower, at 11h. a.m. daily, for the benefit of shipping in the Atlantic. The reports consist of barometric readings, wind direction and force, and state of sea at six stations in western Europe, Iceland, Azores, and Miquelon (Newfoundland), to which a general summary of the weather is added, *e.g.* "Anticyclone over central Europe, fine weather general; depression west of Iceland, travelling toward the east."

IN view of the extensive use which is made of sulphur as an insulator in electroscopes used in ionisation observations, a note in the August number of *Le Radium*, by Mr. F. W. Bates, of the University of Montreal, on the effect of light on the insulating properties of sulphur will be read with interest. Mr. Bates finds that when exposed to light sulphur becomes slightly conducting, the conductivity increasing as the intensity of the light increases. This property, he finds, is shared to a small extent by ebonite, but amber appears unaffected by light. He considers that the importance of the subject justifies a more extended study of it, and this he has commenced.

PROF. A. RIGHI has two interesting papers in vol. xiv. of the *Mem. della R. Accad. di Bologna*. The first deals with the ionisation produced by the magneto-kathode rays. It is found as the rays are more strongly developed, by increasing the axial magnetic field, that the ionisation at a given point in their path is diminished. The explanaton of this effect follows simply from the mode of formation of the rays; the field holds in loose combination pairs of oppositely charged ions which would otherwise escape from each other's attraction, the number of free ions in the discharge tube is therefore diminished. Sir J. J. Thomson has shown how complex are the phenomena in the region in which the canal rays are usually studied; it therefore seems possible that other plausible explanations could be given of the observed effects. The second of the two papers deals with less explored ground, viz. the influence of a magnetic field on the sparking potential. The results here are so complicated that Prof. Righi thinks more data will have to be collected before an explanation can be given. As the magnetic field is increased the sparking potential falls to a minimum, then rises to a maximum, and finally decreases very slowly. The magnetic and electric fields are parallel. Of other papers of physical interest, one by Prof. Amaduzzi deals with the photoelectric effect in selenium, while Prof. P. Burgatti treats of the vortical motion of a liquid, using vector analysis.

WE have received from the Patent Office Library a new "Subject List of Works on Chemistry (including Alchemy, Electrochemistry, and Radio-activity) in the Library of the Patent Office." It is a work of 218 pages, and supersedes a list published in 1901. A valuable feature of the list is the use of the dates of the volumes as one of the chief items in the scheme of classification; under this system it is easy to follow the gradual development of a subject or process, and new publications fall naturally into their proper places at the end of the series. The classification is somewhat complex, and some practice would be needed to trace quickly the volumes that one wished to consult; but this is perhaps inevitable in view of the bewildering array of books, journals, theses, dictionaries, and pamphlets which compose the literature of chemistry.

A PAPER by M. Paul Sabatier on hydrogenation and dehydrogenation by catalysis has recently appeared in the *Revue Scientifique*. Originally delivered in the form of a lecture to the German Chemical Society, the paper contains a review of the new and important branch of organic chemistry which has been developed during the past twelve years by the author and his colleagues. The catalytic action of the metals, and especially of finely divided nickel, has been utilised in a very large number of organic changes, and has proved of peculiar value in the addition and removal of hydrogen; more recently the catalytic influence of a number of oxides, such as thorium dioxide, has been investigated, and has proved to be of great service in effecting processes of condensation, such as the conversion of acids into ketones, and of alcohols into thiols, esters, ethers, and amines. The summary now given is both opportune and useful.

THE solubility of hydrogen in copper, nickel, and iron is the subject of a communication by A. Sieverts to the current number of the *Zeitschrift für physikalische Chemie*. The solubilities were studied for pressures up to $1\frac{1}{2}$ atmospheres, and over the temperature range 400° C. to 1600° C. For a given temperature and pressure it was found that the amount of gas taken up per unit weight of metal was independent of the metal surface. At constant temperature the solubility in both solid and liquid metal is approximately proportional to the square root of the gas pressure; at constant gas pressure the solubility of the hydrogen increases with the temperature, a sudden increase in the amount absorbed taking place at the melting point of the metal. As a consequence of the latter property, there is a spitting when the metal solidifies, copper giving off at its melting point about 2 volumes of hydrogen, iron 7 volumes, and nickel 12 volumes.

THE August issue of the Journal of the Franklin Institute contains a paper by Dr. Charles Baskerville on the chemistry of anæsthetics. In the case of chloroform especially, and to a less extent in the case of other anæsthetics, it is important not merely to ensure the initial purity of the material, but also to store it under such conditions as to prevent the formation of deleterious substances. The deterioration of chloroform is mainly due to oxidation, as shown by the equation

$$CHCl_3 + O = COCl_2 + HCl.$$

This change is usually checked in the case of anæsthetic chloroform by the addition of alcohol; and it has been shown that the initial oxidation of the mixture proceeds entirely at the expense of the alcohol, and that the chloroform is not attacked until later. Nevertheless, it is desirable to restrict oxidation by storing the liquid in small bottles which can be opened as required, and to make use of anactinic glass; it has even been suggested that the liquid should be stored in contact with nitrogen, and drawn off by means of a syphon, in order to avoid all risk of oxidation.

AN article in *The Engineer* for September 22 deals with hydraulic excavation on the Panama Canal. The method has been borrowed from hydraulic gold-mining as practised in California, and has been used on the largest scale in the area extending southward from the lower locks at Miraflores to opposite Corozal. Some 330,000 cubic yards of alluvial material were disintegrated between October and February last. The chief difficulty experienced during the progress of the work was the frequency with which limbs and trunks of cocoanut trees, washed from the mud several feet below the surface of the ground, were drawn into and choked the suction pumps. When this occurred, a coloured workman dived to the mouth of the pipe and extracted the débris. The cost sheets indicate that the economy of this method of excavation is undoubted.

AN illustrated description of the Trollhättan Hydroelectric Power Station, Sweden, appears in *Engineering* for September 22. This station will represent, when completed, an aggregate of 100,000 horse-power, half of which has just been installed. The Swedish State now controls the entire water-power of the Göta River, which connects Lake Vänern, the largest lake in Sweden, with the sea, there being a difference in level of 144 feet, of which 108 feet occur in the Trollhättan Falls. The present low-water volume is 11,520 cubic feet per second, and the high-level volume of water is about 32,400 cubic feet per second. When Lake Vänern is regulated, the State will be able to reckon on an aggregate of not fewer than 200,000 horse-power at the Göta Falls. The district is at no great distance from Gothenburg, and is in the midst of a populous part of the country. Francis turbines of a nominal capacity of 10,000 horse-power and a maximum capacity of 12,500 horse-power have been installed. The generators produce three-phase current, twenty-five periods, and 10,000 volts. The energy is distributed partly at 10,000 and partly at 50,000 volts.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR OCTOBER:—

Oct. 1. 12h. 4m. Uranus in conjunction with the Moon (Uranus 4° 44′ N.).
4. 5h. 0m. Venus stationary.
5. 15h. 0m. Uranus stationary.
10. 6h. 28m. Saturn in conjunction with the Moon (Saturn 4° 27′ S.).
11. 17h. 52m. Mars in conjunction with the Moon (Mars 4° 21′ S.).
17. 12h. 0m. Mars stationary.
,, 19h. 0m. Neptune at quadrature to the Sun.
19. 12h. 0m. Uranus ,, ,,
21. 15h. 55m. Sun eclipsed, invisible at Greenwich.
22. 4h. 0m. Venus at greatest brilliancy.
23. 9h. 0m. Mercury in superior conjunction with the Sun.
,, 11h. 31m. Jupiter in conjunction with the Moon (Jupiter 2° 40′ N.).
27. 14h. 0m. Neptune stationary.
28. 20h. 40m. Uranus in conjunction with the Moon (Uranus 4° 48′ N.).

ANOTHER NEW COMET, 1911*f*.—A telegram from the Kiel Centralstelle announces the discovery of a new comet by M. Quénisset, at Juvisy, on September 23. Its position at 10h. 25m. (Juvisy M.T.) was

R.A. = 14h. 24·8m., dec. = 75° 4′ N.,

and its daily movement was +3·8m. in R.A. and −2° 11′ in declination.

We also learn that this comet was discovered independently by Mr. Francis Brown, of Lee, S.E., on Sunday, September 24, at 9 p.m. Mr. Brown gives its position then as R.A. = 14h. 37m., dec. = 73° 40′ N.

The magnitude of the new comet is given as 7·5, and, as it is situated so high up in Ursa Minor, it should not prove a difficult object.

DISCOVERY OF BORRELLY'S COMET (1905 II., 1911*e*).—According to a telegram from the Kiel Centralstelle, the credit of rediscovering Borrelly's comet, for which, as we mentioned in last week's issue, M. Fayet has just published search-ephemerides, belongs to Mr. Knox Shaw, of the Helwan Observatory, Egypt, who found it in R.A. 3h. 46m. 20s., dec. −32° 54′, at 15h. 5m. (Helwan M.T.) on September 19. The discovery was probably made on a photograph taken with the Reynolds 30-inch reflector, which, it will be remembered, was the first instrument to secure a recognised photograph of Halley's comet; the magnitude is given as 13·0.

M. Fayet gave three ephemerides based on the assumptions of perihelion passage taking place on December 18·6, 14·6, or 22·6; the observed position is more nearly in accordance with the first of these. He also shows that by the middle of October the quantity $1 : r^2\Delta^2$ will be as great as it was at the time of the comet's maximum brightness in 1905; after that it will increase considerably, from 0·57 to 1·90, so that the conditions of this return will be much better, for southern observatories, than at the previous apparition.

THE KIESS COMET, 1911*b*.—Numerous observations of comet 1911*b* are published in No. 4525 of the *Astronomische Nachrichten*, all of which direct attention to the diffused nebulous character of this object. On August 11 Herr Ernst, at the Königstuhl Observatory, found the diameter to be 12′, the coma appearing slightly elongated in the direction N.-S., and the nucleus being easy to see.

Dr. Konkoly at O'Gyalla found the three hydrocarbon bands to be very bright, their relative intensities, reckoning from the red, being 0·6, 1·0, and 0·3; a short continuous spectrum passed through the middle of the lines.

Dr. Holetschek gives a list of brightnesses of the whole comet and the nucleus as observed at Vienna, the maximum brightness, 5·5 mag., of the former occurring on August 3, although the greatest estimated magnitude of the nucleus, 7·0, was recorded on July 18.

Photographic observations at Innsbruck indicated possible changes in the extent of the tail on successive nights, and Herr Prey records tails up to ½° in length. Considerable changes of form are also recorded by M. Quénisset, who reproduces an excellent photograph of the comet on a plate accompanying the September number of *L'Astronomie*. This was taken at Juvisy on July 29 with an exposure of 78m., and shows a tail 5½° long issuing as a hard, fine streamer from the centre of the coma; but M. Quénisset records that on August 6, when the tail was fainter and 2½° long, it was strongly eccentric, and certainly appeared to emerge from the northern edge of the coma.

In *La Nature* for September 23 Dr. Mascart discusses the observed form and spectrum of this comet, and directs attention to the method of repeated copying by contact for the purpose of strengthening the fainter details on comet photographs. The advantage accruing from this process is well illustrated by two reproductions of one of the photographs of Halley's comet which he took at Tenerife in April, 1910. That direct from the original negative is very weak and shows little tail, whereas the one from the recopied negative is much stronger and shows a fair amount of tail.

BROOKS'S COMET, 1911*c*.—M. Quénisset also reports that he has taken several photographs of Brooks's comet, which is now such a prominent object in Boötes. Photographs taken on August 24, 25, and 27, the last with 5h. exposure, show a head having a diameter of 12′ or more in a direction perpendicular to that of the tail; the latter feature shows a length of 4°, and is slightly divergent.

THE SPECTRUM OF MOREHOUSE'S COMET (1908*c*).—Count de la Baume Pluvinel and M. Baldet have a paper in No. 2, vol. xxxiv., of *The Astrophysical Journal* in which they discuss twenty-eight negatives of the spectrum of Morehouse's comet, which they photographed at the Juvisy Observatory during October and November, 1908.

The discussion is a very thorough one, in which the authors show that the spectrum of the comet agrees excellently with the spectrum discovered by Prof. Fowler. The doubling of the bands in the cometary as in the laboratory spectra is very striking. The four band-spectra disclosed are attributed by the authors to carbon monoxide, nitrogen at low pressure, cyanogen, and carbon; in addition, there are some fainter radiations, not yet origined. While cyanogen and carbon were restricted to the head, carbon monoxide and nitrogen were distributed throughout the comet. The bands were also studied from the point of view of "series," and the authors find them classifiable into a "strong" and a "weak" series. An excellent reproduction of the spectrum accompanies the paper.

METEOR OBSERVATIONS.—A number of observations of bright meteors are reported in No. 4525 of the *Astronomische Nachrichten*. Mr. Denning gives the paths and velocities of eleven meteors seen in July and August, Prof. Konkoly reports 200 meteors seen at Nagy Tagyos during the July and August swarms, and Herr Dziewulski gives particulars of two bright meteors seen at 11h. 55·6m. (M.E.T.) and 11h. 57·6m., respectively, on July 6. At Cracow the apparent paths were 317°, −2° to 350°, +10° and 307°, +23° to 327°, +46°, respectively; the first lasted ten seconds, and was three times as bright as Venus, while the second was as bright as Venus and endured for four seconds.

Mr. W. Moss reports that he observed a first-magnitude meteor at South Kensington at 10h. 1m. on September 20. The meteor was moderately rapid, yellowish in colour, and left no trail. Its apparent path was from 40°, +40° to $52\frac{1}{2}°$, $+32\frac{1}{2}°$.

THE BRITISH ASSOCIATION AT PORTSMOUTH.

SECTION L.

EDUCATIONAL SCIENCE.

OPENING ADDRESS (ABRIDGED) BY THE RIGHT REV. J. E. C. WELLDON, D.D., PRESIDENT OF THE SECTION.

An Educational Review.

IT is my duty, as it is my pleasure, to express my cordial thanks to the council of the British Association for the honour it has done me in asking me to occupy the presidential chair of the Educational Section at the annual meeting. It has remembered what I was almost beginning to forget—that I was once a schoolmaster. Yet perhaps he who has once been a schoolmaster can never entirely lose the scholastic temper or, at least, I am afraid, the scholastic manner. Some slight comfort, however, I find in reflecting that there is probably no profession which has been adopted and, I must regretfully add, has been abandoned, by so many distinguished men and women as the educational. It happened to me at one time to examine for a special purpose all the lives recorded in the "Dictionary of National Biography"; and the number of the persons who were there stated to have been more or less constantly engaged in tuition was not less surprising than pleasing to an old schoolmaster. Apart from such persons as were born, in the proverbial phrase, with a golden spoon in their mouths, it is safe, I think, to assert that one out of every three or four eminent Englishmen has at some time or other been a teacher. Nor is this the truth in England or in Great Britain alone; it is true everywhere. Not to speak of lifelong educators or of persons whose principal work was done in education, there occur to me the names of such men as Isocrates, Aristotle, Origen, St. Jerome, Cardinal Wolsey, Erasmus, Milton, Rousseau, Thomas Paine, Dr. Johnson, Diderot, Cardinal Mezzofanti, Mazzini, President Garfield, Emerson, and Carlyle, who were all content at one time or other to make a scanty living by teaching.

Perhaps the fact that so many persons have taken up education simply as a means of livelihood is the reason why there have been so many educational failures. In no profession have good men and good women done so much lasting harm, or have done it so often without being aware of it, as in education. For an educator, like a poet, is born; he is seldom made: if he is deficient in discipline or insight or sympathy, they are hard to win by practice; harder still is it to win the passion for young souls; yet the educational profession demands enthusiasm above all other qualities; and I used sometimes to say to young candidates for office at Harrow that, unless a man honestly felt he would sooner be a teacher of boys than a Cabinet Minister, he would not be a master altogether after my own heart.

Yet the educational profession in itself, if it is not the most striking or shining in the eyes of the world, may be said to be the most inspiring and the most satisfying of all professions. It is the only profession which is naturally and necessarily concerned with all the three elements of man's composite nature, his body, mind, and spirit. It aims immediately and instinctively at the two highest objects of human aspiratinn, viz. the diffusion of knowledge and the promotion of virtue. Nor does any schoolmaster rise to the full height of his own calling unless he realises that his true object is to prepare his pupils, in all their faculties and in all the relations of their after-lives, for good citizenship. I cannot help thinking that a teacher who ignores or neglects the spiritual side of his pupils falls as far short of the scholastic ideal as if he were to think little or nothing of their bodies or their minds. The educational profession, when it is rightly understood, is capable of conferring signal benefits upon the community at large. There is an Oriental apologue which tells that in a time of grievous drought, when the king had vainly called upon the wizards, astrologers, and magicians to bring down rain upon his country, one humble unknown man at last stood forth to pray, and at his prayer the heaven above grew dark with clouds, and there was a great rain; the king desired to know who and what was he that had prevailed alone with God, and the answer was, "I am a teacher of small boys."

Education, as has often been said, is to-day in the air. More and more deeply the civilised nations of the world, and among them, at last, even Great Britain, are coming to realise that in the future the battle will be, not to the swift nor to the strong, but to the highly educated. It is the nation of the highest intelligence and widest cultivation which will assert its pre-eminence in the coming days.

But before any attempt can be made to criticise the existing educational system or want of system in Great Britain, and especially in England, it is necessary to state the principles underlying all true progress or reform in education. In the briefest possible language they are, I think, these:

(1) That every child shall enjoy the opportunity of developing in full measure the intellectual and moral faculties with which God has endowed him or her.

(2) That no difference of opportunity, or as little difference as possible, shall exist between the richer and the poorer classes of society.

(3) That the supreme object of education is to provide good citizens—citizens who, in Milton's stately language, will be able to "perform justly, skilfully, and magnanimously all the offices, both public and private, of Peace and War."

(4) That, as the personal influence of the teacher is a potent factor in education, it is the business of the State to ensure the highest possible efficiency, not only of intelligence, but of character, in the men and women who adopt the educational profession as their life-work.

It seems to me that all the educational questions of the day may naturally be ranged under these four heads. The first includes physiology and psychology as subjects directly bearing upon the teacher's art, the study of individual character, the size of classes, the specialisation of studies, the opportunity of self-culture, the time-table and the constituents of the curriculum, above all, the practical insight by which a teacher discerns, and the sympathy by which he or she encourages, the signs of genius or talent, even when they are overlaid by many faults and failings in a pupil. There is no more humiliating reflection than that teachers have so frequently been blind to the promise of distinction in their pupils. Of the public schools especially it is only too true that they have been, and in some degree still are, the homes of the average and the commonplace. They have applauded mediocrity if it conformed to the rules made by the masters for boys, and the yet stricter rules made by boys for one another; they have been not only oblivious, but even contemptuous, of such conduct as was felt to be a departure from, if not a reflection upon, the established norm of public-school life.

The second head includes such difficult matters as the *carrière ouverte aux talents*, the ladder set up from the lowest educational standard to the highest, the provision of scholarships, the equalisation, so far as possible, of the conditions under which boys and girls compete for pecuniary and other rewards, the danger of social exclusiveness in schools and colleges, and the appreciation of qualities, other than mere learning, as adapting students for their parts at home and abroad in after-life.

Under the third head, if it be granted that citizenship is, or ought to be, everywhere the educational goal, it follows that the teacher may not unfairly claim from the State the opportunity of giving such an education to children, especially in the wage-earning class, where parents are tempted to take their children away from school at an early age in the hope of making them contributors to the family purse, that it may not be hopeless to implant in them a certain knowledge, and with it that love of knowledge without which education, so soon as it ceases to be compulsory, is only too apt to become a negligible factor in the citizen's life. It follows, too, that where the interest of the State is not wholly connected with the interest of the parent, or the class, or the Church, some degree of regard for the State will ultimately prove to be a not unjust condition of receiving public money.

Yet, again, a sense of the importance attaching to the personal and professional qualities of the teacher leads almost necessarily to an insistence upon official registration as a condition of undertaking educational work, upon the training and testing of teachers by all such means as are suitable to prepare them for their responsible duties, and upon pension schemes for facilitating the retirement of teachers when they have lost or are losing their vigour and have earned a period of repose. For education is a science; it is exacting, as all sciences are; and while the educational profession needs to be made as attractive as possible, especially in days when so many other professions enter into competition with it, and while it loses attractiveness if teachers, both men and women, are compelled to retire from it at too early an age, yet it is obviously wrong to sacrifice the many to the individual or the scholars to the teacher by obliging a schoolmaster or mistress to continue in office when he or she is no longer able to perform the duties of the scholastic calling with full efficiency.

More than forty years have elapsed since the passing of the Education Act of 1870. That Act was a signal legislative achievement; it still reflects lustre on the names of Mr. Gladstone and Mr. Forster. In the intervening years it has been subjected to severe controversy, not so much on educational as on ecclesiastical grounds. It has undergone some grave modifications at various times, especially in 1902. But, after all, the main principles embodied in the Act of 1870, viz. that education is a national concern, that the children are the greatest asset of a State, and that it is the interest no less than the duty of the State to provide, or to see that provision is made, for the education of all children in elementary or other schools, have not been, and in all probability will not be, seriously challenged.

The Act of 1870 has proved to be a great moral reform. It lifted the nation as a whole to a new level of self-respect. For the child who has acquired even such elementary learning as is popularly symbolised by the "Three R's" is a higher being than the child who cannot read or write. The elementary-school teacher, not in denominational schools alone, has been a missionary of civilisation, and, I think I may say, of Christianity, in many a dark region of many a populous city. I have been told that to the influence of the Board Schools in East London was traceable a marked advance among children in kindness to the lower animals. Any disparagement or depreciation of the Education Act of 1870 is little less than treason to the moral interests of the people at large.

But it is permissible to inquire what fresh light has been shed by the experience of forty years upon the established system of elementary education in England.

Perhaps the two dangers most evident at the present time are the tendency of the Board of Education towards bureaucratic control over all the schools coming under its jurisdiction, and the habit of imposing upon the local education authorities, whether by Act of Parliament or by ordinance of the Board of Education, a number of new duties without ensuring any corresponding increase of the public funds which are placed at their service.

It is idle, and it would probably be foolish, to resist the concentration of educational authority in the Board of Education. There are signs that the Board will before long exercise a direct influence even upon the great public schools. But who or what the Board of Education is remains somewhat of a mystery. It is too apt to mean a subordinate individual acting in the name, but without the knowledge, of his superiors.

The Board may have stereotyped elementary education overmuch; it may have laid down too rigid rules or have administered its own rules with too much rigidity; it may have set an excessive store by results which could be easily tested by examination, forgetting that the best and most lasting results of the teacher's influence are just such as cannot be easily weighed in the examiner's balances. But there can be no doubt that the control of the Board has exercised a wholesome influence upon the less satisfactory schools. It assures at least a minimum of efficiency. But the maximum of efficiency lies beyond the power of the Board. It depends upon the close, intimate, sympathetic, personal relation of the teacher to his or her pupils.

Nor, again, is there any doubt of the advantage arising from the gradual pressure of one and the same education authority, not only upon all schools of the same type, but upon schools of different types in the educational field. It is well that elementary schools should within certain limits exhibit something like uniformity of system; it is well, too, that the ladder by which students rise or may hope to rise from the lowest to the highest rungs of educational competency should be so set up as to make the process of climbing them no more difficult than it must needs be. But freedom, spontaneity, individualism, have been the rule in all departments of English life. No power can be more chilling in its effect upon intellectual enthusiasm than the dead hand of a code. Individualism with all its faults is better suited than the rigidity of the French or the formality of the German educational system to the hereditary genius of the English people. It is necessary, therefore, that the control of the Board of Education, while it is definite, should be as elastic as possible.

Again, the State has laid upon the local education authority the duty of supplying the necessary accommodation in elementary schools, except so far as it is supplied in non-provided or denominational schools through the agency of voluntary subscriptions. But it has scarcely taken account of the difficulties lying in the way of an education authority which can issue no precept of its own. Every education committee in England to-day is harassed by the obligation of persuading a body so hard-hearted as a city council, which is naturally inclined to look upon economy with more favour than upon education. The antagonism between the schools and the rates remains constant. Happy indeed is the education committee in a city where the council rises above the temptation of regarding education as an extravagance or a luxury.

The provision of free meals for hungry children is an admirable reform. For if children under the law must go to school, they cannot go with any advantage if they are hungry. But free meals cost money; and the money spent upon the meals may easily be deducted from the total sum which is spent, or ought to be sepent, upon education.

Not less admirable a reform is the physical inspection of children in elementary schools. Educational as well as medical science has learnt that hygiene is a powerful factor in the success of schools. But it is necessary to pay for a doctor's time and a doctor's skill; and if the physical welfare of the children is improved by medical attention, it is possible that their mental welfare may be impaired for lack of money.

It must be added that, in proportion as Education Committees undertake and prosecute the benevolent work of caring for the crippled and afflicted children of the country, their just demands upon the public purse will necessarily become more pressing.

Upon the whole I am not disposed to criticise the education which is given in the different standards of elementary schools. It is not, I think, ill adapted to the twofold object of preparing the children for their normal duties in after-life, and of offering to especially intelligent children the chance of rising to a higher position than that in which they have been brought up. But no teaching, however reasonable in itself, can be properly imparted where the classes of children are too large. If I have learnt any lesson by my educational experience, it is that difficult cases—and these are the cases which try the teacher's skill—need a great deal of individual time and thought. I used to feel, when I was a schoolmaster, that there were not more than two or three of my pupils whom I did not think I could have helped and possibly saved, had it been in my power to spend sufficient thought and time upon them. It is overcrowding which is the difficulty in schools as well as in homes; and I do not believe that any schoolmaster or schoolmistress can do full justice to a class of more than twenty or at the most twenty-five small children.

But this, again, is a matter of expense, and as a matter of expense it touches the rates.

Upon the whole, too, I do not regret the substitution of Education Committees for the original School Boards. It is true that the ideal picture of School Boards consisting of educational experts who cared pre-eminently or exclusively for the educational needs of their city is naturally pleasing to the imagination. But the School Board, with its power of invading the public purse, lent itself to friction with the civic authority. At present the Education Committees connect the education of a city by a direct personal chain with its civic administration; and if the civic element upon the Education Committees should ever seem to fail in educational knowledge or interest, the opportunity of coopting educational experts, and among these experts men and women who might often shrink from the ordeal of a hotly contested election, would seem to afford a sufficient guarantee against indifference.

But after some careful consultation with persons who in Manchester and elsewhere have studied for many years the problem of public elementary education, I have been led to the conclusion that the reforms needed at the present time are principally the following:

The control of the Board of Education over local education authorities has become too strong and too stringent. It is probably stronger and more stringent now than it has ever been since 1870. It would be wise, I think, to leave or to place greater administrative power in the hands of the local education authority. Local authorities understand local needs. So long as they do not depart from the general principles laid down by the Board of Education, they should be free to expend each its share of the public monetary grant in the way which they hold to be best for their own communities.

I see no need for a dual system of inspectors in elementary schools, and I think it tends to the interference of H.M. inspectors with details upon which their judgment is sometimes more confident than their knowledge is profound.

It is difficult in speaking of inspection to refrain from all allusion to the notorious circular letter which was issued some time ago in the name of Mr. Holmes. That letter was not, I think, so wrong in sentiment as in language. Inspectors chosen from the ranks of the elementary-school teachers may be deficient in breadth of sympathy, as other inspectors educated in the ancient universities may be deficient in practical experience. It is much to be hoped that the unnatural contrast between the antecedents of two classes of inspectors will pass into the background, and that the duty, which lies upon all education authorities, of appointing the best men or women as inspectors, whatever anyone's antecedents may have been, will regulate all appointments in the future.

The period of a child's school life is now too brief. There should, I think, be a universal minimum age at which children may leave school. It should probably be fourteen years. But whatever that age is, it should be absolute. It should be wholly independent of local by-laws, of the passing of standards, or of attendance at school before the age of fourteen.

The question of evening schools is fraught with difficulty. To make attendance at such schools compulsory would be to run a serious risk of over-pressure. It is probable that sympathetic cooperation between local education authorities and the employers of labour in the locality will in this matter afford the best hope of success. For it is the interest of the employers themselves that their employees should not cease to improve themselves in knowledge so soon as they leave the elementary schools.

The need of the local education authority for increased financial help out of public funds was recognised, I think, in Parliament during the debates on the last Education Bill. The State cannot make fresh demands upon the education authorities without granting them fresh funds. Yet there can be little doubt that the feeding of necessitous children and the care of the epileptic, feeble-minded, and crippled children will soon or late become duties imposed by Parliament on all local education authorities.

Lastly, the connection between the elementary school and the university or the technical school should be made complete. At present the elementary school provides education for children up to their fifteenth year. The university or the technical school does not admit pupils under sixteen years. But education, when it is once broken, is hard to resume. The educational system, if it is to be efficacious, must be continuous.

A public elementary system of education must be complete in itself, so far as it prepares children physically, intellectually, and morally for the affairs of life. But it must not lose sight of the possibility that some, and those the most promising, of the children educated in elementary schools will deserve to rise to a higher than an elementary educational standard.

It is probable that the ascent of pupils from one class of school to another will become more usual in future years. This ascent will be effected or facilitated, as to some extent it already is, by the provision of free places, bursaries, exhibitions, and scholarships. Even now boys educated in elementary schools have attained the highest honours in the ancient as well as in the modern universities. Some such boys have won admission to the public schools, and among these schools to boarding schools as well as to day schools. Whatever amount of social exclusiveness may still apparently linger in that most truly democratic of English institutions, a public school, it seems to me impossible that in a democratic age there should ultimately remain any school which will not open its doors to pupils who are drawn from every social section of the community. In the education of girls, the schools of the Girls' Public Day School Company and other similar schools, whether publicly or privately governed, have done much to mitigate, if not to dissipate, the social differences among girls living in the same locality.

But the agencies by which children of comparatively poor parents have in the past been enabled to receive an education in the schools, and indeed in the universities, of the rich are, I am afraid, coming to be gravely abused. Scholarships and exhibitions were designed to remedy the disadvantage of the poor, not to accentuate the privilege of the rich. To confer pecuniary rewards upon boys and girls whose parents can well afford to dispense with them is to foster a double abuse. It is to spend money where money is not needed, and to withhold money where it is needed. Yet in the public schools, and to some extent in the universities, scholarships and exhibitions tend to become the perquisites of the rich. In the field of secondary education the competition for scholarships and exhibitions has become so severe that scarcely any boy in the examination for them stands a chance of success, except at the cost of three or four years spent beforehand in an expensive preparatory school. But as rich boys are the only boys whose parents can afford this preparatory expenditure, it follows that rich boys are generally the successful candidates for scholarships and exhibitions. The evil is scarcely capable of exaggeration. It were bad enough that a rich boy, if he competed on equal terms with poor boys, should obtain a pecuniary reward which they do, and he does not, need for educational purposes. But when it is the rich alone who enjoy the opportunity, or the most favourable opportunity, of winning the pecuniary rewards which were justly intended for the poor, a case for drastic reform seems to be made out.

At the ancient universities the sons of rich parents, although they are generally eligible for such prizes as scholarships and exhibitions, do not possess the same advantage in competing for them. More, too, has been done in the universities than in the public schools to provide means by which the sons of rich parents may enjoy the distinction without the emolument of a scholarship. But it is an urgent matter that, alike in the colleges of the universities and in the public schools, the pecuniary benefits, by which alone deserving boys can rise above their hereditary surroundings, whether bursaries, exhibitions, or scholarships, should be strictly confined to the sons of the poor.

Here perhaps it is permissible, as it is certainly natural, to enter a protest against the established tyranny of examinations. Examination was once the obvious remedy for favouritism. But a mere examination in knowledge can never test some of the highest qualities which fit men and women for the service of the State. In India even more than in Great Britain the failure of examinations is conspicuous. A facility for answering questions upon paper is easily associated with grave defects of intellect and character. In proportion, then, as favouritism ceases to be a public danger, examinations will, I think, lose something of their fatal authority. It is difficult to doubt that in the future candidates for public office will be required to pass a qualifying examination, but that the election will, at least in some degree, turn upon qualities which are not so easily tested by examination in writing.

Nor is this the whole evil. There is only too much danger that examinations may create a false ideal of educational success. The object of all education, as I have said, is to prepare pupils for the civic duties of mature life. It is not the intellectual attainment of the young at the age of thirteen or eighteen or even twenty-two, it is rather the service which they render to the State in the maturity of their powers, which is the proof of the teacher's influence upon their lives. The preparatory schools, which have become such important features in the field of secondary education, have done much useful work. The decadence of bullying and perhaps of other evils in public schools is largely due to the elimination of quite young boys from public-school life. The years of a boy's life from nine to twelve, but not, I think, to a later age, may well be reserved for the preparatory school, as the years from thirteen to eighteen for the public school. But the forcing process which is sometimes applied to young boys in preparatory schools, not only in their lessons but in their games, is fraught with serious peril. A preparatory-school master, if he thinks of his own school alone, may do even worse harm than a public-school master by sacrificing the future of his pupils to the present. When I was a headmaster, I knew of one preparatory-school master who tried to win boys to his school by offering what he called pre-preparatory scholarships to boys of eight or nine years of age, in the hope that these boys might after a time serve as advertisements for his preparatory school by winning scholarships from it at the public schools. But preparatory-school masters are not alone in fault. It is, I am afraid, easy to think of headmasters who have attained what I can only call an ill-deserved reputation, because their pupils have won numerous scholarships and exhibitions upon leaving school, when those same pupils had been mentally exhausted in youth, and their after-life in no way answered to the promise of their early days. "By their fruits ye shall know them": but the fruits of a true education are seen not in the spring but in the summer or the autumn of a well-spent life.

It is with reference to the final goal of education that the subjects suited to the secondary curriculum must be judged. If the possible subjects are too many, it becomes necessary to strike the balance between utility and culture, and so to decide which subjects are indispensable and which may fairly be subordinated or postponed.

The most striking change which has come over secondary education has arisen from the number of subjects now claiming admission to the curriculum. Scarcely more than fifty years ago the headmaster of a public school was almost at his wits' end to fill up the time-table of his pupils. Dr. Arnold was appointed to the headmastership of Rugby in 1828, and Dean Stanley says of him that "he was the first Englishman who drew attention in our public schools to the historical, political, and philosophical value of philology of the ancient writers, as distinguished from the mere verbal criticism and elegant scholarship of the last century." He adds that, "besides the general impulse which he gave to miscellaneous reading both in the regular examinations and by encouraging the tastes of particular boys for geology and other like pursuits, he incorporated the study of modern history, modern languages, and mathematics into the work of the school, which attempt, as it was the first of its kind, so it was at one time the chief topic of blame and praise in his system of instruction." Other public-school masters followed suit, but they followed slowly. What the system of education had hitherto been may be judged from Malim's "Consuetudinarium," which specifies no subject of instruction except Latin, with a little Greek grammar in the sixth and seventh forms. The dancing-master was a more ancient and more honourable figure in some public schools than any mathematical master. Mathematics, in fact, were not introduced into Eton until 1836. Other subjects in addition to the classics came even later.

But within the last fifty years, not only mathematics but the English language and literature, foreign languages, natural science in its various branches, history and geography, have become competitors with the ancient classical languages for recognition in the curriculum of public schools. There is no one of them which is not worthy of such recognition. But the average intelligence of a public-school boy has remained the same, and the average length of his life in the public school has been diminished by as much as one-half. It has become necessary, therefore, to make a selection between the subjects which might well, if they could, be taught to all boys alike. Nor is this truth less applicable to girls than to boys.

It may be thought that not enough attention has been paid to the order in which particular subjects are taught. The number of subjects imposed upon a child of ten to twelve years is at times not less alarming than forbidding. Psychology suggests the adaptation of particular subjects to the awakening of particular powers at different ages. Even in literature there is a natural affinity which is too often disregarded between books and the ages at which they ought to be read. How many children have read "The Pilgrim's Progress" at too late, or have read "Hamlet" and "Paradise Lost" at too early, an age for true appreciation! In literature as elsewhere discrimination is the watchword of educational success.

From these considerations it seems to follow that the scientific educator must choose certain subjects as the basis of secondary education, and I venture to think that these subjects should be as nearly as possible common to boys and to girls. Other subjects can be left to the choice of particular students at a later period of their lives. Not all subjects are possible or useful to all students. Soon or late, then, uniformity of teaching must give way to specialisation.

Yet education loses a great part of its value unless it ensures to all educated men and women what may be described as a common educational property. It is desirable that they should not only all learn some things which are worth knowing, but that they should learn the same things. For upon community of information or of interest depends the sympathy of all educated people. If one person knows nothing but French, a second nothing but chemistry, and a third nothing but mathematics, it is evident that they possess no common stock of knowledge; no interchange of sentiments or ideas is possible between them. All sound secondary education, then, postulates a broad basis of common knowledge, or, in other words, a certain body of knowledge which is possessed by all students in common. Upon this basis must be built a superstructure varying in accordance with the needs or capacities of the pupils.

What, then, are to be the basal subjects of secondary education?

They must be few, they must be suitable to the tender years of school life, they must be practically useful, and yet they must possess the element of culture.

Religion, of course, will be one, for it is the paramount factor in the discipline of character.

The study of mathematics possesses the unique merit that it shows what proof is; it distinguishes certainty from probability; it evidences the narrow limits within which certainty is possible.

Natural science in its various branches is especially valuable as cultivating the faculty of observation. Scientific facts can be generally tested by experiment. It is only the pupil who has learnt at least the elements of natural science that begins to feel at home in the world in which he or she lives.

But among educational subjects the palm, I think, belongs to language, if only because language is the subject which stands, by its character as well as by its origin, in the most intimate relation to human nature. Men and women are not generally concerned with questions which can be absolutely and ultimately determined. Most questions in life are probable, but not certain; it is "probability," as Bishop Butler says, which is "the very guide of life"; and such, too, are generally linguistic questions. They do not admit of certainty; they can be decided only probably; and the decision of them requires tact, judgment, and feeling. That is the reason why the school of languages is called Literae Humaniores at Oxford. Language is the one pre-eminently human or humane study.

But it is evident that different languages, as instruments of education, may stand on different grounds.

English boys and girls cannot afford to be ignorant of their own language or literature or history. For they use every day the English language; their minds are fed by English literature; and the past history of their country affords them guidance in the present and the future.

Foreign languages, on the other hand, are practically useful in the relation of Englishmen to other nations. It is possible that these languages will become less important as the English language spreads over the world. But for the present at least a knowledge of some modern language is desirable, not only as a means of mental discipline, but also as a means of intercommunication. One modern language at least, then, may fairly be regarded as entering into the basis of secondary education; and that language at the present time would naturally be French, although much is to be said for German and something for Spanish.

The educational difference between languages and other subjects is, I think, more clearly marked than the difference between one language and another. Whatever intellectual benefit is derivable from an ancient language may in a greater or less degree be derived from a modern language. But it has been shown by many writers, as, for instance, by J. S. Mill in his rectorial address at the University of St. Andrews, that a classical language, like ancient history, if only in virtue of its remoteness from present interests, possesses some educational advantage, and this advantage is particularly clear when an ancient language stands in the relation of Latin to the Romance languages or to any considerable number of languages in actual use. Latin must therefore enter into the general curriculum, and I attach great value to keeping Latin as a subject of general study in secondary schools. For the prejudice of parents in the present day against dead languages is unhappily strong. I have spent much of my time in trying to convince parents that their sons would be better educated by the study of Latin, if not of Greek also. It is for this reason that I regret the somewhat pedantic insistence upon pronunciation of Latin according to a method which, whether it be historically correct or not, will certainly tell against the universality of Latin as a subject of study. I do not believe the modern pronunciation is correct; but whatever may be the philological value of that pronunciation, I feel no doubt that the artificiality, as it seems to parents, of the non-English way of pronouncing Latin will, like the artificiality of the Greek type, create a prejudice in many minds against the study of Latin. Nor is this all; for the study of Latin loses a good deal of its practical value if every or nearly every Latin word is by the method of its pronunciation divorced from the corresponding word in English. It does not really matter in the present day how Latin is pronounced. Latin is no longer a medium of oral communication, even amongst scholars. The vital matter is that Latin should be one of the subjects constituting the permanent basis of education in all secondary schools.

Apart from these subjects, viz. religion, English, French, Latin, mathematics, and natural science, there is none, I think, which can justly claim a part in that knowledge which I have ventured to describe as the common property of all boys and girls in secondary schools. It is, in my judgment, a happy circumstance that preparatory-school masters have practically decided to relinquish the teaching of Greek, and to concentrate their efforts upon such subjects as form the natural basis of secondary education.

But upon the basis so constituted the teacher will try to erect a varying superstructure, by offering as wide a range as possible to individual tastes. For if the secret of education lies in discovering what a pupil's capacity is, and so in helping him or her to cultivate it, education must pass soon or late from the common basis of subjects to specialisation. It is not my business now to decide how the principle of specialisation should be applied. That is a problem which the individual schoolmaster or schoolmistress must work out for himself or herself. The two points upon which I would venture to insist are the common educational property and the wide elasticity allowable so soon as this common property has been gained. But I am of opinion that, while specialisation is allowable and desirable in the later years of a boy's or girl's life, it should never be complete. The dying out of double degrees in the Universities of Oxford and Cambridge has always seemed, and still seems, to me unfortunate. For it means that nobody now gets so thorough an education as was possible if the student applied himself through his life at school, as well as at the university, both to classical and mathematical studies. The amplification of the several studies may have justly affected the course of education in the universities; but it is my deliberate conviction that a boy or girl whose time is wholly or mainly given to one subject only during school life loses a signal opportunity of obtaining a generous education.

It is tempting to me as an old schoolmaster to linger on the field of secondary education. But the limit of time at the disposal even of the president of a section forbids me to think of adverting to more problems of secondary education than the two following:

Public opinion has always been divided in the education, whether of boys or of girls, between boarding schools and day schools. Adam Smith in his "Theory of Moral Sentiments" went so far as to say "that the education of boys at distant great schools, of young men at distant colleges, as well as ladies in distant nunneries and boarding schools, seems in the higher ranks of life to have hurt most essentially the domestic morals, and consequently the domestic happiness, both of France and of England." The complete severance of a boy or a girl, except during the holidays, from parents and family is evidently, or may evidently prove to be, an evil. It tends to undermine some of the graces of character; it produces in boarding schools the same defects, but perhaps, too, the same merits, as are observable in celibate religious institutions, like monasteries and nunneries. There is too much tendency, especially among parents of the wealthy class, to feel that they have done their duty to their children in paying their children's school fees, and to hand them over to the schoolmaster or the schoolmistress without any thought of the influence which the home ought to exercise upon young lives. It is reasonable to suppose that, if the sense of parental responsibility could be revived, fathers and mothers would be more anxious than they are now to keep their children at home in the early years of their lives. Preparatory day schools, at least in the great cities, will, I think, acquire a growing importance. But at present the choice between boarding schools and day schools for boys, and in a less degree for girls, is largely determined by pecuniary considerations. For in truth the great public boarding schools are such characteristic features of English life among the upper social class, they have gathered to themselves such a wealth of tradition and influence, they are so deeply rooted in the confidence and affection of the English-speaking world, that it would be difficult, if not impossible, to replace them. Nor can it be doubted that the education given in these schools, however rough and ready, however deficient in some respects it may have been, has yet done much, in Canning's bold ecclesiastical phrase, to produce "a supply of persons duly qualified to serve God both in Church and State," and has tended to foster some of the qualities by which the English race has attained its sovereign position in the world.

Again, there is the question of co-education. For if the early education of boys and girls may, as I have argued, safely proceed on the same lines, it may be held that they can well be educated together. Nor is there any valid educational reason why boys and girls should not be educated together, as they are in the United States of America. In England itself they receive their early education, and they are beginning to receive their academic education, together. It is at least conceivable that co-education throughout the period of school life may come to be the rule in day schools. In boarding schools, however, where the life is ordered on somewhat artificial principles, co-education would almost certainly create problems which would enhance the difficulties of the master or mistress. I do not, therefore, anticipate that co-education in schools will assume a large importance in English life.

So far I have tried to indicate a few of the problems calling for the attention of persons who are engaged or interested in secondary education. Here at least I may claim to speak with some degree of experience. It is with hesitation that I approach the subject of the highest education as given in the universities, especially in the Universities of Oxford and Cambridge.

The elasticity which is characteristic of English life has in the last half-century created a number of local universities beside the two ancient universities. It would be unwise, even if it were feasible, to aim at assimilating the ancient and the modern universities. It is not impossible that the modern universities will lead the way in educational reform. The dead hand of the past lies heavily upon the historical seats of learning. No fact of educational history seems to be stranger than the inability, perhaps I ought to say the unwillingness, of the universities to reform themselves. It might have been anticipated that a home of learning would be a seat of powerful reforming energy. It has not proved to be so. The Universities of Oxford and Cambridge have been reformed more than once, but the reform has come from without and not from within. Whether the present Chancellor of the University of Oxford will succeed in persuading the university of which he is the distinguished head to reform itself without waiting for the action of Parliament is a question on which it would be unsafe for me to venture an opinion. But his plea for reform is itself a proof that reform is needed. It will not, however, be unfitting that I should insist upon the value, and the ever-increasing value as I think, of the work belonging to the modern universities in the great cities of the land—can I be wrong in saying pre-eminently to the Victoria University of Manchester? History seems to suggest that the association of a seat of learning with a great centre of industry may produce the best results, in so far as it imparts culture to industry and practicality to learning. The modern universities have appealed with striking success to the generous instincts of local patriotism. They have shown the possibility of gathering an earnest body of teachers, and through them of imparting a genuine intellectual culture to a large number of students, without imposing artificial restrictions upon their studies. They have proved the possibility of uniting men and women upon equal terms in the same academic institutions. The Victoria University has aimed with conspicuous success at solving the difficult problem of uniting the teachers who belong to the different branches of the Church in a common faculty of theological learning. In some of these respects if not in all, the Universities of Oxford and Cambridge will probably follow suit. It can scarcely be doubted that the time is not distant when Oxford and Cambridge will open their doors to students without insisting upon the so-called compulsory study of the Greek language. I speak as one who more than a quarter of a century ago argued against the policy of requiring some knowledge of two dead languages from all students as a condition of entrance into the ancient universities. Such a requirement may have been possible, and even reasonable, when educational subjects were few. It cannot be maintained when those subjects have been greatly multiplied. For the result is either that the study of two dead languages, or at least of one among them, is little more than a farce, or that it causes an unhappy disturbance at a critical period of a boy's intellectual life. Nay, I should be tempted to say that to boys who have received their education on the modern sides of public schools the obligation of acquiring some smattering of Greek knowledge is both a farce and a nuisance.

Nobody feels more keenly than I the intellectual benefit of studying the Greek language and literature. It is my sincere hope, as it is my firm belief, that, when Greek rests upon its own intrinsic merits as a factor in human culture, the study of Greek, if it is less general, will not be less profound than it has been. But times change, and compulsory Greek as a universal subject is unsuitable to the present time, not because it is useless in itself, but because it bars the way more or less against other studies which are still more important. The universities enforce their law upon secondary schools. The schools must teach what the universities require; they cannot teach, or they can only teach within a fixed limit, what is not required at the universities.

In my own mind, however, the abolition of compulsory Greek is only a step to a change in the intellectual atmosphere of the universities. I hope that Oxford and Cambridge will cease to insist upon Greek; but I hope that, when they cease to insist upon Greek, they will require from all students the evidence of some serious learning in some subject or subjects of higher education. Nobody who is conversant both with the ancient and with the modern universities can fail to be aware of the difference in their tone. The atmosphere of a modern university is intellectual. Men and women come there as students; they come to learn, and they do learn. At Oxford and Cambridge the atmosphere is much more social; and the number of undergraduates who can in any sense be called serious students is but a fraction of the undergraduate body. The time is, I hope, approaching when a degree conferred by the Universities of Oxford and Cambridge even upon a passman will be a certificate of a certain definite proficiency in some recognised subject of academic study. For it seems to me that the ancient universities in conferring degrees without an adequate guarantee of knowledge are largely responsible for the indifference of English society as a whole to the value and dignity of learning.

No doubt there is force in the plea that the universities cannot afford the pecuniary loss which would result from the policy of excluding passmen, or of pressing hardly upon them. It may be answered that no pecuniary consideration can justify a university in ceasing to be primarily a learned body. But women students are more earnest than men; and if the universities grant degrees, as I hope they will, to women equally with men, they will probably find that they will receive as much money from the addition of the serious students, who will then belong to them, as they now receive from those students who are not serious at all.

The Universities of Oxford and Cambridge have made frequent appeals for pecuniary support. Education—especially scientific education—is expensive, and it tends to increase in expensiveness. But I have sometimes wished that, before money is poured into the exchequers of the universities, a commission, composed of men who are fully sympathetic with academic culture and yet have been trained in the habits of business, could issue a report upon the use now made by the universities and by the colleges of the funds which they severally command. I am of opinion that such a commission would not prove unable to suggest the possibility of large economies which might be carried out without impairing the efficiency of the universities as seats of learning, or even of the colleges as homes for the students whose proper object in their academic life is to acquire learning.

All that remains is to offer an opinion in some few brief words upon some subordinate matters of academic education.

There is something to be said in favour of, but more perhaps to be said against, the proposal for two concurrent kinds of degrees, the degrees of Bachelor and Master in Arts and of Bachelor and Master in Science. For the academic degree possesses a recognised advantage as setting one and the same hall-mark upon all persons who possess it. It would be less distinctive, and therefore less valuable, if its significance were not uniform. Nor does there seem to be any valid reason against conferring the degree of B.A. and M.A. upon all students who have shown themselves to possess a certain uniform culture, whatever special study or studies they may have pursued and whatever degree of excellence they may there have attained, after satisfying the requirement of culture demanded from all persons who aspire to the possession of an academic degree.

Again, it is desirable that every university should be free from theological restrictions. I look forward, therefore, to the time when the Universities of Oxford and Cambridge will recognise Nonconformists no less than Churchmen as eligible, not only for degrees, but for lectureships and professorships in the technological faculty. There is a broad distinction between the study of theology and the profession of theological beliefs. It is no hardship upon a student that he should be examined in theology so long as he retains his complete freedom of theological opinion. That theological recognition should be accorded to none but persons of particular views upon theology is in conflict with the highest interests of theological learning. At present the Universities of Oxford and Cambridge are the close preserves of the Church of England; the natural result is that the modern universities tend to become the preserves of Nonconformity, and neither class of university is benefited by the consequent one-sidedness of theological study.

The co-education of men and women in the universities, whether ancient or modern, is already an established reality. The only difference is that co-education is recognised in the modern, and is not recognised in the ancient, universities as necessarily leading to an equality in the matter of degrees. The real objection to placing women on an equality with men in their relation to a residential university is the difficulty of finding room for a number of female as well as male students within the precincts of the same university. On that ground alone there is some advantage in universities or colleges for women only, such as the Royal Holloway College; but experience has shown that colleges for women do not flourish except in close relation to a university in which the education of men is carried on, and I feel no doubt that the granting of academic degrees at Oxford and Cambridge to women as well as to men is merely a question of time.

No critic of the ancient universities, and certainly no one who has spent some happy years there as an undergraduate and a Fellow, can forget that the social as well as the intellectual side of the life is a part of its privilege and benefit. But that social intercourse would lose something of its value if students of different classes and different creeds did not mix freely. It is too often forgotten, in the zeal for ecclesiastical propaganda, that one element of education lies in teaching people who do not agree to work together. To make the least, and not the most, of personal differences is a factor in the life of universities. It is for this reason that I do not look with any great favour upon the institution of special colleges set apart for Churchmen or for Nonconformists or for men of poor and humble circumstances. It is better that such students should, as far as possible, associate with other students; for in such proportion as undergraduates of religious feeling or of strenuous self-denying character are educated by themselves, there is a diminution of their valuable influence on the mass of the undergraduate body. There might as well be Conservative Colleges and Liberal Colleges as colleges of a special and exclusive theological character.

Colleges are expensive features of academic life, and they tend to become more expensive; but the expense is justified by the benefit which the students may receive from the influence of their teachers upon their lives. But if colleges are to exist as integral parts of the university, there should be a sufficient number of Fellows and tutors living within their walls. No feature of modern life at Oxford or Cambridge is more pitiable than the spectacle of a married don coming into his college at a late hour of the evening, with his carpet-bag in his hand, to fulfil the statutory obligation of sleeping within the walls. No deep personal interest or influence of a tutor in the lives of his pupils is possible in such circumstances as these. If only it were possible to defer the opportunity of marriage until a man has rendered some years of service by residence within the walls of his college, and then to grant it only to men whose service the college wishes to retain, the collegiate life of the ancient universities would be less likely to lose its effective value.

But when all is said, how great is the charm of the ancient English universities! They are unique; they exercise a lifelong spell upon pupils who have spent three or four years within their ancient walls; they foster, even if unconsciously, a noble sense of patriotic duty; they haunt the memory; they are fruitful in high and generous and sacred inspirations.

What is the spirit of a university? How is it born? How does it operate? Why is Cambridge in a special sense the home of mathematics, and Oxford of letters? Why is it that Oxford finds so many, and Cambridge so few, representatives upon the public Press? Cambridge, it seems, has played the greater part in the thought, and Oxford in the life, of the nation. But why is it that Cambridge has given to the world sons more famous, it may be, than any whose names belong to the sister university—Bacon, Newton, Cromwell, Milton, and Darwin? Why, above all, is Cambridge in so pre-eminent a degree the university of the poets? Such names as Milton, Ben Jonson, Herrick, Cowley, Byron, Gray, Wordsworth, Tennyson, belong to Cambridge alone. Nothing can replace, nothing perhaps can greatly affect, the relation of the ancient universities to the country the ornaments of which they are. What is needed, and will be more and more needed as democracy extends its power, is to enhance the strength of the influence which the universities exercise upon the national life at large.

So I bring this imperfect review of the educational problem in its present aspects to a close by insisting in two or three final sentences upon the supreme dignity of the teacher's profession. The man or woman who elects to become a teacher chooses a great responsibility. It is well that teachers should be disciplined for their calling by a system of training in the educational art. The theory of education as set forth in the writings of great educators like Comenius, Froebel, Pestalozzi, Arnold, Thring, Fitch, and many others, should be well known to them, even if the practical side of education is best learnt, or can only be learnt, by practice. Education needs the best men and the best women. It must, therefore, be set free from such bonds as have tied it to the clerical profession; nor can I think it is ever well to exact religious tests of teachers, for tests are apt to affect tender consciences alone. If only teachers are asked whether they wish to give definite religious instruction or not, and are subjected to no drawback or disadvantage if they choose not to give it, I think the teachers in all grades of schools may be trusted not to abuse their sacred opportunity. They must teach their pupils to love learning and virtue, and to love them for their own sakes. They must remember that it is the personality of the teacher which is the chief source of his or her influence on the pupils. They must ever be trying to make themselves more and more worthy of their responsibility. "Thou that teachest another, teachest thou not thyself?" must be the motto of their daily lives. But where the educational profession is one in all its branches, where it is actuated by a due sense of responsibility, where it aims in season and out of season at cultivating habits of self-respect, self-sacrifice, patriotism, and religion in the children who will be the citizens of the future, where it remembers that the supreme triumphs of educational skill are good men and women, good fathers and mothers, good servants of the State and of the Church, there is no ground of fear for the country or the Empire.

CHEMISTRY AT THE BRITISH ASSOCIATION.

THE meetings of the Chemistry Section were of unusual interest and briskness, all the speakers copying the example of clearness combined with brevity so admirably set by Prof. Walker in his presidential address. The section had organised its programme carefully beforehand and the arrangements made were strictly adhered to: as was to be expected, the subjects discussed were largely of a physical chemical character. A feature of the attendance was the presence of a number of members from the Physical and other sections; it was evident that papers of a type likely to bring sections together and to provoke discussion between the sections are those most required at the sectional meetings of the association.

There still remains much to be done by those responsible for the organisation of the Association in the way of preventing overlapping; it was noticeable, for example, that several chemical papers were read in other sections which should properly have been brought before Section B. It seems a pity also for a section which is taking part in a joint discussion to arrange for a separate meeting of the section at the same time, as this procedure affords specialists an excuse for avoiding the joint meeting. They thus neglect the opportunity of realising how differently in many cases the same facts are interpreted by followers of another branch of science.

The sectional meeting room was at first situated in Fawcett Road, a considerable distance from the other sections; this position was found to be so inconvenient that a move was made to the Municipal College. It would appear important that Sections A, B, and G be housed in close proximity, so as to facilitate exchange of views between members of these sections. The section was supported by several foreign chemists of distinction.

The proceedings were opened with Prof. J. Walker's address, following which Prof. Carl Barus, of Providence University, U.S.A., read a paper on the diffusion of gases through water in which a novel and simple experimental method was described. The method consists in finding the temperature-pressure conditions for the flotation at a given level of a cylindrical cartesian diver, in which the gas to be examined has been imprisoned. Slides were exhibited showing the details of the apparatus and the mass-time graphs for the interdiffusion of gases through water. Whereas the graphs for a single gas are linear, those for pairs of gases are of indefinite variety, and the very curious result of a gas apparently diffusing against the pressure gradient is frequently met with. Such anomalous results are explained in terms of the partial pressures of the constituents of the imprisoned impure gas.

Dr. W. C. McC. Lewis dealt with the compressibility of mercury. He regards the usually accepted value as incorrect, since for mercury the difference between the latent heat of vaporisation as determined and calculated from a formula involving the compressibility is large. Dr. Lewis suggests as possible sources of error in the experimental determination :—

(1) Effects produced by a layer of absorbed air or moisture, or both, between the mercury and the walls of the vessel;

(2) That the liquid (molasses mixture) into which the piston was dipped before insertion in the mercury is not completely removed; and

(3) The unavoidable slip of the mercury past the piston.

All these effects act in the same direction; *i.e.* they give rise to too great a volume decrease, that is, to too high values of the compressibility.

Dr. J. F. Thorpe followed with a somewhat technical paper on the chemistry of the glutaconic acids, in which he quoted experimental evidence to show that the molecule of glutaconic acid must have a symmetrical structure, and that the cause of the identity of the α and γ positions must be of the same order as that determining the equality of the meta positions in the benzene ring. Some interesting conclusions based on the experimental study of the properties of the alkylglutaconic acids were also described.

In a discussion, Dr. Lowry differed from the author's interpretation of his experiments.

Mr. G. Le Bas gave a summary of an elaborate paper on the effect of constitutive influences on the molecular volumes of organic compounds at the boiling point; the subject is too complex to allow of a brief abstract.

The last paper, by Prof. R. Wegscheider, dealt with the influence of substituents on reaction velocities. The elucidation of the laws governing the transformation of organic compounds is to be found in the study of reaction velocities. Prof. Wegscheider has chosen for this purpose the esterification of asymmetric dibasic acids and the saponification of their esters. He finds there are at least two different properties of the substituting groups which act to determine their influence on reaction velocities. One of these is the influence on the electrolytic dissociation; the other is termed steric hindrance, though it is a function of several single properties. Laws for the esterification of dibasic carboxylic acids were based on these considerations and their behaviour in actual practice exemplified; though on the whole satisfactory, there are numerous exceptions, but this was to be expected, as the assumption, that one property only of the substituent influenced the reaction velocity, can only be a rough approximation.

A report on the present position of electric steel making was presented by Prof. A. McWilliam. This is in type, and can be obtained at the British Association offices. The report shows the progress in the electric steel melting industry made during the year, whilst the actual state of the industry can be judged from two tables, in which are shown the furnaces, capacities, and kind of work done by the firms of Kjellin, Röchling-Rodenhauser, and Héroult. In this country we have Héroult's furnaces of a united size of 25 tons. A list is given of the applications of the electric furnace. The report is mainly a statement of industrial advance, and is somewhat disappointing from the point of view of the chemist.

The commitee appointed at the Sheffield meeting with a grant to study the influence of carbon and other elements on the corrosion of steel, reports on the behaviour of a series of six pure iron-carbon alloys prepared by the coke crucible process at Sheffield University. Carbon exerts two types of influence on the corrodibility dependent upon the condition of the carbide in the steel. In the rolled and annealed specimens the corrodibility rises to a maximum at the saturation point (0·89 per cent. of carbon), and then decreases upon the appearance of cementite in the steel. In the hardened and tempered specimens the corrodibility rises continuously from 0·1 per cent. to 0·96 per cent. of carbon, no maximum being observed at the saturation point. It is considered that the finer the state of division of the carbide in the pearlite the greater the liability to corrosion when immersed in sea water.

The treatment previously undergone by the steel also influences the solubility in acid solution. Curves are given for steels treated in different ways, showing the effect of increasing proportions of carbon. It is established that the resistance offered by carbon steels when immersed in solutions varies considerably, acording as to whether the solution is of the sea-water type or is acid in character. Each case must therefore be considered separately, and it is impossible to specify any particular composition or treatment offering the best resistance to attack under all conditions.

Friday, September 1, was devoted to papers on indicators and colour. Mr. Tizard's paper on the sensitiveness of indicators will be published in full, and copies will be available at the offices of the British Association. His main conclusions are as follows :—An indicator is now regarded as a pseudo-acid or base: the undissociated molecule consists of two, or more than two, tautomeric forms in equilibrium. This conception does not affect Ostwald's method of treatment, provided that the tautomeric changes that may take place are practically instantaneous. From a physico-chemical point of view the ions may still be regarded as differently coloured from the "undissociated molecule," if it be understood by this expression not one particular molecular species, but the equilibrium mixture of the various forms which the indicator can assume in its undissociated form. Applying Ostwald's dilution law to the special case of indicators, it is easy to show that when the colour of an indicator in solution is exactly midway between the extreme colours of its dissociated and undissociated forms, then the concentration of hydrogen ions (C_H) in the solution must be numerically equal to the dissociation constant of the indicator. Further, if this be denoted by $K\alpha$, the colour change takes place mainly between concentrations of hydrogen ions of $10K\alpha$ and $\frac{1}{10}K\alpha$. It follows that the most useful indicators are those which have dissociation constants not very far removed from 10^{-7} (the concentration of hydrogen ions at the true "neutral point"), between 10^{-5} and 10^{-9}, for example. An indicator which is a very weak acid or base is of no more value than one which is very strong. It is of importance to know the dissociation constants of indicators accurately.

If the range of sensitiveness of an indicator is known, it is possible to deduce the "end-point" of an indicator: that is to say, the probable concentration of hydrogen (hydroxyl) ions in a titrating solution at the point where titration is usually stopped. The end points of indicators can also be found by direct experiment; as a rule it is, of course, only possible to stop a titration *between* certain concentrations of hydrogen ions, the extent of the range depending on a number of factors.

The accuracy of a titration of any acid by any base depends very largely on the proper choice of an indicator. This may be seen most clearly by drawing curves showing the concentration of hydrogen ions in a solution of a salt when small quantities of acid or base are added in excess. From such curves it can be deduced that an indicator which has a sharp end point in any particular volumetric operation gives an accurate result to within about two parts in a thousand.

Dr. Lowry gave a valuable paper on the origin of general and specific absorption, virtually an extension of the report of the Commitee on Dynamic Isomerism, which is doing work of extreme value in this difficult field. During the past year attention has been directed to the study of general absorption, and attempts have been made to determine the approximate positions of the inaccessible bands to which this type of absorption curve appears to be due. The method adopted depends on the fact that most of the optical constants of a substance increase with great rapidity when an absorption band is approached, and appear to tend towards an infinite value in the case of a sharply defined absorption-line. With carbon compounds the magnetic rotatory dispersion has been found a convenient property to discuss, and the measurements have been used to calculate the position of the heads of the inaccessible bands by which the general absorption is produced.

The chief conclusions drawn are that the optical properties of most saturated carbon compounds are determined by an absorption in the far ultra-violet. The dominant absorption is brought nearer to the visible region by introducing an ethnoid linkage, as in allyl alcohol, or a benzenoid nucleus, as in phenylethylcarbinol, but in none of the simple compounds investigated does it fall within the region usually photographed in the study of absorption spectra.

Mr. J. E. Purvis described the ultra-violet absorption spectra of the vapours of organic substances, as compared with their absorption in solution and in thin films, and discussed the results from a consideration of the movements of the atoms of the molecules being influenced by their nature, weight, type, and orientation. The vapour molecules have a greater freedom of movement and a considerable number of bands are produced. In solution the solvent acts partly as a constraint on the vibrations, partly as a barrier to the number of encounters, and partly as an absorbent of the radiant energy, so that the narrow absorption bands of the vapours are usually replaced by wide diffuse bands. In thin films the movements of the molecules are further restricted; the selective absorption is not unlike that in solutions, but the bands are shifted more towards the less refrangible regions.

Dr. P. V. Bevan introduced the subject of absorption and dispersion in metallic vapours. Following the work done by R. W. Wood in the case of sodium, he has measured the characteristic lines of other alkali metals. These all appear as absorption lines when white light is passed through the vapours of the metals; with increase of density of the metal more lines come into view. They form a series, getting closer together at the ultra-violet end of the spectrum. The bearing of the phenomena of dispersion in metallic vapours on the optical theory was discussed, particularly the views as to the nature of the atom and the vibrating systems that give rise to spectrum lines. Each line of the series is probably due to a special set of atoms, and there are indications that the complexity of a spectrum is not due to complexity of each individual atom, but to differences actually existent in the atom. There is a good deal of evidence leading in the same direction.

Rubidium and cæsium vapours are obtained practically pure by heating the chlorides with lithium, owing to the much greater temperature required for vaporising lithium than for the other metals.

The concluding paper read by Prof. Pope summarised work done jointly with Prof. W. H. Perkin on optically active substances which contain no asymmetric atom in the molecule. The demonstration of the somewhat involved conceptions employed was rendered intelligible by the use of models. The authors have synthesised 1-methyl*cyclo*hexylidene-4-acetic acid and resolved it into optically active components by means of brucine. It is proposed to distinguish this type of asymmetry as "centroasymmetry." The action of bromine and other substances on these acids was described; it is remarkable that no evidence of any optical inversion was obtained. It is noteworthy, further, that the long series of changes to which the centroasymmetric acids were subjected yielded products, which did or did not show optical activity precisely in accordance with anticipations based on the study of the solid models representing the substances concerned. This is an important demonstration of the fidelity with which constitutional formulæ depict molecular configuration, and should not be overlooked by physicists.

Prof. H. Euler, of Stockholm, opened the proceedings on the Monday with a brief paper on the velocity of formation of enzyme systems. The results described, though of a preliminary character, were significant as showing how the amount of a particular enzyme in an organism can be caused to increase by cultivating the organism for several generations under suitable conditions. Experiments on the formation of invertase and of enzymes fermenting glucose and galactose were described. Prof. Euler had been unable to train certain yeasts to acquire the power to ferment galactose. In discussing the paper, Dr. E. F. Armstrong expressed the belief that there was an essential difference between the power to acquire an entirely new enzyme and that of regaining an enzyme, which had not been required by the yeast for many generations, and so had fallen into disuse. The former was impossible, whereas many brewery yeasts were able to regain, as the result of training, the lost property of fermenting galactose.

In opening a discussion on the part played by enzymes in the economy of plants and animals at a joint meeting of the Chemical and Agricultural Sections, Dr. E. Frankland Armstrong gave a definition of enzymes, pointing out their connection with practically all processes of metabolism in living organisms, and emphasising their specific nature. One function of enzymes is to break down complexes in the cell; there is a necessity for some restriction of action; otherwise the cell would soon be killed. The safeguards of nature to prevent this were described. It was shown how the leaves of the cherry laurel, which give off hydrogen cyanide, or those of the Japanese laurel, which blacken, can be used to indicate that changes are taking place in the plant cell. The resting leaf can be stimulated into activity by a number of substances, of which toluene and chloroform are examples, which as a class are characterised by being chemically inert substances, and further by having but little affinity for water. It is suggested that such substances, to which the general name hormone is applied, are able to penetrate the cell and bring about hydrolytic changes within it. A large number of substances which act as very weak hormones are found in plants combined with glucose, as the so-called glucosides. It is believed that one function of glucosides is to act as hormones when a specific mild stimulus is required by the plant. Each glucoside requires an appropriate enzyme to hydrolyse it before its constituents can be effective as hormones. The speaker alluded to the wide distribution of glucosides in plants, and gave an account of work done in localising and studying their appropriate enzymes. Whereas the leaves of a plant contain, as a rule, an enzyme adapted only for the glucoside contained in them, the seeds of the same plant contain an enzyme or mixture of enzymes able to attack a variety of glucosides. The practical application of these researches to a number of problems in animal and vegetable physiology and agriculture was illustrated in detail. The discussion was general, and mainly turned on controversial points.

The rest of the morning was devoted to a paper by Mr. A. E. Humphries entitled "Some Points concerning the Treatment of Wheaten Flour." This contained one new point of very considerable importance. It has been found that the addition of very small amounts of salts, natural to flour or to the ash of wheat, increases the size of the loaf, though it has no effect on the production of gas in fermentation. In one instance the mere addition of water to flour, so long as it was made at a time substantially prior to dough-making, increased the strength of the flour to an extraordinary extent. Investigation showed that, following the addition of water, there was actual change of the organic phosphorus compounds of the flour into inorganic, and that further a still larger proportion of the organic phosphorus compounds are transformed during bread-making. The change is probably enzymic in character.

In conclusion, Mr. Humphries alluded to the difficulties millers have to face, and claimed that they should be allowed to make use of the advances in chemical knowledge in the treatment of wheats and flours.

Tuesday, September 5, was reserved for papers on colloids. A very admirable and fluent introduction on the general theory of colloids was given by Dr. H. Freundlich, of Leipzig. Colloidal solutions stand between the two extremes of true solutions and coarse suspension, such as formed by very sparingly soluble substances which do not react with the solvent. Colloidal metals, sulphides and hydroxides are termed "suspension" colloids or lyophobic sols; organic colloids, which approach more nearly to the true solutions, are lyophilic sols, or "emulsion" colloids. In the coagulation of suspension colloids the electric charge is of importance, and the addition of an electrolyte, by discharging the particles, facilitates coagulation. In the case of emulsion colloids, the individual characters of the substances concerned are the determining factors, electrical conditions being of far less importance. An account was given of the phenomena of adsorption, which the author is inclined to regard as an effect of surface condensation. Finally attention was directed to the bearing of colloid chemistry in a number of directions. A very full discussion followed, in which Sir Wm. Ramsay, Prof. Martin, Prof. Trouton, and others took part.

The ensuing paper by Dr. Barger dealt specially with some applications of colloidal chemistry and its theories to pharmacology. In a second paper Dr. Barger gave an account of the adsorption of iodine by the glucoside saponarin, which, on account of its being a pure substance of definite composition and molecular weight, affords a more favourable instance than starch for the study of the iodine colouration.

The colloid theory of cements was the subject of a very lucid paper by Dr. C. H. Desch. The explanation of the setting of calcareous cements, as caused by the crystallisation of the products of hydrolysis from a supersaturated solution, fails to account for the great mechanical strength of such cements. The colloid hypothesis proposed by Michaelis attributes the setting to the formation of a gel of calcium silicate, which subsequently hardens by loss of water and adsorption of lime. Microscopical examination confirms Michaelis's view. The only constituent of the cement which is acted on is the alite. The hydrolysis of the complex substances contained in the alite first sets free calcium aluminate, which separates in the form of crystals. This constitutes the initial set. The calcium silicate is more slowly hydrolysed, and the calcium monosilicate produced, being extremely insoluble, separates as a colloidal gel. A part of the calcium hydroxide liberated crystallises in large plates, and is readily detected by the microscope, whilst another part is adsorbed by the silicate gel. The gradual increase of strength which is characteristic of calcareous cements is a consequence of the continued adsorption, and of the physical changes in the structure of the gel.

The colloids formed may be examined and characterised by staining with dyes, such as methylene blue, patent blue, and safranin. The principal difficulty in the microscopical examination of cements has hitherto been the brittleness of the material, making it impossible to grind very thin sections, resulting in loss of clearness. This may be avoided by treating the cement as a metallographic specimen, grinding and polishing one surface only, and examining under vertical illumination after etching with weak acids or staining with other reagents.

A brief paper on the rate of coagulation of colloidal copper, by Mr. H. H. Paine, described the preparation of the solutions and their coagulation by simple salts; there is an initial period during which the solution remains clear. The rate of precipitation is proportional to the square of the initial concentration of the colloid; for varying amounts of the electrolyte the rate of coagulation is proportional to some power of the concentration of the salt.

Reports were presented by all the sectional committees, and a new committee was appointed by the section for the study of plant enzymes, with Mr. A. D. Hall as chairman and Dr. E. F. Armstrong as secretary. Dr. Orton reported on the transformation of chloro- and bromo-amines into halogen anilides, on the velocity of chlorination of anilides, and on the formation of nitroamines. The attention of the Electroanalysis Committee has been directed during the past year particularly to the application of the electrometric method to the titration of weak acids in such liquids as tan liquors.

GEOLOGY AT THE BRITISH ASSOCIATION.

THE proceedings of Section C (Geology) were not marked by any epoch-making paper, but a number of subjects of geological interest were dealt with. On Thursday (August 31) the section opened with the address of the president (Mr. A. Harker, F.R.S.), which was a scholarly and stimulating treatment of some aspects of modern petrology, in which the arguments of his treatise on "The Natural History of Igneous Rocks" were followed to further conclusions on the conditions of their distribution and genesis.

Of those who did yeoman service to the section, Mr. Clement Reid, F.R.S., came easily first, his intimate knowledge of the locality being freely drawn upon at two meetings, and a third being made notable by a masterly paper on the relations of the Glacial period to the plant population of the British Isles.

Following the president's address came Mr. Reid's paper on the local geology. Portsmouth, he pointed out, was the centre of geological features of considerable interest, in which the student was brought face to face with many difficult problems. The geological map showed bands of colour ranging east and west, which in a flat country indicated inclined strata having a well-marked strike, and Portsmouth was near the central axis of the Hampshire Basin. It was also close to one of the subsidiary ripples on the great earth-wave, which formed Portsdown Hill. The Hampshire Basin was a great synclinal fold, and the planing of this fold by river and sea rendered visible 6000 feet of strata within short distance of Portsmouth. The oldest rocks seen on the surface were the Wealden and Lower Cretaceous beds of the Isle of Wight. The Chalk which forms all the higher hills may be taken as a foundation, as it is the oldest formation which plays any obvious part in the geology of Portsmouth. The upper zones had been carved away before the deposition of the Lower Tertiaries, and much of the Lower Eocene was also missing. The lowest brackish-water clays have yielded no fossils near Portsmouth, but the London Clay includes an irregular, siliceous bed (Bognor Rock) which is very fossiliferous. Succeeding these come the Lower Bagshot beds, which are poorly displayed near Portsmouth, but thicken out at Alum Bay into a mass of current-bedded sands in which occur beds of lignite and lenticles of pipe-clay containing leaves of tropical plants. These sands pass up imperceptibly into the marine Bracklesham beds, which contain many drifted plants, and include a prolific marine fauna of tropical appearance. Following in regular succession comes the deeper water Barton Clay with its great variety of beautifully preserved Mollusca, followed by the Barton Sands, at the top of which it has been the custom in England to draw the line between the Eocene and Oligocene formations, because the succeeding strata are markedly different in character, and the junction is rendered conspicuous by an underclay and a swampy land-surface; but the line of demarcation is now drawn higher up to suit the general European classification. The Fluvio-marine series of the Isle of Wight and the New Forest form a well-marked natural group of strata consisting in the main of mottled clays and silts of lagoon and brackish-water origin, with subordinate bands of white tufaceous limestone and marl. Bands of marine origin are quite subordinate except at the top. The occurrence of scattered angular chalk flints at various levels seems to point to the proximity of dry land against which the strata abutted. The Fluvio-marine series carries the succession up to the Middle Oligocene. All the higher Tertiary strata have been destroyed, and the next deposit is of Pleistocene date.

The remarkable folds which have affected all the strata of the Hampshire Basin, from the evidence of the Portsmouth district, are in the main newer than the Middle Oligocene. But evidence obtained lately in Devon seems to show that the folding was of Upper Oligocene or of Lower Miocene date. That is to say, these disturbances date from the same period which saw so much folding, disturbance, and mountain-building throughout Europe, and originated the chief Tertiary basins. The Miocene and Pliocene periods have left no legible traces in this neighbourhood, and all we can say is that during these periods were initiated the curious courses of the rivers of the district. The intricate channels and harbours of the Hampshire coast are the product of this long denudation combined with oscillations of land-level. The Hampshire and Sussex coasts yield particularly clear evidence of the curious alternations of climate which characterised the Pleistocene period. The ice-sheet did not extend so far south, but there is abundant evidence of two cold periods separated by a milder stage. Man must have seen many of the later of these changes. He certainly hunted the reindeer on Salisbury Plain, and probably hunted the seal and walrus amid the pack-ice of the Portsmouth coast.

Prof. S. H. Reynolds gave a description of further work on the Silurian rocks of the Eastern Mendips, in which the results of opening a series of fresh trenches were detailed. The fossils obtained showed that the sandy mudstones to the south-east of the Moon's Hill Quarry are of Wenlock rather than of Llandovery age. The strike of these Wenlock rocks is completely discordant with that of the underlying Old Red Sandstone, and precludes the possibility of a conformable passage from Silurian to Old Red Sandstone. No trace has been found of a Ludlow fauna. The dip of the Wenlock rocks is such that they clearly overlie the andesite of Moon's Hill.

Dr. A. R. Dwerryhouse outlined his recent investigations on the glaciation of the north-east of Ireland. He concluded that the area including the Antrim basaltic plateau, the Silurian uplands of County Down, and the Mourne Mountains had been completely overriden by the Firth of Clyde glacier, during the retreat of which the drainage of the district was impounded and a number of lakes formed. The overflow channels of these lakes have left "dry gaps," which mark the various stages in the shrinkage of the ice, the earliest of which appear on the flanks of the Mourne Mountains at an elevation of 1200 feet. Many interesting examples of the diversion of rivers by morainic material occur, and the changes in the history of the Lough Neagh area were outlined. It has been stated that the Antrim plateau was glaciated by local ice after the retreat of the Firth of Clyde glacier; but Dr. Dwerryhouse had failed to find any direct evidence of this, though the valleys of the Sperrin Mountains to the west were occupied by local glaciers.

The Glacial period and climatic changes in north-east Africa was the subject of a paper by Dr. W. F. Hume and Mr. J. I. Craig. They predicted a southerly shift in the system of westerly moist winds of the northern hemisphere due to the ice-cap by several degrees, with a decrease in temperature below the normal. These winds, which now barely touch the north coast of Egypt in winter, would then impinge upon the loftiest portions of the Red Sea mountain range. Evidence of this increased rainfall is found in the gravel terraces on their western slopes, the materials of which could only have come from the hills to the north-east. The precipitation was most active where the range was highest. Further evidences of such a westerly current are to be found in the existence of calcareous tufas on the borders of the eastern scarp of Kharga Oasis and elsewhere. The authors also found evidence of changes in the monsoon effects during the Glacial period. It is known from the investigations of the Meteorological Department of India that an increased snowfall in the Himalayas in spring exercises a measurable prejudicial effect on the Indian monsoon of the present day, and the enormously greater ice-covering of the Glacial period would exercise a more powerful inhibition on the monsoon of that period. The more extensive ice-sheet of East Africa, by preventing the abnormal heating of the land in summer, would act further in the same direction, and it is extremely probable that the monsoon current partook of the southerly displacement. The general result would be a decreased precipitation over Abyssinia and a much reduced Sobat, Blue Nile, and Atbara, which at the present account for 96 per cent. of the flood proper of the Nile. The study of the alluvial muds of the Lower Nile indicates a much smaller rainfall in Abyssinia about 14,000 years ago, previous to which the mud-laden waters of the Abyssinian Nile system do not seem to have reached Egypt. Mr. Grabham confirmed this conclusion by evidence from the Sudan of an earlier, moister climate further south than now is the case.

Friday, September 1, was devoted to a joint meeting with Section E (Geography), which was opened by a discussion on the former connection of the Isle of Wight with the mainland, the subject being introduced by Mr. Clement Reid, F.R.S. Mr. Reid pointed out that the Solent and Spithead occupy parts of a wide river-valley in which terraces of gravel slope up to 400 feet, though in the centre of the valley they pass actually beneath the present sea-level. These gravels have a very peculiar composition, and the higher terraces are full of Greensand chert, and contain fragments of Palæozoic rocks belonging originally to the West Country. The old idea that these cherts came from the central area of the Weald has been found to be untenable, and it has now been found possible to trace these stones to their origin, and so unfold a beautiful example of river development and river destruction. When first earth-movements formed the Tertiary basins of Hants and London, each of these basins was closed by harder rocks to the west, and was occupied by an eastward-flowing river, the Thames and the Solent. The valley of the Thames seems merely to have deepened, retaining all along approximately its original course. The valley of the Solent, on the other hand, ran for some distance parallel to the sea, and at no great distance from it, the result of which was that the sea finally broke through the narrower ridge of chalk which once ran continuously from the Needles to the Dorset coast, thus diverting the Frome and all the western rivers from their natural course to the Solent, and isolating the Isle of Wight. This flank attack had still other effects, for the Lower Avon was then only a short river, having a gentle fall of many miles before reaching the sea somewhere near Portsmouth. Subsequently it reached the sea by a short, steep, direct course, and consequently, as the Lower Avon flowed over soft Tertiary strata, it lowered its bed so rapidly as to cut back its valley and capture the whole of the drainage of Salisbury Plain, which previously had continued its natural course to Southampton Water. Clear evidence of this diversion and alteration of drainage areas was forthcoming in the high-level gravels of the Vale of Wardour, containing peculiar fossiliferous Purbeck cherts, which went straight across the present Avon Valley and were found on its west side, showing that when the rivers flowed some 300 feet higher they were tributaries of Southampton Water. Thus the great River Solent had all its headwaters cut off, and was divided into several separate river-basins, each with its own outlet. This happened in late Pliocene times. These flank attacks are still going on further west, and if they continue much longer the breach at Lulworth Cove may widen and deepen in the same way, so that with slight submergence the so-called Isle of Purbeck may become a true island exactly comparable in its geological structure with the Isle of Wight. Though at this early period the Isle of Wight was cut off from the mainland, it was probably at first only separated by a small stream and marshes, and was sometimes an island, sometimes part of the mainland, as the sea-level varied. The final isolation took place at quite a recent period, as the Isle of Wight was probably the ancient Ictis or Vectis of classical writers, to which the ancients traded for tin, and which is described as being cut off at high tide, but connected at low tide by a narrow causeway. The causeway was probably the ledge of Bembridge Limestone which swept across what is now the Solent from Yarmouth to Hurst Castle, and was intact 2000 years ago. It has now been destroyed by the attacks of the sea, and was apparently impassable at the Roman occupation, for the roads then led to a ferry further east and out of the run of the sea.

Dr. J. W. Evans thought that the submergence which was the immediate cause of the separation of the Isle of Wight was connected with the disappearance of glacial conditions from this country. The presence of accumulations of ice appears to cause a local lowering of the earth's crust accompanied by compensatory elevation in adjoining areas which, like the south of England, were unglaciated. When the ice passed away these movements were reversed in direction, as is now seen in Scandinavia. The period of elevation in our southern coast coinciding with the maximum of the glaciation of the British Isles was one of great precipitation, and it was then that the river valleys were excavated, or at least deepened, the submergence of which had given rise to our magnificent harbours. The discussion was continued by Profs. W. W. Watts, E. Hull, and others, and Mr. Clement Reid, in replying, pointed to the angles at which the tributary streams entered the main valley as confirmatory of his views. The slope of the ancient river-course from the Purbeck outcrops to the sea was almost that of the present river. Pebbles of Purbeck chert were now in a different drainage area from their source.

The earlier hours of Monday were devoted by the geologists to a joint discussion with Sections E and K on the relation of the Glacial period to the plant population of the British Isles, a report of which will be given by Section K (Botany). At 12 o'clock Section C reassembled in its own room, when papers were read by Mr. W. B. Wright and Mr. A. R. Horwood. Mr. Wright, in describing the Lower Carboniferous of the Bundoran district of South Donegal, gave an account of recent investigations by officers of the Geological Survey on the fossils of this area. The Lower Limestone has a conglomeratic base resting on the gneiss, the Lower Limestone Shale being completely absent. The study of the brachiopods and corals showed that the Carboniferous beds of this area were throughout of Viséan age, and leads to an interesting stratigraphical result, for it establishes palæontologically for this area the transgression invoked by Jukes, on purely lithological grounds, to account for the anomalies of the Lower Carboniferous series in various parts of Ireland. It shows, moreover, that this transgression reached the Bundoran district about the end of Tournasian or the beginning of Viséan times.

Mr. W. B. Wright also directed attention to the existence in a number of inland lakes in South Donegal and the Western Isles of Scotland of submerged pine-tree stools in position of growth. They occur at a level several feet beneath that of the outlet, which, being in many cases over broken rock or boulder-clay, precludes any explanation of a rise in the water-level due to peat growth. These cases are unquestionably similar to some described in Sweden, and are probably due to a drier climate, during which the lakes rarely had any overflow. He pointed out, however, that the mere presence of forests in the catchment basin might, by checking drainage and promoting transpiration, have in itself caused the partial drying of the lakes.

Mr. Horwood's papers dealt with some new Rhætic fossils from Glen Parva, and with the shell-layer in Mollusca.

On Tuesday, September 2, Mr. R. W. Hooley read a paper on the discovery of remains of *Iguanodon mantelli* in the Wealden beds of the Isle of Wight, in which the existence of two forms, a smaller and a larger, as in Belgium, was revealed. These variations he attributed to sexual rather than to specific differences. He exhibited a model in wood of the pelvic bones which showed a remarkable balance, and the bones gave evidence that the animal was fitted for bipedal progress, the pressure of the heavy tail upon the pelvic bones enabling it easily to assume an upright position.

Prof. E. S. Moore, of the State College, Pennsylvania, described beds on the border of the Appalachian system which comprised a complex series of impure limestones and sandstones forming a transition between the Cambrian and Ordovician, which included calcareous and siliceous oolites and beds of chert and limonite. The oolites form thin and irregular beds covering an area of more than forty square miles. The calcareous variety probably owes its origin to a mixture of sand grains and calcium carbonate, and to the fact that there were frequent alternations from a condition of deposition of limestone to a disintegration, solution, and redeposition of this rock. The evidence for this conclusion is found in the fact that the oolites occur in a complex mixture of calcareous sandstone and limestone, with alternations to thin beds of limestone-conglomerate, and also that sand grains or fragments of sandstone usually form the nuclei of the concretions. The siliceous oolites originated by replacement of the calcareous concretions, because they occur together, and the former grade into the latter. The source of the silica is to be found in the chert nodules and in the sand grains occurring in the limestone. The chief solvents for the silica are believed to have been organic acids and meteoric water.

Following this paper Prof. Moore gave a lecture on the pre-Cambrian beds of Ontario, illustrated by a fine series of lantern-slides. The Rev. Dr. Irving described a freshwater limestone in the Lower Eocenes of the northern flank of the Thames Basin, and a remarkable greywether or sarsen stone, and Mr. T. Ross Thomson exhibited lantern-slides to explain the various forms of the Wealden ostracoda.

Dr. W. F. Hume, of the Egyptian Survey, described the first meteorite recorded in Egypt, and exhibited specimens. It fell in the neighbourhood of the Alexandria-Cairo Railway, about 44 kilometres E.S.E. of Alexandria, and was seen by numerous natives. All accounts agreed that the stones fell out of a clear sky from the northwest, appearing as a white cloud variously estimated from 1 to 3 metres long. The meteorite exploded, breaking into several fragments, the fall being accompanied by a thunderclap. Numerous specimens were obtained from localities lying in a north and south line, the extreme points of which were separated about 1½ miles from each other. They are all characterised by an intense black and highly polished varnish of iron oxide, coating a green granular rock resembling a dunite, and probably mainly olivine.

In addition to the older committees of research, new committees were appointed to deal with excavations on Creechbarrow Hill, Dorset, and in the Coralline Crag at Sutton, at the base of which chipped flints had been recorded.

The instruction and pleasure of the geologists was much enhanced by excursions to the Portsmouth Waterworks and the Isle of Wight. Saturday's full-day excursion, under the able direction of Mr. G. W. Colenutt, was very successful, and enabled the members to see the lowest beds of the Wealden anticline at Brook Point and the wonderful sections of vertically tilted Chalk and Tertiaries at Alum Bay.

AËRONAUTICS AT THE BRITISH ASSOCIATION.

THE feeling produced by the discussion on the principles of flight, which took place at Portsmouth on September 4 at a joint session of the Sections of Mathematical and Physical Science, and Mechanical Science, of the British Association, is one of disappointment. The expressed purpose of Mr. A. E. Berriman, who opened the meeting, was to ask for the serious attention of matured scientific minds to be directed to a variety of specific problems that have suggested themselves to students of aëronautics during the recent development of flying-machines; but the discussion following his thoughtful and suggestive paper practically ignored the lines for debate that he had indicated, and the net result was to produce a mass of mainly irrelevant remarks.

The subjects to which Mr. Berriman confined his remarks were:—

(1) A consideration of the efficiency of the aëroplane as represented by the ratio of thrust to load, suggesting certain basic formulæ, and insisting on the relative importance of skin-friction.

(2) The necessity for evidence showing how the effective angle of a plane and its effective dimensions might be measured.

(3) The question of stability.

In reference to these subjects, he said that an hypothesis that aëroplanes were supported in flight by the inertia of the air led to the necessity of finding plausible expressions for mass acceleration. Two dimensions of the mass of air deflected were plausibly functions of the span and the chord of the plane; the third, which defined the depth of the stratus engaged and was known as the "sweep," was taken as the empirical function of the chord. Acceleration was obviously a function of the angle of the plane, and it was suggested that the angle should be measured by "the angle of deflection" at the point of intersection of two tangents drawn to the entering and trailing edges of the plane.

In order to extend the premises to cover a plausible expression for the resistance to flight and power expended, it was necessary to adopt a value for skin-friction. At present Zahm's formula was adopted, but the matter needed further research. Skin-friction was of such fundamental importance in aërodynamics that it was imperative to put it upon an accepted basis analogous to the position occupied by normal pressure. The coefficient of flight, representing the resistance per unit load, might be shown to be independent of speed, and to depend on the angle of the plane, and, further, to have a minimum value depending on the coefficient of skin-friction.

On the present hypothesis the minimum coefficient of flight obtained with planes of a very small effective angle—about 5°—such as would necessitate flying at much higher speeds than had hitherto been realised. The existence of an angle of least resistance was very important in connection with the problem of variable speed machines. Body resistance in a practical aëroplane was a supplementary resistance to that of the planes, and should always be considered as such.

Turning to the question of stability, in practical aëroplanes natural stability, both longitudinal and lateral, was mainly based on the principle of the dihedral angle. The acentric centre of gravity, in which the principal masses were placed well below the centre of pressure, was frequently suggested as a stabilising influence, but the permanent existence of a couple between the centre of gravity and the centre of pressure indicated liability to pronounced oscillation and did not find general favour.

Apart from the question of stability, progress in flying-machine design was mainly a problem of increasing the efficiency of the machine. The need for further information on such subjects as the effective angle of the plane, sweep, skin-friction, and other similar problems that come within the province of research work in physical science, was all-important. If the aëroplane of the future was to carry heavy loads and to fly far and fast, it needed to be more efficient than the aëroplanes of to-day.

Dr. W. N. Shaw, who followed, spoke of the dangers to aviators that lay in the constant fluctuations in the speed and direction of air-currents, and pointed out that over sea the oscillation of the wind speed was generally less than that over the land.

Prof. Petavel discussed the various suggested means of obtaining stability from the practical aviator's point of view, and stated his opinion that, given an aëroplane with a fair proportion of natural stability, the experience and control of the pilot might be very well left to supply the rest.

The subject of motors was broached by Mr. Beaumont, who said that, so far as the engine itself was concerned, it was very questionable whether any great increase in either the mechanical or dynamic efficiency could be made: and Sir William White, in the course of some general remarks, stated that the question of propeller efficiency must be dealt with, as in the case of ships, experimentally, by means of models.

THE INSTITUTE OF METALS.

THE annual autumn meeting of the Institute of Metals was held at Newcastle-on-Tyne on September 20–22. The Lord Mayor (Sir W. H. Stephenson), in offering a welcome to the institute, said the institute has made substantial progress with the objects it has in view, to serve the industries connected with the non-ferrous metals in a similar manner to that in which the Iron and Steel Institute has served the iron and steel trades. Research work to meet the needs of industrial development is clearly needed. Such work is constantly in progress at the National Physical Laboratory and in the universities and the university colleges. The Institute of Metals affords a means of communication among the many workers in the field covered by its activities, and the knowledge acquired by research can thus be applied to practical work. An important research which illustrates the services which such an institute may render is being carried out by the Corrosion Committee. Sir Gerard Muntz, in acknowledging the welcome, referred to the research on the causes of corrosion in condenser tubes. He said that a plant which should imitate as closely as possible the conditions obtaining in a marine condenser is being erected at Liverpool, and will be ready for inspection and testing in a few weeks. It is intended to investigate the conditions obtaining under Admiralty and commercial conditions, and it is believed that a large number of the baffling problems connected with corrosion can be investigated adequately. Generous assistance has been given by the University of Liverpool, but additions to the research fund are urgently needed, as the work, to yield useful results, must extend over a period of two or three years. Several papers were afterwards read and discussed, and the following brief summaries will indicate their scope.

Mr. J. L. Haughton and Prof. T. Turner contributed a paper on volume changes in the alloys of copper with tin. The work described is a continuation of previous researches on the changes in length which occur in a cast bar during and after solidification. The method employed has been that of applying an extensometer to one end of a cast bar while the other was kept fixed. The apparatus employed has been modified in order to allow a single operator to observe both pyrometer and extensometer readings at the same instant, and to record these results by means of a chronograph on a paper tape. There are four maxima in the expansion curve, and three of these, with about 10, 46, and 65 per cent. of tin respectively, agree with the "crystallisation interval" as determined from the accepted equilibrium diagrams.

The aim of a paper by Dr. W. M. Guertler, on the electrical conductivity and constitution of alloys, was to direct attention to the property of electrical conductivity in its bearing upon the practical determination of the constitution of alloys. The relationship between concentration, temperature, and any given property—electrical conductivity, specific volume, magnetism, &c.—is best brought out by the employment of a coordinate system, as in the equilibrium diagram. The converse problem is one of great importance, viz. that of obtaining the equilibrium diagram (when it is unknown) by projection from these surfaces on to the basal plane. The best method for the determination of the equilibrium diagram is known by the name of "thermal analysis." Dr. Guertler discussed the limitations of "thermal analysis," and in particular explained why it fails in those cases where, as so often happens in practice, a state of complete stable equilibrium is unattainable within a comparatively short interval of time.

In a paper by Mr. D. R. Pye, on the mechanical properties of hard-drawn copper, the lack of any satisfactory definition of standard hard-drawn copper was pointed out. Experiments were described confirming a suggestion made by Mr. A. P. Trotter that the tensile strength per square inch diminishes with increase of diameter according to a linear law. It was also shown that the elongation at fracture for similarly manufactured wires depends very much on the diameter, being considerably greater for larger sizes of wire. It was suggested that a satisfactory definition of hard-drawn copper wire would fix a minimum tensile strength per square inch given by the formula

$$T = 30 - 20D,$$

and a minimum elongation per cent. at fracture given by the formula

$$e = 5D,$$

where D = diameter in inches.

In a paper by Mr. George Hughes, on non-ferrous metals in railway work, he placed on record some of the methods of working, and uses pertaining to, the non-ferrous metals in locomotive and carriage construction. A short account of the bearing metals used under the name of white metals was included, together with a note on non-ferrous metals and alloys used in the railway carriage department.

The main object of Mr. C. A. Edwards's paper, on further notes on the nature of solid solutions, was to deal with points of interest raised in the discussion on a previous paper by Mr. Edwards on the same subject, and to stimulate further discussion.

The paper by Prof. H. Louis, on the failure of a brazed joint, gave an account of the investigation of the cause of a failure in the braze of a steam-pipe on a steamer, undertaken at the instance of the Board of Trade. The failure was due to corrosion following certain well-defined lines in the brass, and he traced the cause of these lines to the presence of small quantities of lead and tin in the original brazing spelter. The lead-tin alloy, separating out between the crystals of brass, formed planes of weakness that gave access to the corroding solutions, and this brought about the gradual corrosion of the entire brazing material.

A paper by Dr. Walter Rosenhain and Mr. S. L. Archbutt, on the alloys of aluminium and zinc, described a detailed investigation of the constitution of the alloys of aluminium and zinc which was undertaken in connection with an extended research on the light alloys of aluminium. A series of cooling curves were taken at a slow rate of cooling, and in many cases the ingots of the alloys were subjected to prolonged annealing before the cooling curves were taken. The microscopic examination of the cooled alloys was supplemented by the study of specimens which had been annealed and quenched at definite temperatures. The results were embodied in an equilibrium diagram which differs from the diagram of Shepherd; these differences result from the discovery of the existence of the definite compound Al_2Zn_3, which has a stable existence only between 443° C. and 256° C.

It was urged by Mr. Paul T. Bruhl in a paper on the corrosion of brass, with special reference to condenser tubes, that so important a subject as the corrosion of brass by sea water should induce steamship companies to keep records bearing on the subject. The conclusions arrived at by the author were:—That the presence of air or an increase of temperature up to a certain point accelerate corrosion. That iron, nickel, and small amounts of lead are injurious; tin up to about 1 per cent., large amounts of lead, and aluminium are useful in diminishing corrosion. That the inlet pipe and the condenser plates should preferably be made of brass. That the condenser should be protected against stray currents. Protective coatings are not recommended.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

ST. ANDREWS.—Mr. W. O. Redman King has been appointed demonstrator in zoology and lecturer on embryology, in succession to Dr. J. R. Tosh, who has returned to Australia.

BIRMINGHAM.—A lectureship in civic design and town planning has been established in the University of Birmingham. The cost will be defrayed by the Bournville Village Trust, which was founded by Mr. George Cadbury as a practical attempt to solve the problem of the housing of the less wealthy classes. Mr. Raymond Unwin, who is well known for his work in connection with the Garden City at Letchworth and the Hampstead Garden Suburb, has accepted the lectureship for the first year, and will begin his course during the present session. The lectureship will be associated with the department of civil engineering, but it is hoped that students of other faculties will take advantage of the lectures, especially those who are working in the course on social study.

THE new science buildings at Shrewsbury School, which have been erected at a cost of 2500*l*., will be opened on October 20 by Dr. Francis Darwin, F.R.S.

ON Wednesday, October 4, at 4 p.m., a public inaugural lecture will be delivered at King's College (University of London) by Dr. William Brown on "Emotions and Morals." The chair will be taken by Prof. James Sully.

BY the will of the late Lord James of Hereford, the sum of 3500*l*. is bequeathed to the governing body of Cheltenham College for the purpose of founding "James of Hereford" scholarships at that school. Lord James of Hereford was president of the council of the school.

MR. M. GREENWOOD, jun., will begin a course of lectures and demonstrations on "Statistical Methods and their Applications in Preventive Medicine and Pathology" at the Lister Institute of Preventive Medicine on Monday, October 16, at 5 p.m. This course is open, without fee, to all medical men and to others interested in the subject.

FOUR lectures on "Flies as Carriers of Disease" will be delivered on Tuesday–Friday, October 10, 11, 12, and 13, by Dr. F. M. Sandwith, Gresham professor of physic. The lectures will be delivered at the City of London School, Victoria Embankment, E.C.; they are free to the public, and will begin each evening at six o'clock.

THE calendar for the sixty-third session, that of the present academic year, of the Bedford College for Women gives full particulars of the varied arrangements for the higher education of women made at this constituent college of the University of London. Bedford College was recognised in 1900 as a school of the University in the faculties of arts and sciences, and it is further recognised for preliminary medical studies and for advanced medical studies in chemistry and physiology. The college cooperates in a scheme of inter-collegiate teaching with other colleges of the University for honours and post-graduate work. We notice that the new buildings for the college at York Gate, Regent's Park, London, will, it is hoped, be ready for occupation next year.

THE eighty-ninth session of Birkbeck College commenced on Wednesday, September 27, with an opening address by Sir William Tilden, F.R.S. The classrooms, &c., were afterwards open for inspection, and there was an exhibition in the art school. The college is conducted in relation with the University of London; classes are held both in the day and evening; thirty members of the staff are recognised teachers of the University. There is a very complete curriculum for chemistry, physics, mathematics, botany, zoology, and geology. The laboratories are well equipped with modern apparatus and appliances, and research work is encouraged in all the science departments. According to the calendar, more than 140 students passed some examination of the University during the last session; forty-seven took degrees in arts or science, twenty-one with honours, two the LL.B. degree, one with honours, and several students gained distinction at other universities.

THE Bethnal Green Free Library was founded in 1876 to meet the requirements of a crowded working class and poor borough, and is supported entirely by voluntary contributions. The main library now contains more than 30,000 volumes; the lending section has 8000 more. Commercial, evening, and other classes are held, and free instruction in design, brushwork, needlework, &c., is given to young girls. To earnest students the library is scarcely less than a local British Museum, where skilled artisans may find technical books of service to them in their trades. Free lectures and concerts provide healthful recreation. A deficiency in the annual income of 200*l*. is causing the council some anxiety. In order that the work shall not suffer in any department, the council has opened a reserve fund of 10,000*l*., and to this the present King has subscribed. Both Queen Victoria, King Edward VII., and Queen Mary also extended their favour to this institute. Donations to the general fund may be sent to the librarian, or to Mr. F. A. Bevan, treasurer, 54 Lombard Street, and Mr. Stephen A. Gard, honorary secretary, will receive donations to the reserve fund.

THE announcements for the present session of the Northampton Polytechnic Institute, Clerkenwell, London, show that day and evening courses have been arranged in mechanical and electrical engineering, in electro-chemistry, technical optics, and horology. The engineering courses include automobile work, aëronautics, and radio-telegraphy. Several new developments have been arranged. In the electrical engineering department, the new generating station, which was opened last winter, is now available for the instruction of senior students. The equipment of this station is very complete in all details of the generation and distribution of continuous and alternating current. In the mechanical engineering department the equipment for experimental work in aëronautics has been increased, and it is hoped that work of a research character will be done during the coming winter. New departures have been made in the day work of the technical chemistry and of the horological departments by the institution of morning classes for apprentices in workshops. In these classes students, all of whom are engaged in commercial workshops, are in attendance from 9 a.m. to 1 p.m., and spend the afternoons in their employers' workshops. The experiment is interesting as an attempt to solve the problem of providing instruction for the artisan without the drawbacks involved in attendance at evening classes after a strenuous day's work. In the evening classes an important series of lectures on illuminating engineering is being given jointly by the electrical engineering, technical chemistry, and technical optics departments.

THE calendar of the University of Bristol for the session 1911–12, which is now available, reminds us that the University of Bristol Act was passed in 1909 only, and that excellent progress has been made since that date in establishing the various departments of the University which is to serve the west of England. Several institutions in the neighbourhood have been affiliated with the University. The work of the faculty of engineering in all its branches is carried on in the Merchant Venturers' Technical College, agreements between the University and the Society of Merchant Venturers having been signed in July, 1909, and May, 1911. In July, 1910, the Royal Agricultural College, Cirencester, became associated with the University for the purpose of instruction in agriculture, forestry, veterinary science, and kindred subjects. Two theological colleges in Bristol are similarly associated for instruction in theology and certain linguistic subjects. There are, in addition, day training colleges for teachers, and the University is fortunate in the number of institutions near it open to students of medicine for hospital practice and clinical instruction. A public health laboratory has been established to enable medical men in the area to obtain trustworthy information and reports upon pathological material, and of placing at the disposal of authorities dealing with drinking water, persons concerned with the supply or consumption of milk, and those engaged in manufacturing processes, the resources of a properly equipped bacteriological research laboratory. It is clear that the University authorities are fully alive to their opportunities of influencing the life and industries of the counties surrounding the University, and that it will not be long before the good effects of higher instruction in the various branches of knowledge will follow.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, September 18.—M. Armand Gautier in the chair.—Ch. **Lallemand**: The deformations resulting from the mode of construction of the international map of the world on the scale of one millionth. The author establishes simplified formula for the construction of the map, having regard to the accuracy possible with the scale chosen. It is shown that the linear and angular errors, due to the method employed, would be much less than those due to the hygrometric deformations of the paper on which the map is printed.—Edm. **van Aubel**: Hall's phenomenon and the transversal thermo-magnetic effect in graphite. Details of measurement of the thermo-electric power of a graphite-copper thermocouple. This was found to be +17·8 microvolts per degree between 21·0° C. and 57·6° C., and 18·1 microvolts per degree between 20·9° C. and 98·55° C.—Georges **Baume** and Albert F. O. **Germann**: Fusibility curves of gaseous mixtures: the oxonian systems formed by acetylene, ethylene, nitric oxide, and methyl oxide. Diagrams are given showing the fusibility curves of the systems (methyl oxide-acetylene), (methyl oxide-ethylene), and (methyl oxide-nitric oxide). Each of these curves shows a clearly marked angular point corresponding to the molecular proportions $((CH_3)_2O+C_2H_2)$, $((CH_3)_2O+C_2H_4)$, and $((CH_3)_2O+2NO)$.—J. **Bougault** and C. **Charaux**: Lactarinic acid, a keto-stearic acid extracted from some fungi of the genus Lactarius. This acid is present in the free state in *L. theiogalus*, *L. plumbeus*, *L. pyrogalus*, and *L. uvidus*, and can be extracted by boiling alcohol. The properties of the acid are described; it is shown to be a ketostearic acid of the composition $C_{18}H_{34}O_3$.—P. **Gaubert**: The indices of refraction of some crystalline liquids. Measurements of the refractive indices of propionate, benzoate, acetate, and caproate of cholesterol are given.—E. **Kayser** and H. **Delaval**: Contribution to the study of ropy bread.—Charles **Nicolle**, A. **Conor**, and E. **Conseil**: The nature and the seat of the pathogenic agent in exanthematic typhus. Experiments are adduced in support of the hypothesis that the virus is localised in the leucocytes. The blood was separated by centrifugation; the white corpuscles proved on inoculation to be the most virulent; the plasma is less active, and appears to owe its poisonous action to the leucocytic débris difficult of removal; the wasted red corpuscles are inactive. The blood serum was proved to be inoffensive to man, and the cephalorachidian fluid, devoid of cells, proved to be also inactive.

DIARY OF SOCIETIES.

TUESDAY, OCTOBER 3.

FARADAY SOCIETY, at 8.—The "Paragon" Electric Furnace and Recent Developments in Metallurgy: J. Hardén.—Progress in the Electro-metallurgy of Iron and Steel: Donald F. Campbell.—The Hering "Pinch Effect" Furnace: E. Kilburn Scott.

WEDNESDAY, OCTOBER 4.

ENTOMOLOGICAL SOCIETY, at 8.—Report on a Collection of Bombyliidæ (Diptera) from Central Africa, with Descriptions of New Species: Prof. Mario Bezzi.

THURSDAY, OCTOBER 5, 1911.

A ZOOLOGICAL TRIBUTE.

Festschrift zum Sechzigsten Geburtstag Richard Hertwigs (München) geboren den 23. September, 1850, zu Friedrich, i.H. Erster Band, "Arbeiten aus dem Gebiet der Zellenlehre and Protozoenkunde." Pp. v+674+49 plates. Price 110 marks. Zweiter Band, "Arbeiten Morphologischen, Biologischen und Deszendenztheoretischen Inhalts." Pp. iii+624+30 plates. Price 70 marks. Dritter Band, "Experimentelle Arbeiten." Pp. iii+308+20 plates. Price 50 marks. (Jena: Gustav Fischer, 1910.)

THE three volumes before us represent one of the most remarkable tributes ever paid to a professor of zoology. We refer not merely to their size and weight, which have unfortunately hindered us from reviewing them more promptly, but to their high standard of workmanship and to the cordiality with which the various authors recognise indebtedness to their master for inspiration and instruction, for precept and example. It is true, of course, that those who have joined in this "Festschrift" to their highly esteemed teacher are now strongly marked individualities, ploughing their own furrows; yet it would be less than fair not to see that the diversity of contributions is correlated with the diversity of gifts in Richard Hertwig himself. For he has worked along many lines of zoology, and always with signal success—with a carefulness, thoroughness, and thoughtfulness which we should not presume to praise were they not reflected so clearly in the volumes which it is our business to-day to review. He has dealt with Protozoa and Metazoa, with morphology and physiology, with the most minute intricacies of the cell, with the big questions of sex and reproduction, and with the general problems of evolution. The congratulations of NATURE to Richard Hertwig, as one of the big international educationists in zoology of recent years, may be, through the reviewer's fault, a little belated, but they are none the less sincere. We wish for him many years of pleasant work, judiciously mingled with as much holiday as he can enjoy.

But how are we to review three enormous volumes with 1600 pages and a hundred plates? Perhaps the most useful way is the objective one of giving a rapid inventory of the treasures of this great Festschrift.

W. T. Howard leads off with an account of a peculiar kind of nuclear budding which occurs in the "depressed" cells of some tumours. It represents a reversion on the part of these cells to a primitive type of division common among certain Protozoa (such as Podophrya, according to Hertwig), and the author also suggests that the degeneration and extrusion of nuclear buds followed by mitosis of the mother nucleus is, in principle, comparable to the maturation division of egg cells. M. Popoff describes in various cells of Muscidæ what Hertwig called the formation of chromidia—the extrusion of chromatin from the nucleus into the cytoplasm. This colonisation of the cytoplasm by nucleoplasm seems to bear a relation to the functioning of the cell; thus the chromidia may be distributed along lines of diffusion currents. The author points out that what have been described as mitochondria, chondriomites, chondriokonts, pseudochromosomes, ergastoplasm, and so on, are simply phases of chromidia. Prof. Vlad. Ružička has studied in *Bacterium nitri* the relations of chromatin and of plastin to the life of the cell, and finds that these two substances tend to be distributed respectively in areas of active and of reduced metabolism. In a paper with very striking illustrations, Th. Moroff describes what goes on inside the large Radiolarian Thalassicolla, the nucleus of which can be seen easily with the naked eye. The vegetative and reproductive phases are contrasted, and an account is given of the formation of isospores and anisospores. The author discusses such points as the significance of nucleoli, which are interpreted as forms of chromidia.

C. Clifford Dobell gives an account of his study of an interesting blood parasite, Hæmocystidium, discovered by Castellani and Willey in a Ceylon Gecko. He describes the schizogony and the formation of gametocytes, and contrasts the genus with the malarial organism, Plasmodium, to which it is closely akin. Hubert Erhard shows, in reference to the cells of the bile-duct in the snail, and of the epididymis in the white mouse, that the "trophospongia" of Holmgren is really a chromidial apparatus of nuclear origin. In regard to the epididymis he brings forward strong evidence that the secretion is due to the activity of the chromidia in the cytoplasm. In the next study Julius Schaxel describes the oogenesis of the well-known jellyfish Pelagia. He lays emphasis on the interesting give and take between nucleus and cytoplasm; from nutritive material supplied by the cytoplasm the nucleus forms chromatin, part of which is emitted from the nucleus into the cytoplasm to form physiologically important "kineto-chromidia." The history of the chromosomes in the larval salamander is the subject of a study by Karl Camillo Schneider—a kind of study which is difficult for those who have not a clue to the labyrinth of the nucleus. We may, however, point out that according to the author each chromosome of the nucleus in the prophase before division is bivalent, being composed of two "elementary structures" or "Mites," which are spirally coiled! In following the history of these spirals Schneider has found strong corroboration of Boveri's theory of the individuality of the chromosomes. In the next paper Paul Buchner gives a redescription—more penetrating than ever—of the spermatogenesis and oogenesis, the maturation and fertilisation in Sagitta.

E. A. Minchin describes *Malpighiella refringens*, a new amœboid parasite which he found in the malpighian tubes of the rat-flea (*Ceratophyllus fasciatus*), in which he was studying the transmission of *Trypanosoma lewisi*. It occurs principally in two forms—an amœboid form with a single nucleus, and an encysted form with four nuclei. In the next paper we are brought back again to chromidia, for Alexander Issakowitsch describes these on the marginal gland cells of Porpita, and shows that they play an essential part in the production of mucus. Then follows an interesting study by Rh. Erdmann, dealing with

O

Amoeba diploidea, which he kept at a temperature far above the normal. Nuclear degenerations and disturbances ensued, the culture became quite asexual, and sooner or later died off. In short, a state of "facultative apogamy" was experimentally induced, and the result afforded indirect evidence that part of the utility of the sexual process is to counteract "depressions" and disturbances of the cellular functions. Max Hartmann describes from the gut of a Termite a new representative of the very remarkable Protozoa known as Trichonymphidæ. He is inclined to make the family into a class comparable to Ciliata, but one almost hopes that this is going too far. Very remarkable they certainly are, with their males and females and young stages, their fission and gametogeny, their unique "head-organ" (probably a complicated blepharoplast), and their compound or "polyenergid" nucleus. Another interesting Protozoon, *Trypanosoma rotatorium,* Grube, from the frog, is redescribed by W. Lebedeff. It is remarkable for its striking polymorphism, for four principal forms occur. Another interesting parasite, a species of Lankesteria which lives in the food-canal of Turbellarians in Lake Baikal, is described by B. Swarczewsky. An account is given of the formation of gametes, their conjugation, the development of sporocysts, and of the life-history in general.

Very prominent in more ways than one is the description which Max Jörgensen gives of the growth of the ovarian ovum in Proteus. It occupies nearly 200 pages, and it is illustrated by twenty-three beautiful plates of cytological details. The author tells us all sorts of wonderful things, *e.g.* how the chromatin in the second stage of growth becomes pulverised, how the chromidium helps in the reconstruction, how the remarkable "lamp-brush" chromosomes arise, how the nucleoli migrate and what they do (probably serving as reservoirs for certain products of metabolism, and furnishing ferments which are useful in plasm-growth and yolk-formation. A most interesting account is given of the conditions of ooplasm-growth and of yolk-forming, and, in general, of the marvellous interactions between the different members of the cell-firm.

The second volume begins with a paper by J. P. Schtschelkanowzew on the internal and external male organs of Chelifer and Chernes. Among other interesting points the absence of a tail in the ripe spermatozoa may be noted. A discussion of the affinities of the Chelonethi leads to the conclusion that they are most nearly related to the Urotricha or Holopeltidia. Bruno Wahl deals with the classification of two families of Turbellarians, Dalyellidæ and Umagillidæ, which include a number of interesting and, in part, parasitic forms, such as Graffilla, Anoplodium, and Syndesmis. There seems to be some puzzle about *Graffilla parasitica,* which is abundant inside Tethys, for Wahl could find no trace of male gonads. Great interest attaches to the fine account which Sergius Kuschakewitsch gives of the development of the gonads in the edible frogs. It is a fine study in the origin and differentation of gonads, but it is also welcome in connection with experiments on sex-determination. The author contrasts the ovary and the testis stage after stage. There seems to be a remarkable lability in the details of the development, and the differences seem to depend partly on the locality and partly on the degree of ripeness of the eggs when they are fertilised. Confirmation is given of Hertwig's conclusion that over-ripeness of the ova results in a great preponderance of males. Philipp Lehrs takes us to a different kind of zoological problem in his discussion of a new species of Lacerta from Lebanon. He compares it with other mountain lizards, and shows the interest of it in binding together the Neo-Lacerta and Archæo-Lacerta species. C. Sasaki relates how he has almost cleared up the life-history of a rather famous aphis—*Schlechtendalia chinensis*—which makes galls on *Rhus semi-alata* in Japan and China. The galls are used in dyeing and tanning—they are rich in tannin, and in former times they served the Japanese women as a tooth-powder for blackening the teeth. Sasaki has succeeded in finding the wingless mother-insect, the fundatrix, who sets the ball a-rolling. Wingless females, parthenogenetic and viviparous, come and go; at length winged females appear which lay eggs, containing well-advanced embryos that soon hatch out. But no males have been seen, and we have a glimpse of a possibly continuous Parthenopeia.

R. Goldschmidt devotes a hundred pages to a searching account of the minute structure of the glia, the nerve-fibres, and the ganglion cells in the common threadworms of horse and man. He devotes particular attention to the neurofibrils, only, however, to rob them of their supposed nervosity, for he strongly maintains, with Apathy and others, that neurofibrils simply represent cellular skeleton. Goldschmidt has made in previous memoirs such a thorough analysis of the nervous system of Ascaris that he has the cells all numbered, and, as it were, ticketed. It is extraordinary indeed to read that "cell 26 of the internal lateral cephalic ganglion is present only in the males"—a fine instance, on the one hand, of penetrating analysis, and, on the other, of the penetrating nature of sex. O. Steche takes us to the open sea with his interesting study of the Portuguese man-of-war. He has introduced order into what he calls the "perplexing Wirrwar" of zooids, by discovering the law of budding. What is even more important, he shows how the development of the huge pneumatophore that projects above the waves has reacted on the architecture, leading to a great shortening of the stem and a giving up of the usual budding-zone. Incidentally, he mentions that Physalia has great power of regenerating lost appendages—a capacity which other Siphonophora are not known to possess.

In the next paper Harry Marcus makes another contribution to the much studied problem of the architecture of the head. He deals with Hypogeophis, one of the Gymnophiona, and discusses the "neuromerie, mesomerie, dermatomerie, and branchiomeric" of the head, which has at least nine segments. Adjoining this important, but highly technical contribution, there is a practical study by Schwangart, an authority on vine diseases. He deals with the deadly "Traubenwickler," caterpillars of two species of Tortricidæ, the ravages of which are nothing short of calamitous. In 1906 the loss in the Pfalz alone was estimated at six millions of marks. After discussing the life-history and habits, and the natural enemies of the caterpillars, as well as a variety of chemical, mechanical, and physical methods of dealing with the pest, the author gives an interesting account of their infection with a pathogenic mould, a species of Cordyceps. Ernst Stromer takes us back to ancient days in his discussion of the phylogeny of the Dipnoan stock, a subject raised by his very interesting discovery of teeth of both Protopterus and Lepidosiren in the Lower Oligocene of Egypt.

Plate's contribution to the Festschrift is an expanded version of the inaugural lecture which he gave in entering upon his duties as professor of zoology in Jena. He deals with the laws of inheritance in their relation to general evolution-theory. He has been breeding mice and has found not a single fact against the Mendelian theory. But he does not think that the selection theory has lost any of its importance. Some of his analyses of current conceptions are very interesting; thus he distinguishes seven forms of germinal variation, five kinds of atavism, and several kinds of correlation.

The third volume begins with observations by Arnold Lang on the heart-beats of hibernating snails. As the temperature falls the beats become fewer and fewer, but even at -3° C. they were still observed. A heart that can beat fifty times a minute in summer may only beat 2·36 times a minute at a temperature of 2·65° C. in February. In the next study Karl von Frisch takes us out to brooks and streams, and inquires into the colour-change of the trout and the minnow. It is many years since Pouchet demonstrated the importance of the sympathetic system in this connection, but von Frisch has already in this "vorlaüfige Mitteilung" got further into the business. He has shown that there is in the anterior end of the medulla oblongata a special centre, the stimulation of which makes the fish lighter, *i.e.* makes the chromatophores contract. He has also found the place where the nerve-fibres that control the chromatophores pass out of the spinal cord into the sympathetic, in which they extend forwards and backwards.

By means of ingenious experiments, especially on bicephalous Planarians, Paul Steinmann has shown, for Triclads, that the nature of what is regenerated, *e.g.* whether a head or a tail, depends, not on the line of cutting, nor on the adjacent tissue, but on the regenerating organism as a whole. Even distant parts of the regenerant have their "organising" influence on the regenerate. Another paper dealing with regeneration is by Gustav Wolff, who reports on the continuation of his studies on newts. He has previously shown that the regeneration of the lens takes place apart from nervous stimulus, but now he shows that in the regeneration of the hind limb a nervous factor is indisputable. He makes much, for instance, of the remarkable fact that when an abnormal limb, say one with only two toes, is cut off, the regenerated limb has also only two toes. There is a very interesting historical reference to a forgotten paper by T. J. Todd, who directed attention, in 1823, to the influence of the nerve in the regeneration of the newt's leg.

An investigation of a very different type is that of W. F. Ewald on the contraction of the adductors in freshwater mussels. He has discovered a special "tonus-current," and gives a definition of the "tonic muscle-contraction." It is not oscillatory or discontinuous, but a persistent process, both in its mechanical and its electrical aspects. Albrecht Bethe deals with the equilibration of aquatic animals, discussing those with statocysts and those without, those the construction of which gives them an automatic stability, and those "labile" forms that keep themselves in a particular position by a coordination of movements. In some young fishes there is at first an automatic determination of the position, and the coordination is subsequently acquired. O. Maas has studied the peculiar involution-processes which occur in various sponges when they are starved or kept without sufficient lime salts. By passing into a resting stage, comparable to gemmules, the sponge may survive the disadvantageous conditions and exhibit subsequent revivification. One of the interesting general results is the corroboration of the view that sponges are essentially diploblastic. Th. Boveri has studied the developmental potencies of Ascaris-blastomeres in cases where the normal type of cleavage has been departed from, either as the result of double fertilisation or in consequence of centrifugal rotation. He gives the *coup de grâce* to the hypothesis of differential nuclear division.

F. Doflein takes us into the open-air again with his very interesting—though admittedly preliminary—study of the behaviour of two prawns, species of Leander, common on the Riviera coast. He discusses their fine coloration and its changes; the different kinds of chromatophores and pigments, red, blue, yellow, and white; their behaviour when feeding, when cleaning themselves, and so on; and the reactions to diverse stimuli.

This remarkable tribute, a credit alike to the genial professor and his school, ends with an interesting study of the awakening of the hibernating hedgehog. Whether automatically, or by "pulling itself together," the hedgehog warms itself up, and that rapidly. The chemistry of this, according to Tanzo Yoshida and Ernst Weinland, is that a rapid combustion of glycogen occurs, and that fat serves as an accessory fuel to the vital fire.

THE AGRICULTURAL DEVELOPMENT OF EGYPT.

Text-book of Egyptian Agriculture. Edited by G. P. Foaden and F. Fletcher. Vol. ii. Pp. viii+321–878. (Cairo: National Printing Department, 1910.) Price 9*s.*

IN the agricultural development of a country two lines of attack have always to be followed: investigations are made with the objects of discovering the best crops to grow and the best methods to follow; and the cultivator—who is generally constitutionally conservative—has to be persuaded that the new methods really are an improvement on the old. Egypt, old as she is, has to adapt herself to the changed economic conditions of the world, and the problem before her agricultural advisers is fundamentally the same as in new countries, though in its details more complex.

The book before us is the second volume of the complete work, the first having been reviewed in these columns about eighteen months ago. It deals with individual crops, with farm pests and farm animals, and its object is to present the student with a general summary of the work done, and the information collected and sorted out, by the experts attached to the various agricultural institutions in the country. The writing of each section of the book has been entrusted to one man, generally one who has done much work on the subject, so that the volume consists of a detached series of contributions. It is therefore extremely useful for the expert who can evaluate the various chapters, but it has not quite the organic unity desirable for a student's text-book. Indeed, it is, in any case, rather large for an elementary student, and the editors will probably find advantages in drawing up an abridgment of the whole work for general use, leaving these larger and more authoritative volumes for the advanced student.

Cotton is at present the crop to which the Egyptian looks for profit, and where it can be grown everything else is made subsidiary to it. If the land will grow cotton every two years so much the better; but Mr. Cartwright, who has charge of this section, enters a wise caution against overcropping:—

"Egypt depends on the quality of its staple for its position in the cotton world. This quality of staple is intimately bound up with the fertility of the land, and any loss of the second will almost certainly be accompanied by deterioration in the first."

A common rotation is cotton, berseem, wheat; berseem being the Egyptian clover (*Trifolium alexandrinum*), which keeps up the supply of humus in the soil, thus counteracting the effect of the extremely rapid decomposition going on.

The wheat is mainly of the durum type. Red, white, bearded, and beardless varieties can all be found, and the samples are usually very mixed in quality. Wheat forms an important crop in basin cultivation; indeed, the red wheats from the Upper Egypt basins are considered the best type. In Lower Egypt wheat is grown under irrigation as a winter crop.

In Upper Egypt sugar cane is often the basis of the rotation instead of cotton, the course being sugar cane, sugar cane, berseem, followed by doura, wheat with or without doura; sometimes, however, the cane is only grown one year, and the wheat is replaced by a bare fallow. The two great classes of cane in general cultivation are Beladi, for long the commonest grown, and Roumi, now replacing the older class because of higher producing capacity. Ordinarily the sugar obtained is 10 to 15 per cent. of the weight of the cane, about 2·5 per cent. being molasses. Doura or maize is an extremely useful crop for the fellah. Its thinnings supply a large quantity of green food for his cattle when "keep" is scarce; its grain supplies him and his family with food; moreover, it responds well to liberal treatment.

Fungoid diseases are ably dealt with by Mr. Balls, who has, on the whole, a very cheerful account to give of the cultivator's lot.

"The immunity of the important cultivated plants from disease induced by fungi is most remarkable; berseem and maize, although grown in enormous quantities, are practically free from disease; wheat only bears rust-pustules commonly after the flowering period; and although cotton is inhabited by four common fungi, it is yet attacked by them at such times as to be but little affected thereby."

But Mr. Balls will not leave the cultivator to be lulled into a false sense of security: this happy immunity, he insists, is not entirely due to climatic conditions, although it is in part; thus the high temperature is unfavourable to fungi, and the unvarying character of the climate enables the pathologist to know exactly what to expect.

On the other hand, insect pests are numerous and do a good deal of damage. Mr. Willcocks, who writes this section, inclines to the belief that they are more or less indigenous. Their life-histories are being steadily worked out and remedial measures designed. But it is not always easy to apply remedies in practice. The psychology of the cultivator counts for much, and Oriental fatalism is a bar to the taking of active precautionary measures. The cultivator always hopes that Providence, or at least Government, will do something, but does not himself do what the Western man would do at once.

Perhaps the cotton boll-worm is the most serious pest, but the cotton worm (*Prodenia littoralis*), the small green cotton worm (*Caradrina exigua*), and the cut worm (*Agrotis ypsilon*) also do harm, not only to cotton, but to other crops as well.

Farm animals are dealt with by Mr. McCall. The native cattle are described as races of *Bos indicus*, but have not undergone artificial selection and improvement, like the European races of *Bos taurus*. It is considered that some very fine strains could be produced by proper breeding.

The book concludes with tables of useful statistics and some good illustrations of live stock. Altogether it will be found very helpful to all who are interested in Egyptian agriculture. E. J. R.

THE PROPAGATION OF ELECTRIC CURRENTS.

The Propagation of Electric Currents in Telephone and Telegraph Conductors: a Course of Post-Graduate Lectures delivered before the University of London. By Prof. J. A. Fleming, F.R.S. Pp. xiv+316. (London: Constable and Co., Ltd., 1911.) Price 8s. 6d. net.

THIS book is an elaboration of lectures which the author has given in the Pender Laboratory to telegraph and telephone engineers. The immediate and practical object of the book is to show how by a scientific treatment of the problem of electric wave propagation higher speed in telegraphy and better articulation on long telephone lines may be obtained. The problems involved are, however, fundamental to all electrical engineering, and thus the usefulness of the book is by no means limited to the class of readers for which, to judge by the title, it has been written. The phenomena of electric wave propagation play an important part in long power-lines, and much of what the author has to tell us about the waves in telephone cables may, with some obvious modifications, be directly translated into the domain of heavy electrical work. Problems connected with propagation are most easily treated by the use of the symbolic method, and although Heaviside, Steimetz, Pupin, Kennelly, and others have for some years used this method in their publications, the majority of electrical engineering text-books still ignore it. Electrical engineers will therefore feel grateful to the author for having given them in his book a very clear and readable exposition of the treatment of electric problems by complex quantities. This is done in the first chapter. Then follows a chapter on wave propagation generally. The subject is introduced by the investigation of sound waves in air. In this way the main principles of such an investigation are established by reference to a problem with which all engineers are more or less familiar, and this is a material help to the more complicated problems of magnetic and electric waves, which are treated next.

In the third chapter we come to the general case of an infinitely long cable having at one end impressed on it an alternating e.m.f. It is this case which is of interest not only to the telephone engineer, but also to the designer of a power-line. By making use of the symbolic methods outlined in the first chapter, the author shows how the current gets weaker as we proceed from the home end, and how at the same time the phase angle between e.m.f. and current increases. He distinguishes thus between an "attenuation factor," which applies to the real part, and a "phase factor," which applies to the imaginary part of the complex quantity. In telephony the attenuation factor is not of paramount importance, since the ear is able to appreciate even very weak sounds, provided their general character as determined by the sequence of the waves of different frequency remains the same. But this is just the condition which in an ordinary telephone cable only exists if its length is moderate. The phase factor is different for each wave-length, and thus the longer the line the greater is the distortion in the arriving waves. A moderate amount of distortion the human ear is able to analyse, in the same way as we are able to recognise a person's face from a caricature if the distortion of the true features is moderate, but on very long lines the attenuation and phase factors have so altered the character of the waves that the ear is no longer able to analyse them, and telephony becomes impossible.

This refers to an ordinary cable in which there is little inductance, but much capacity. The author shows that the old rule according to which the product of capacity and resistance was considered, the important item on which clearness of speech depended, is wrong, and that, as was first pointed out by Heaviside, the condition for perfect transmission is equality between two products, namely, that of capacity and resistance per mile and that of inductance and leakage per mile. In a cable of this kind the velocity of propagation is the same for all frequencies, and consequently all parts of a composite wave travel at the same speed and arrive without distortion, although, of course, attenuated. Heaviside called a cable of this kind a "distortionless cable."

By reference to Pupin's theory it is next shown how an approach to the perfection of such a cable may be obtained by "loading," that is, putting inductances at intervals along the line in series with the conductor. This approach to perfection will obviously be the closer the more it approaches the condition of a uniformly loaded line. This means that the impedance coils must not be too far apart. Eight to nine coils per wave-length is the number theoretically found in an example given of a 90 ohms per mile line, where coils of 0·2 henry every two miles satisfy this condition. In the Anglo-French telephone cable laid by the British Post Office last year the impedance coils have each an inductance of 0·1 henry, and are spaced 1·53 miles apart. The construction of this cable is fully described. There is also a chapter devoted to submarine telegraphy, and another to the study of the propagation of waves of very high frequency along wires. Here, again, the power engineer will find much useful information.

GISBERT KAPP.

MARINE REFRIGERATION.

Cold Storage, Heating, and Ventilating on Board Ship. By Sydney F. Walker, R.N. Pp. vi+269. (London: Constable and Co., Ltd., 1911.) Price 8s. net.

THE increasing luxury of modern sea-travel makes the use of cold storage almost a necessity for any but the smallest passenger boats. In the large liners the most elaborate arrangements are used to preserve the food and to keep a continual flow of air at the proper degrees of temperature and dryness through the passenger regions. In this book the author has brought together the general principles which must be used to get such a result, and in the section on cold storage considers the principal methods used to convey the enormous quantity of food now brought to this country in cold storage.

An improvement would be an index, especially to designers and freezer engineers, for whom the book is primarily intended, as it is not easy to find if a reference is made to any particular fitting or arrangement. It is well known, for instance, that there are two distinct methods of treatment suitable for different kinds of food. In one, so soon as the natural heat has gone out, the food is frozen to some degrees below freezing-point, and maintained frozen—but at no particular temperature—until ultimately thawed for use; in the other, the food is never frozen, but is maintained at as constant a temperature as possible a few degrees above freezing-point, and in an atmosphere with a definite degree of humidity. There is no difficulty about the first method, which is used, for instance, for mutton; but in the latter, used for beef, fish, and fruit, the constancy both of the temperature and the humidity is most important. There are at the present time various devices for maintaining the constancy of these factors more or less automatically, so as to relieve the operating staff from the continual strain of watching gauges, but no reference seems to be made to them.

Again, the advantages of the various methods for producing cold are given, but no attempt at summarising the knowledge so that a marine engineer could easily determine which system would be the most suitable for his particular case.

Considerable attention is paid to the discovery and prevention of faults in the whole storage system, and the advice given would doubtless be of great use to the freezer engineer. In the sections on ventilating and heating, which are clearly to be taken together, the various methods in use are considered in some detail. The author obviously inclines to electrical methods, which certainly have the great advantage that the transference of air and the generation of heat can be far more easily controlled at a large number of points. An interesting calculation is made as to the expense of running electric heating on a large liner, and appears to show that the cost is quite disproportionate to the extra comfort obtained.

There are some curious instances of the inclusion of really extraneous matter, such as the question of ventilation in mines, where the problem is essentially different and the presence of poisonous or explosive gases makes the failure of the ventilation a cause of real danger and not merely of discomfort.

In the heating section also there are a large number of illustrations of electric heaters differing very little, and more suitable to a catalogue. The book is well illustrated, and should find a distinct place in the literature of the subject. F. H.

RADIOGRAPHY.

Disease in Bone and its Detection by the X-Rays. By E. W. H. Shenton. Pp. xii+72+46 figures. (London: Macmillan and Co., Ltd, 1911.) Price 4s. 6d. net.

MR. E. W. H. SHENTON was one of the first medical men to take up the use of the Röntgen-rays for the purposes of medical diagnosis. His experience extends to more than fourteen years, and thus dates back almost to the time of the publication of Prof. Röntgen's discovery. Mr. Shenton points out in his preface the necessity for skill in carrying out the examinations and in interpreting the results. Many laymen are able to take "clear" X-ray photographs, but only an expert can be sure of taking photographs in the best way for obtaining the maximum diagnostic information. The final words of Mr. Shenton's preface are—

"To the staff of Guy's Hospital I owe more than I can acknowledge here, but for nothing am I more grateful than their attitude towards the whole subject of X-ray work. In my opinion, it has raised radiography from a branch of photography to a branch of practical medicine. As a pioneer I might have had the rough time pioneers look for, but my way has been considerably smoothed by their generous encouragement."

In the diagnosis of diseases and injuries of bones, changes of form or of density are those chiefly concerned, for opacity to X-rays is a function of density. Mr. Shenton makes the helpful general statement that acute bone disease is made evident by increase of transparency, and chronic disease by increase of opacity. He warns us against the common error of mistaking apparent variations in density of bone, due to the condition of the X-ray tube, for actual variations in density. The exposure should be such as to give the greatest possible amount of detail of texture of the bones, and a "very clear" skiagram, where the contrast between the bones and the soft parts is extremely sharp, is usually lacking in detail of bone texture.

Mr. Shenton goes fully into the subject of fracture, and directs especial attention to the subject of "callus," the new material formed around fractures, uniting the fragments. When first formed this callus is entirely transparent to the X-rays. This is a very fortunate fact, as otherwise we should not be able to judge the nature and extent of a bony lesion except just after its occurrence; not for many weeks as we are able to do. The author directs special attention also to the absence of unnecessary callus in fractures treated by Mr. W. Arbuthnot Lane's method of bringing the fragments into accurate apposition by metal plates and screws.

Various diseases of bone—abscesses, tumours, and inflammatory diseases—are described and illustrated, as are also the rheumatic and gouty conditions which affect bones in the proximity of joints. The appearance of the teeth in normal and abnormal conditions is illustrated and described.

The book is full of information, the result of the author's almost unequalled experience. It is beautifully printed in large clear type on art paper, so that the illustrations show to the best possible advantage. A. C. J.

OUR BOOK SHELF.

A Text-book of Elementary Foundry Practice for the Use of Students in Colleges and Secondary Schools. By W. A. Richards. Pp. xii+121. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1910.) Price 5s. 6d. net.

THAT a text-book of elementary foundry practice should be required for the use of students in secondary schools reads strangely in this country, but indicates how far trade practice is being brought into school curricula in the United States; and this work is by the instructor in forge and foundry practice in the University High School and the University, Chicago. A careful perusal of the book shows that it is the practice of the foundry—and that mainly of moulding—that is treated of, and not the science underlying foundry work. Only hand tools and such moulding as can be done with them are described, and the making of moulds for the production of steel castings is not included.

The author claims that though his book is written for boys in secondary schools, he hopes it may suit the college student, and that it is so plain and practical that it may be used without an instructor. A series of exercises in moulding is explained in great detail, but wherever the author ventures into the field of the science underlying any portion of foundry practice, his theory is wild and not helpful. He quotes McWilliam and Longmuir with approval (McWilliams and Longair he calls them), but is not in agreement with them when he recommends that the vent wire should be pushed down to the pattern. It is a pity that the author did not leave the science of the subject alone, for it is disheartening to find the student being told that fireclay is almost pure oxide of alumina, that copper and manganese form manganese bronze, copper and phosphorus phosphorus bronze, and like statements.

The main body of the book is, however, devoted to a simply worded and painstaking explanation of a series of exercises in moulding, so selected and arranged as to illustrate as many as practicable of the principles used in the more elementary parts of the moulder's art.

Moxly's Theory of the Tides. With a Chapter of Extracts from Moxly's Original Work. By J. F. Ruthven. Revised and enlarged edition. Pp. 103. (London: J. D. Potter, 1911.)

THIS monograph is an attempt to uphold the claims of the equilibrium theory of the tides as opposed to those of the dynamical theory now generally maintained. It is seldom possible to return to older scientific hypotheses which are of so general a nature and have been superseded, and it is impossible here.

The gist of the matter is contained in a statement by Sir George Airy, which the author quotes on page 72—"Suppose now that the water assumed the form which we have found, and that the earth revolves within its coating of water. This supposition, absurd as it is, is the only one upon which it is possible to apply the equilibrium theory." The author, following Moxly, denies the truth of this statement, and states that the equilibrium theory assumes that it is only the *form* and not the *mass* of the water which is fixed relatively to the moon. But if the form only be fixed (as *must* be assumed), then the particles of water are in relative oscillatory motion, and the tidal wave is a species of oscillation (an idea to which Moxly greatly objected, page 83)—a forced oscillation, the characteristics of which therefore depend partly on the nature of the free oscillations, and the problem is essentially dynamical.

The author seems to labour under some misconceptions of the dynamical theory in thinking, for instance, that it implies impossible ocean currents, and that the tidal crest must be 90° behind the moon (pages 8 and 9).

However, the book is a very clear exposition of the principles of the equilibrium theory, and claims to explain in general terms a number of anomalous tides; but sometimes one fails to see why the same explanation cannot hold good on the dynamical theory. The note on the tides in the Bay of Fundy (pages 88 and 89) is interesting.

W. J. HARRISON.

An Introduction to Vegetable Physiology. By Prof. J. Reynolds Green, F.R.S. Third edition. Pp. xxii+470. (London: J. and A. Churchill, 1911.) Price 10s. 6d. net.

IN the preface to the present edition Prof. Reynolds Green states that he has carried out a careful revision in order to introduce alterations suggested by practical use, and to incorporate such new ideas as have met with approval. Additional paragraphs have been inserted in the second chapter to emphasise the general relations of the individual with its environment, and further explanations are given with regard to perception of stimuli; the recasting of the sections dealing with energy and respiration was prepared for the second edition.

The book has been found particularly useful for the instruction of students up to an intermediate stage. Generally speaking, the author treats his subject so far as facts are established or theories have received acceptance. Therefore the student proceeds along a course that is, for the most part, non-contentious, and his progress is made easy by the careful arrangement and clear presentation of the subject-matter. The value of the book to the advanced student would be increased if references to literature dealing with debatable or more recent arguments were provided; for instance, it would be useful to find a reference to the description of the original experiments concerned with the detection of formaldehyde in leaves.

A History of England for Schools, with Documents, Problems, and Exercises. By M. W. Keatinge and N. L. Frazer. Part i., pp. x+388. Part ii., pp. x+324. (London: A. and C. Black, 1911.) Price 2s. 6d. each part.

IN addition to its immediate good effect on the pupils themselves, the introduction of laboratory methods of teaching science has had an indirect, beneficial influence on the other work of schools. Practical exercises are becoming a necessary part of courses of study in geometry, geography, and other subjects in which originally boys and girls had little else to do than listen to the exposition of their teachers. The most recent experiment in this direction is the introduction of the "research" method in the study of history, which is, in some schools, done in specially equipped rooms.

This work is a welcome indication of the improvement in teaching history which has taken place in recent years, and it may be recommended to the careful consideration of teachers who believe in securing the active cooperation of their pupils by setting them problems to study by themselves with the view of arriving at conclusions. An excellent collection of documents is provided, and they are intended to supply the apparatus for work which to some extent at least is analogous to that provided in the laboratory in the teaching of science.

Calendar of Papers in Washington Archives relating to the Territories of the United States (to 1873). By David W. Parker. Pp. 476. (Washington, D.C.: The Carnegie Institution of Washington, 1911.)

THIS volume is the first calendar of archive materials in Washington issued by the Department of Historical Research in the Carnegie Institution. It follows upon Messrs. Van Tyne and Leland's "Guide to the Archives of the Government of the United States in Washington." Mr. J. Franklin Jameson, the editor of the series to which this book belongs, says that the interest of historical writers at the present time is greatest in respect of papers which have to do with territories as a whole, especially with their government and their constitutional and political history. Accordingly attention has, in the present volume, been concentrated upon papers of this class.

Lehrbuch der Zoologie für Studierende. By Prof. J. E. V. Boas. Sechste vermehrte und verbesserte Auflage. Pp. x+690. (Jena: Gustav Fischer, 1911.) Price 12.50 marks.

PROF. BOAS's text-book is so well known—both the original text and the translation—that no description is necessary of the sixth revised edition now before us. The fifth edition was reviewed in NATURE of April 22, 1909 (vol. lxxx., p. 214), and the present issue differs from it only by the addition of a few pages and fifteen new illustrations.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Non-Euclidean Geometry.

MR. FRANKLAND (NATURE, September 7) has raised the old problem of Bertrand's proof of the parallel-axiom by a consideration of infinite areas. This is perhaps the most subtle and the most specious of all the attempted proofs, and this character it owes to the fact that a process of reasoning which is sound for finite magnitudes is extended to a field which is beyond our powers of comprehension—the field of infinity. The fallacy which underlies Bertrand's proof becomes more apparent in Legendre's simpler device ("Éléments de Géométrie," 12 éd., Note ii.). A straight line divides a plane in which it lies into two congruent parts—this, of course, has no real meaning, since we are dealing with infinite areas, but such is the argument—and two rays from a point enclose an (infinite) area which is less than half the whole plane. Hence, if two intersecting lines are both parallel to the same straight line, the area of half the plane can be enclosed within an area which is less than half the plane.

This is the same sort of paradox as the well-known one by which the part is made to appear equal to, or even greater than, the whole. The even numbers 2, 4, 6, . . . form a part of the aggregate of integral numbers 1, 2, 3, . . ., but a (1, 1) correspondence can be established between them, viz. to $2n$ in the part corresponds n in the whole aggregate, and to n in the whole corresponds $2n$ in the part. Hence the part is equal to the whole. And, again, a (2, 1) correspondence can be established between the part and the whole, viz. to $4n$ in the part corresponds n in the whole, while the numbers of the form $4n+2$ have no correspondent. Thus the part is greater than the whole.

Mr. Frankland's comparison of the areas of a circle and a regular inscribed polygon is not quite fair to the polygon. The area of a regular N-gon, as its radius tends to infinity, tends to a finite limit, $\pi k^2(N-2)$, which, of course, tends to infinity as N is increased. The area of a circle is $4\pi k^2 \sinh^2 r/2k$, which also tends to infinity as r is increased. The first he calls a linear infinity, and the second an exponential infinity, and certainly e^x/x^n tends to infinity with x, if n is any finite number. But what is the relation between r and N? If we take the expression for the area of a regular N-gon inscribed in a circle of radius r, and then let N increase, we get a limit $4\pi k^2 \sinh^2 r/2k$, which is the expression for the area of the circle. Again, if in the regular N-gon with infinite radius we inscribe a circle, its area is $2\pi k^2(\operatorname{cosec}\frac{\pi}{N}-1)$ and this always bears a finite ratio to the area of the N-gon; it is thus an infinity of the same order, if N is increased indefinitely, and the N-gon, the inscribed circle, and the circumscribed circle all tend to the same geometrical limit—the absolute.

The fact that the cuspidal edge of the surface of rotation of the tractrix forms a line of discontinuity in this representation, and that none of the types of surfaces of constant negative curvature exactly images the hyperbolic plane in the properties belonging to analysis situs, appears to be no objection to hyperbolic geometry. An exactly similar difficulty occurs in the representation of elliptic geometry, since there is no continuous surface of constant positive curvature on which two geodesics have but one point of intersection. Geometry has become entirely a matter of postulation; but, at the same time, it is of interest to observe that the non-Euclidean geometries are capable of being truly represented, even within a restricted field, in Euclidean space.

D. M. Y. SOMMERVILLE.

The University, St. Andrews, September 30.

Elements of Comet 1911*f*.

FROM M. Quénisset's observation of September 23, and my own of September 26 and 30, I obtain the following approximate elements:—

$$T = 1911 \text{ November } 12{\cdot}67$$
$$\omega = 123^\circ\ 13{\cdot}4'$$
$$\Omega = 35^\circ\ 36{\cdot}6'$$
$$i = 102^\circ\ 19{\cdot}8'$$
$$\log q = \bar{1}{\cdot}89116.$$

The comet is now receding from the earth and approaching the sun, and there is no reason to expect much increase in brilliancy. The only point of interest is that when at the descending node on December 16 it will be about half a million miles outside the earth's orbit. The difference of the heliocentric longitudes of the earth and comet will, however, be 132°, so that no near approach is possible.

J. B. DALE.

Craigness, New Malden, Surrey, October 3.

Rainfall in the Summer of 1911 and of 1912.

HAS Mr. MacDowall the courage to apply his own experience, to which he refers in NATURE of September 28, to "supply long-range forecasts of months, seasons, &c."? Will he publish in advance a forecast for the winter 1911–12 or for the spring and summer of 1912, such as he considers could have been done for the summer of 1911? Or is it only after the event that he can discover what points in the past have to be considered and in what grouping they have to be compared in order to yield an *a posteriori* "forecast"?

HUGH ROBERT MILL.

62 Camden Square, London, N.W., October 2.

Miniature Rainbows.

WHEN returning one day in August of last year from the Farne Islands to Berwick in a pleasure steamer, I was standing in the bow of the boat, and was much struck by the display of a permanent rainbow in the spray that was thrown up. The rainbow was inverted, the result, presumably, of my position above it. The sea was very rough, and thus the spray was constant.

EDWARD A. MARTIN.

285 Holmesdale Road, South Norwood, S.E.

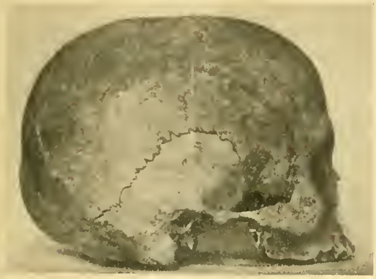
THE STONE AGES OF SOUTH AFRICA.[1]

THE papers in this volume are a very full and important addition to the work already published by Mr. J. P. Johnson; but it is doubtful whether they bring us any nearer to a solution of one of the most interesting questions connected with archæological or palæontological discoveries in South or Central Africa —namely, the approximate age to which the existence of man can be traced back in South Africa, East Africa, the Congo basin, West Africa, and the Sudan. Though Dr. Péringuey would seem, from one or two phrases, to lean to the theory of a very ancient date for the human colonisation of tropical Africa, he has to admit repeatedly that so far no cogent evidence has been produced in the shape of geological features associated with the finds of human remains or implements to indicate, as positively as is the case in Europe and Asia, the period in the earth's history with which such remains are to be associated.

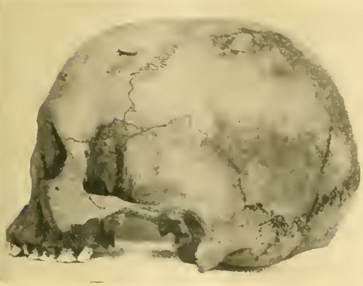
As our knowledge advances towards perfection, as we become better and better able to read that new Bible, the book of the Earth itself, we may have to revise our estimate of the ages of the hitherto discovered prehistoric, palæolithic, and eolithic human remains in Europe and Asia. Still, there can be little

[1] Annals of the South African Museum: vol. viii., part 1, containing the Stone Ages of South Africa, &c. By Dr. L. Péringuey, with further contributions by Mr. A. L. Du Toit and Dr. F. C. Shrubsall. (London: Printed for the Trustees of the South African Museum by West, Newman and Co.) Price 40*s*.

question within a few thousand years, more or less, of the relative ancientness of the calvarium, the molar teeth, and thigh-bones of *Pithecanthropus erectus* in Java; of the *Homo primigenius* type of lower jaw found near Heidelberg; and of the Grimaldi skeletons, &c. Of course, the mere finding of stone implements



(i) Strandlooper.



(ii) Bushman.

(iii) Hottentot.
Crania from South Africa.

in any part of Europe or temperate Asia argues some degree of antiquity in the specimens, because we know more or less historically the period at which they were abandoned for implements or weapons of metal. But in tropical Africa no such argument can apply, for a few small portions of the continent are still in the Palæolithic, or even Eolithic, Stone age. The south-western extremity of Africa was certainly in the palæolithic age 400 years ago, when Europeans first arrived there; though the Bantu tribes bordering on the Hottentot and Bushman domain had for many centuries before been mining, smelting, and using copper and iron.

So far as the reviewer is concerned, he continues to adhere obstinately to the belief, not as yet shaken by any registered fact, that man is a relatively recent immigrant into Southern Africa, and that Africa in general south of the Sahara Desert and of Somaliland has been much more newly populated by man (almost entirely of the negro subspecies) than has been the case with Asia—the original birthplace of the human species and genus—and with Europe.

Much interesting palæontological and geological evidence is collected and laid before the reader in chapter vii. (p. 74 and onwards). In this, Dr. Péringuey mentions that a portion of a molar tooth of a mastodon has been found in close proximity to a deposit of palæoliths and fragments of stone, evidently used as human implements, at Barkly West, in Cape Colony. Human implements have also been found in association with the lower jaw of an extinct horse of large size and of the gigantic long-horned buffalo—*Bos* or *Bubalus baini* (a close ally of the *Bos antiquus* of Algeria). But from the rock drawings in Algeria we know that this gigantic North African buffalo not only was contemporaneous with man, but even with neolithic man, and only seems to have become extinct a few thousand years ago. Similarly, in the extremity of South Africa a mastodon, a large horse, and the South African type of gigantic buffalo may have lingered down to quite a late period, since this same portion of the continent contains in a living state at the present day creatures which became extinct in Europe a hundred thousand years ago. (In this portion of his narrative Dr. Péringuey persists in confusing *Hyena brunnea* of South Africa with *Hyena striata* of East, West, and North Africa and Western Asia. I write under correction, but had always believed that *Hyena brunnea* was a very distinct species which hitherto had not been found north of the Zambezi and South Angola, and, though allied to the various types of *striata* far more than to *crocuta*, was nevertheless a very distinct species.)

Some of Dr. Péringuey's deductions are very interesting, especially as combined with the observations of Dr. Shrubsall. One of these would seem to be that the earliest human invaders of South Africa were of somewhat higher culture, of different head-form, and better brain development than the modern Bushman. These people are the now celebrated Strandloopers. At one time it was assumed, on the strength of some very prognathous skulls found in the coast regions of South Africa, that the Strandlooper was more "simian" (if that word may be applied to a very slight approximation towards the basal human type) than the Bushman. This deduction would seem to be wrong. The sub-nasal prognathism in the skulls of the earliest cave-men of Strandlooper types is less than in the Kalahari Bushmen and the Nama Hottentots of to-day, or in the general mass of negroes. One of the Strandlooper skulls, according to Dr. Shrubsall, has a more prominent nose and face than the typical negro, and in some respects recalls the river-bed type of early Europeans. The cranial capacity of these primitive Strandloopers was distinctly greater than either Bushmen or Hottentots, and this feature is present in the oldest skulls. One of these has a cranial capacity of 1600 c.c., while in a female skull of the Bush race from the Kalahari Desert there is a capacity of only 950 c.c.

Moreover, it would seem to be as though there had been a marked degeneration not only in the physical conformation of the pre-Bantu inhabitants of South Africa from the earliest Strandlooper type downwards, but also in the character and size of the stone implements manufactured by these primitive South African peoples.

Dr. Péringuey in some of his remarks (p. 168) would seem to regard the Bushman as not being a primitive race, but an example of retrogression in some directions and a singular advance in others. He puts forward the interesting hypothesis that the ancestors of the Bushman having discovered the potency of vegetable and animal poisons, gave all their attention to the manufacture and shooting of poisoned arrows, and therefore no longer cared to fabricate large stone weapons.

Dr. Péringuey writes as a South African, and South Africans are apt to hold heretical notions regarding the Bantu. One is that there is a Bantu physical type of negro, which is not the case; and the other is that the Bantu languages in their present form are of immense antiquity, and came to Africa from India. The Bantu-speaking peoples of South Africa vary in physical type, just as they do in the rest of Bantu Africa, and do not present any collective difference from millions of other negroes not speaking a Bantu language. As to this language family, I have given at different times reasons which appear to me conclusive for supposing that it cannot have originated in North Central Africa more than some 3,000 years ago. It was brought into existence in the heart of Africa, just like its neighbour Hausa, by the intrusion of some half-white race similar to the Hamite or the Fula.

This book gives interesting illustrations of the steatopygia and peculiarities of the external genitalia of the Bushman race. H. H. JOHNSTON.

CALIFORNIAN TREES.[1]

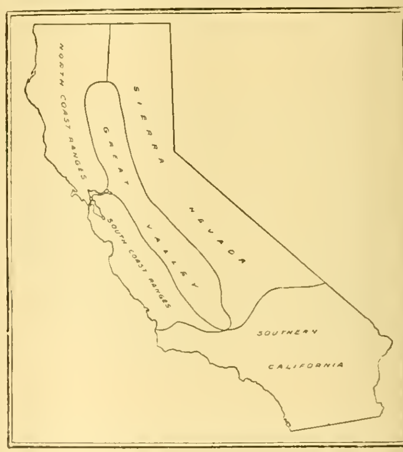
PERHAPS the noblest and most fascinating of all subjects for the writer and student of trees is the sylva of California. The arboreal vegetation of no other area of similar dimensions rivals it in interest or in the size of its individual types. Three trees alone—the two Sequoias ("Big Tree" and "Redwood") and the Douglas Fir—give to it a unique distinction, and they are supplemented by a group of scarcely less wonderful pines, firs, and spruces. Whilst it is the immense coniferous trees that give to the Californian sylva its remarkable fascination, many of the "broad-leaved," or non-coniferous, species are scarcely inferior in interest and distinction. There are, for instance, the magnificent Madroña—*Arbutus Menziesii*—a close ally of the Killarney arbutus, but reaching 125 feet in height, with a trunk 5 feet in diameter; the golden chestnut (*Castanopsis chrysophylla*), its leaves a tawny gold beneath, also over 100 feet high; the Mountain dogwood (*Cornus Nuttallii*), an ally of our Cornelian cherry, but often 50 to 60, sometimes 100, feet high, with its beautiful white involucres 6 inches across. Mr. Jepson, therefore, may well be congratulated on his subject.

To us in the British Isles it possesses an exceptional interest, because most of the Californian trees can be cultivated in the open air in many parts of our country. Nowhere else, indeed, out of California itself, can its coniferous trees be seen to such perfection as in the Perthshire valleys and in various places in the south and west of England and Ireland.

[1] Memoirs of the University of California. Vol. ii., "The Silva of California." By W. L. Jepson. Pp. 480+85 plates+3 maps. (London: T. Fisher Unwin; Berkeley: University Press, 1910.) Price 2l. 2s. net.

The history of the Californian sylva as known to Europeans strikes one as curiously recent. Botanical knowledge began with the visits of the Malaspina and the Vancouver expeditions. The latter, a voyage of survey organised by the British Government, touched California about 1793. Most of the botanical work accomplished on this journey was done by Archibald Menzies, but he only penetrated a few miles from the coast. David Douglas visited and explored California in the interests of the Horticultural Society of London about 1827, and with him may be said to have commenced the real revelation of its sylva. It was carried on by Nuttall, Fremont, Kellogg, Brewer, Bolander, and others. But even the existence of the "big trees" (*Sequoia gigantea*) was not definitely and authoritatively made known till nearly the middle of the nineteenth century, although hunters and wandering pioneers had previously brought home accounts of marvellous trees—mostly received, however, with the scepticism the stories of such folk obtain.

Among the later investigators of the Californian sylva a foremost place is held by the author of this



The Five Forest Provinces of California.

volume. Only two years ago he published an admirable little book, "The Trees of California," of which the present elaborate work is an amplification. The new volume opens with an interesting essay on the remarkable topography of California, its climate, rainfall, and tree distribution. The two great mountain systems (the Coast Ranges and the Sierra Nevada) enclose a great oval plain known as the "Great Valley," drained by the San Joaquin and Sacramento rivers, which meet about midway, and empty into the Pacific. This region, 400 miles long and averaging about 50 miles in width, is sparsely wooded and weak in number of species. One peculiar characteristic of its scenery is the park-like grouping and disposition of a few species of oak, chiefly the Valley oak (*Quercus lobata*) and the Live oak (*Q. Wislizenii*). They never form forests as the coniferous trees of the foot hills and mountain slopes do, and scarcely anywhere on this central plain does an aggregation of individuals amount to more than what may be termed a grove.

Besides the great valley of the Sacramento and San Joaquin, the author discusses his subject from the point of view of four other great geographical areas:

(1) the Sierra Nevada, the chief sylvan interest of which belongs to the long western slope, where occur the Big Tree groves, the eastern slope being remarkably abrupt; (2) the North Coast Ranges, a region rich in individuals and species, including the Redwood and many others which extend northwards into Oregon and Washington; (3) the South Coast Ranges, which form an interesting area richest forestally on the seaward slopes, where, among others, flourish the Redwood, Douglas Fir, and *Pinus ponderosa*. This region includes the remarkable peninsula of Monterey, where the well-known Monterey cypress of our gardens (*Cupressus macrocarpa*) is endemic; (4) Southern California, where the rainfall is deficient and the arboreal growth confined to mountain valleys and cañons, and where, in many places, the vegetation is of a purely desert character.

Spread over these five forest provinces are the ninety-four species of trees which come under the author's purview. The whole essay, which is one of remarkable interest, is the result, as Mr. Jepson tells us, of nineteen years' travel and study in the field. The only criticism we would make is that the exclusive use of vernacular names renders it impossible to follow the author without a continual and rather irritating reference to the body of the work in order to ascertain what species it is to which he is alluding. Such names as "Interior Live oak," "Santa Lucia fir," convey no meaning to the majority of readers, and their general adoption (which the author is anxious to bring about), as well as the reader's convenience, would have been furthered by a citation of the botanical name as well.

The treatment of the individual species is admirable. A very full synonymy is given, and a copious list of references. After an adequate and not very technical description of the tree, the author discusses its geographical distribution, its history, economic value, and any other matter of interest concerning it. To the Redwood and Big Tree, ten and eight pages respectively are devoted, and the distribution of the latter is shown by two large maps. The book is illustrated by eighty-five full-page plates, many of them reproductions of photographs showing the trees in their native habitats, and, incidentally, characteristic bits of Californian scenery.

Mr. Jepson has the orthodox conception of a species, which is decidedly refreshing after the orgy of species-making his compatriots of recent times have indulged in As presenting an original and authoritative account of a group of trees of particular interest to arboriculturists in the British Isles, his book may be strongly recommended. W. J. BEAN.

IMPERIAL SURVEYING.[1]

IN response to an invitation sent by the Colonial Office in March, 1909, to the Dominion, Commonwealth, State, and Provincial Governments in the Empire, delegates for the Commonwealth of Australia and the Dominion of Canada met in London in June last to discuss the proposal for establishing some system of reciprocal admission for surveyors between the different portions of the Empire. The question had been raised originally as a resolution submitted by the Government of New Zealand to the Colonial Conference of 1907, at which a memorandum drawn up by the council of the Surveyors' Institution was discussed, and a resolution was adopted affirming the desirability of reciprocity with regard to the examination and authorisation of land surveyors. The outcome of this was that particulars of examinations and other requirements with regard to the authorisation of surveyors were obtained from several Dominions, and were coordinated and compared in a second memorandum by the council of the Surveyors' Institution, in which the desirability of a conference between those concerned was pointed out.

This conference recommends as a first essential the formation of a central board, which would use its influence to keep up a uniform standard of examination, and on which the different Governments of the Empire would be represented. All examination papers set in any part of the Empire under any scheme of reciprocity would be sent to the board, which would direct attention to any questions falling below the standard agreed upon, and would consider any proposals for improving the working arrangements for reciprocity. Further, a syllabus was drawn up for a preliminary examination in English, arithmetic, algebra, plane and solid geometry, plane trigonometry, and mensuration; and for another of more advanced type to be passed after two years' field service, and including practical and theoretical surveying up to secondary triangulation.

Though this may appear a slight basis on which to construct a scheme of imperial reciprocity in this direction, the complexity of the whole subject must be remembered. In the United Kingdom the Ordnance Survey has provided an accurate topographical survey of every portion, though a true cadastral survey indicating all property boundaries does not yet exist, and, according to the recent report of the Royal Commission on the Land Transfer Acts, is not recommended, since therein verbal description of boundaries is preferred, maps being used in all cases, but only for assisting identity. Consequently there is no profession of highly trained surveyors having an intimate knowledge and full experience of the most precise methods of land and earth measurement, nor is geodesy studied at the higher educational institutions as is the case on the Continent. A moderate knowledge of land measurement enables the necessary interpolations and additions to be made to an ordnance map, and a land surveyor's duties are very largely concerned with valuation. The Surveyors' Institution has arranged a special advanced examination in land surveying, but being of no great value at home, and not recognised in a colony, use is not made of it.

In the various colonies the conditions are wholly different, for large areas remain unsurveyed, the demand for the location of property boundaries is urgent, and in many cases the surveyor has no official control points to connect with, but must make his own survey self-contained. It is therefore necessary for the Governments of these colonies to insist upon a high standard of technical efficiency in land measurement, including an acquaintance with geodetic work in all its branches. With such very different conditions existing any arrangement for the free interchange of surveyors must be difficult, and the proposals now put forward may be a first step as providing a guarantee of a certain standard of efficiency which may in some Dominions, Provinces, or States require to be supplemented to qualify for their special certificates.

In the United Kingdom at the present time there is no place where higher surveying and geodesy are regularly taught to those who are already acquainted with the ordinary and more approximate methods, and an improvement in this respect would do much to enable a surveyor in this country, wishing to practise in the colonies, to acquire the additional technical equipment which is required by some of their regulations. But besides the self-governing colonies there are vast tracts administered by the Crown colonies, and in these administration and development are de-

[1] Report of a Conference on the Question of Reciprocity throughout the Empire in the Examination and Authorisation of Surveyors. [Cd. 5776.] (London: Stationery Office, 1911.) Price 2½*d*.

manding both topographical and cadastral surveys as rapidly as they can be prepared. If these are to be both efficient and economical, and if as little as possible of the work done in early stages is to need complete revision at a later date, then those engaged in directing them should have a thorough knowledge of the methods, principles, and requirements of surveying of the highest grade, and not merely a certain proficiency in the simpler classes of topography that is now demanded; but for the acquirement of such knowledge there are not as yet in this country facilities such as exist on the Continent, where numerous chairs of geodesy and precise surveying are to be found.

H. G. L.

FRANCE AND CLASSICAL EDUCATION.

AT the Dijon meeting of the French Association for the Advancement of Science last August the president, M. Ch. Lallemand, delivered an informing and luminous address on the question of modern *versus* classical education. The address should be particularly instructive to English educationists, for the home of the traditional curriculum of our public schools is France, the direct heir of Roman literary culture.

Recently there has been something of a crusade against "modernism" in education, the chief argument being that the French language and French culture are being endangered by the abandonment of what the French call "Latin education," which, like our classical education, is chiefly based on Latin and Greek. But, as will be seen, there is no abandonment, and the crusade is probably no more significant than its predecessor of forty years ago, or the longer-continued counter-crusade against "Latin education." We shall refer to it more fully below.

Science and modern languages were introduced as parallel lines of education, but not as superseding the classical system, under the Second Empire. The growing needs of industry and commerce and the enormous development of science forced this on the nation. This "bifurcation" was continuously successful, though it was at once attacked. A counter-attack on the classical course followed, increasing in vigour towards the end of the century. M. Jules Lemaître put the weight of his great authority into the scale against classics. A similar attack was meanwhile being made in Germany, the Emperor William pronouncing strongly against classical education. From 1882 to 1900 the proportion of German students not learning Latin increased from 9 per cent. to 43. Then in 1902, as the result of a parliamentary commission, came further concessions to the claims of modernism. The resulting system, known as the "quadrifurcation," comprises, besides the general classical course, Latin and modern languages, Latin and science, and the specially "modern" course of modern languages and science.

The system is attacked both by literary and, significantly, by commercial authorities. M. Marcel Prévost says: "The new crop of graduates does not know more algebra, or physics, or modern languages than the old, and of their own language they know less." The chambers of commerce and great financial administrations have complained of the decay of correct writing and spelling, and demand the restoration of Greek and Latin as being indispensable for proficiency in commercial composition. Societies have recently been formed for the protection of French culture and the French tongue.

M. Lallemand disproves the notion that there is *une crise du français*. Recently in China the mandarins complained that young students were neglecting the study of the "characters" under the baneful influence of occidental ideas. When the classical system in France was "uncontaminated" by modernism, the complaint was made that the engineers of the public departments could not write or spell, and a special course was instituted to make this defect good.

Further, statistics show conclusively that if this ignorance of the principles of composition and orthography exists, it is not due to the abandonment of Latin and Greek. As a matter of fact, the number of students taking Latin has steadily increased since 1902. In 1910, of 1875 first-year students in Paris, only 362 had not learnt Latin. Of 646 students leaving L'Ecole Polytechnique between 1906 and 1910, there are 203 "moderns" as against 443 "Latins." Finally, as to the writing question, the Polytechnique examinations in French composition during the last ten years show a considerable superiority on the part of the "moderns"!

As to the alleged decadence of correct writing and calligraphy, M. Lallemand suggests that the increasing congestion of curricula, necessary in view of increasing knowledge, may be a factor. Perhaps in France, as in England, no serious attempt has ever been made to teach the native language. The present writer holds that this defect, together with the retention of Latin and Greek, constitutes the crying evil of present-day education.

M. Lallemand has some good remarks and quotations on the alleged educative virtue of dead languages and on the inconsistent arguments of those who advance it. They might form the basis of a logical inquiry, which is much needed, into the "educative" processes. He also has some penetrating observations on caste-feeling, which has a good deal to do with the recent crusade. The smallest shopkeeper is in favour of Latin, because his son can learn it as well as the son of the noble. If science were the cornerstone of education, the smallest shopkeeper would, on the same principle, vote for science.

A. E. CRAWLEY.

SIR HERBERT RISLEY, K.C.I.E.

BY the untimely death of Sir Herbert Hope Risley on September 30, at the age of sixty, science has lost an eminent anthropologist and India an official of no ordinary ability. Born in 1851, educated at Winchester and New College, Oxford, he joined the Indian Civil Service in 1873, and was posted to Bengal. He was soon transferred to the secretariat, a class of work for which his qualifications were better suited than that of an executive officer. But already he had acquired a taste for ethnological research during a short period of service in Chota Nagpur, where, on the basis of Colonel E. T. Dalton's "Descriptive Ethnology of Bengal," he compiled an account of the interesting hill races, which appeared in vol. xvi. of Sir W. Hunter's "Statistical Survey" of the province, issued in 1875–7. This, with the period spent on special duty as ethnographical superintendent in Bengal, was the only opportunity he enjoyed of obtaining that intimate familiarity with the rural classes which can be gained only by lifelong service in their midst.

The results of his researches in Bengal were embodied in his work on the tribes and castes of that province which appeared in 1891. Aided by a band of skilled co-workers, and utilising the materials privately published by Dr. J. Wise in 1883 under the title of "Notes on the Races, Castes, and Trades of

Eastern Bengal," he produced a work of considerable interest and authority, which at once attracted the attention of European scholars. He admitted that this work was only provisional and that it was merely "circulated for criticism"; but he had no opportunity for the preparation of a revised edition. Under the guidance of the late Sir W. Flower he mastered the principles of craniometry, and his receptive mind familiarised him with the general problems of ethnography and their bearing on the special conditions of the Indian races. Appointed director of the Ethnographical Survey in 1901, he suggested a scheme for research which, for reasons of finance, was rejected. On a limited scale it was sanctioned by the Government of Lord Curzon, and is now in progress in certain provinces.

Risley's reputation as an anthropologist must depend upon his account of the Bengal tribes and castes, and the chapters on caste and race contributed to the report on the census of India of 1901, conducted under his supervision. The latter was a remarkable *tour de force,* considering that it was written amidst the pressure of other arduous duties. In this class of work his lucid style and grasp of principles enabled him to present in an attractive form the results of the researches into Indian anthropology and sociology made by his assistants and himself. Had he lived longer he would probably have revised some of the theories advanced in his census report, which, with some modifications, was re-issued under the title of "The People of India." In particular he must have realised that craniometry alone is a slippery foundation for an analysis of the complex of Indian races; that he was mistaken in denying the influence of the Scythian and Hun invasions, particularly in relation to the origin of some of the Rajput tribes; and that his scheme of classification to some extent ignored the influence of environment, and the confusion of groups resulting from long ages of internal war and social disorganisation. But in his skilful account of the caste system and its working his powers of systematisation, aided by considerable literary ability, are fully displayed.

It may be feared that he was unable to complete a work on the people of eastern Bengal, which was announced for publication soon after his retirement from India. But he has left enough to show that, with more opportunity for personal study of the people and more leisure for examination of the material which he had collected, he might have attained a scientific reputation even higher than that to which he attained. Besides his published work, the initiation of the Ethnographical Survey of India is the best memorial of his services to the cause of science.

NOTES.

A meeting of the International Commission on Mathematical Teaching was held at Milan on September 18–21, Prof. F. Klein presiding. The main subjects discussed were:—(1) The question of rigour in teaching mathematics, especially geometry. It appears that of European countries Italy is the most wedded to rigorous methods, while Germany and Austria stand at the other end of the scale, and admit intuitive methods freely. France and England adopt a middle course, France inclining toward the Italian practice and England toward the German. It was agreed that Euclid does not satisfy modern standards of mathematical rigour. (2) The question of "fusion," *e.g.* of geometry with algebra, of plane with solid geometry, of geometry with trigonometry, of solid geometry with descriptive geometry, of analytical with geometrical conics, of differential with integral calculus. (3) The provision of mathematical instruction for students of such subjects as chemistry, biology, and economics. Such courses were at one time provided in French universities, but are now entrusted to the schools. In other countries there does not appear to be any systematic provision of this kind. The reports issued by the various national subcommissions were presented; of these, the French reports are now complete; eight of the thirty-four English reports have been issued by the Board of Education (Wyman and Co.), and a large amount of literature has been issued by the German subcommittee, whose labours, however, will not be completed for two years more. Arrangements were made for the educational subsection at the International Mathematical Congress to be held at Cambridge (England) on August 22–28, 1913. A full report of the Milan meeting will be published in due course in *L'Enseignement Mathématique.*

The summary of the weather for the first nine months of the present year, which has just been issued by the Meteorological Office, shows that the temperature for the period was in excess of the average over the entire area of the British Islands, the excess being greatest over England. The rainfall was everywhere deficient, the deficiency amounting to 7·20 inches in the north of Ireland, to 6·71 inches in the Midland counties, and to 6·20 inches in the south-west of England. In the south-east of England, which district embraces London, the deficiency of rain for the nine months amounts to 5·57 inches. Over the north of England the deficiency is little more than 2 inches, and in the north of Scotland it is only 0·05 inch. The largest aggregate rainfall for the nine months is 35·58 inches, in the north of Scotland, the least 11·94 inches, in the Midland counties. Rain fell on 163 days in the north of Scotland, but only on 97 days in the south-east of England. There was an excess of sunshine in the nine months over the entire kingdom, the greatest excess being 334 hours, in the south-east of England. The greatest aggregate duration of sunshine for the nine months is 1799 hours, in the Channel Islands, but it was very little less in the south-east of England, where the aggregate duration was 1720 hours. In the north of Scotland it was only 1116 hours. The summary for September shows that it was only in the English districts that the temperature was in excess of the average. The rainfall for the month was deficient over the entire kingdom, except in the north-east and north-west of England and in the south of Ireland. The sunshine was again in excess of the average over the entire country. At Greenwich the mean temperature for the month was 61°, which is 3° in excess of the average; the temperatures in the early part of the month beat all previous records, both for the absolute readings and for the mean of the period. The total rainfall for the month was 1·34 inches, which is 0·85 inch less than the average, and rain only fell on eight days. The sun was shining for 222 hours, which is nearly 70 hours more than the normal.

Sir Thomas Crosby, who has been elected Lord Mayor of London for the ensuing year, is the first medical man to occupy that office (though his term will be the 723rd Mayoralty of the City), and is probably the oldest citizen upon whom the honour has been conferred, his age being eighty-one. He took the degree of M.D. at St. Andrews University in 1862, after being in practice for ten years, and filled the office of president of the Hunterian Society in 1871. He is a member of the Senate of the University of London.

New regulations for the sale of mineral acids have now come into force. They have been made by the Privy

Council with the object of preventing the misuse of sulphuric, nitric, and hydrochloric acids. These acids, and also salt of lemon, must now only be sold by retail in bottles, distinguishable by touch from ordinary bottles, and bearing on a label the name and address of the seller, together with the words "Poisonous" and "Not to be taken." Ammonia will also be subject to the same regulations in four months' time.

THE popular science lectures which are given at the Royal Victoria Hall, Waterloo Road, S.E., every Tuesday evening from October to May, will commence on Tuesday, October 10, when Prof. W. Flinders Petrie, F.R.S., will lecture on "Life in Egypt 2000 Years Ago." Other lectures during this month are:—October 17, "The Modern Gun and Armour Plate," J. S. S. Brame; October 24, "Seeing Canada," Miss A. D. Cameron; and October 31, "Mountaineering," Mr. H. V. Reade.

WE notice with regret the announcement of the death, on September 26, of Mr. G. C. Donington, senior chemistry master at the City of London School. Mr. Donington was for a time demonstrator in chemistry at the Central Technical College, South Kensington, and was afterwards successively science master at Highgate School, Christ's Hospital, and Leeds Grammar School before his appointment to the City of London School. He was the author of a laboratory manual entitled "Practical Exercises in Chemistry," issued in 1906, and of a helpful "Class-book of Chemistry," published a few months ago. His death at the early age of thirty-seven will be deeply regretted by many friends and pupils.

AN investigation of the disease known as "sprue" is to be undertaken by the London School of Tropical Medicine. It is hoped that funds to the amount of 1000*l.* will be available for this purpose, of which the Government of Ceylon has provided 750*l.*, and the remainder will probably be subscribed by the Ceylon Tea Planters' Association. It has not yet been decided what representative of the school will undertake the investigation. The disease occurs in Ceylon, Malaya, Indo-China, China, and other districts, and is of considerable importance, causing a large amount of sickness and disability, and in some instances a fatal issue. At present little is known of the causation of the malady.

IT is proposed to erect a memorial to Mungo Park and Richard Lander. A committee has been formed consisting of Lord Curzon, Sir George T. Goldie, Lord Scarbrough, Major Leonard Darwin, Sir Walter Egerton, and Sir Hesketh Ball to take the necessary steps to secure funds for this purpose. Both explorers have been honoured in their native towns of Selkirk and Truro, but no record of any kind exists in the land to which their lives were consecrated and sacrificed. In appealing for support, the committee remarks:—"As the main object of their travels was to discover where the Niger joined the ocean, the most suitable site would seem to be its principal ocean port. It is therefore proposed to erect an obelisk of similar design and dimensions to Cleopatra's Needle on a projecting point of land at Forcados, where it would both attract general attention and serve as a landmark to vessels approaching the port. The total cost is estimated at 2000*l.*, exclusive of the foundations, which it is understood will be undertaken by the Government of Southern Nigeria." Donations may be sent to the honorary treasurer of the fund, Dr. J. Scott Keltie, 1 Savile Row, London.

THE new session of the Royal Geographical Society will be opened on November 6, when Dr. Nansen will read a paper on the Norsemen in America. On November 20 Dr. Tempest Anderson will give a paper on volcanic craters and explosions. On December 4 Sir Alfred Sharpe, until recently Governor of Nyasaland, will deal with the geography and economic development of British Central Africa. On December 18 Dr. T. McDougal, of the Carnegie Institution of Washington, will contribute a paper on American deserts. In the new year Sir William Willcocks will deal with his further researches on the Garden of Eden and its restoration. Dr. Mackintosh Bell, late director of the Geological Survey of New Zealand, will describe an unknown corner of South Island. Mr. Douglas Carruthers will describe, probably in March, his travels in Central Asia. Mr. A. J. Sargent will deal with the commercial geography of the Tyne Basin, and Mr. P. A. Talbot with the journeys in the Central Sudan. In January or February a course of three lectures will be given in the afternoon on the desert of North Africa, by Captain H. G. Lyons, F.R.S. The Christmas lectures this session will be:—on January 5, by Mr. Julian Grande, on "Amongst the Alps"; on January 8, by Mr. W. Herbert Garrison, on "Our World-wide Empire"; and on January 11, "A Lady's Journeys in the Central Sudan," by Miss Olive MacLeod.

A COPY of the first monthly number of the eighth volume of *The South African Journal of Science*, being the issue for August last, has been received. The periodical is the organ of the South African Association for the Advancement of Science, and the present issue is concerned with the Bulawayo meeting of the association held in July last. The presidential address of Prof. P. D. Hahn is printed, and in it he dealt, we find, with the advance in the teaching of science during the last forty years. "There was," he said, "no professorship or lectureship for any branch of science in existence in any of the schools or colleges of South Africa forty years ago, whilst at the present time we have over sixty professors and lecturers appointed to teach certain branches of science in our colleges and technical and agricultural schools." In Section A of the association, concerned with astronomy, mathematics, physics, meteorology, geodesy, surveying, engineering, architecture, and geography, the Rev. E. Goetz was president, and took "weather forecasting" for the subject of his address, which is printed in part in this issue. The South Africa Medal and Fund, which was raised by members of the British Association in commemoration of their visit to South Africa in 1905, were presented to Dr. L. Péringuey, director of the South African Museum, in recognition of his entomological research in South Africa. The fund amounted to 50*l.* The 1912 meeting of the association is to be held at Port Elizabeth.

MR. A. HAMILTON, director of the Dominions Museum at Wellington, New Zealand, has issued a useful hand-list of pamphlets and papers containing information relating more or less directly to the Maori race, supplementing the earlier catalogue published by him in vol. **xxxiii.** of the Transactions of the New Zealand Institute for 1900. He has excluded from his collection anything which might be called a "book," as these are to be found in various library catalogues and bibliographies. The present list is therefore confined to detached articles, many found only in obscure sources, which supply information on this interesting people. The publication is thus of much value to students of sociology, ethnography, folk-lore, and comparative religion and mythology.

IN his paper issued by the University of London Press on the pronunciation and orthography of the Chindau dialect, one of the Bantu group, spoken in that part of south-east Africa lying to the west of Sofala, Mr. D. Jones, lecturer in phonetics at University College, has provided a useful addition to our knowledge of African linguistics and phonology. He pleads for the general adoption of the national phonetic alphabet, because, in the first place, it is scientifically constructed on the "one sound one symbol" principle; secondly, because it is not the pet system of any single individual, but was prepared by representatives of a number of European languages; and, thirdly, because it is in more general use than any other existing system and is international. Missionaries engaged in the study of the languages of savage or barbaric tribes, and natives desirous of acquiring the correct pronunciation of English, French, or German, would be well advised to adopt it.

The second part of vol. xi. of the Annals of the South African Museum is devoted to a continuation of Messrs. Gilchrist and Wardlaw Thompson's descriptions of Natal marine fishes. Five species, including a mullet, are described as new.

As the result of a study of the luminous organs of certain fishes, Mr. H. Ohshima, writing in the Journal of the Tokyo College of Science (vol. xxviii., art. 15, finds that whereas in sharks these structures lack definite numerical arrangement, and are merely diffuse, minute epidermal swellings partially sunk in the cutis, in the Sternoptychidæ they are arranged in a definite order and limited in number, with a complicated structure. Still greater specialisation attends these organs in the Myctophidæ, in which there may be a sexual difference in arrangement. The luminosity in sharks is faint and diffuse.

In a continuation of his notes on zoological gardens, museums, &c., in the September *Zoologist*, Captain Stanley Flower expresses his admiration of the large size of the paddocks accorded to ungulates in the municipal menagerie at Lyons, which is further notable on account of the large amount of water running through the grounds. This establishment is open free to the public. Admiration is likewise expressed for the site of the new zoological gardens at Munich, which occupy a picturesque position on the Isar, are well timbered and watered, and contain scarped cliffs, bushy coverts, wooded ponds, and open meadows admirably suited for animals of many kinds. At the Naples Aquarium Captain Flower was interested in some living file-fishes (Balistes), which, although healthy at the time of his visit, were not likely to live long, as in confinement these fishes generally die at the approach of winter. They feed on molluscs and crustaceans, the shells of which are cracked so smartly by the powerful teeth that the sound is audible through the glass of the tank.

Biologisches Centralblatt for September 15 (vol. xxxi., No. 18) contains a preliminary account of investigations undertaken by Mr. S. Kowalewsky in regard to sex-determination in animals, the second title of the paper being the capricious determination of the sex in the germ of mammals and birds. Previous theories on the subject are reviewed, notably the opinion that poor nutrition in the female parent is conducive to the production of male offspring, and *vice versa*. Considerable importance appears to attach to this from the circumstance that, according to the author, female fœtuses are found in that portion of the ovary of guinea-pigs and rabbits which receives the greatest supply of blood, males being developed in the less richly nourished area, while where the blood-supply is still poorer the germs are infertile. It is also shown that subcutaneous injection of alcohol leads to a great preponderance of males in guinea-pigs, as does also a poverty of acid. The latter phenomenon seems connected with the fact that in races (such as Tatars and Australians) in which the females arrive early at puberty there is a marked preponderance of males over females.

We have received two parts (Nos. 27 and 29) of Dr. F. E. Schulze's *Das Tierreich*, now in course of publication by Messrs. Friedländer. In the former Dr. F. Werner deals with the chamæleons (Chamæleontidæ), while in the latter Mr. R. von Ritter-Záhony treats of that remarkable pelagic organism known as Sagitta, and its relatives, which collectively form the group Chætognathi. The chamæleons comprise a much larger number of species than are recognised in the third volume of Mr. Boulenger's British Museum Catalogue of Lizards (1887). In the latter work forty-four species of the typical genus Chamæleon are catalogued, whereas the number is now raised to seventy-four. In 1887 the Malagasy genus Brookia was represented by three species; it now includes seven. A still greater increase occurs in the tropical African Rhampholeon, of which Mr. Boulenger recognised but two species in 1887, whereas the present author enumerates seven. The Chætognathi are classified under six generic headings, one of the genera having been named by the author during the present year; twenty species are included in the type genus, while the other genera contain from one to three. Excellent figures of the structure of these organisms are given, and the diagnosis of the group is clear and succinct, but nothing is said with regard to certain views which have been recently expressed as to the taxonomic position of the Chætognathi.

An interesting paper on plant-inhabiting mites of a useful nature, contributed by Prof. G. F. Scott-Elliot, appears in the Transactions and Proceedings of the Botanical Society of Edinburgh (vol. xxiv., part iii.). The red spider and other inimical mites are well known, but the beneficial mites, although exceedingly common, have received less attention. Their homes, in the shape of small hollows behind hairs on the undersides of leaves on trees, are termed acarodomatia; they are not confined to dicotyledonous trees and shrubs, as was supposed, but are common on tall herbaceous plants, and the author has found them on the leaves of Solomon's Seal. With respect to their sphere of usefulness, it is asserted that they feed on scale insects, fungus spores, and other pests. The author suggests that with bacteria they help to prepare organic dust particles for the benefit of plants.

The Quarterly Journal of the Geological Society of London for August is concerned with British zones and fossils. E. S. Cobbold and C. A. Matley respectively describe trilobites and brachiopods from the Lower Cambrian beds of Comley. D. Woolacott directs attention to the brecciation of the Permian rocks of Durham, which may be due to thrusts of Miocene age. H. Bolton brings his intimate knowledge of our Coal-measures to bear on the stratigraphy of the Bristol Coalfield. He finds that the fossils of the marine bands are of no service in marking zones. S. H. Reynolds and A. Vaughan have investigated the Avonian series of Burrington Combe in Somerset in the light of modern research, and now publish work that has extended over several years. The paper concludes with some interesting evolutionary generalisations (p. 389). The Carboniferous system receives further study from F. G. Collins, E. N. Arber, and G. C. Crick in a paper on the Culm of the Exeter district. The Lower Culm-measures are regarded as equivalent to the Midland Pendleside series. The name Culm thus becomes misleading, especially from a Continental point of view (see p. 399).

Finally, A. Wade describes Silurian rocks from near Welshpool, including some of igneous origin.

A MAP by the Edinburgh Geographical Institute, showing the density of population in Scotland as given by the census of 1911, appears in *The Scottish Geographical Magazine* for September. The method of Bosse is employed in calculating the density values, in which all uninhabited country and all urban districts and towns of 10,000 inhabitants and upwards are left out of account. Comparing it with the map setting forth the results of the 1901 census, the areas of densest population show a marked increase in spite of the reduced rate of increase of the population as a whole. The south shore of Moray Firth and the neighbourhood of Wick are also areas where population density has increased. These last two areas are connected with the fishing industry, which has improved of late, while the mining and manufacturing industries of the lowland region has drawn people to it.

THE valuable rainfall reports for the German protectorates of (1) Togoland (West Africa) for 1910, and (2) South-West Africa, for two years ended June, 1910, published by Baron v. Danckelman in *Mitteilungen aus den Deutschen Schutzgebieten* (vol. xxiv., part ii., 1911), show that in the first case the amount of rainfall was very favourable; in the coastal and central districts it was a record year, and at most of the stations the wettest since the commencement of regular observations in 1901. In the second case the rainfall for the fiscal year ended June, 1909, everywhere exceeded the average of the last ten years. The excessive amount caused an undue development of injurious insects, malaria, and sickness among cattle. In 1909–10 the amount was generally satisfactory, but not nearly so abundant as in the previous year. Rain is mostly accompanied by thunderstorms; in places thunderstorms frequently occur without rain.

A DETAILED summary of the meteorological observations made at the municipal observatory of the city of Bremen has just been published under the title "Beiträge zur Klimabeurteilung Bremens." The work is in two parts. In the first section the diurnal variations of the various meteorological elements are set out, both for the seasons and for the whole year, but the harmonic coefficients have not been determined. The second section concerns itself with monthly means and extremes, and for purposes of comparison corresponding values are given for Berlin and Frankfurt. The moderating influence of the ocean on the climate of the seaport is very strikingly brought out by this juxtaposition of figures, and the full meteorological statistics which are given for all three towns form a very useful book of reference. The work has been compiled by Prof. W. Grosse, the director of the observatory.

WE have received copies of the valuable meteorological charts of the great oceans issued by the U.S. Weather Bureau for October. The reverse sides of those for the North Atlantic and North Pacific Oceans contain interesting papers by Prof. W. J. Humphreys (1) on the origin of the permanent ocean "highs," and (2) the Aleutian and Icelandic "lows," illustrated by maps. There is a close connection between the positions and intensities of these areas and the weather of adjacent continents; they are the maxima and minima, with closed isobars, in the belts of high and low pressure, or so-called centres of atmospheric action. The subject of the importance of observations in these belts was brought before the International Meteorological Committee at the St. Petersburg meeting in 1899, and at the conference at Innsbruck, in 1905, a resolution of the Solar Commission advocating the establishment of permanent stations in the regions in question was unanimously adopted. Few attempts have been made to explain the origin of the maxima and minima; the author refers to the hypotheses put forward by Ferrel and Angot, and has supplemented them by one of his own. He concludes, *inter alia*, that a maximum ocean "high" must be at that place where the mechanical and thermal causes combine to produce the greatest result, *i.e.* a little to the west of the intersection of the coldest portion of an ocean current with a high-pressure belt.

FROM the observations of Eve at Montreal, Ashman at Chicago, and Satterly at Cambridge, it has been concluded that in each cubic metre of air near the ground there is an amount of radium emanation which would be in equilibrium with 80×10^{-12} grams of radium. This conclusion has been confirmed by observations made at Tokyo by Messrs. Kinoshita, Nishikawa, and Ono, which are described in the June number of the Proceedings of the Tokyo Mathematico-Physical Society. The amount of emanation decreases with distance from the ground, but if a homogeneous layer only 5 kilometres thick be taken as the equivalent of the whole atmosphere, over each square metre, there is an amount of emanation which would be in equilibrium with 4×10^{-7} grams of radium. Half of this breaks up in 3·7 days, and the question arises, how is the supply to be kept up? If it is derived, as it has been thought to be, from the strongly active air which exists in the pores of the soil, it must be possible to show by measurement that a large amount of emanation is exhaled from a square metre of soil. This has just been done by Prof. Joly and Mr. Smyth, who describe their observations in the August number of the Proceedings of the Royal Dublin Society. They find that near Dublin the amount exhaled often exceeds the $2·9 \times 10^{-9}$ grams per square metre per hour necessary to maintain the atmospheric emanation.

WITH the year 1910 the *Ergebnisse der magnetischen Beobachtungen* of the Royal Observatory of Wilhelmshaven commences a new series, edited by Prof. Bidlingmaier, the assistant director. The volume extends to forty-five pages, and possesses two charts. It contains an account of the absolute and self-recording instruments. At present the latter consist of declination (D) and horizontal force (H) magnetographs of the Kew pattern by Adie, but a vertical force instrument seems under construction. The methods of observation and reduction, and the base values of the curves, are treated in great detail. One reason for this doubtless is that, following the example of Potsdam, mean values are assigned to every day of the year, which go to 1 γ in H and to 0·1′ in D. Again, following Potsdam, the hourly values represent mean ordinates from sixty minutes centring, not at exact hours of the day, but at half hours. Mean diurnal inequalities are given for individual months, going to 0·01′ in D and to 0·1 γ in H and in the north and east components. Corresponding values are also given in the case of the components for the Fourier 24, 12, 8, and 6-hour terms. The last two pages give vector diagrams for the diurnal inequality for individual months. In the diagrams and diurnal inequalities use is made of all days, whether quiet or disturbed, which probably explains the rather striking irregularities in the diagrams. While the influence of Potsdam example is manifest in the more normal parts of the volume, the treatment of disturbances affords scope for the ventilation of Dr. Bidlingmaier's own methods of treatment.

THE experimental study of vortex rings has in the past been qualitative rather than quantitative; but, according to the Journal of the Franklin Institute for September, Dr. E. F. Northrup, of Princeton University, has so materially improved the apparatus used in their production that accurate observations of them may now be made. A coloured ring of liquid is projected from the opening in the front of a metal box by a blow struck by an electromagnet on the back, and travels through a transparent liquid, which gradually decolourises the projected liquid. If the box is pointed slightly upwards, the issuing vortex ring is reflected on reaching the surface of the liquid, the angle of reflection being apparently equal to that of incidence. By the use of two liquids of different densities in the observing tank, refraction may also be shown. While, however, the actual matter of the vortex ring is carried forward into the second liquid if the density of the latter is greater than that of the ring, this is not the case if the ring is denser than the liquid into which refraction is about to take place. By projecting molten paraffin wax into cold water, solid rings can be obtained. A subsequent number of the Journal will contain photographs of rings in a variety of conditions.

We have received from the authors, Messrs. H. R. Hamley and A. L. Rossiter, a copy of a paper on the magnetic properties of stalloy, reprinted from the Proceedings of the Royal Society of Victoria. The remarkable magnetic properties of stalloy—essentially an iron-silicon alloy containing 3·4 per cent. of silicon—have already been investigated very fully in this country, principally by methods involving the use of a wattmeter; the present research emanates from two Government research scholars working in the University of Melbourne, and the methods used are entirely different, since they depend upon Prof. T. R. Lyle's method of tracing out the wave-forms. This application of Lyle's method is interesting, and it is satisfactory to find that the results substantially confirm those obtained by the wattmeter methods.

Three interesting equilibria are discussed in the Memoirs of the College of Science and Engineering of the Kyoto Imperial University, the third volume of which is now being issued. In the case of sodium acetate dissolving in acetic acid solutions of different strength, the complete equilibrium diagram for 20° C. plotted by R. Abe shows the existence of three salts having the formulæ

$$NaC_2H_3O_2,3H_2O;\ NaC_2H_3O_2,C_2H_4O_2,\ \text{and}\ NaC_2H_3O_2,2C_2H_4O_2.$$

In the case of sodium and potassium carbonates dissolving in water at 25° C., Y. Osaka finds that the only double salt which can exist in contact with its solution at that temperature is the salt $Na_2CO_3,K_2CO_3,12H_2O$. In the case of the system water, ethyl alcohol, ethyl ether, studied by S. Horiba, physical methods of analysis were adopted, the composition of the phases being determined from measurements of density, refractive power, and viscosity. The critical composition at which the two phases become identical was found to be: water 40 per cent., alcohol 28·4 per cent., ether 31·6 per cent., for a temperature of 25° C.

Some months ago attention was directed in these columns to a paper by Flint in *The American Journal of Science*, in which he claimed to have separated, by fractional precipitation of tellurium tetrachloride, a portion of the tellurium with an atomic weight so low as 124·32. This method of resolution had already been tried some years previously by Baker and Bennett, but without success. In view of the results recorded by Flint, Prof. Baker repeated his experiments in collaboration with Prof. Vernon Harcourt, and found once more that no resolution could be effected by this method. In describing their experiments in the Journal of the Chemical Society, these authors explain the probable origin of the anomalous results of the American observer. In recovering the tellurium which they had used, they noticed that an orange-coloured precipitate was formed from material that had previously been quite white. This yellow precipitate was found to be tellurium trioxide, which had been produced by the oxidising action of hydrochloric acid previously exposed to bright sunlight, and thereby contaminated with chlorine. A basic nitrate prepared from the trioxide and analysed by Flint's method gave (on the assumption that the tellurium was present as dioxide in the form $2TeO_2,HNO_3$) an atomic weight so low as 118·31, instead of the normal value 127·54. There can be little doubt, therefore, that the low figures given by Flint were due to oxidation of the material, and not to any resolution of the element.

The City of Paris depends upon its supply of fuel, food, and other commodities to a large extent on the traffic carried by water, the quantity brought into the city by this means of transport being greater than by the railways. Ever since the formation of the Manchester Ship Canal, the question of rendering the Seine between Rouen and Paris navigable for sea-borne vessels has been in agitation. The serious inundations that occurred in the lower parts of Paris about a year ago again directed attention to the condition of the river, and a commission was appointed by the Minister of Public Works to report on the matter. Recently this commission has presented its report. The question of making the river navigable for sea-borne vessels, and making Paris a seaport, is not, however, dealt with, the commission being of opinion that the present conditions of traffic can be considerably improved by the works proposed for dealing with the prevention of overflow and inundations. The widening and deepening of the channel in some parts where required, and the construction of a new channel across the bend between the Rivers Marne and Seine below Paris, proposed by the flood commission, would be of great service to the traffic. A large sum of money has already been expended in enlarging and improving the locks and the channel between Rouen and Paris, and boats carrying more than 200 tons can navigate the waterway.

Commenting on the wreck of the naval airship at Barrow on September 24, *The Engineer* for September 29 believes that had this vessel survived a few months longer even the Admiralty officials responsible for her inception would have become convinced that the airship in general is a hopelessly impracticable affair. The vessel will in all likelihood be repaired; indeed, even already there is news to this effect. Sufficient has not yet been done, our contemporary supposes, to justify the official abandonment of the whole idea. *Engineering* of the same date is more sympathetic, and considers that it would be a mistake to attach too much importance to the accident. The airship is still, like the aëroplane, in an experimental stage; and the Admiralty airship must be regarded as a great practical experiment, in which the results of trial and error, when carefully analysed, must yield important lessons. The material used for the outer envelope proved of high resisting quality, only yielding when there was abnormal tension. The duralumin girder-work proved very ductile and of great tensile strength against the racking stresses set up. The material of which the ballonets are made, as supplied through the War Department, has all along been a source of uncertainty and of little accidents, and the facts point to the cause of the collapse being due to the rupture of a gas-bag when the vessel was being drawn out of the shed.

OUR ASTRONOMICAL COLUMN.

DISCOVERY OF A THIRD-MAGNITUDE COMET (1911*g*).—Yet another object is added to the list of recently discovered comets. On September 28 M. Beljawsky, at the Simeis Observatory, saw a third-magnitude comet, of which the position at 17h. 8m. (Simeis M.T.) was

R.A. 10h. 43m., dec. 8° 15′ N.

This position lies in Leo, about half-way between χ and ρ Leonis, and rises just before dawn.

A further observation, secured by Dr. Strömgren at Copenhagen on September 29, 17h. 12·7m. (Copenhagen M.T.), gave the position of the new comet as

R.A. = 10h. 52m., 59·8s., dec. = 8° 57′ 49″ N.

According to telegrams published in *The Daily Mail*, this object was observed at the Greenwich Observatory at 16h. 30m. on Monday morning; it has a very bright tail, which shows up well on the photographs. At the same hour on Sunday morning it was seen at the Royal Observatory, Edinburgh, and its magnitude, soon after rising, was estimated as 3·0. The observers there describe the tail as curved and fan-shaped, and state that it could be traced for a distance of 2°.

Beljawsky's comet is the seventh comet to be discovered this year, and so will take the designation 1911*g*.

BROOKS'S COMET, 1911*c*.—Brooks's comet is now an object of general interest, and in a clear atmosphere shows a tail even to the naked eye; on Sunday last, at Gunnersbury, with a pair of ordinary opera-glasses, there was no difficulty in seeing a filmy appendage, which stretched for some 2° or 3° in a north-easterly direction.

Writing from Malta on September 20, Mr. C. Leach said the comet had been visible to the naked eye for some time, but no tail was seen until September 16; on the two succeeding nights he saw, without optical aid, some 3° or 4° of tail quite easily, and concluded that its brightness was increasing.

A number of observations are recorded in No. 4526 of the *Astronomische Nachrichten*. Prof. Nijland publishes some measures of magnitudes which suggest an oscillation in the brightness of the comet, and M. Esclangon records the phenomena observed during the occultation of a 10·5-magnitude star by the comet on August 17. From 10h. 1m. 0s. to 10h. 1m. 12s. (Bordeaux M.T.) he was unable to separate the star from the well-defined but slightly fainter stellar nucleus of the comet. Although he could detect no change of brightness while the star was passing through the nebulosity forming the coma, he noticed a distinct diminution of the star's light as it passed behind the nucleus.

QUÉNISSET'S COMET, 1911*f*.—Several observations of comet 1911*f* appear in No. 4526 of the *Astronomische Nachrichten*, where the discoverer and M. Baldet describe the object as being of magnitude 7·5, round in form, having a nucleus, and showing the hydrocarbon-cyanogen spectrum.

In the *Comptes rendus* for September 25 they give further details of the discovery, and briefly describe their photographs. Short exposures (34 mins.) on September 23 showed a round head and traces of a tail, while the spectrograms showed the blue band of the "Swan" spectrum and the cyanogen band at λ 388. On September 24 exposures of 2h. 9m. were possible, and a tail 1° long, in position angle 322°, was clearly visible on the direct photographs; the comet was sensibly brighter, and was suspected to be visible to the naked eye, its estimated magnitude then being 6·5. The spectrum was much denser, and in addition to the bands showed a fairly strong continuous radiation.

A set of elements and an ephemeris, based on observations made on September 24, 25, and 26, are published by Dr. Ebell in a supplement to No. 4527 of the *Astronomische Nachrichten*. The elements give November 12 as the time of perihelion passage, and the following is taken from the ephemeris:—

Ephemeris 12h. (M.T. Berlin).

1911		α (true) h. m.	δ (true) ° ′	log *r*	log Δ	mag.

CALCIUM VAPOUR IN THE SOLAR ATMOSPHERE.—Continuing his discussion of Mount Wilson observations of the movements and condition of calcium vapour over sun-spots and other special regions of the solar surface, Mr. C. E. St. John arrives at some valuable conclusions regarding the conditions obtaining in the solar atmosphere, in No. 2, vol. xxxiv., of *The Astrophysical Journal*; only a very brief summary of the principal results can be given here. In most sun-spots the calcium vapour is descending at from 0·68 to 2·2 km. per second, but over the penumbræ that vapour which produces the bright K_2 line appears to be in vertical equilibrium. Over flocculi a very doubtful upward motion of this emitting vapour is suggested, but in both cases the absorbing vapour descends as it does over the general disc. Both absorbing and emitting vapours appear to participate in the occasionally occurring rotary motion around spot umbræ, but the former have the greater velocity; this is also true for the inward radial motion of vapour across the penumbræ, and the combinations of the two produce the vortical motions converging on the umbra. Large masses of relatively cool calcium vapour high above the chromosphere, that is to say, projected prominences, are held responsible for the abnormal absorption line sometimes splitting or bordering the K_2 bright lines. In addition to the general circulation, there appear to be local systems in which emitting vapour rises around the flocculi, and, flowing across the penumbra, descends into the umbra of the spot. The apparent changes of intensity in the bright K_2 line, at the sun's centre and limb, is shown to be probably no more than a contrast effect. The differences and changes in the intensities of the K_1, K_2, and K_3 lines, and hence the different results obtained for various levels in the sun's atmosphere, find a possible explanation in the modifications of the radiation coefficients by several agencies.

ELEMENTS AND DESIGNATIONS FOR RECENTLY DISCOVERED MINOR PLANETS.—The usual list of elements and numbers for minor planets recently discovered is published by Dr. Cohn, of the Berlin Astronomisches Rechen-Institut, in No. 4521 of the *Astronomische Nachrichten*. It includes twenty-three asteroids discovered in 1909, 1910, and 1911 at the Königstuhl, Taunton, Vienna, and Teramo Observatories, and the final number given is 714.

THE MASSES OF SPECTROSCOPIC BINARIES.—An interesting paper in which Dr. Ludendorff discusses generally the masses of different classes of spectroscopic binary stars appears in No. 4520 of the *Astronomische Nachrichten*. *Inter alia*, he shows, from the study of twenty-five binaries of the spectral classes O*e*5 to B8, that they have combined masses two or three times as great as have the twenty-six systems of classes A to K stars which he considered.

PUBLICATIONS OF THE U.S. NAVAL OBSERVATORY.—A number of works recently received from the U.S. Naval Observatory includes the following:—Vol. vi. of the Publications describes the equatorial observations of the satellites of the major planets, made during the period 1893–1907. It also contains a number of miscellaneous observations, an account of the transit of Mercury observations in 1894, and a list of the Naval Observatory publications. In the introduction to the part dealing with the equatorial observations there are some excellent plate illustrations of the various instruments employed. Vol. vii. is a catalogue of 23,521 stars in the Washington zones for which the observations were made in 1846–52, and are reduced to epoch 1850.

FORTHCOMING BOOKS OF SCIENCE.

AGRICULTURE.

Crosby Lockwood and Son.—The Rubber Planter's Note-book, F. Braham, illustrated. *Longmans and Co.*—The Profitable Culture of Vegetables; for Market Gardeners, Small Holders and Others, T. TWO MINOR AUSTRALIAN GOLDFIELDS AND THE ANTIQUITY OF MAN IN AUSTRALIA.[1]

THE goldfield of Forbes and Parkes is situated about 200 miles to the west of Sydney, where the old rocks of the East Australian Highlands disappear beneath the Black Soil Plains. Low spurs from the Palæozoic rocks project westward into the plains, and wide valleys of alluvium run eastward into the foothills. Gold was found during 1861 in the river gravels at Forbes, near the bank of the Lachlan River, and a gold-quartz lode was discovered in the following year at Parkes, on Gooban Creek, a tributary of the Lachlan. Further leads and lodes were discovered at both localities. Mining on the field has, however, been very irregular in its results. The alluvial deposits at Forbes yielded 212,547 oz. in 1862 and 71,493 oz. in 1863; but since then the output from both fields has varied from 57,851 oz. in 1875 down to as low as 1583 oz. Mining at Forbes has at times ceased entirely, and the field is now almost derelict. In the hope of reviving mining there, Mr. Pittman, the Government geologist of New South Wales, arranged for a geological survey of the field to collect trustworthy evidence as to its past history and determine the most likely directions for future mining. The problem of the field is mainly physiographic; and the work was entrusted to Mr. E. C. Andrews, who has already made his mark as an able physiographer. His interesting report is a valuable contribution to the geology of central New South Wales.

The main gold supply of the field has come from its leads, which are buried river channels containing auriferous gravels. These old river beds lie beneath the alluvium, and their working has been hampered by the excessive water with which they are saturated. Alluvial mining has ceased owing to the difficulty of following the deposits into the deeper ground. The methods of deep-lead mining were developed in Victoria, where, as a rule, the gold is found most abundantly in the deep, central river channels. In the Forbes area, however, for reasons which Mr. Andrews clearly explains, some of the richest patches of gold are on the sides of the buried valleys, and he advances weighty arguments that the deep drifts of the old Lachlan Valley would, if discovered, prove too poor in gold for profitable working.

The lode mines of the field are of two types. The foundation of the area consists of Ordovician and Silurian rocks associated with intrusive andesites and andesitic lavas, and covered in places by some Devonian rocks. To the east are some large areas of granite of post-Silurian, but pre-Devonian or Devonian, age. The gold-quartz lodes are associated with the intrusive andesites or occur along crush-zones. Mr. Andrews concludes that the gold has been introduced into the lodes in solution, and did not come from the igneous rocks, and that where gold has been found in igneous rocks in New South Wales it is of secondary origin.

The report includes one item of anthropological evidence that may prove of unusual importance. Hitherto Australia has remained the one continent on which there is no direct evidence of the antiquity of man. It has often been pointed out that, in spite of the thorough search of Australian drifts during mining operations, no early trace of man has yet been found in them. Mr. Andrews records (pp. 19 and 27) the occurrence of some blackfellows' ovens 18 feet below the surface, and associated with remains of Diprotodon. It is to be hoped that a more detailed account of this discovery will be published. On the theory that the Australian aborigines entered Australia in the north-west, and were specialised for desert existence, as they worked their way across Central Australia, it is in such localities as Forbes, where mining operations expose the drifts on the borders of the central plains, that early remains of the aborigines would be expected. Though under special conditions 18 feet of alluvium might accumulate in a short time, the association of the ovens with bones of Diprotodon appears to indicate that Forbes has yielded the earliest trace of man yet found in Australia. Mr. Andrews holds that the whole series of drifts, of which that containing the ovens is one of the later members, is of post-Tertiary age.

Mr. Andrews's memoir is of great interest and unusual merit. The history of the field, too often neglected in such reports, has been carefully compiled, and the features of the country are graphically described and suggestively interpreted. Considering that the closing of the mines prevented the author from inspecting the old workings, he has collected instructive evidence as to the structure of the lodes. His sections, however, give no strong support to his suggestion that the Silurian rocks have been overthrust on to the Ordovicians. As such memoirs are for the benefit of the mining industry, the less familiar terms, such as miarolitic, might be explained in footnotes. The most serious omission is the absence of heights from the map. The scarcity of altitudes on Australian maps is at

[1] The Forbes-Parkes Goldfield, New South Wales, Department of Mines. Mineral Resources, No. 13. Sydney, 1910 (issued 1911). By E. C. Andrews. Pp. iii+109+map+7 plates of plans and sections.

General Report on Tanami Goldfield and District (North-western Central Australia). By L. C. E. Gee. Pp. 2.+map+19 illustrations. (Adelaide, 1911.)

present their greatest defect, which is especially marked in this case, as they are indispensable in the study of deep leads.

The map accompanying Mr. Gee's report on Tanami is also heightless. That report tells a very different story. The field was only discovered in 1900, and the great difficulties in its development are in access and scarcity of water. The locality is 50 miles from the frontier of West Australia, 800 miles from the end of the South Australian railways at Oodnatta, and 696 miles from Port Darwin, on the northern coast. The goldfield was visited by Mr. H. Y. L. Brown, the Government geologist, in 1909, and in consequence of his favourable report and the increased number of prospectors, the Government sent Mr. L. C. E. Gee there as warden and magistrate. Mr. Gee has now furnished a very interesting report on the district, the prospecting mining work, the rainfall, climate, and aborigines, with lists of plants collected and birds observed. In spite of its tropical position, Mr. Gee describes the climate as very healthy. The rainfall observed in ten months was 15½ inches, and a good supply of water is often obtained from wells at about the depth of 150 feet. The surrounding country is called desert, but Mr. Gee describes it as containing much fair and some good pastoral country. The mining results hitherto have done little to fulfil the original expectation that at length a great goldfield had been discovered in South Australia.

J. W. GREGORY.

ENTOMOLOGICAL NOTES.

THE U.S. Department of Agriculture is anxious lest the mango-weevil (*Cryptorhynchus mangiferae*), which does so much harm to mango-plantations in other parts of the world, should be introduced into those recently established in Florida. The larva burrows into the seed while soft, where it remains for a considerable period, and is thus carried all over the tropics. In a circular issued by the Bureau of Entomology it is recommended that all mango seeds introduced into America should be opened and examined, and those selected for planting made to germinate under a wire-gauze screen.

The advent between 1900 and 1902 of the sugar-cane leaf-hopper (*Perkinsiella saccharicida*) into the sugar-cane plantations of Hawaii was the beginning of a great calamity which has befallen sugar-growers in four of those islands; for by February, 1903, the insect had spread over the whole area devoted to sugar-culture, and had become so numerous as to constitute a serious pest. Its spread was greatly facilitated by the fact that in those islands only half the crop is harvested at a time, so that there is a continuous supply of nutriment. Moreover, there was an absence of indigenous enemies, although some native species have since taken to preying on the leaf-hopper. The species was introduced from Queensland; and the loss to planters in Hawaii during 1903 and 1904 from this and other insects is estimated at three million dollars. Bulletin No. 93 of the U.S. Bureau of Entomology is devoted to an account of the life-history of the leaf-hopper and the best means of checking its ravages.

In part ii. of the sixth volume of Records of the Indian Museum Dr. J. J. Kieffer continues his description (in French) of the gnats and midges of the family Chironomidæ in the collection of the Indian Museum, naming eighty-seven species as new, the majority of which come from the Oriental region, although others are from the Suez Canal.

Parasitic Hymenoptera from the Transvaal form the subject of a paper by Mr. P. Cameron in vol. ii., No. 4, of Annals of the Transvaal Museum. In a previous paper the author was able to record, from material in the museum, only thirteen local representatives, but, thanks to a collection made by Mr. A. J. T. Janse, he now describes a very large number, some of which represent peculiar generic types, as new. The larval hosts of many of the species are likewise recorded. In this connection it may be noted that the serial quoted suffers from the absence of a table of contents or index to the various numbers.

Mr. J. W. Shoebotham has favoured us with a copy of a paper by himself from the July number of *The Annals and Magazine of Natural History* on spring-tails (Collembola) new to the British fauna, with the description of a new species of Oncopodura, typically from Berkhampstead, Herts. The collection on which the paper is based was mainly made in the counties of Hertford, Buckingham, and Stafford.

Another addition to the British fauna is a coccid taken in ants' nests in Somersetshire by Mr. H. St. J. Donisthorpe, and identified by Mr. E. E. Green, in *The Entomologist's Monthly Magazine* for August, with *Ortheziola rejdovskyi*, a species hitherto apparently known only from Bohemia. At the conclusion of his paper Mr. Green discusses the serial homology of the segments of the antennæ in various members of the Coccidæ.

THE CULTIVATION OF LUCIDITY IN SCIENTIFIC WRITING.[1]

ACCORDING to the reports of examiners for medical degrees, many students seem unable to write an essay or thesis exhibiting any literary quality and style. The fault is not entirely that of the candidates. Whatever subjects they may have learnt at school, the writing of their own language has, in general, not been one of them. Even during their university career the use of the written English language, except as a machine for taking notes or answering examination questions, has not formed any regular part of their course.

The teaching of English is often understood to mean the attempt to teach a literary style by the imitation of good models; but what is really wanted is the power of expressing clearly one's own ideas in one's own language, and this ought now to be within reach of every English-speaking man and woman. The usual methods of teaching English still leave the average boy and girl singularly deficient in the art of saying what they mean on paper, however ready they may be in expressing themselves by the spoken word. This is largely due to the want of systematic practice in writing; moreover, essays are generally criticised by the teacher from the point of view of style rather than in respect of intelligibility. Students should learn to express their own meaning in absolutely clear and intelligible language before they think about the manner in which that language is to be manipulated. A split infinitive is a less important fault than a failure to make the meaning clear. Teachers and examiners of scientific subjects often say of a pupil or an examinee that he evidently understands what he is trying to say, but is merely unable to express his meaning, and then give him full credit for the knowledge and pardon him the failure to express it.

In these circumstances it is not surprising that much scientific writing of the present time is loose and unintelligible in its expression. The remedy is to cultivate the quality of lucidity; this will lay the foundation for a good style.

There cannot be clear writing without clear thinking, and he who learns to write clearly will in the process learn to think clearly. Except in the drafting of resolutions and telegrams, most people have little practice in making their meaning absolutely clear. Letters in the daily papers and many books and memoirs on scientific subjects fail singularly in the quality of lucidity. It would be a good thing if schools and universities had societies which gave their students the same valuable training in the use of the pen which their debating clubs give in the practice of fluent speaking.

In the scientific revival of the nineteenth century the great expositors who wrote with such admirable lucidity led the public to see that the study of science, like that of philosophy, is an education in clear thinking; but now that so much scientific writing is badly expressed, the impression is conveyed that the studies which lead to such loose writing cannot really be conducive to accurate and clear thought. The remedy is in the hands of students themselves, who can, by constant practice in everything that they write and by determination to make their meaning clear, cultivate the essential quality of lucidity before they try to acquire the graces of a good style.

[1] From the introductory address delivered at St. George's Hospital on October 2 by Dr. H. A. Miers, F.R.S., principal of the University o London.

SOME QUANTITATIVE STUDIES IN EPIDEMIOLOGY.

AN account of some quantitative studies in epidemiology has recently been published in the second edition of my book on the "Prevention of Malaria" (Murray), and the Editor of NATURE has asked me to give a general description of them here. The attempts originated in the following manner. Shortly after Anophelines were shown to carry malaria, it was often observed that little apparent correlation could be found between their numbers and the numbers of infected persons in a locality. The observations were always far too scanty to establish any real absence of correlation; but they were used, nevertheless, to support the thesis that the *amount* of malaria does not depend upon the *number* of the Anophelines, and that therefore the proposed anti-malarial measure of mosquito reduction (then very unpopular) was useless. For many reasons a trustworthy experimental investigation would have been very difficult and costly, and it was therefore all the more necessary to examine the subject by a carefully reasoned analysis of the relations which must hold between the amount of the disease and the various factors which influence it. My first attempt in this direction was made in an official report on the "Prevention of Malaria in Mauritius" (Waterlow and Sons, 1908), and fell into the form of a simple difference equation. This was further developed in the first edition of my book already mentioned, and the subject was at the same time ably attacked by Mr. H. Waite, at the instance of Prof. Karl Pearson, in *Biometrika*, October, 1910.

The attempt now referred to aims at extending the reasoning to infectious diseases in general. The object is as follows. Suppose that a given proportion of a population in a given locality at a given moment are infected with some disease. Then we know from experience that the number will not remain fixed, but will vary from time to time and from place to place. The problem is to calculate these variations on the supposition that all the coefficients are known, which, of course, is by no means always the case. The use of the calculation will be (1) to obtain more light regarding the coefficients by comparing calculated with observed results; (2) to obtain quantitative estimates as to how far each coefficient should affect the result; and (3) to improve preventive measures by showing which factors they should be directed against. My studies have been hitherto concerned only with time-to-time variations, and the reader will understand that they require verification and completion by better mathematicians than myself. So far as I can ascertain, the subject has been little dealt with hitherto.

We must first obtain clear ideas on some points. Infectedness is not the same thing as sickness. *Infectedness* begins when the infecting organisms first enter the body of the host (man, animal, or plant), and ceases only when the last of them die out of him or leave him, or when he himself dies. *Sickness* may be quite absent during the whole of this period, or may begin after an "incubation period"; may cease long before or long after infectedness ceases, or may be intermittent. It is therefore merely an episode of infectedness, and one which does not concern us greatly just now. Another episode, and a more important one at the moment, is *infectiveness*, that is, the state of the infected person during which the infecting organisms are able to pass from him to others. The period or periods of infectiveness are always contained within the period of infectedness, but do not necessarily coincide with the periods of sickness. Thus typhoid or diphtheria carriers may be ill for only a week or so, or not at all, but may remain infective for months. In yellow fever, according to good researches, sickness and infectiveness begin together a few days after the commencement of infectedness at inoculation; but infectiveness ceases three days later, often long before the sickness is over. In malaria, sickness and infectiveness are intermittent and not coincident episodes, and may recur for years. Infectedness itself is only the preliminary stage of *affectedness*, which begins at inoculation and does not end until the last trace of the resulting sickness or acquired immunity has vanished. Reinfection often occurs during existing affectedness, and may increase its duration and that of the episodes. Medical treatment may have the opposite effect, and natural immunity and prevention may reduce susceptibility to infection. Lastly, the natural fluctuations of population, due to births, deaths, immigration, and emigration, must be considered, and these may vary in consequence of the epidemic.

Hence many coefficients have to be taken into account; and the principal difficulty lies, I fancy, in arranging for all of them in the equations. The course which I have adopted as being perhaps the best for a beginning is to conceive the matter in the most general terms possible by taking the act of infection as being one of any kind of event, such as accident, death, marriage, bankruptcy, receipt of bequests, insect-bite, &c., which may occur to a population, the various coefficients being at present taken as constant during the period considered. If such an event occurs to a given constant proportion of the population in unit of time, how many affected people will there be in the locality on a given date, on a most probable estimate, and how many of these have been affected once, twice, thrice, &c.? This simple form may be called the problem of *happenings*, and its solution will often be useful in epidemiology, as, for instance, in estimating the most probable frequency of reinfections or of insect-bites. But for some kinds of events, such as marriage, wealth, and infectedness, we must contemplate a continuance of the event in the individual, with a possible reversion to the unaffected class after the cessation of affectedness. Such events may be called *becomings*; and we have now to find the proportion of the population in this condition on a given date.

I will treat the equations as briefly as possible. Consider the following:—

$$\begin{aligned} a_{t+1} &= (1-h)va_t + \mathrm{HV}z_t \\ z_{t+1} &= h\,va_t + (1-\mathrm{H})\mathrm{V}z_t \\ p_{t+1} &= va_t + \mathrm{V}z_t \quad . \quad . \quad . \quad . \quad . \quad . \quad . \quad (1) \end{aligned}$$

Here a_t and z_t are respectively the numbers of unaffected and affected individuals, and p_t is the total population at the end of t units of time; v and V are respectively the variations in number of the unaffected and the affected due to births, deaths, immigrations, and emigration in unit of time; h is the proportion of the unaffected which become affected, and H the proportion of the affected which become unaffected (to be better defined presently) in unit of time. Thus $1-h$ and $1-\mathrm{H}$ are respectively the proportions which remain unaffected and which remain affected, and a_{t+1} and z_{t+1} are the numbers of the groups after the lapse of one unit of time. The gain of one group is the loss of the other group, and the total population is the sum of the two groups, the factors h and H disappearing in the summation.

If n, m, i, e denote the (constant) nativity, mortality, immigration, and emigration rates among the unaffected, and N, M, I, E the similar rates among the affected, it is correct, I believe, to write $v=(1+n)(1-m)(1+i)(1-e)$, and a similar equation for V. Different symbols are necessary for the two groups, because all the quantities, even the immigration, may differ. We now take the equations in more exact detail, but omitting v and V for the moment. Thus

$$\begin{aligned} a_{t+1} &= (1-h)a_t + (1-h)na_t + (1-h)\mathrm{N}z_t + (1-h)rz_t \\ z_{t+1} &= h\,a_t + h\,na_t + h\,\mathrm{N}z_t + h\,rz_t + (1-r)z_t \\ p_{t+1} &= a_t + na_t + \mathrm{N}z_t + z_t \quad . \quad . \quad . \quad (2 \end{aligned}$$

Here n and N are the birth-rates of the two groups. The second and third columns give the happenings among the births; rz_t is the proportion of the affected which *revert* to the unaffected group in unit of time, and hrz_t the (very small) proportion of these which immediately become reaffected; $(1-r)z_t$ is the proportion of the affected which do not revert, and $(1-h)rz_t$ the proportion of the reverted which are not immediately reaffected. Obviously p_{t+1} is merely the sum of the two groups a_t and z_t *plus* the births that have occurred to both in the unit of time, and the symbols h and r disappear in the summation. The equations are not symmetrical, because, though the progeny of the unaffected are born in this group and belong to it, the progeny of the affected are not born affected, and therefore do not belong to the latter group. I think that this is the better arrangement; but it would be possible to add a term for affected births, as in syphilis. The first two of the above equations may be written

$$a_{t+1}=(1-h)(1+n)a_t+(1-h)\frac{N+r}{1+N}(1+N)z_t$$

$$z_{t+1}=\quad h(1+n)a_t+\left\{1-(1-h)\frac{N+r}{1+N}\right\}(1+N)z_t \qquad (3)$$

If, now, we restore the mortality, immigration, and emigration rates, that is, affix to a_t in both equations the coefficient $(1-m)(1+i)(1-e)$ and to z_t the coefficient $(1-N)(1+I)(1-E)$, we have

$$a_{t+1}=(1-h)va_t+(1-h)\frac{N+r}{1+N}Vz_t$$

$$z_{t+1}=\quad h\,va_t+\left\{1-(1-h)\frac{N+r}{1+N}\right\}Vz_t \quad . \quad . \quad . \quad (4)$$

which are obviously the same as equations (1) if H is now defined as the value of $(1-h)(N+r)/(1+N)$.

The complete solution of these difference equations is

$$(X-Y)a_t=(a_1-a_0Y)X^t-(a_1-a_0X)Y^t$$
$$(X-Y)z_t=(z_1-z_0Y)X^t-(z_1-z_0X)Y^t$$
$$(X-Y)p_t=(p_1-p_0Y)X^t-(p_1-p_0X)Y^t \quad . \quad . \quad . \quad (5)$$

where

$$a_1=(1-h)va_0+HVz_0 \qquad z_1=hva_t+(1-H)Vz_0$$
$$p_1=va_0+Vz_0 \qquad p_0=a_0+z_0$$

and X and Y are the roots of the auxiliary algebraic quadratic equation

$$x^2-\{(1-h)v+(1-H)V\}x+(1-h-H)vV=0.$$

These roots are rational for several particular values of the constants. The most important instance is when $v=V$, that is, when the happening does not affect the normal fluctuations of the population. Here $X=v$ and $Y=(1-h)(1-r)/(1+N)$, and

$$z_t-Y^tz_0=\frac{h(1+N)}{N+r+h-hr}(p_t-Y^tp_0). \quad . \quad . \quad . \quad (6)$$

As Y is in this case less than unity, Y^t diminishes without limit as t increases, and therefore z_t, the number of affected individuals, asymptotes to a fixed proportion of the total population, provided that all the elements remain constant. I call this proportion the *static value.* In disease it gives what is called the *endemic index*, or *ratio.*

In epidemiological applications the symbol z refers, not to sickness or even infectedness, but to affectedness as defined above; and the symbol r does not mean recovery from sickness or infectedness, but reversion to a susceptibility to a fresh happening (inoculation), that is, to loss of acquired immunity. Thus in drawing curves of epidemics we must remember that this last factor may not come into play until long after the commencement of the epidemic, or not at all.

In my book the above equations are treated also in the infinitesimal form, when the integrals become exponential. Thus the second of equations (2) becomes

$$\frac{dz}{dt}=h(p-z)+qz,$$

where $q=V-1-r-N$. If the total population p remains constant, this is easily integrable if h is also constant, or (what more probably happens in epidemics) is a linear function of z, say cz.

Numerous applications are possible; but I have space to refer only to the important case of "metaxenous diseases," that is, to infections common to two species of animals or plants. The same equations apply to both species, but the happening-factor h in one equation must be a function of z in the other equation. We thus have two simultaneous equations to solve, namely,

$$\frac{dz}{dt}=k'z'(p-z)+qz$$

$$\frac{dz'}{dt}=kz(p'-z')+q'z'$$

where the marked symbols apply to one species of animals (say, mosquitoes) and the unmarked ones to the other species (say, man), and k and k' are constants composed of the most probable frequencies of communication between the two species, of infectivity and of natural immunity. Prof. F. S. Carey has referred these equations to Prof. A. R. Forsyth, who thinks that they are not likely to be easily integrable in finite terms; but the most important case is where both z and z' have reached static values, when the differential coefficients vanish. We then obtain at once

$$z=\frac{kpk'p'-qq'}{kk'p'-kq}$$

with the similar equation for z'. In the case of some insect-borne diseases this becomes (reduced)

$$z\{(1-r)fb'f'b'A+rfb'\}=p\{fb'f'b'A-rN'\},$$

where z is the ratio of affectedness among men (say), f and f' the proportion of infective men and insects, b' the frequency of bites, r the reversion rate among the human patients, N′ the birth-rate of the insects, and A the ratio of the number of the insects to head of human population. Numerical estimates of the constants in malaria are attempted in the book, and a table of calculated values of A for various values of z and b' are given (as already partly done by Mr. Waite).

The following important laws seem to be established:—(1) the disease (z) will not maintain itself unless the proportion of Anophelines (A) is sufficiently large; (2) a small increase of A above this figure will cause a large increase of z; and (3) z will tend to reach a fixed value, depending on A and the other constants. I doubt whether these laws could have been reached except by such mathematical attempts. The second one is especially important. If A is just at the critical value, z will be zero, or only just above it; but if A is only about double this critical value, a serious epidemic, amounting to about half the whole population, may follow. Yet such a small increase in the number of Anophelines will scarcely be detectable except after very careful study, a fact which easily explains why marked correlation has not always been observed. The same equation shows that, if certain experiments are to be trusted, yellow fever can scarcely be considered an endemic disease of men at all; and it also explains the absence of certain diseases in the presence of capable carriers, and the general phenomena of smouldering epidemics.

The most probable numbers of individuals to which a happening has occurred never, once, twice, &c., can easily be obtained, and are equal to the successive terms in the expansion of $\{(1-h)+h\}^tV^tp_0$ in ascending powers of h. This enables us to estimate the number of persons who have been bitten, or the number of insects which have succeeded in biting never, once, twice, &c., in a given period, and to calculate the average number of bites received or inflicted by each individual. It also enables us to calculate (what I think has not been done before) the frequency of *reinfections.* At present such reinfections are not much considered during the course of an already existing infection, but I estimate that in a locality where half the people are statically affected with malaria no fewer than about 63 per cent. will be infected or re-infected every four months (under constant conditions). In 1898 I showed that birds reinoculated with malaria could exhibit renewed and severe infections.

Lastly, to complete the study, it is necessary to estimate the most probable proportion of affected individuals who are also infected, or infective, or sick at a given moment. This will be the same as the proportion of the average number of days lived during these "episodes" to the average number lived during the whole period of "affectedness," which can be calculated from the special pathological data.

These studies require to be developed much further; but they will already be useful if they help to suggest a more precise and quantitative consideration of the numerous factors concerned in epidemics. At present medical ideas regarding these factors are generally so nebulous that almost any statements about them pass muster, and often retard or misdirect important preventive measures for years.

RONALD ROSS.

RESEARCH IN MEDICINE.[1]

THE object of research is to discover something which was not previously known, or to correct or to confirm some previous observations. There are two methods of research—one by *observation*, the other by *experiment*. In medical research the method by observation is much out of fashion; it is slow, and may be often interrupted for want of material. The imperfection of the material is often very disappointing. The method by experiment (not by any means limited to experiments on animals), on the other hand, is the fashion of the day; it is quicker, less liable to be interrupted, and may yield brilliant results in a very short space of time. But it is a two-edged weapon, and needs to be used, and its results to be accepted, with great caution. Mr. Hunter, who was a confirmed and most ingenious experimenter, said in the course of his evidence at the trial of Captain Donellan:—"I apprehend a great deal depends upon the mode of experiment; no man is fit to make one but those who have made many and paid attention to all the circumstances that relate to experiments."

Let me give you my experience of the two methods in the investigation of cancer. Many years ago there was great confusion in the minds of pathologists and surgeons regarding the differences and resemblances between sarcoma and carcinoma. I made a diligent study of them by observation of the cases at my hospital, the cases at other hospitals, and the cases recorded in the literature of many countries. The research was very long, very tedious, and very disappointing by reason of the small number of cases which were sufficiently recorded to be available for use. The results formed the subject of the Erasmus Wilson lectures thirty years ago, and proved that the life-history of the varieties of malignant disease does not depend merely on their structure, but upon their seat of origin, and that the varieties of malignant disease of every part of the body must be separately studied if they are to be treated with success. Observations of a similar kind have been made by other clinical pathologists, with the result that the most successful operations for cancer at the present time are based on the results of clinical pathology. For no part of the body has this been done with greater success than for the breast. Charles Moore and Mitchell Banks urged the importance of very large operations many years ago; but surgeons fought shy of them, because they lacked that which was supplied many years later by Heidenhain and Styles—a scientific basis. Recently Handley has again added valuable information on the same subject, founded on clinical and microscopical observation.

I have never engaged personally in experimental investigation on account of the difficulty of doing so thirty years ago. But I have been associated with the Imperial Cancer Research, and in touch with its staff from the foundation of the research, and have been a member of the publication committee of all its scientific reports. It has done nothing on the lines in which observation has been so useful. It has not unfolded the life-history of a single variety of cancer so that we can base our operations on the information. It has not even discovered whether spontaneous cancer of a particular part of the body in the rat or mouse runs a similar course to spontaneous cancer of the same part of the body in the human subject. These problems are not suited for experimental investigation; they are determined by observation. On the other hand, within the space of eight or ten years it has definitely settled a matter of dispute which was discussed and fought long before I became a student, perhaps for centuries. It has proved, beyond the possibility of doubt, that cancer in its early stages is a local, not a constitutional or blood, disease. It is impossible to overrate the value of this knowledge to the surgeon. So long as he believed that cancer is in the blood, and that an operation only removes the local manifestation of it, he was hopeless of the results of his operations, and removed the tumour solely to afford the patient temporary relief. Now he goes to his operation filled with hope that, if the disease is limited and in an early stage, and his operation is well designed and skilfully carried out, it may be quite successful. Thus it will be seen that the two methods, *observation* and *experiment*, have their special values in relation to cancer, that each is supplementary to the other, and that neither is fitted to take the place of the other.

It will be noticed that I have dwelt on the use to which these researches have been put in the treatment of cancer and of the value of them to human beings. You may fairly think these ought to be the immediate objects of all research in medicine, and that researches which are not likely to be immediately useful should be discouraged. But while I freely admit that my sympathy is in favour of this view, I am bound also to admit that it is wholly erroneous. The investigator should be solely interested in discovering the truth, and his attention should not be diverted and his judgment warped by the desire that his research should terminate in a particular manner because that might seem likely to be more useful to medicine and surgery. It is notorious that some of the researches which have seemed to fulfil no useful purpose have yielded the most valuable practical results, while other researches, pursued with a useful end in view, have furnished nothing good. If a utilitarian value were considered essential to research, many young investigators who have later produced the most brilliant work would have been discouraged, so that they might never have persevered in original research. I need only give two illustrious examples, Pasteur and Lister.[1] Their first researches had no utilitarian object. What a lamentable thing it would have been if they had been discouraged from research on that account. The great thing is that young people who are fitted to do so should be encouraged to search. What they search for is of comparatively small consequence. On the other hand, I would not have it supposed that a utilitarian research is derogatory to the dignity of the worker or necessarily damages his *moral*. Sir Humphry Davy deliberately worked out the problem of coal gas and explosions, and invented a safety-lamp at the urgent request of the coal-owners. Pasteur investigated the nature of the Pébrine disease of silkworms at the request of Dumas, and moved by pity at the wretched condition into which the silkworm industry had fallen. He discovered that it depended on a parasitic protozoon, and devised a successful method of stamping it out.

Just a few words on the cost of research. Dr. Leonard Hill[2] pointed out some years ago what great results could be achieved by an able worker with the simplest materials and at the smallest cost, and that fine laboratories and costly apparatus are not essential to research in medicine. All this is very true, just as it is true that David killed Goliath with a stone cunningly hurled from a sling. I do not think David at the present day would sally forth with a sling to oppose a foreign host; and our profession is continually urging on the wealthy public the financial claims of research.

In order to determine whether women are likely to be useful and successful in research, it is necessary to consider the qualities which should be looked for in an investigator—I mean in an investigator who has the sole charge of a research, even though it be carried out in a laboratory where other persons are at work. I am not speaking of an expert assistant or even of a joint investigator.

For (1) experimental research (including experiments on animals) I should set down: dexterity and neatness in manipulation; a knowledge not only of the principles, but of the practice, of aseptic and antiseptic surgery; and certainly humanity, so that the experiments which are necessary should be performed with as little suffering to the animals as possible.

For (2) every kind of research I should look for personal cleanliness; cleanliness of habit; industry, which must be extended to mean continued industry; patience, and a large stock of it; perseverance, and a determination to pursue

[1] From the introductory address delivered at the opening of the winter session, October 2, at the London School of Medicine for Women, by Sir Henry T. Butlin, Bart.

[1] The first researches of Pasteur were on the crystallisation of tartaric acid and its salts. The first researches of Lister were on the contractile tissue of the iris and on the muscular tissue of the skin.

[2] *Brit. Med. Jour.*, 1907, vol. i., p. 660. "Men of science are not made by institutes, money, or apparatus. Helmholtz did his best work on 120*l.* a year, and modelled his inventions out of spectacle lenses and his wife's sewing gear. Faraday did his epoch-making work with bits of wood, glass, and wire. Claude Bernard filled his pupils with enthusiasm in a laboratory little better than a cellar."

the research to the end; extreme care in observation and strict attention to detail; careful recording of observations, which should be done at the earliest possible moment; thorough belief in the importance of the particular research, amounting even to enthusiasm; conscientiousness.

Many of these desirable qualities will at once commend themselves to you; they need no more than enumeration. But you may wonder why I have set down others of them. For instance, what has conscientiousness to do with research any more than it has to do with any other of the affairs of life? Do I mean that an investigator should be honest and not appropriate or use unfairly the work of other investigators? Oh, no! I assume such honesty as this in every investigator. The conscientiousness of which I speak is of the worker to himself and his own work. In this way. A worker has been engaged in a research during many months. He has made many experiments and observations, and they have all gone to prove the correctness of the result at which he has arrived. But there is still one experiment which it would be well to try. He tries it, and curiously it does not turn out quite right. He puts two and two together and they do not make four. And everyone agrees with "The Professor in the Case" that two and two do make four, "not *some* times, but *all* the time." Now is the moment when his conscientiousness should come into play. The temptation is overwhelming to explain the failure by some fault in technique, and to set the result of that experiment on one side rather than to repeat it again and again as he ought certainly to have done. Had he done so it would again have failed, and he would have learned in the end, not that two and two do not make four, but that one of his twos was not a two, and he would have avoided publishing that result of his research which was afterwards discovered to be incorrect by a more careful and conscientious worker. It must always be borne in mind that the mischief of a faulty result does not end with that research, but may be the starting point of a long series of equally faulty results.

GEOGRAPHY AT THE BRITISH ASSOCIATION.

IN his presidential address Colonel Close, the recently appointed Director-General of the Ordnance Survey, raised again the oft-debated question, "What is geography?" His contention that geography, apart from cartography, cannot be treated as a science in itself, but must serve as a common meeting-place and popularising medium for various other sciences, will certainly not be accepted by modern geographers without considerable modification and amplification.

Prof. Herbertson exhibited and explained a new series of thermal maps which he has constructed to show the actual mean temperatures prevailing over the globe instead of the temperatures reduced to sea-level, as indicated on the ordinary meteorological maps. Among other papers on cartography were two by Mr. A. R. Hinks, one dealing with the use of colour on contour maps, and the other with the most suitable projections for atlas maps. Captain Henrici discussed the present state of our knowledge—not altogether satisfactory—of the mean sea-level round our coasts, and arrived at the conclusion that there is no evidence, from the observations made, to justify the belief that mean sea-level is not constant around the British Isles. Captain Henrici also contributed a note on the height of Ruwenzori as determined by him from observations made by Captain Jack. His result is $16,801 \cdot 3 \pm 5 \cdot 3$ feet.

Among the papers on physical geography, two of the most interesting were contributed by Prof. J. W. Gregory and Prof. O. Pettersson. The former showed that while waterfalls have generally been regarded as destructive, they may in certain circumstances be constructive and act as agents of deposition instead of denudation. In support of this he instanced certain waterfalls in Dalmatia, Bosnia, and Herzegovina. In the former country, for example, the Kerka Falls are due to a barrier of calcareous tufa which the Kerka River has built across its valley. Prof. Pettersson discussed the deep-water movements in the Skagerrak, and showed that they occurred when the earth is in perihelion. His theory is that these waves are influenced by the phases of the moon, but still more by its declination and distance from the earth. He also showed that since 1753 the herring fishery on the coasts of Sweden has been most prolific in years of maximum declination and least prolific in years of minimum declination, a result which he attributes to the influence of the movements in the deep water. Captain Rawling gave an account of the British expedition to Dutch New Guinea, and showed some excellent views of the Nassau Range with its precipitous front more than eighty miles in length and from 8000 to 10,500 feet in sheer height.

The work of the section was concluded by an interesting discussion on aëronautical maps. M. Lallemand described the resolutions recently adopted at his suggestion by the Permanent Committee for Aërial Navigation of the Public Works Department of the French Government on the production of an international air-map, and the establishment of marks required by aviators and aëronauts. Captain Lyons followed with certain general suggestions for the construction of aëronautical maps, and in the subsequent discussion several officers of the air battalion and others took part. A full report of this discussion is to be published in *The Geographical Journal*.

MECHANICAL SCIENCE AT THE BRITISH ASSOCIATION.

THE meeting of the Mechanical Science Section of the British Association at Portsmouth, under the presidency of so distinguished a naval architect as Prof. Harvard Biles, was naturally the occasion for a very interesting programme of papers relating to many branches of marine engineering work ranging over a wide field of applied science, and dealing with some of the most important developments which are now engaging the attention of engineers and men of science in this branch of engineering activity.

The programme contained important papers on the rolling of ships, by the president, the gyro-compass, electrical steering and propulsion of ships, and the developments of wireless telegraphy, especially in its relation to naval problems; while in the purely mechanical section the advances in methods of generating motive power were dealt with in a series of related papers on internal-combustion engines and the superheated steam engine. Not only had the members who attended this section an opportunity of hearing these papers and the very interesting discussions to which they gave rise, but all the sections took the opportunity so kindly afforded them by Admiral Sir A. W. Moore of witnessing, from a battleship which carried them into the Solent, a combined attack by numerous torpedo-boats and submarine vessels with as near an approach to the conditions of naval warfare as practicable.

The interest which all members of the association take in the practical applications of scientific discovery to naval matters was manifested by the close attention to the wonderful evolutions and diving performances of the attacking vessels, while the swift and silent attack of the torpedoes, invariably marked by the final dull thud of impact as each one found its mark, gave a thrill of the possibilities of actual warfare not easily forgotten.

Although the proceedings of the section were so largely devoted to naval matters, other subjects of importance also claimed the attention of the members, like the non-stop train, the peculiar corrugations produced on rails by the long-continued passage of trains; while subjects of more general interest were afforded by papers on smoke abatement, and the possibilities of the manufacture of nitrogen products in this country by electric power, a question of great importance in connection with agriculture and the manufacture of explosives.

The discussion between Sections A and G on aërial flight at the Monday's meeting attracted a very large gathering, and has been dealt with in a separate article (September 28, p. 439).

We now turn to a more detailed examination of the papers in their order, and the discussions to which they gave rise. The president's address, on the rolling of ships, dealt very largely with the question of the effects of the combinations of the natural oscillations of a vessel with the forced oscillations produced by wave systems, which in general produce their most dangerous effects before a permanent *régime* is established. In spite of the labours of previous investigators, the magnitudes of the oscillations produced in this transition period under various conditions are still to a large extent unknown; and Prof. Biles was able to indicate the methods of the investigation he is making for solving these problems experimentally, but owing to an unfortunate illness these were not completed in time for the meeting.

The important paper on the corrugation of tramway rails, which was brought before the section by Mr. Worby Beaumont immediately after the president's address, gave an interesting account of the phenomena observed on rails in service, and also particulars of an experimental investigation by the author on the contact areas between loaded wheels and rails, which enable conclusions to be drawn as to the intensities of the compressions and tensions produced by wheels rolling on rails of differing degrees of hardness. In the discussion which followed, Mr. Alexander Siemens suggested the use of hard metal for the sides of the rail with a softer metal composing the head; he considered that a reduction of speed and weight, and the use of larger wheels, such as the author suggested, were impossible under modern conditions. Sir William White gave particulars of the wear of rollers due to gun fire in turrets, and could not agree with Mr. Siemens's suggestion of a composite rail, while in reply the author defended his proposals. The proceedings on Thursday concluded with a paper on the Anschutz gyro-compass by Mr. Elphinstone, accompanied by a demonstration on a machine which was on view during the remainder of the meeting.

This instrument depends for its action on the precession effect of a rapidly rotating wheel due to the influence of gravity and its movement over the surface of the earth, and this effect is utilised for the purpose of a compass by employing a gyroscope running at 20,000 revolutions per minute, and floating in a mercury bath. The precession effect tends to cause the axis of the rotating mass to lie in the plane of the meridian, and hence true north is obtained. Unfortunately, time did not permit of a discussion on this paper.

The first paper at Friday's meeting of the association dealt with the question of electric drives for screw propellers, and Mr. Mavor advocated the use of steam turbines or internal-combustion engines running at a high speed and coupled to a generator. The current so obtained is used to drive a motor on a slow-speed propeller shaft, and the author claimed for this arrangement a high efficiency of power-generating plant and propeller, with an increased flexibility in the system, which offered great advantages and increased economies beyond those given by existing systems in many kinds of vessels. The president, Sir William White, Prof. Dalby, and others took part in a detailed technical discussion, in which the progress in the design of electric generators and propellers for ships and the uses of the author's system were clearly indicated.

A second paper on electrical steering, by Mr. Haigh, described an arrangement of a constantly running motor operating the steering gear by magnetic face clutches, an arrangement which allows of an extremely sensitive regulation of the rudder with great economy of power, since the motor may, if required, be run from the lighting circuit of the ship. Sir William White in opening the discussion said that he viewed electrically operated steering gears with much favour. The sensitiveness of the control was remarkable, almost too much so for the ordinary quartermaster, who would never let the helm alone, although this incessant movement had no real value in keeping the vessel to her course; as a consequence, it had been found necessary to provide hunting gear to diminish the sensitiveness of electric steering gears. Mr. Hawksley pointed out how very necessary it was still to provide auxiliary hand gear for emergencies.

The next paper, by Mr. T. F. Wall, on the repulsion motor, was essentially mathematical, and after a short discussion upon it by Mr. Haigh, Captain Sankey and Mr. Pollard Digby read a paper on a study of human susceptibility to vibration by aid of an instrument consisting essentially of a small mirror centred on a fine spindle and floating in a mercury bath. When the mercury is set in vibration by any disturbance, it causes the mirror to oscillate and throw a spot of light on a screen. The authors pointed out that the effects of vibration on individuals depend to a large extent on the frequency as well as on the amplitude, and that the perceptive faculty is very variable and often untrustworthy, points also emphasised by Sir William White and Prof. Petavel, the latter pointing out that the association of sound and mechanical vibration had in general a very disturbing effect on individuals.

A paper on some new aluminium alloys, by Prof. Wilson, concluded Friday's proceedings, and in the absence of the author was taken as read.

The section, which met again on Monday, devoted a couple of hours to a joint discussion on aëronautics with Section A, of which an account has been given already, and on its conclusion Prof. Howe gave a very striking demonstration of the recent developments in wireless telegraphy by aid of an aërial running from the top of the Town Hall into the lecture-room. With the aid of a Brown telephonic relay the audience was able to follow the time signals sent out from Wilhelmshaven, and to distinguish these from signals from other stations like that on the Eiffel Tower. In his paper the author dealt very fully with the improvements which have been made to prevent interference, and in a succeeding paper Captain Sankey described a portable wireless plant of the Marconi Company adapted for carriage on horseback, and capable of erection in a few minutes for use up to 100 miles. A short discussion by Profs. Dalby and Howe and Mr. Kilburn Scott concluded the day's proceedings.

On Tuesday three papers dealing with some modern methods of generating power were grouped together for discussion. Mr. Marshall described the special features and merits of the superheated over-type steam engine, Mr. Tookey gave a careful analysis of the costs of power production with suction gas engines, and Mr. Day gave a similar analysis for Diesel engines. The long and detailed discussion which followed was of the greatest interest, and was prolonged much beyond the time originally fixed for its termination. Mr. Rosenthal, who followed with a paper on marine oil engines, dealt with the most recent developments in this important subject; and the discussion, in which the president, Sir William White, Mr. Day, and Mr. Rosenthal joined, was chiefly remarkable in showing how confident these authorities are in the continuance of the supremacy of the steam turbine in naval work for many years to come

An overflow meeting on Wednesday was devoted to three papers of a more general nature and of great interest.

Mr. Kilburn Scott described the manufacture of nitrogen products by electric power, and particularly emphasised the importance he attached to this country's possessing the means for manufacturing all the nitrogen compounds required for explosives, and the danger of depending on foreign supplies in times of war. Sir William Ramsay agreed with the author that it was most desirable to locate factories in the neighbourhood of coal mines, and Sir William White expressed his general agreement with the author's views, although he did not consider that the present impossibility of manufacturing all the essential constituents of explosives in this country was a national danger. Prof. Petavel discussed the efficiency of the electric process, and Mr. Wimperis suggested the utilisation of the waste gases from blast furnaces for the process, and estimated the power available. In the following paper, on smoke abatement, by Dr. J. S. Owens, the fixing of a new standard of smoke emission from factory chimneys was suggested, and an instrument for measuring smoke density was exhibited. After a spirited discussion the final paper of the section was read by Mr. Yorath Lewis, on a new system of continuous transportation for passenger and other train services

The distinctive feature of the system is an endless screw of variable pitch, which enables the speed of passenger carriages to be varied at will, while the energy now lost in stopping trains by brakes is given back to the screw during the retardation, thereby avoiding a large waste of power when stations are frequent. The author enumerated many other advantages of his system, among which were included the abolition of signalling arrangements, increased mean speed of travelling, and increased comfort due to more gradual acceleration and retardation of the train.

Owing to the late hour only a brief discussion was possible; and a very successful meeting terminated with votes of thanks to the president and vice-presidents.

E. G. COKER.

ANTHROPOLOGY AT THE BRITISH ASSOCIATION.

NOTWITHSTANDING the comparatively small numbers attending the meeting of the association at Portsmouth, the audiences in Section H, which met under the presidency of Dr. W. H. R. Rivers, F.R.S., were well up to the average, at any rate in the morning sessions. In the afternoons the attendances were sometimes small, owing, no doubt, to the attractive nature of the local arrangements for the entertainment of members. In the circumstances it was thought advisable to abandon the sectional meeting on the afternoon of the naval display, and to adopt the unusual course of holding an evening session. The wisdom of the change was made apparent by the large audience which listened to the postponed papers by Mr. R. R. Marett and Prof. A. Keith.

The papers communicated to the section attained a uniformly high level: some may be counted as of first importance; and it is perhaps not unsafe to say that the discussions on totemism and on the institution of an Imperial Bureau of Anthropology will be of far-reaching effect.

The discussion on totemism, to which the whole of a morning session was devoted, was opened by Dr. A. C. Haddon, who explained that totemism was usually regarded as the association of definite human groups with non-human groups. After citing typical instances, he pointed out that even in Australia there was much variation, and other customs and beliefs might be present. Similar variability also obtained in other parts of the world, so that it had become extremely difficult to frame a definition of totemism that would hold good everywhere. Although it was primarily a social and not a definitely religious institution, in most cases it could not be distinguished from a religious sentiment. Dr. A. A. Goldenweiser remarked that all attempts to characterise totemism by a more or less definite set of features must needs be artificial. Consequently, its distinctive characteristics were not the individual features, but the relation into which they entered. Dr. Graebner, whose paper, in the unavoidable absence of the author, was read by the president, said that every attempt to account for the origin of totemism must first deal with the question whether this institution was a cultural entity, for if it were once conceded that the form of totemism found in different parts of the earth had arisen independently, there could be no justification for the assumption that it had had everywhere the same origin. An examination of the evidence from the South Seas, from Africa, from South and North America, and from Asia would appear to show that this was the case; there were no older forms from which group totemism could be derived. In the older form, in which totems were animals, there was an indefinite and unstable relation of sympathy between man and beast which could be explained simply by certain groups of men and animals having co-existed locally in a region of diversified physical character. Prof. Hutton Webster in his paper on the relations between totem clans and secret societies pointed out that secret societies, although acting as a native police in West Africa and Melanesia, were not consciously devised for this purpose. Investigation revealed the importance of the part played by them in funeral rites, and especially in initiation ceremonies at puberty. These and other features appeared to be closely connected with the structure and function of totemic clans, and he suggested that they had been transferred to the secret society in the course of the disintegration of ancient totemic groupings. In discussing methods of investigation, Prof. E. Waxweiler said that light could only be thrown on the question of totemism by the application of a scrupulously accurate method of analysis, which should be mainly sociological, *i.e.* it should consider the so-called totemic facts as being imposed by the conditions of organised social life amongst men. Further, its starting point should be "functional"; it must search for the social function from which totemism had sprung. Analysing the phenomena of totemism on these lines, it would appear that functionally it was a social device for sanctioning permanent situations, which were considered essential or peculiar in the organisation of the group, wherein individuals, or more frequently groups of individuals, appeared to remain.

The discussion on an Imperial Bureau of Anthropology was opened by a paper by Mr. J. Gray, who dealt specifically with the anthropometric work which might be carried out under the supervision of such a bureau, and laid stress upon its importance not only to the man of science but to the statesman and social reformer. Mr. T. C. Hodson, in a paper dealing with the ethnographic side of the work, gave an account in outline of the ethnographic and linguistic investigations instituted by the Government in India, the Sudan, and southern Nigeria, and dwelt on the importance of the extension and organisation of such work through a central body as a means of securing sympathetic administration of the affairs of dependent races and of ensuring that they should be trained on right lines to take their place as constituent parts of the Empire. In the discussion which followed the reading of the papers, Prof. J. L. Myres made a detailed survey of the efforts of the British Association at various times to obtain the cooperation of the Government, and expressed a hope that urgent pressure might bring Government departments and public opinion to a sense of the responsibility of this country for a proper record of our own population and of the ways of life of our large masses of native dependents abroad. Prof. Ridgeway recalled the memorials which had been presented to the Government by the Royal Anthropological Institute, and emphasised, by an apt citation of Mr. Crooke's paper on the cow in India, the importance to administrators and commercial men of the information concerning customs and beliefs which such a bureau would make accessible. The Rev. Dr. Bryce explained the organisation of the Canadian Ethnographical Survey, which had been set up as a department of the Geological Survey as a result of the representations made to the Canadian Government by the association at its Winnipeg meeting, and Prof. Hutton Webster gave a brief description of the work of the United States Bureau of Ethnology.

Among the remaining contributions to the proceedings, archæology held first place in point of numbers, although papers of an ethnographical character were more numerous than they had been for the last few years. With one exception, however, these dealt with particular points of research, and were not generally descriptive of a geographical or cultural area. The exception was Captain Rawling's account of the tribes of the Mimika district, of the tribes of the sea coast, and of the Tapiro pygmies encountered by the recent expedition to Dutch New Guinea, which is likely to provide ethnologists with material for discussion for some time to come. Mr. Crooke's paper on the reverence for the cow in India attributed the recent extension of the recognition of the sanctity of the cow, which had existed in a more restricted degree since Indo-Iranian times, to the rise of Neo-Brahmanism. Prof. Hutton Webster's paper on the origin of rest-days proffered an elucidation of Hebrew and Babylonian Sabbatical observances by bringing them into relation with the periods of communal cessation from work and of fasting, as a protective or conciliatory measure, among lower races on critical, usually seasonal, occasions. Mr. Hobley's account of the religious beliefs of the Akikuyu and Akamba of British East Africa dealt, among other matters of belief and ritual, with the *Thahu*, an analogue of the mediæval curse, and its effect on social custom and culture. Major A. J. N. Tremearne described the customs and beliefs of the Hausas in so far as these may be deduced from, or illustrated by, an analysis of their legends and folklore. Dr. C. G. Seligmann raised many points of interest in his important paper on the divine kings of the Shilluk. It is noteworthy that these kings, who trace their descent from Nyakan, a semi-divine founder, are sacrificed ceremonially when they become senile or ill to avert disaster to men, crops, and animals. Mr. Malinowski's paper on the economic influence of the Intichiuma ceremonies opened up an interesting field of research by suggesting that in the totemic ceremonies of the Australian tribes we may find the educative influence which led man first to overcome the primitive reluctance to systematic, continuous, or periodic organised effort which is the essential feature of economic labour.

In physical anthropology, Prof. C. J. Patten communicated further results of investigations of division of the parietal bone in the crania of certain Primates. A group of papers was offered by Prof. Arthur Keith describing a cranium of Cro-Magnon type from Dartford, a second skeleton from Galley Hill, and fossil bones of man discovered by Colonel Willoughby Verner in a cave near Ronda, in Spain. These papers, in conjunction with a paper by Mr. R. R. Marett on the excavation of caves in Jersey, in which Mousterian implements were found associated with remains of Pleistocene mammals, and human teeth which Prof. Keith regards, on morphological grounds, as belonging to the most primitive human type yet known, gave rise to an interesting discussion on the antiquity of man.

In addition to the paper by Mr. Marett, the archæological papers included three papers on American archæology. These were a short account by Mr. Warren K. Moorehead of the classification of American types of artefacts made by a committee of the American Association and of the Anthropological Society, a description of the paintings in the Temple of the Tiger at Chichen Itza by Miss A. C. Breton, and a comprehensive account of the present position of archæological study in Peru by the same author.

The study of British archæology was represented by papers by the Rev. Dr. Irving on further finds of horse and other prehistoric mammalian remains at Bishop's Stortford; by Mr. T. Davies Pryce on excavations on a Roman fortified post on the Nottinghamshire Fosseway, covering the excavations of 1910 and 1911; an exhaustive summary of our knowledge of prehistoric man in Hampshire, by Mr. W. Dale; and a suggestive paper by Mr. O. G. S. Crawfurd on the early Bronze age in Britain, in which he endeavoured to trace the main lines of communication and indicate the chief centres of population from a study of geographical conditions and the distribution of Bronze age finds. A paper by Mr. A. L. Lewis entitled "Dolmens or Cromlechs," in which the author, as the result of comparative study of a large number of stone monuments, arrived at the conclusion that these were not the work of one race, but rather a phase of culture through which many races have passed, was especially interesting on account of its variance from the conclusion of Prof. Elliot Smith in his paper on the relations and influence of the Egyptians under the ancient Empire. The latter attempted to explain the distribution of megalithic monuments by the hypothesis that they were introduced into European culture by the Armenoid population in Egypt, of which he had found traces. The Armenoid or Celtic peoples who invaded Europe through the Balkan Peninsula, although they had acquired the use of metal from contact with the Egyptians in Asia, did not build megalithic monuments, because they were not acquainted with Egyptian methods of architecture. Egyptian archæology was further represented by papers from Prof. W. M. Flinders Petrie on his recent discoveries of Roman portraits at Hawara, and Mr. G. A. Wainwright's paper on his important discovery of iron beads of pre-dynastic date in unplundered graves at El-Gerzeh.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Glasgow.—The appointments made to the new chairs in the medical faculty in connection with the clinical school at the Royal Infirmary are as follows:—St. Mungo chair of pathology, Dr. John A. Teacher; Muirhead chair of obstetrics and gynæcology, Dr. John M. Munro Kerr; Muirhead chair of medicine, Dr. Walter K. Hunter; St. Mungo chair of surgery, Dr. Robert Kennedy.

Mr. A. J. Grove, 1851 Exhibition scholar, has been appointed supernumerary entomologist to the Indian Agricultural Service at Pusa, under the Indian Government.

The foundation-stone of a new wing for the applied science department of Sheffield University was laid on September 28 by Judge Denman Benson. The buildings of the applied science department have become crowded, and the Drapers' Company has given 15,000*l.* for extensions. The total cost will be nearly 40,000*l.*, and towards this the sum of more than 8000*l.* is still required.

It has been reported to the executive committee of Ruskin College, Oxford, that the late Mr. C. S. Buxton, formerly vice-principal of the college, son of Mr. Sydney C. Buxton, President of the Board of Trade, has bequeathed to the college the sum of 5000*l.* unconditionally. It is proposed to name the lecture-room in the new college buildings "The Buxton Hall," and a suitable memorial tablet will be erected.

The programme of lectures and discussions arranged by the Child Study Society, London, for October–December includes the following:—October 19, "Co-education during Adolescence," Dr. A. Beresford Kingsford; November 2, "Psychology and Grammar," H. Holman; November 9, "Psychology of Speech," Prof. W. Rippmann; November 23, "Psychology of Reading," T. G. Tibbey; December 7, "Psychology of Mathematics," Dr. W. Brown.

At the Sir John Cass Technical Institute, E.C., to-morrow, October 6, the inaugural lecture of a course on colloids will be given by Mr. E. Hatschek, his subject being "The Properties of Colloids and their Relation to Industrial Processes." On Tuesday, October 10, Mr. Hugh Abbot will give an inaugural lecture on the fermentation industries, entitled "A Review of Modern Practice in the Bottled Beer Trade"; and on Monday, October 16, Mr. J. S. S. Brame will lecture on "Coal for Steam Raising: its Purchase on a Scientific Basis and its Economic Use," being the inaugural lecture of the courses on fuel.

Attention has been directed already (August 10 and September 21) to the new arrangements for the session 1911–12 at University College, London, in the faculties of engineering and medical sciences. The recent issue of the complete calendar of the college makes it possible to add to the information in the note referred to. The organisation of the department of applied statistics is being completed, and it now includes the Galton laboratory for national eugenics and the Drapers' Company biometric laboratory, under the direction of Prof. Karl Pearson, F.R.S. In the faculty of engineering a new lectureship in heating and ventilating engineering has been instituted.

The Home Universities Committee held a meeting at the University of London on September 29 to arrange the subjects for discussion at the Congress of the Universities of the Empire to be held next summer. Each of the universities of the United Kingdom was represented by its Vice-Chancellor or his deputy, and various representatives from Government offices were also present. The suggestions received from overseas universities in response to the communications sent after the last meeting of the Home Universities Committee, and the report of a preliminary Conference of Canadian Universities, were considered. Some of the more important topics for discussion were decided upon, and the committee appointed a subcommittee to draw up a programme for the consideration of the full committee, which will meet again on November 4. A draft paper of subjects which the committee sent out in November last includes the following topics:—(1) university organisation; (2) universities in their relations to teachers and undergraduate students; (3) universities in their relation to post-graduate and research work; (4) universities in their relation to schools and to other agencies for higher education.

The regulations for the establishment of a post-graduate scholarship in naval architecture, offered by the Royal Commissioners for the Exhibition of 1851, have just been issued by the Institution of Naval Architects. Candidates for the scholarship must be British subjects under the age of thirty who have passed with marked distinction through a course of study in naval architecture at one of the following institutions:—the Royal Naval College, Greenwich; University of Glasgow; Armstrong College, Newcastle-upon-Tyne (Durham University); or University of Liverpool. The value of the scholarship is to be 200*l*. per annum, and it may be tenable in ordinary circumstances for two years. The holder will be required to engage in research work at some approved institution at home or abroad where special facilities are available for advanced study in naval architecture, and/or to investigate the development of the shipbuilding industry by attaching himself to some recognised firm or establishment at home or abroad. The results of research carried on by the scholar will be published in the Transactions of the Institution of Naval Architects if the council of the institution deem advisable.

It is announced in *The Pioneer Mail* that the Secretary of State for India has recently sanctioned the modified scheme proposed by the local government authorities for the establishment of a technological institute at Cawnpore. The original scheme, which was put forward in 1907, on the recommendations of the Naini Tal Industrial Conference, proposed the formation of an institute with a staff of four technological chemists, and four assistant professors, with large laboratories. Financial considerations rendered its immediate introduction impossible, and it became evident that a more modest beginning must be made. The proposals, however, have been framed so as to admit of future expansion, and the new institute will be such that it can be adapted to form part of any more extensive organisation that may be required subsequently. For the present it is proposed to employ a chemist with four assistants to carry on research and to train students. Close to the institute will be a scientific library, which will be shared with the Agricultural Department. One of the main causes which operate against the success of scientific and technical research in India will thus be removed, and the staff of the new institute will be provided with facilities which in India are too rare. The sanction is conditional on funds being available from provincial revenues, but it is to be hoped that no difficulty will be experienced in finding such funds.

The Department of Agriculture and Technical Instruction for Ireland has issued in the form of a pamphlet an article which appeared in its Journal (vol. xi., No. 4) on "Technical Education in Clonmel," by Mr. Cecil Webb, principal of the Technical and Day Trades Preparatory Schools, Clonmel. Mr. Webb points out that in the towns of the south of Ireland technical education often finds a difficult task, namely, to arrest decay and rekindle hope in a declining and disheartened population. Clonmel presents this problem. After reviewing the history of the attempts in Clonmel to develop a system of technical education, Mr. Webb directs attention to a special feature of the present scheme of instruction in the town. This has been the endeavour to make the work of the school a means of reviving the road carriage-building industry which, when the technical school was started, still existed in Clonmel in a precarious way. A class in coach-building was formed under a well-qualified local carriage-builder. The effect upon the local industry has been very gratifying. The design and construction of cars have greatly improved. At show after show through the country Clonmel cars have carried off the prizes. Their repute has spread, and summer and winter the coachbuilders in Clonmel are now kept busy. Such an effect could only be attained by the technological training which the school provided, being backed by enterprise and perseverance on the part of those engaged in the trade.

In the recently published "Statistics of Public Education in England and Wales, Part i.," some interesting numbers are given referring to the further education or occupation of pupils above twelve years of age who left secondary schools on the grant list of the Board of Education during the year ending July 31, 1909. The table in which the information is contained is based on data collected by the schools and recorded for each pupil in the admission registers. The total number of such boys and girls was 38,200, and of these 6790, or 17·8 per cent., went to a place of further education; 6048, or 15·8 per cent., became teachers (including pupil-teachers) in elementary schools, or entered training colleges for elementary-school teachers; 11,136, or 29·2 per cent., entered upon some professional, commercial, or clerical occupation; 3356, or 8·8 per cent., entered upon some industrial or manual avocation; 1001, or 2·6 per cent., took up agriculture or some rural pursuit; and of the residue—9869, or 25·8 per cent.—12·8 per cent. remained at home, 2·4 per cent. went abroad, 1·2 per cent. left owing to illness or died, and in the case of 9·4 per cent. the occupation was unknown or unclassified. Another table shows that on January 31, 1910, there were in the secondary schools on the grant list 141,149 pupils, of whom 106,248 were twelve years of age or over. Of these, 23·5 per cent. were twelve and under thirteen; 26 per cent. were thirteen and under fourteen; 23 per cent. were fourteen and under fifteen; 15·7 per cent. were fifteen and under sixteen; 8·1 per cent. were sixteen and under seventeen; 2·6 per cent. were seventeen and under eighteen; 0·8 per cent. were eighteen and under nineteen; and 0·2 per cent. were nineteen and over.

The Borough Polytechnic Institute authorities have issued a calendar under the title "Higher Education in Central South London," which takes the form of a joint prospectus of the Borough Polytechnic, Morley College, and affiliated evening-school centres. The varied programme of courses of study shows that the wants of every class of worker in the area served by the institute have been considered by the authorities, and met in a very thorough manner. Among other noteworthy departments of the institute may be mentioned the "national" school of bakery and confectionery, which forms a special department. It is managed—subject to the approval of the governing body of the polytechnic—by the Education Committee of the National Association of Master Bakers and Confectioners, which body contributes an annual sum not exceeding 500*l*. Any individual, society, or firm contributing not less than 25*l*. a year may appoint a representative upon the education committee. The London Master Bakers' Protection Society has contributed 50*l*. annually for some years past. A technical day school for boys has been founded for the purpose of affording opportunities for sound preparatory trade training, which will give London boys better chances of becoming skilled workers than they have hitherto had. The governors of the institute feel that the adequate training of bright boys who would be successful in various trades has been almost entirely neglected. They are of opinion that, owing to modern methods of manufacture, there is great need for the preparation of boys for trades on a broad basis, which will enable them to adapt themselves to changing conditions of employment and compete successfully in the industrial world. Boys are trained not to work mechanically, but to think for themselves. A similar trade school for girls has also been provided.

SOCIETIES AND ACADEMIES.

Paris.

Academy of Sciences, September 25.—M. Armand Gautier in the chair.—Paul **Appell**: The θ functions of higher degrees.—F. **Quénisset** and F. **Baldet**: The discovery of a comet at the Flammarion Observatory of Juvisy. The comet was noticed in the constellation Ursa Minor on September 23 as a slightly oval nebulosity, about 4′ in diameter, with a central nucleus. (For further particulars see Our Astronomical Column.)—A. **Demoulin**: The R and Ω surfaces.—A. **Blondel**: The influences of deadening the waves in orientation in wireless telegraphy.—M. **Reutter**: The analysis of a resin from an Egyptian sarcophagus. Besides mineral substances, there could be identified fragments of cypress or cedar wood, cedar resin, resins arising from styrax, mastic, Aleppo pine, and asphalte.—Jules **Cardot**: The mosses collected by the Antarctic expedition of the *Pourquoi-Pas?* The collection comprised thirty-four species, and enriched three genera of eleven species (seven of which are new), and two varieties (one new). The flora of the Antarctic region is poor compared with that of the Arctic region.—Paul **Marchal**: The obliteration of sexual reproduction in *Chermes piceae*.—E. A. **Martel**: The construction of roads and other works in limestone. It is pointed out that limestone is a dangerous material for public works, owing to the infiltration of water into fissures. In constructing roads and tunnels in limestone or dolomite, it should not be forgotten that these pseudo-compact rocks, owing to the existence of water in fissures and pockets, are especially delicate from the engineering point of view: very slight artificial derangement may have very serious effects on the stability of such a rock mass.—Ph. **Négris**: The discovery of the Carboniferous and Eocene formations at Mts. Guiona and Vardoussa, west of Parnassus.

CALCUTTA.

Asiatic Society of Bengal, September 6.—W. **Kirkpatrick**: Exogamous septs of the Gehara section of Kunchhandiya Kanjars. Whatever the social structure of the primæval hordes, the system which requires division into exogamous and endogamous septs and sections has taken on a fresh activity under Brahmanical influence. The exogamous septs of the Geharas are mostly of totemic origin, though an exogamous sept is not always totemic; one can be entirely independent of the other. An exogamous sept may be of local or communal origin, or it may be eponymous, as well as having an occupational origin. In the camp system of "marrying out" practised by the Kanjars and allied tribes of a Gypsy character we are near exogamy in its most primitive form.—Dr. P. T. L. **Dodsworth**: Some notes relating to the classification, habits, and nidification of the ravens of India. The author maintains that the Panjab raven is distinct enough from the Himalayan raven to be regarded as a distinct species, and should not be united with it into *Corvus corax*, Linn. Hume recorded it as different in note and in the sheen of the plumage, and Oates noted it as different in the character and shape of the throat hackles. It is a smaller bird. There is a need for extended observations on the Himalayan raven: (1) To what extent does it show a slight seasonal migration? (2) When does it nest? Mandelli took the eggs in Sikkim on March 5; Stoliczka found the bird building on May 4 at Aktash, and Walton near Kala Tso Lake in Tibet on April 6. (3) Does it habitually nest on cliffs? and (4) in successive years on the same site? (5) What is the number of eggs? (6) Do both birds share in hatching them? and (7) how long do the young stay in the nest? The author adds some observations on the nidification of the plains raven. Five is the usual number of eggs; the nest is built, 18 to 24 feet from the ground, of sticks, lined with rags, sheeps' wool, bits of paper, cows' hair, and grass. Various trees are chosen, such as *Acacia leucophloea*, *Dalbergia Sissoo*, and *Albizzia Lebbek*. When feeding these plains ravens are sociable, but in the breeding season they seem to scatter, and probably many cross into Afghanistan.—J. Coggin **Brown**: Shan and Palung Jew's harps from the Northern States. The Jew's harp used by the Shans and Palungs is distinct from all others in the presence of movable bamboo strips, by means of which the chamber in which the tongue vibrates can be altered and the tone changed in consequence.—R. K. **Bhide**: New and revised species of Gramineæ from Bombay. Diagnosis of the following new grasses:—(1) *Danthonia Gammiei*, from Castle Rock; (2) *Andropogon Paranjpyeanum*, from Castle Rock; (3) *Enteropogon Badamicum*, from Badami; and (4) *Tripogon Roxburghianum*, from Badami. Also a note on the identity of *Woodrowia diandra*, Stapf, with *Dimeria diandra*, Stapf.—I. H. **Burkill** and R. S. **Finlow**: *Corchorus capsularis*, var. *oocarpus*, a new variety of the common jute plant. *C. capsularis*, var. *oocarpus*, a variety distinguished by the elongation of its fruit, is a cultivated plant of south-eastern Mymensingh.—I. H. **Burkill**: The polarity of the bulbils of *Dioscorea bulbifera*, Linn. The bulbils of *D. bulbifera* are capable of growth from any part of their surface, but they grow most readily from the neighbourhood of the scar by which they were attached to the parent stem. If cut into halves equatorially, both hemispheres may put out shoots, and these shoots appear more readily near the cut than remote from it; but they appear in a much more restricted way on the abaxillary half (where almost all arise along the edge of the cut) than on the adaxillary half.—I. H. **Burkill**: Further spreading of *Croton sparsiflorus*, Morung. *C. sparsiflorus*, an alien which obtained an entrance into India by Chittagong, it seems, some fifteen to twenty years ago, and about 1905 reached the banks of the Hughli, and before 1907 had reached Gauhati along the Assam-Bengal Railway, has now reached Narayanganj, in a different direction. It has also appeared newly at many stations along the Assam-Bengal Railway.

GÖTTINGEN.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part iii. for 1911, contains the following memoirs communicated to the society:—

April 4.—K. **Schwarzschild** and E. **Kron**: The distribution of luminosity in the tail of Halley's comet.

March 24.—K. **Stuchtey** and A. **Wegoner**: The *albedo* of the clouds and the earth (measurements made during six balloon voyages).—G. **Hamel**: Contributions to the problem of turbulent motion.

May 13.—G. **Tammann**: Contributions to the thermodynamics of equilibria in systems each composed of a single substance, i.

May 27.—E. **Riecke**: The theory of Michelson's interference experiment.

June 17.—K. **Wegener**: Aërological results for 1910 from the Samoa Observatory.—P. **Furtwangler**: General proof of the partition theorem for *Klassenkörper*.—O. **Mügge**: The structure of magnetite and its transformation into specular iron ore.

July 15.—G. **Tammann**: Contributions to the thermodynamics of equilibria in systems each composed of a single substance, ii.

BIOLOGICAL PHILOSOPHY.

Creative Evolution. By Prof. H. Bergson. Authorised translation by Dr. A. Mitchell. Pp. xv+425. (London: Macmillan and Co., Ltd., 1911.) Price 10*s.* net.

NOT a few of the great philosophers of the past were expert students of science, especially of mathematics and physics. We think at once of men like Descartes, Leibnitz, and Kant, to mention three whose periods are in almost continuous chronological sequence. The widening of the field of knowledge and submission to a correlated division of labour have made it less possible in these later days for a man to be a mathematician in the morning and a metaphysician at night, but the tradition of an alliance between the two disciplines has not been lost. For to a greater extent than is generally recognised there have been of recent years, in the ranks of the philosophers, men having not merely—though that is much—an intelligent sympathy with scientific work, but familiarity therewith and ability to offer competent criticism. We think, for instance, of men like the late Prof. William James, Prof. Royce, Prof. James Ward, and Prof. A. E. Taylor. Within the same period, too, we have seen one department of science after another making its definite contribution to philosophy. Now a mathematician, and again an embryologist, has been as a Saul among the prophets. We think, for instance, of Mr. Bertrand Russell, Dr. Hans Driesch, and Prof. Lloyd Morgan. It seems then that the time is ripening for a closer cooperation of philosophy and science, and the man of the time is Henri Bergson.

Metaphysician as he is, M. Bergson seems to be equally at home with mathematical and biological concepts, and he appreciates the aim of science with a rare sympathy. He recognises that metaphysics, in its endeavour to discover the general conditions of a complete and consistent formulation of experience, may be of great service to science, but he is equally clear that, in forming its coherent conception of the whole scheme of things, metaphysics must utilise the materials which the sciences furnish. It is indeed one of the outstanding features of his "Creative Evolution" that its author insists on finding in a more complete appreciation of the manifoldness of nature a basis for his new philosophy of life.

One of the main motives of the essay before us is the conviction that *theory of knowledge* and *theory of life* are inseparable inquiries. They must join each other and "push each other on unceasingly." In their common enterprise, "they would dig to the very root of nature and of mind."

"For the false evolutionism of Spencer—which consists in cutting up present reality, already evolved, into little bits no less evolved, and then recomposing it with these fragments, thus positing in advance everything that is to be explained—they would substitute a true evolutionism, in which reality would be followed in its generation and its growth."

The book is divided into four chapters, the sequence of which the author explains. In the first chapter "we try on the evolutionary progress the two ready-made garments that our understanding puts at our disposal," mechanism and finalism; neither will fit, but finalism "might be recut and resewn, and in this new form fit less badly than the other." In the second chapter, to get beyond the concepts which the understanding puts at our disposal, the author reconstructs the main lines of evolution along which life has travelled—to vegetative torpor, to instinct, to intelligence. Besides the line of evolution which ends in man, there are others which "also express something that is immanent and essential in the evolutionary movement." Perhaps certain powers within us that are complementary to conceptual and logical thought, "will become clear and distinct when they perceive themselves at work, so to speak, in the evolution of nature." The third chapter is an effort to bring back the intellect to its generating cause, "which we then have to grasp in itself and follow in its movement." "A fourth and last part is meant to show how our understanding itself, by submitting to a certain discipline, might prepare a philosophy which transcends it."

Prof. Bergson's book, the translation of which reflects the highest credit on Dr. Arthur Mitchell, has been called both brilliant and profound, and it is too big for us to praise. We wish to say, however, that we have read it three times with increasing enjoyment and gratitude. When we have read it other three times we may perhaps understand it more perfectly, for it is useless to pretend that it is easy. The style is so brilliant and picturesque, the play of the sword is so fascinating, there is such abundance of interesting illustration that the pages slip easily past, yet for the student of organic evolution, seeking for fresh light, the thought often seems very abstract and subtle. For example, specialists may find no particular difficulty in the conception of "durée," which is so essential to the argument, but that has not been our experience. For the pages of NATURE it may be most suitable that we should leave the more purely philosophical part of the book alone, and confine ourselves to a few of the salient biological ideas, *e.g.* of the organism as a historic being, and of evolution as a succession of creations—expressions of sustained "effort."

One of the pivots of the essay is its conception of the organism, from which, as it seems to us, modern biology has something to learn, something to translate into its own universe of discourse. Bergson dwells on the likeness between the life of the organism and our own personal experience. We change without ceasing and the organism continually exhibits its characteristic metabolism. But both have the mysterious quality of "durée"—a word so difficult to translate, for Bergson means more than duration in the merely physical and chronological sense; he means "the continuous progress of the past which gnaws into the future and which swells as it advances." "Our personality shoots, grows, and ripens without ceasing. Each of its moments is something new added to what was before. We are creating ourselves continually." So of an organism it may be said that "its past, in its entirety, is prolonged into its present, and abides there, actual and acting."

"Continuity of change, preservation of the past in the present, real duration—the living being seems, then, to share these attributes with consciousness. Can we go further and say that life, like conscious activity, is unceasing activity?"

Bergson answers this question by an emphatic affirmative. The spontaneity of life is manifested by a continual creation of new forms.

Many biologists and others have previously expounded the idea of the organism as a historic being, but Bergson has given it a new vividness. "Wherever anything lives, there is, open somewhere, a register in which time is being inscribed." For it is of the essence of Bergson's thinking that time has an effective action and a reality of its own.

"We perceive duration as a stream against which we cannot go. It is the foundation of our being, and, as we feel, the very substance of the world in which we live."

"The evolution of the living being, like that of the embryo, implies a continual recording of duration, a persistence of the past in the present, and so an appearance, at least, of organic memory."

It is this conception, in part, which leads Bergson to reject radical mechanism with some emphasis, and, for that matter, radical finalism as well, though he ends with leaving us with a theory that partakes of finalism to a certain extent.

Prof. Bergson thinks of life as

"the continuation of one and the same impetus, divided into divergent lines of evolution. Something has grown, something has developed by a series of additions which have been so many creations." "Evolution has taken place through millions of individuals, on divergent lines, each ending at a crossing from which new paths radiate, and so on indefinitely."

He believes that the essential causes working along these diverse roads are "of psychological nature." It is to be expected therefore that "they should keep something in common in spite of the divergence of their effects."

"Something of the whole, therefore, must abide in the parts; and this common element will be evident to us in some way, perhaps by the presence of identical organs in very different organisms."

It is this idea which leads Prof. Bergson to devote particular attention to the phenomenon of convergence in evolution, to the occurrence, for instance, of closely similar eyes in molluscs and in vertebrates—eyes which differ greatly in development, and must have had a quite independent evolution.

"What likelihood is there that, by two entirely different series of accidents being added together, two entirely different evolutions will arrive at similar results?"

Of course, the conventional Darwinian and Lamarckian interpretations are carefully considered.

"But such similarity of the two products would be natural, on the contrary, on a hypothesis like ours: even in the latest channel there would be something of the impulsion received at the source. *Pure mechanism, then, would be refutable, and finality, in the special sense in which we understand it, would be demonstrable in a certain aspect, if it could be proved that life may manufacture the like apparatus, by unlike means, on divergent lines of evolution; and the strength of the proof would be proportional both to the divergency between the lines of evolution thus chosen and to the complexity of the similar structures found in them.*"

This is one of the ingenious arguments of this brilliant essay, but we doubt if it would convince anyone against his will.

Prof. Bergson considers various theories of evolution, which he regards as each true in its way. The neo-Darwinians are probably right in teaching that the essential causes of variation are the differences in the germs borne by the individual, but probably wrong in regarding (or if they regard) these differences as purely accidental and individual. Eimer was probably right to some extent in his idea of variation continuing from generation to generation in definite directions, but probably wrong in his claim that combinations of physical and chemical causes are enough to secure the result. The neo-Lamarckians are probably right in insisting on causes of a psychological nature, but they are probably wrong in thinking merely of the conscious effort of the individual and in assuming the regular transmission of acquired characters. The author's own position may be gathered from the following sentences:—

"A hereditary change in a definite direction which continues to accumulate and add to itself so as to build up a more and more complex machine, must certainly be related to some sort of effort, but to an effort of far greater depth than the individual effort, far more independent of circumstances, an effort common to most representatives of the same species, inherent in the germs they bear rather than in their substance alone, an effort thereby assured of being passed on to their descendants."

So we come to the idea of—

"an *original impetus* of life, passing from one generation of germs to the following generation of germs through the developed organisms which bridge the interval between the generations. This impetus, sustained right along the lines of evolution, among which it gets divided, is the fundamental cause of variations, at least of those that are regularly passed on, that accumulate and create new species. In general, when species have begun to diverge from a common stock, they accentuate their divergence as they progress in their evolution. Yet, in certain definite points, they may evolve identically; in fact, they must do so if the hypothesis of a common impetus be accepted."

This remains too shadowy for the working naturalist, but it is a fresh attempt to express what must some day become clearer, the essential thought of Lamarck, of Goethe, of Robert Chambers, of Samuel Butler, and of later vitalists—the idea of variations as intrinsic self-expressions of the organism.

Another cardinal idea of Prof. Bergson's book is that the evolution of life has taken a number of divergent directions, leading to quite different goals. It is neither a series of adaptations to accidental circumstances, as the mechanistic view sees it, nor the realisation of a plan, as the finalist view would have it. A plan is given in advance, but evolution is a creation unceasingly renewed, a development of an original impetus in various directions. Two of these directions are represented by the world of plants with their fixity and insensibility, and the world of animals with their mobility and awakened consciousness.

"But the waking could be effected in two different ways. Life, that is to say, consciousness launched into matter, fixed its attention either on its own movement or on the matter it was passing through; and it has thus been turned either in the direction of intuition or in that of intellect."

Intuition could not go very far, and shrank into instinct. Intelligence became more and more free, and "it can turn inwards on itself, and awaken the potentialities of intuition which still slumber within it." While Bergson shows very finely how the plant may sometimes rouse itself from its torpor and the animal sink into vegetativeness, how instinct may be mingled with intelligence, and intelligence penetrated by instinct, yet his definite conclusion is that the differences between vegetative torpor, instinct, and intelligence are differences of kind.

"*The cardinal error which, from Aristotle onwards, has vitiated most of the philosophies of nature, is to see in vegetative, instinctive and rational life, three successive degrees of the development of one and the same tendency, whereas they are three divergent directions of an activity that has split up as it grew.*"

And it is from this that the author passes to his even more important conclusion that while intelligence guides us into matter and delivers to us the secret of physical operations, it is instinct—which is sympathy—that will give us the key to vital operations.

"Intelligence goes all round life, taking from outside the greatest possible number of views of it, drawing it into itself instead of entering into it. But it is to the very inwardness of life that *intuition* leads us—by intuition I mean instinct that has become disinterested, self-conscious, capable of reflecting upon its object and of enlarging it indefinitely."

Thus while nature-poetry is in no sense biology, it may be a very important complement.

J. A. T.

TIDES AND ORBITS.

Scientific Papers. By Sir George Howard Darwin, K.C.B., F.R.S. Vol. iv., Periodic Orbits and Miscellaneous Papers. Pp. xviii + 592. (Cambridge: University Press, 1911.) Price 15*s*. net.

IN this fourth volume Sir George Darwin has for the present completed the task of editing his papers, a task which he commenced four years ago on the invitation of the syndics of the Cambridge University Press. If we may judge from the fact that nine papers in the present volume have appeared since the publication of the work was started there is reason to hope that a supplementary volume will be needed before many years are past. That volume when it comes will have to contain, if it is to be consistent with former volumes, pioneer investigations of a high order in some difficult branch of applied mathematics. To one who desires to speculate along what line Sir George Darwin's future work is likely to take him the present volume is of especial interest. For in the papers classed under the head "Miscellaneous Papers in Chronological Order" will be found several early papers containing the germ of much of the later more important work. Several of these papers (notably 11, 12, 13) would appear to be by-products of larger investigations which were already (we judge from the chronological list of papers) well in hand when these investigations were published. But the paper "On the perturbation of a comet in the neighbourhood of a planet," which was followed after an interval of four years by the historic investigations on periodic orbits, does look like the first attempt along a new and fruitful line of investigation. In fact, though differing in scope and nature from the larger work, the small paper to which we have just referred might quite fairly, from a historic point of view, have been placed in the section containing the periodic orbits papers, as a preliminary piece of research. This section is the most important part of the volume under review, and we must discuss it in some detail.

In the introduction to the well-known memoir in the *Acta Mathematica*, the author speaks of the prodigious amount of numerical work involved in his attack on the problem of periodic orbits. He adds:—

"It is not for me to say whether the enormous labour I have undertaken was justifiable in the first instance; but I may remark that I have been led on, by the interest of my results, step by step, to investigate more, and again more cases. Now that so much has been attained I cannot but think that the conclusions will prove of interest both to astronomers and mathematicians."

Recent successful applications to problems of celestial astronomy of what are to a large extent Sir George Darwin's methods would alone justify his heavy work. But quite apart from these applications the paper has great intrinsic value. The important stability discussion and the useful account of the method of mechanical quadratures practically developed by the author both serve a very useful purpose to the student. The presence of a paper by Mr. S. S. Hough, his Majesty's astronomer at the Cape, is a valuable addition to the section. It not only serves to bridge over the gap between Darwin's first and third papers and to supply an important addition to the theory of the subject, but it also supplies an account of the orbit work from a different point of view from that of the author. It may not unfairly be compared to Schwarzschild's account of Poincaré's work on revolving bodies, and its presence alongside Darwin's papers is of great value. It should be added that the illustrations have been well reproduced, and that from an interesting appendix some idea may be gleaned of the heavy computing work involved in these researches. Here it seems not unreasonable to refer to Sir George Darwin's generous and thoughtful appreciation of his great co-worker's investigations in his own field. His address on presenting the gold medal of the Royal Astronomical Society to M. Poincaré is full of interest. This, with his two British Association addresses, will form the chief item of interest in this volume to the non-mathematical reader. We can only glance at two points of interest here.

The idea that some physical truth underlies Bode's empirical law seems to persist in these addresses, and we could hope that there lies the germ of Darwin's next attack on the problems of cosmogony. We naturally cannot agree with all the statements made in what are essentially popular addresses, and we signal as one instance of doubtful reasoning the reference to a condensing ring on p. 537. The effect of a mobile central nucleus inside the ring seems to be left out of account.

Among the miscellaneous papers we select first for mention those dealing with mechanical designs, where the collaboration of the author's brother, Horace Darwin, is again suggestive of later developments; the sandthrust and ripple experiments also give evidence of a side of Darwin's nature not suspected from a casual knowledge of his work. It was with something of a start that the writer found in "A Geometrical Puzzle" a note (dated 1877) referring to an old puzzle which has only recently had a return of popularity. The papers on "Marriages between First Cousins and their Effects" form an appendix which is still of considerable interest to the biological statistician. But if we may judge from the preface the paper to which Darwin would ascribe the greatest value himself is the one on "The Mechanical Conditions of a Swarm of Meteorites." The author notes that the paper has received but little notice, and the reason for this does not seem far to seek. The seat of the controversy has moved away from the point to which the investigation was directed, as is indeed clear from Darwin's own addresses referred to above. The assumptions of a spherical distribution do not apply to a spiral nebula—which has become of recent years the chief source of speculative interest. Lastly, we must mention the paper on the Antarctic tides. It is curious to compare Darwin's forecast of a great unsuspected bay in the Antarctic with Harris's forecast of a large piece of undiscovered land in the Arctic Ocean. Both suggestions have been based on tidal observations, supported to some extent by rival theories. Both are open to proof or disproof through subsequent voyages of exploration.

We have left until last the English text of the important article, "Bewegung der Hydrosphäre," in the "Encyklopädie der Mathematischen Wissenschaften." Here again Mr. Hough has collaborated and added a lucid discussion of the dynamical theory of the tides. The practical application of the theory by the harmonic and synthetic methods are fully discussed, though the treatment is somewhat too condensed for the average reader. A useful bibliography and schedule of the symbols in common use is added, and an account of many miscellaneous investigations, such as the Bidston tidal-load experiments. It is perhaps disappointing to gather that we cannot yet with any confidence make any wide generalisations as to the nature of the tide-wave in the open ocean. But in each unsolved problem lies the charm of the unknown, the fascination which lures the born researcher on to investigation after investigation. That George Darwin by right of descent and by natural aptitude is one who must pursue the search in the unknown is amply testified in his collected works. That he has pursued his investigations in the right spirit his own words testify.

"Man is but a microscopic being relative to astronomical space, and he lives on a puny planet circling round a star of inferior rank. Does it not then seem as futile that he can discover the origin and tendency of the universe as to expect a house-fly to instruct us as to the theory of the motions of the planets? And yet, so long as he shall last, he will pursue his search, and will no doubt discover many wonderful things which are still hidden. We may indeed be amazed at all that man has been able to find out, but the immeasurable magnitude of the undiscovered will throughout all time remain to humble his pride. Our children's children will still be gazing and marvelling at the starry heavens, but the riddle will never be read."

THE SCIENCE OF MODERN ARTILLERY.

Modern Artillery in the Field: a Description of the Artillery of the Field Army, and the Principles and Methods of its Employment. By Colonel H. A. Bethell. Pp. ix+393. (London: Macmillan and Co., Ltd., 1911.) Price 7s. 6d. net.

THIS book is a welcome sign that the country is beginning to wake up to the importance of the study of artillery science, in which we see such superior interest everywhere abroad.

The territorial is very keen to make himself acquainted with the science of his arm; and in the absence of official financial support this treatise of Colonel Bethell will prove useful to make him without practice into the theoretical gunner, contrasted with the regular gunner, practical man without practice.

In opposition with what can be seen on the Continent, here in this country we have no practice ranges for artillery—*Champs de Tir*, so plentiful in France. We shall have to trust to territorial enthusiasm in antagonism to official neglect for providing at private expense the best amateur substitutes possible, which the regular gunner will be glad to utilise on an emergency when once a system is started; he too is starved in practice to an equal extent.

The retired general officer is not forgotten—landowner and on a pension, who at the end of the last century was so decided in his refusal to give any facility to volunteer rifle shooting; but soon was sorry he had been so outspoken, when the bad news came streaming home from South Africa shortly after.

Modern artillery has been revolutionised by the introduction of the quick-fire (Q.-F.) gun, described with useful diagrams by Colonel Bethell; but the name should be changed to Q.-A. (quick-aim).

By allowing the gun a long recoil of three or four feet over the carriage, the reaction can be reduced until the wheels do not jump off the ground; the carriage remains still, so that a slight adjustment only is required for the next shot.

Without this Q.-A. arrangement the Q.-F. principle cannot be utilised; and one of these guns is a match for six of the type we used in South Africa.

The gunner who fires the gun is still called by official misnomer the "layer"; but he does not "lay"; he merely keeps the telescopic sight on the mark and fires as fast as the gun can be loaded—twenty times a minute. He is the *pointeur*; other gunners attend to laying of the gun, in giving the elevation to correspond with the range finder, and in setting the fuse, for which a special instrument has at last been introduced; others traverse the gun when required and hand over the ammunition, and all can work in security behind a steel shield. But the man who fires the gun gives his individual attention to "pointing."

Official optimism at the end of the last century had declared our artillery to be perfect—a sure prelude to disaster. We know now that it was fit only for the scrap heap, and would have been knocked out in the first encounter with a European Power; and the German mercenary gunner in Africa was more than a match for our regular artillery.

We must look to France for the most modern development of artillery science, as our military authority is quite content on a back seat.

Parts iii. and iv. have the appearance of being lifted from a French source. The territorial gunner will profit at his leisure by a study of these parts and the useful hand sketches; also in walking over the ground in his neighbourhood with eyes open; his opportunity of actual insight at manœuvres will be small.

The word mobility is always in vogue, with little grasp of its meaning.

After a war the cry is always for a more powerful gun; and our eighteen-pounder weighs 24 cwt. on a pair of wheels. This is too much for the road and the team, and is putting the cart before the horse according to the proverb modified. A field gun must be able to leave the road and cross a ploughed field, so that the old definition of the Act of Parliament of Henry VII. still holds good, of a ton as a cartload, in fixing the standard weight to be carried on a pair of wheels.

But in a long peace, when smart evolutions are considered of more importance than gunnery, and mobility comes to mean a gallop with no reality between the team, the weight decreases to an opposite extreme.

The horse scarcity is becoming acute with the advance of the motor-car. Territorial gunners will have to learn their drill indoors with blocks of wood and toy soldiers, like naval officers playing a war game on the gun-room table; and this book will provide plenty of ideas for abstract tactical problems.

The artillery tactics of the flying machine come in for discussion. These tactics have been worked out long ago by the French, and the dirigible balloon was directed to take up a place of safety hovering vertically overhead, as then the enemy would not dare to fire with the prospect of the shot descending on his own head or his friends'.

We prefer to think of the flying machine as a dragon-fly, in the German name, harmless and lovely for our delectation. But no public funds would be available if it could not be shown that the flying man could be utilised for human destruction, employed as "the light militia of the lower sky."

G. GREENHILL.

INSULATING MATERIALS AND ARMATURE WINDINGS.

(1) *Les Substances Isolantes et les Méthodes d'Isolement utilisées dans l'Industrie Électrique.* By Jean Escard. Pp. xix+313. (Paris: Gauthier-Villars, 1911.) Price 10 francs.

(2) *Les Enroulements Industriels des Machines à Courant continu et à Courants alternatifs: Théorie et Pratique.* By E. Maree. With a preface by Paul Janet. Pp. vii+240. (Paris: Gauthier-Villars, 1911.) Price 9 francs.

(1) A TREATISE on insulating materials conceived in a scientific spirit would certainly be welcome to many electrical engineers, and on reading the author's preface to his attempt to write such a treatise one concludes he has approached his subject from this point of view. He tells us that his work is not intended to be a mere enumeration of the various insulating materials available, but a critical investigation, such as will help the practical engineer to make in each case the best selection possible. Good as the author's intentions were, his performance falls short of them.

There is, to begin with, a good deal of matter in his book which has nothing whatever to do with insulating materials. The first forty pages are devoted to a discussion of metallic and liquid conductors, and here we find merely a repetition of statements and figures which will be found in any text-book on physics. This is padding; so is the picture of a drilling machine, that of a shop in which tissue paper is pasted on to transformer plates, and so are the illustrations of various wooden and ferro-concrete telegraph poles. To drag in the coherer used in wireless telegraphy is also padding, pure and simple. That the insulating properties of concrete are discussed is quite right, but it is misleading to draw any conclusions from it in respect of the insulation of dynamos. Yet on p. 128 we are told that small machines are generally placed on timber, and are thus sufficiently insulated from earth. Large machines must be put on a concrete foundation, and although this is not an absolute insulator, it is a sufficiently poor conductor to prevent any considerable escape of electricity to earth. But precautions are necessary; the foundation must be kept dry, and to this end one must avoid the neighbourhood of steam and water pipes, and one must dry the air in the engine-house by ventilating fans. How a steam dynamo is to be driven without steam and water pipes coming near it the author does not explain.

As regards special insulating compositions, there is little more than enumeration accompanied by some general remarks, such as one might find in a trade list. In some cases the composition is given in detail, but no definite electrical data. We find such trade names as "Radoonite," "Terracite," "Refragor," "Megotalc," "Micacementite." The last-mentioned material is said to withstand vibration, and we are told that certain traction motors which were not insulated with it broke down after a run of 20,000 km., whereas after this material was used they were able to run 40,000 km. Information of this kind is simply valueless.

A good deal of space is devoted to air as an insulating material, and reference is made to the investigations of Ryan, Steinmetz, Scott, and Mershon (the latter's name being persistently spelled Merthon). There is, however, nothing said about Watson's research on the increase of the dielectric strength of air under high pressure, and the practical application he made of it, and brought before the Institution of Electrical Engineers a few years ago. The best chapter in the book is that on porcelain as an insulator. Here we get some definite data, both as to the various types used and the methods of testing.

(2) Formulæ for armature windings are a fascinating subject to the mathematician. It is, of course, possible to represent any winding, no matter how complicated, by some mathematical expression, or even to devise a general winding formula of formidable aspect which, by a suitable choice of coefficients and constants, may be reduced to represent any winding, even the simplest. To an accomplished mathematician there must be a great temptation to treat the subject in this comprehensive way; and we may feel grateful to the author for having withstood the temptation and given us a treatise which restricts the subject to those windings that are of importance to the manufacturer. But these he treats thoroughly, not only as mathematical problems, but also from the manufacturer's point of view, that is, including detailed descriptions of the various special tools required. The use of winding tables instead of drawings of connections is, of course, well known, but the author's way of arranging the winding table is extremely useful. It contains not only the sequence of the conductors (or in a coil winding of the coil sides) proper, but also the sequence of slots and commutator sections, so that the division of current between the armature circuits and the potential difference between any two conductors or any two commutator segments can be seen at a glance.

The use of open slots and binding hoops is recommended for peripheral speeds under 6000 feet a minute; beyond that wooden wedges should be used, or, better still, slots with an overlapping lip. As regards equipotential connections the author seems to think them of equal importance for wave and lap winding, and he fails to point out that with four-pole machines, even if lap wound, they are not nearly so necessary as in a six-pole machine. This is, however, a minor matter, and, moreover, does not affect the system of winding, which is, strictly speaking, a geometrical and not a dynamical problem.

In the second part of the book we come to windings for alternating-current machinery. These are generally more simple than direct-current windings, but the author treats them with equal thoroughness. Even such questions as the shape of the e.m.f. curve as influenced by the number of slots per phase per pole, the comparative merits of six-phase and three-phase windings for converters, those of two-phase *versus* three-phase generators, and other more theoretical matters receive due attention. The special tools required are fully discussed and illustrated, and questions of insulation, such as the thickness of cotton covering, thickness of micanite tubes, covering and protection of coil ends, are not overlooked. The work is profusely illustrated both with line drawings and with perspective views of windings in different stages. These are very clear, and, as examples, well chosen. Polyphase winding diagrams are shown in different colours, so that it is easy to follow out the circuits for each phase separately.

GISBERT KAPP.

AGRICULTURAL BACTERIOLOGY.

(1) *Handbuch der landwirtschaftlichen Bakteriologie.* By Dr. F. Löhnis. Pp. xii+907. (Berlin: Gebrüder Borntraeger, 1910.) Price 36 marks.

(2) *Landwirtschaftlich-bakteriologisches Praktikum.* Anleitung zur Ausführung von landwirtschaftlich-bakteriologischen Untersuchungen und Demonstrations-Experimenten. By Dr. F. Löhnis. Pp. vii+156. (Berlin: Gebrüder Borntraeger, 1911.) Price 3.40 marks.

AS the fertility of virgin soils becomes exhausted and the world's population increases, man will become more and more dependent on artificial methods for increasing the fertility of the soil and on intensive cultivation. Research during the last twenty years has shown how important lowly forms of life are in these connections. The microbiologist has already indicated that, for instance, by increasing the nitrogen-fixing micro-organisms in the soil by inoculation, or by partial sterilisation whereby forms inimical to them may be destroyed, much may be done to increase the yield of crops without the actual addition of plant-food elements by means of manures.

(1) There has of late been an enormous output of work from various laboratories and experimental stations, and the first work under review gives an admirable summary of the more important researches on agricultural microbiology. It is a large volume of 900 pages, and has been compiled with true German industry from the original papers, the references to which are given. The latter occupy from a quarter to one-half, and in many cases three-quarters, of every page, often with a line or two of comment or explanation appended, so that the book forms a very complete bibliography of the subject, and it is pleasing to note that British, Colonial, and American work appears to have received full recognition, which is not always the case in German literature. The volume is divided into five main sections, which respectively deal with the occurrence and activity of micro-organisms in (1) fodder and agricultural foodstuffs, (2) the "retting" of flax and of hemp, and tobacco fermentation, (3) milk and milk products, (4) manure, and (5) the soil, and the treatment of each is very complete. Thus, in the first named, after a general discussion of the number and nature of micro-organisms in fodder and foodstuffs (hay, straw, grain and seeds, meal and roots), the subjects of the influence of micro-organisms in the preparation, heating, and firing of hay, in ensilage, in the decomposition of the starchy, saccharine, protein, and fatty constituents of fodder, &c., on digestion in the animal which consumes them,

and on its intestinal flora, are all treated. Finally, to every section or subdivision of a section a description of the physical, chemical, and biological methods of investigation is appended.

That we have much yet to learn concerning many of the natural processes involved is apparent from a perusal of such a section as that on the heating and firing of hay. This appears to take place in three stages, a first in which the temperature rises to 45–50° C., a second in which the temperature rises from 50° C. to 70° C., and a third which proceeds above 70° C. The first two stages are caused by the activities of micro-organisms involving processes of decomposition and oxidation ("thermophilic" bacteria being active between 50° and 70° C.), but the cause in the third stage of the production of heat above 70° C. and ultimately culminating in ignition is not so obvious. It is probably a physico-chemical process due to the production of carbonaceous and other matters which adsorb, condense, and oxidise the hydrogen, marsh and other inflammable gases, which have resulted from decomposition in the earlier stages, and cause their ignition, much in the same way as spongy platinum causes the ignition of hydrogen.

Nor is the subject-matter strictly confined to "bacteriological" details, but if others are of importance in relation to the general treatment of a subject, they are included. Thus, as regards milk, not only is the importance of streptococci discussed, but the nature and significance of the cellular elements which are constantly present in less or greater number are reviewed. These cellular elements when in small numbers have generally been considered to be leucocytes, when in large numbers as pus cells and to be abnormal, but investigation has shown that under normal conditions and with perfectly healthy cows these cells are occasionally present in enormous numbers; all this is summarised.

Considerable space is also devoted to the chemistry of the changes and decompositions which occur in the various processes, and while the vegetable micro-organisms claim most attention, some reference is made to the protozoa and higher animal organisms, *e.g.* earth-worms and their importance. Had the work been compiled later, doubtless more space would have been devoted to the protozoa, the treatment of which as it stands is too brief.

The book, which is not illustrated, is clearly printed on good paper with numbered lines for facility of reference, and concludes with very full and complete indexes of authors and subjects.

(2) This little book, by the same author as the preceding, gives in the briefest outline a general account of bacteriological methods followed by a series of simple practical lessons on the bacteriology and biochemistry of milk, manure, and soil. The student who works through these lessons will certainly gain a considerable amount of knowledge of the subjects treated, and will be ready to undertake more advanced work. Many illustrations are given, most of which are good and appropriate, though the methods of inoculating tubes given in Figs. 19 and 24 seem clumsy and archaic. R. T. H.

OUR BOOK SHELF.

British Rainfall, 1910. *On the Distribution of Rain in Space and Time over the British Isles during the Year* 1910, *as recorded by nearly* 5000 *Observers in Great Britain and Ireland, and discussed with Articles upon Various Branches of Rainfall Work.* By Dr. H. R. Mill. The fiftieth annual volume. Pp. 112+328. (London: Edward Stanford, 1911.) Price 10*s.*

THE author remarks in his report to the trustees that the chief object of the rainfall organisation is to present the results of the labours of the observers in the best and most useful way. An inspection of the volume under review leaves no doubt that this desirable aim has been fully attained. As in former years, the work is divided into three principal sections, including, *inter alia*, (1) organisation and special articles, (2) monthly and seasonal rainfall and its relation to the average and heavy falls of rain (see NATURE, February 2), and (3) general table of annual rainfall and number of rain-days at 4874 stations. The cartographic treatment has been carried further than in previous volumes; the maps referring to heavy falls on rainfall days are of exceptional interest, and include a series of remarkable thunderstorms which occurred chiefly in the south of England from June 5 to 10, with a coloured map (as frontispiece) showing the distribution of torrential rains in the Thames valley on June 9.

The most laborious of the changes this year is the more satisfactory arrangement of the stations of the general table for England and Wales in river basins, although for convenience of reference the counties are retained as the units. This forms the subject of a special article, illustrated by maps of each division showing the county boundaries and watershed lines. The treatment of the stations in Scotland and Ireland has been postponed. Another laborious piece of work has been the introduction of a new rainfall average based on the thirty-five years 1875–1909. For the British Isles generally and for Ireland this makes practically no change, so far as the annual totals are concerned, from the thirty years' average. For England the new average is 5 per cent. less, in Wales 3 per cent. less, and in Scotland 4 per cent. more.

In a special article on the greatest rainfall which may occur on the wettest day of the year it is shown that during the last forty-seven years falls of 4 inches have occurred in a great number of counties, even exceeding 6 inches in a few. Another useful article on the rain-gauge in theory and practice will remove several of the difficulties usually experienced by beginners of rainfall observations. We cannot conclude this notice without expressing regret that this very valuable organisation is not self-supporting, and that a considerable financial burden has to be borne by the director.

Partridges and Partridge Manors. By Captain A. Maxwell. Pp. xii+327. (London: A. and C. Black, 1911.) Price 7*s.* 6*d.* net.

WHAT the author accomplished with the assistance of Mr. George Malcolm in 1910 for the grouse he has succeeded in doing single-handed for the partridge in 1911, and the praise we felt bound to accord to his former effort we have pleasure in re-echoing in the case of the present beautifully illustrated volume. It contains, in fact, practically all that the sportsman ought to know with regard to the plump brown gamebird of our stubbles, and much that ought to interest the ornithologist. For Captain Maxwell appears to be a good field observer himself, and has likewise availed himself largely of the stores of information possessed by the better class of gamekeepers. Among such information, it may be mentioned, is a heavy and apparently conclusive indictment against the hedgehog as a game-poacher of the blackest dye.

Partridge-preserving the author considers to be decidedly beneficial to the farmer, as it not only brings money into country districts, which otherwise would be spent elsewhere, but it provides him with "a small machine [in the shape of the partridge] which turns noxious weeds and useless insects into a valuable food." After discussing the economical question in chapter i., the author takes the natural history of the partridge as the subject of chapter ii. Here we are told at the outset that "no fewer than 152 species of partridges and their affinities" are recognised by ornithologists—a statement difficult to understand owing to the ambiguity of the term "affinities." A few other minor criticisms might be made on this chapter, but in the succeeding chapters, dealing with rearing, driving, and shooting partridges, the author appears to be thoroughly in his element and a master of his subject. Every sportsman should buy a copy of the book. R. L.

Practical Drawing. A Preliminary Course of Work for Technical Students. By T. S. Usherwood. Pp. viii+163. (London: Macmillan and Co., Ltd., 1910.) Price 2*s*.

THIS useful little manual provides an excellent course of instruction in instrumental drawing, very suitable for the junior classes of technical institutes. The beginner is first shown the use of the rule and callipers in the making of dimensioned hand sketches of simple objects. Then full explanations are given of the manipulation and handling of drawing instruments, including tee and set squares, in the production of accurate work to scale. Facility in the use of instruments is acquired along with a working knowledge of geometrical principles, by the plotting of lines, angles, figures, vectors, and the drawing of simple mechanical and architectural details.

The subsequent work in plane geometry includes the construction of scales, circles, triangles, polygons, geometrical patterns, and similar figures; also graphing on squared paper, the calculation of areas, and the plotting of the paths of points moving under geometrical or mechanical constraint. The author wisely devotes a chapter to the method of representing solid objects by plans and elevations, and by metric projections to scale. The book is provided with an index, and the student with answers to the numerical exercises. The author is evidently an experienced teacher. He supplies good examples in great variety. The scheme of instruction is a sound and desirable one, and affords a thorough groundwork for subsequent study.

Die praktische Bodenuntersuchung. By Prof. E. Heine. Pp. xii+162+plate. (Berlin: Gebrüder Borntraeger, 1911.) Price 3.50 marks.

WHILST there are many works in German dealing with the properties of soil from the purely scientific point of view, there is none, according to the author, that gives the practical farmer the kind of knowledge he wants in order to understand the nature of the soil and the processes going on therein. While it is not denied that a farmer can get on sufficiently well without this knowledge, nevertheless he will find not only a source of interest, but also of profit, in learning something about the fundamental properties and laws on which the cultural operations and the fertility relationships of the soil are based. The author therefore deals in successive chapters with the soil as a medium for plant growth, the physical properties, chemical composition, and biological relationships of soils, methods of classification and improvement. In the second part of the book the soils of North Germany are described, and instructions are given for the use of soil maps.

The information is clearly set out, and in its general style will appeal to the farm student and to the young farmer who has sufficient energy and interest to read after his day's work is done. Indeed, the information is better than the method: a book written for the same class of readers in England would be expected to give many more actual illustrations of the application of general principles than are here attempted. The reviewer's experience is that general principles as such have little meaning to the farm student, and copious illustrations are necessary to give point to them. The present book is deficient in this respect.

More stress might well have been laid on the part played by calcium carbonate in soil fertility. No soil deficient in calcium carbonate can be regarded as very satisfactory; vegetation relationships are markedly different according as calcium carbonate is present or not. Thus in the description of humus the differences between the various types is attributed to differences in air supply, the part played by calcium carbonate not being considered important. It is evident, also, that the German method of mechanical analysis is less satisfactory than our own, which would have formed the basis of several of the chapters in such a book.

But apart from these points the little book is very good, and conveys in simple language an accurate presentation of our present ideas on the soil.

E. J. R.

Conic Template. J. T. Dufton's design. For Junior Students of Conics. (London: Macmillan and Co., Ltd.) Price, nickel-plated metal, 4*d*. net; transparent celluloid, 8*d*. net.

STUDENTS of geometrical conics should not fail to provide themselves with this accurately made and handy little "Conic Template." By merely passing a pencil round its curved edges, a true ellipse, parabola, and hyperbola can be drawn, the three curves having closely related elements, which are specified in the instructions accompanying each instrument. The regular employment of accurate figures, instead of rough diagrams sketched freehand, will add interest to the work, and will materially assist in fixing on the mind of the student the forms and properties of these important curves.

How to become a Pharmacist in Great Britain. With Appendixes on Pharmaceutical Qualification in Ireland, Pharmaceutical Registration in the British Empire, Degrees in Pharmacy, and the Schedule of Poisons. Edited by John Humphrey. Pp. 52. (London: The Pharmaceutical Press, 1911.) Price 1*s*. net.

CLEAR and precise information is given here about each stage in the preparation for the work of a pharmaceutical chemist, from apprenticeship to the passing of the major examination of the Pharmaceutical Society. The appendixes give details as to the particular conditions under which qualification to practise pharmacy may be secured in Ireland and in other parts of the British Empire. The advice offered is sound and helpful; and the view throughout is to regard the work of the pharmacist as a branch of applied science needing the practice of scientific methods for its successful performance.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

The Simultaneity of Certain Abruptly-beginning Magnetic Disturbances.

IN the first volume of my work "The Norwegian Aurora Polaris Expedition, 1902–3," I stated (p. 63), after studying the magnetograms from seventeen stations in all quarters of the earth, that the characteristic sudden similar magnetic changes occurring often during positive equatorial perturbations "appear *simultaneously*, or rather, the differences in time are less than the amount that can be detected by these registerings." "The above question on simultaneity, which is of great importance, cannot be definitely decided until we are in possession of rapid registerings."

In the spring of 1911 I made an investigation of the zodiacal light in the Sudan and Egypt, during which I had mounted two complete sets of registering apparatus, the one for slow, the other for rapid, registrations, which were working every night near Aswan for one month under the supervision of Mr. Krogness.

The instruments were set up in the depth of an ancient Egyptian tomb, in which the temperature was fairly constant. Thanks mainly to Mr. Keeling, the superintendent of the Khedivial Observatory in Helwan, we enjoyed all the facilities for our work that we could desire.

In order to obtain "quick-run" magnetograms from other stations taken at the same time, I published in NATURE for March 16 (No. 2159, p. 79) a letter requesting other observatories to take such registrations at the same hours as we. I have, unfortunately, not received any intimation of any such "quick-run" registrations having been taken except in Samoa, where Dr. Augenheister commenced the registrations on April 10, while the only sudden equatorial storm registered in the prescribed period of one month occurred on April 9.

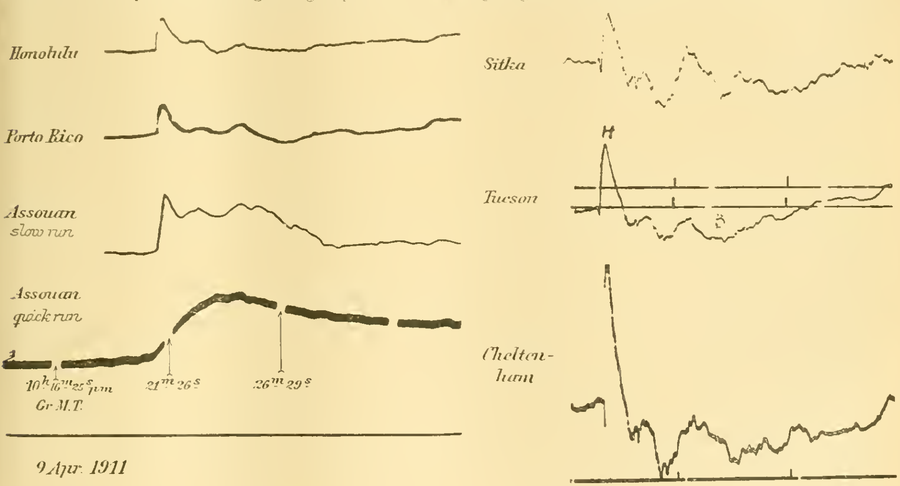
Mr. Tittmann, superintendent of the U.S. Coast and Geodetic Survey, has been good enough to send me some copies of slow-run registerings for April 9 from Cheltenham, Porto Rico, Tucson, Sitka, and Honolulu. Of these, the curves from Honolulu (158° W.) and Porto Rico (65° W.) are of special interest, because these stations, together with Aswan (33° E.), form a particularly happy distribution of stations about the earth.

The figure shows that on this day an equatorial perturbation occurred the character of which on these three stations is very similar. The times of commencement in H are as follows:—

Honolulu		Porto Rico		Aswan
10h. 20m. 7s. p.m. G.M.T.	...	20m. 8s.	...	20m. 44s.

The changes in D at the same time were very small, as might be expected would be the case with this kind of perturbation.

The first notices of time are given in a letter from the Coast and Geodetic Survey; the last value is found by the quick-run magnetogram from Aswan, as shown by the diagram. The time-marks here, which refer to the central point for the obliterated parts, are certainly correct to one second, but a greater uncertainty arises when it is a question of determining when the perturbation shall be said to have commenced. I consider we may be safe when we estimate the possible error at ±4 seconds. But the values of the slow-run magnetograms lie within this margin in Honolulu and Porto Rico, where, however, the readings are naturally not so trustworthy as those of the quick-run magnetograms from Aswan.



9 Apr. 1911

The curves from Sitka, Tucson, and Cheltenham show that the perturbations in those places have had a somewhat different character from those at the three first-named stations, for it appears as though a magnetic polar storm interferes. The curves for D and Z show the same thing.

The times we have been given from the Coast and Geodetic Survey for these stations are:—for Sitka, 10h. 21m.; Tucson, 10h. 20m.; and Cheltenham, 10h. 21m. 9s.; and these refer to the "larger displacement" in H. This occurs shortly after the first abrupt beginning, and the times are, as may be seen, with the exception of Tucson, slightly greater than the others.

As regards Tucson, we notice that the first time-mark is considerably smaller than the later ones; for this reason I think this value perhaps ought to be taken with some reservation.

From Trondhjem I have only one slow-run magnetogram, as the corresponding quick-run, unfortunately, is wanting for the only hour in question. At this station the polar character of the storm is distinctly apparent, as might be expected from so high a latitude. On the occasion of the magnetic storm we are here studying, the similar sudden changes occurred thus around the terrestrial equator *simultaneously* within the limits of error in the observations.

When several observations of such magnetic storms around the equator, obtained by quick-run registerings, are available, as I hope may be the case soon, this important question on simultaneity will be finally determined.

It may be of interest in connection with this to call to mind that, in 1900, quick-run registerings were taken simultaneously in Potsdam and at my observatory at Haldde, near Bossekop. In my work "Expédition Norvégienne de 1899–1900 pour l'étude des aurores boréales," Christiania, 1901, photographs of these registerings are given which show that corresponding small sudden alterations in D were simultaneous within three seconds in Potsdam and Bossekop.

According to my theories of magnetic storms, it might be expected that sudden similar magnetic changes which occur in different parts of the earth arise rather simultaneously. When the sun suddenly sends forth a strong pencil of kathode rays towards the earth, this pencil will, owing to earth-magnetism, be broken up in such a way as to form different partial systems of magnetic impulses—polar and equatorial. The various groups of rays have to travel different way-lengths in space before reaching nearest to the earth, and may arrive at very different earth-regions for the different groups. But the difference in time between these various impulses affecting any particular locality on the earth can scarcely be more than a couple of seconds, while the difference in the intensity of the effects can be very considerable. We know of corresponding phenomena in the case of aurora, as I demonstrate in my first above-cited work.

Christiania, September 29. Kr. Birkeland.

The Library and the Specialist.

Nature of August 17 has just come to hand, and I am much pleased to see the article in it (p. 222) on "The Library and the Specialist." The reference there made (not quite accurately) to my own difficulties as a bibliographer and student I gladly pass over: the troubles of an individual are of little moment when they are known to be shared by practically all scientific men.

The general argument in favour of reform is excellently put in the last paragraph of the article, and there is no need to add to it. I ask leave merely to bring things to a practical issue by stating briefly and clearly what steps are necessary to be taken to attain the important object we all have in view.

(1) A hand-list has to be drawn up containing the names of all current mathematical serials. This could be done in a few hours by any competent librarian having a mathematical adviser within reach, the material being all ready to hand in the lists given in the *Jahrbuch*, the *Revue Semestrielle*, and the International Catalogue.

(2) Six copies would have to be made of the said hand-list when finally revised, and one each sent to the librarians of the Mathematical Society, the Royal Society, the British Museum, University College, South Kensington, and the Patent Office, in order that each librarian might indicate which of the serials his library possesses. From all I know of these libraries, I am sure that there is not one of them but would wish to help.

(3) A new list would then have to be made containing the combined details provided by the six, and a copy of this to be furnished to each library.

Any serious obstacle in the way of accomplishing this scheme it is impossible for an outsider to conceive. One of your influential correspondents in 1906 seemed to imply that the librarians would "stand upon the order of their going." Personally, I esteem them too highly to believe this. Any one of three of them might fairly expect the others to follow, the Mathematical Society having a claim to lead because of the special science concerned, the Royal Society because of its outstanding position among scientific bodies, and the British Museum because of its unique position among libraries. Will none of the three risk a rebuff for the work's sake?

I fail even to see that there is a money difficulty in the way. The libraries concerned are constantly being put to greater expense by private individuals. But if money really be wanted, the least we can ask for is to be told the amount. Thos. Muir.

Cape Town, South Africa, September 5.

I am glad to be able to assure Dr. Muir and others interested in the matter that steps are about to be taken to carry out the plan he suggests, and to supply each of the six London libraries with the list in its final form. It may even be possible to draw up a more comprehensive scheme, and to publish the list in a periodical readily accessible to mathematicians. If the librarians will give their aid, the minimum for which Dr. Muir appeals will be accomplished before the meeting of the International Congress in 1912.

The Writer of the Article.

Two Undescribed Giraffes.

A piece of tanned giraffe-skin in my possession, which I intend to present to the British Museum, indicates, apparently, an undescribed race of the netted giraffe (*Giraffa reticulata*) of Somaliland and British East Africa. That species is characterised by the markings taking the form of a coarse network of narrow white lines on a liver-red ground, the dark meshes being large and quadrangular on the neck, but becoming smaller and more irregular in shape on the body. There may be small white spots in the centre of the dark patches, which are otherwise uniformly coloured, even in adult bulls. In the piece of skin referred to above, which is from the forepart of the body, and came from British East Africa—probably the Kenia district—the white lines are rather wider and the dark areas smaller and brownish rufous, with a tinge of blackness, and a distinct blackish streak or star in the centre. For this giraffe, which in a slight degree tends to connect *reticulata* with the eastern forms of *camelopardalis*, the name *G. reticulata nigrescens* will be appropriate.

The second race is typified by a mounted adult bull from north-eastern Rhodesia, the skin and part of the skeleton of which were presented to the British Museum by Mr. H. S. Thornicroft, Native Commissioner of the Petauke district. This giraffe—a member of a single isolated herd—is characterised by the low and conical frontal horn, the grey colour and scattered spotting of the sides of the face, the chestnut-brown forehead, deepening into black on the tips of the horns, the absence of a distinctly stellate pattern in the neck and body spots, which are light brown on a yellowish-fawn ground, and the uniformly tawny colour of the lower portion of the limbs. This giraffe, which I propose to call *G. camelopardalis thornicrofti*, appears to be related to the Kilimanjaro *G. c. tippelskirchi*, but differs by the more compact frontal horn, the brown, in place of grey, forehead, and the uniformly fawn lower part of the legs, the latter being whitish in adult bulls, but fawn and spotted in cows and young bulls. I have to thank the trustees of the British Museum for permission to describe this specimen. R. Lydekker.

The Distastefulness of *Anosia plexippus*.

In "Essays on Evolution," p. 274, 1908, Prof. Poulton directed attention to the instance of mimicry amongst Lepidoptera supplied by the American Danaine, *Anosia plexippus*, otherwise known as *Danaida archippus*, and its mimetic species. It occurred to me, therefore, that it would be interesting to test the distastefulness of this butterfly. This I was enabled to do through the kindness of Mr. F. W. Frowhawk, who at my request sent me a newly emerged female on September 22 of this year.

The following are the results of my experiments. Two Indian shamas (*Cittocincla macrura*) in succession tasted it, but left it alone after one or two pecks. It was then taken by an Indian sibia (*Sibia capistrata*), which quickly dropped it. A red-vented bulbul (*Pycnonotus haemorrhous*) then pounced upon it, with the same result. A ground thrush (*Geocichla cyanonotus*) tried it, but soon left it. A mynah (*Gracula intermedia*) took it, but quickly let it fall. Two South African bustards (*Otis ludwigi*) persevered for a long time, but finally rejected it. A kagu (*Rhinochaetus jubatus*), a kind of rail or crane from New Caledonia, behaved in the same way, shaking his head after each peck. An Australian water-hen (*Tribonyx ventralis*) and a crow-shrike (*Barita destructor*) pecked it only once, the latter vigorously shaking his head and wiping his beak after the taste. A Cuban mocking-bird (*Mimus orpheus*) and a Brazilian hangnest (*Ostinops viridis*) attempted it, but after a few pecks gave it up. Finally, the mangled remains were eaten with much hesitation by a rufous tinamou (*Rhynchotus rufescens*). Whether the latter would have eaten it, if given the first refusal, it is, of course, impossible to say; but there is no doubt that the other birds found the butterfly highly distasteful. I was particularly impressed by its rejection by the two bustards, which on previous occasions have eaten some of the most unpalatable of British insects (see Proc. Zool. Soc., 1911, pp. 809–68).

The birds used for these experiments belong to tropical American, Asiatic, Australian, and African species, and were purposely selected from a variety of families. *Anosia plexippus* has, I understand, comparatively recently invaded the Old World from the New; and the result of the above-recorded experiments suggests that no serious barrier to its dispersal will be offered by insectivorous birds. If it succeeds in widely distributing itself it may, as a useful model, bring about marked mimetic changes in the Lepidoptera of the districts in which it settles.

The Zoological Society. R. I. POCOCK.

The Arithmetic of Hyperbolic Functions.

THROUGHOUT the books treating of hyperbolic functions, although elaborate series for their determination are given, the possibility of calculating them directly from their definitions, by means of common logarithms, is never suggested, and it would appear, therefore, that the merits of the direct method are insufficiently recognised.

If the hyperbolic functions of a quantity U are required, it is convenient, for purposes of writing and printing, to get rid of the exponential and to write $A=e$. Then $\log_{10} A = 0{\cdot}43429448\,U$, and A is thus found at once from a book of common logarithms. The functions can then be calculated by a slide-rule, or by logarithms, in the simple form

$$\cosh U = \tfrac{1}{2}(A + 1/A)$$
$$\sinh U = \tfrac{1}{2}(A - 1/A);$$

and similarly for tanh U, coth U, sech U, cosech U, and versh U—all in terms of A.

For example, calculate cosh 2 and sinh 2. Here

$$\log_{10} A = 0{\cdot}43429448 \times 2 = 0{\cdot}86858896;$$

A is therefore 7·389060, and 1/A is 0·135335. Hence cosh 2 = 3·76220 and sinh 2 = 3·62686

In the more general case the functions of a complex quantity $(U+i\theta)$ are required, and they have consequently to be expanded in terms of cosh U, sinh U, cos θ, and sin θ. So far as cosh U and sinh U are concerned, the direct method by common logarithms is still available, and the result is best dealt with in the form, for example,

$$\sinh(U+i\theta) = \tfrac{1}{2}\{(A - 1/A)\cos\theta + i(A + 1/A)\sin\theta\}.$$

The only real difficulty then left for the student is in ensuring that cos θ and sin θ are given their proper signs. That is to say, he must be clear regarding how many quadrants are contained in θ, how many degrees there are in θ beyond that number of quadrants, and the proper sign of cos θ and sin θ, respectively, in each quadrant.

In general, as is well known, if the functions are not required to a greater degree of accuracy than 1 in 10,000, it is permissible for all real values of U greater than 5 to write

$$\cosh U = \sinh U = \tfrac{1}{2}A;$$

and the direct method has obvious advantages. For values of U less than 8, Ligowski's excellent tables give sinh U and cosh U, proceeding by increments of 0·01 of U; but for practical purposes these 0·01 steps are too great, and "difference" columns have to be used. Consequently, to find the functions for values of U less than 5, where U is given to three or more places of decimals, it will usually be as quick and as accurate to adopt the direct method as to worry through the irksome arithmetic involved in estimating "differences."

In cable problems it is, as a rule, desirable to retain at least four significant figures for U.

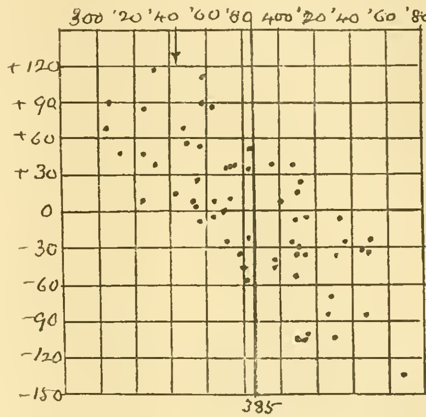
October 3. ROLLO APPLEYARD.

Hot Days in 1911.

BY a "hot day" will here be meant one with 70° or more. There are about seventy-seven of these at Greenwich, on an average, in the year. I propose to show how a method of forecasting recently described would apply to those days in 1911.

The series of annual numbers (1841–1910) is first smoothed with sums of five; then we compare, in a dot-diagram, each sum with the difference between it and the fifth after.

The last comparison before this summer was that between 324 (for 1903) and its difference with 335 (for



Comparison of hot day numbers, Greenwich.

1908), *i.e.* +11. Next we come to 343 (for 1904) and the position of the new dot (for 1909, representing the sum of 1907–11).

Placing an arrow-head at 343 in the horizontal scale, we might fairly expect the new dot to be above the zero line. Suppose, however, to be on the safe side, we say not below −10. Then 343 − 10 = 333. Now the four years 1907–10 yield 243, and 333 − 243 = 90. So that we might say the year 1911 was likely to have at least 90 hot days.

The actual number is 101.

The method may be commended, perhaps, for application to various weather items. ALEX. B. MACDOWALL.

Frequency of Lightning Flashes.

A LETTER on rainless thunderstorms in NATURE of August 31 leads me to ask if any accurate counts have ever been taken of the frequency of lightning flashes.

Watching a severe storm from my bungalow about a year ago, I made an attempt to separate and count the flashes—to the unassisted eye the lightning was as continuous as a flickering arc-lamp.

The only thing I could find to help me was a gramophone; I took its top works off, and on the horizontal disc I put one radial white chalk line. The speed of the disc was adjusted, by trial, exactly to 100 revolutions per minute, and the instrument was placed where the storm-light fell directly on it.

The appearance of the revolving disc was as if irregularly spaced phosphorescent spokes were being shown instantaneously in sections of various sizes in continually changing positions. It was difficult to estimate the number of separate streaks in one revolution, but I finally settled on eight as a fair average during the whole storm—sufficiently exact to show the order of figures being dealt with.

This works out at 800 flashes per minute, or, say, 50,000 an hour. H. O. WELLER.

Jamalpore (Dist. Mymensingh), E. Bengal,
September 19.

THE AUTOMATIC TELEPHONE EXCHANGE.

AT an ordinary or manual telephone exchange, as is generally known, the subscribers' lines terminate on "jacks," and are put through to each other by means of "plugs" and flexible conductors. The jacks, mounted on a suitable surface, form a "switchboard," and it is the business of the exchange operator to make the necessary connections and to sever them at the proper time, to answer calling subscribers and to ring up wanted ones. Large modern exchanges are worked on the common-battery plan; that is, no batteries whatever are placed at the subscribers' offices, but a large single battery is installed at the exchange, and this supplies all the current for speaking and signalling. The switchboard is of the "multiple" type. All the subscribers are brought to each division or section of the complete board; that is, all the subscribers' jacks in the entire exchange are repeated or multipled at each section, the latter forming a kind of unit of area representing the maximum reach of an operator. Every subscriber is thus within the reach of every operator. A simple "busy" test is arranged, so that before making a connection it can instantly be seen whether the required subscriber is free or already engaged at some other section. This grouping of the jacks, or "multiple" proper, is used only for ringing up and connecting to wanted subscribers. In addition, each operator has a certain number of subscribers brought to other—"answering"—jacks, placed in her immediate vicinity, and it is on these that calls from subscribers are received. At the subscriber's end everything is arranged with a view to simplicity. The signalling is automatic; that is, the subscriber has simply to lift his receiver and the exchange is called automatically, and when the conversation is finished the replacing of the receiver upon its hook advises the operator that the connection is to be severed.

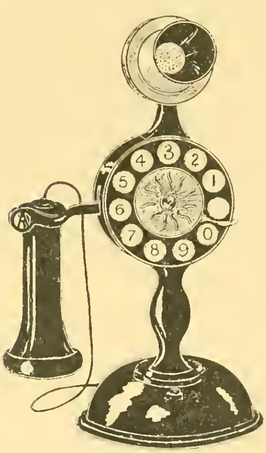


FIG. 1.—Subscriber's Telephone, with calling arrangement.

For automatic exchange working we have to substitute mechanism for the exchange operator, and the place of the large common switchboard is taken by a number of small individual switches, one of which is allotted to each subscriber and is entirely under his control. The plan which we are about to outline is the Strowger system, as applied to a small exchange of less than a hundred subscribers and operated on the common-battery plan. Other excellent systems are in use, but it is thought that some degree of detail of one system will be more useful than the statement of the main principles of several.

Considering the subscriber's end first. In addition to the usual speaking apparatus, transmitter, receiver, &c., we have the selecting and calling mechanism, as the subscriber has to "get through" to his correspondent by his own unaided efforts. Fig. 1 illustrates a "table set." In the central portion the figures 1 to 0 are arranged in a circle, and over them is a movable disc, perforated near the edge so that the figures, which are fixed, are visible through the holes. Suppose subscriber No. 58 is required. The receiver is first removed from its hook. A finger is then inserted in the hole through which the figure 5 shows, and the disc turned in a clockwise direction until a stop bars the way. This turning of the disc winds up an inner spring. The finger is then withdrawn and the spring carries the disc back again. In its return journey it causes one of the lines of the loop to be earthed (momentarily) five times, and at the

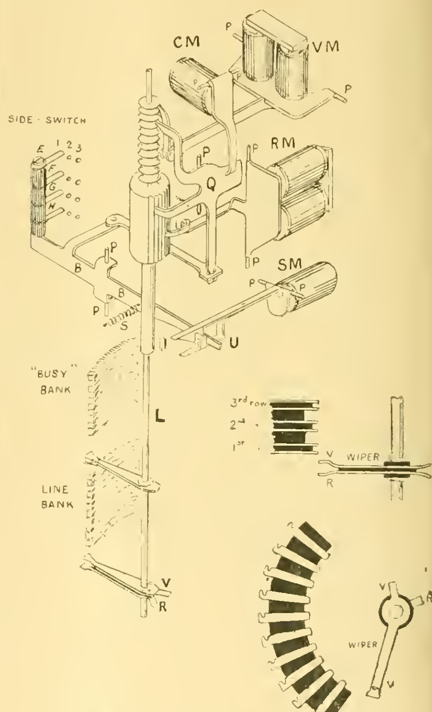

FIG. 2.—Details of Subscriber's Switch at Exchange.

end of this series the other line is earthed once. The finger is then inserted in the hole over the 8 and the disc brought round again—again winding up the spring. Its release and return to normal earths the first line eight times and then the second line once, as before. As the exchange battery is permanently on the lines, this earthing causes impulses of current to be sent over them by way of certain apparatus, and the calling subscriber is now through to No. 58 line. When any subscriber's receiver is on its hook, a magneto bell, in series with a condenser, is across the two lines. The calling subscriber now depresses a push-button, which action again earths the first wire of his own loop and actuates a relay at the exchange, which applies the generator to the required line.

After conversation, both subscribers hang up their receivers, this action momentarily earthing both wires of each loop. In the case of the originating subscriber, the effect of this is to "clear," and to restore to normal his mechanism at the exchange.

At the exchange end of each loop a separate switch is placed, the mechanical outlines of which are given in Fig. 2 and the electrical connections in Fig. 3. Considering the former, we have an upright steel shaft L which has on its upper portion a series of horizontal teeth, cut the whole way round the shaft. VM is an electromagnet having a pawl on the end of its armature, the latter being pivoted at PP. When VM is energised, this pawl lifts the shaft by means of one of the horizontal teeth. Below these teeth the diameter of L is much increased, and on the surface of the cylinder thus formed, a series of vertical grooves or teeth are cut. RM is another electromagnet, the armature of which, pivoted at PP, carries at its extremity a second pawl. When this armature is attracted L is forced round a tooth. The double pawl Q engages with both the horizontal and vertical teeth, and prevents the return of the shaft after its movements in an upward and rotary direction. Each of these two electromagnets is placed, in turn, in the local circuit of a relay at the required time, and whenever an impulse passes through VM the shaft L is raised a tooth, whilst an impulse through RM causes the shaft to be rotated a tooth. They are therefore termed the "vertical" and "rotary" magnets. CM is the clearing magnet; when this is energised, its armature strikes the double pawl Q and causes it to release the shaft. The latter, in its previous turning movement, winds up a spring, and on its release the spring brings it back, and by its own weight the shaft falls to its normal position.

At the lower end of L two arms are carried which, when desired, make connection with any one of a series or "bank" of contacts. The essential parts of these contacts and of the arms are best seen in the right-hand lower corner of Fig. 2. First we have a thin semicircular strip of fibre or other insulating material. On the upper surface of this ten thin strips of metal are placed radially, and on the under surface ten other similar strips are placed. To an upper and a lower metal piece the lines of each loop

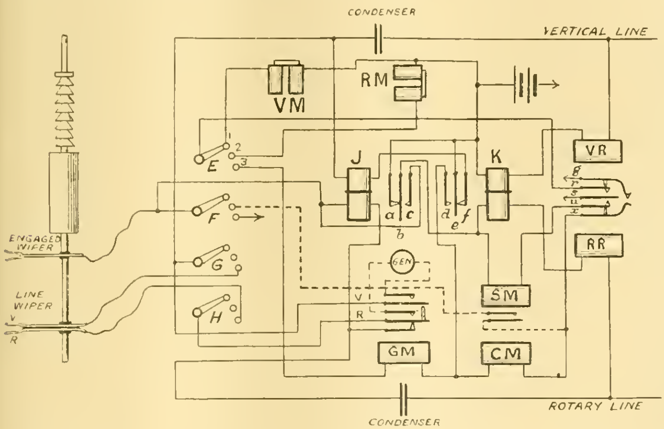

Fig. 3.—Subscriber's Switch—Connections.

are connected, so that one semicircular piece carries the twenty contacts of ten loops. Above this horizontal row of ten circuits a second, third, and tenth semicircular pieces are placed, each being separated from its upper and lower neighbours by further insulation. We have thus the contacts of a hundred loops arranged in ten layers of ten each.

As already seen, every subscriber has one of these switches, and the banks are all multipled together. That is, No. 58 line is brought to the fifty-eighth position on the banks of all the hundred switches constituting the exchange.

The two arms, or "wipers"—so called from their brushing or wiping action in passing over the contacts—each consist of two metallic strips, insulated from each other and from the shaft, the outer ends having a slight inward tendency, so that when they engage the two springs of a loop there is sufficient friction to ensure electric contact.

As will be seen from Fig. 2, there are two banks of contacts, one above the other, and two arms or wipers to engage with them. On the lower bank are the hundred loops as already detailed. The upper bank is employed for giving the "busy" signal. Its arm has the two contacts connected together, so that only a single connection is made in any one of the hundred positions. Like the lower bank, these are multiplied on all the switches of the exchange. There are indeed, two multiples, the line multiple and the "busy," or "engaged," multiple. In the normal position of the shaft the wipers are just to the left of the banks and just beneath them. When L is raised one, two, &c., teeth, the wipers rise to the level of the first, second, &c., row. A single rotary movement then brings the wipers to the first loop in the row; two three, or more rotary movements bring the wipers to corresponding loops on that horizontal level.

Returning to the upper mechanism of the switch. BB is an arm pivoted at PP, and carrying on its left a four-lever switch. On its right it engages with the escapement U, which is carried on a long extension of the armature of the switch-magnet SM. A spring S keeps the right-hand end of BB against U. When SM is actuated, the movement of attraction and release allows BB to slip forward one step in the escapement, and causes E, F, G, and H to quit their first contact and move to the second. The action of this "side-switch" is to bring the various pieces of apparatus into action at the required time. A second movement of SM allows BB to move forward another step in U and brings the side-switch into the third position. Any further movement of SM does not affect BB. When, however, the clearing magnet CM is actuated, the movement of Q restores BB to its original position, the escapement springs opening and allowing the right-hand end to pass. The side-switch thus returns to position 1.

The electrical conditions are shown in Fig. 3. VM, RM, CM, and SM are the electromagnets already described. VR and RR are the vertical and rotary relays, mounted side by side. The armatures of these when attracted act upon the contacts shown between them. If VR is energised, *g* is pressed forward together with *r*. The latter then makes contact with the centre spring *s*, but the movement is not suffi-

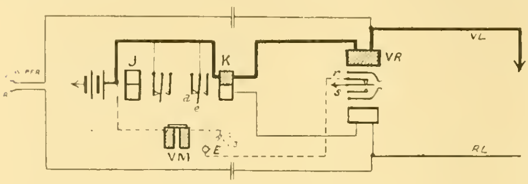

FIG. 4.—Earthing of Vertical Line.

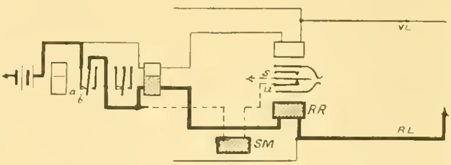

FIG. 5.—Earthing of Rotary Line.

cient to bring *g* and *x* together. When RR is actuated *x* is pressed forward, carrying *u* with it to make contact with *s*, but *x* does not reach *g*. When both relays are energised, *g* and *x* make contact in addition to the other two. Two other relays, J and K, are mounted together, and act upon the springs shown between them. Each of these two relays has two coils. If current circulates in one coil the armature responds: similarly if current flows in both coils in the same direction. If, however, the two currents are in opposite directions, they nullify each other's effects, and the armature is not attracted. The movement of J's armature breaks the contact between *b* and *a*, and makes a new one between *b* and *c*. Similarly with K: *e* breaks from *f* and makes with *d*. GM is the generator magnet. When this is actuated the two long springs move upwards, disconnecting from the lowest and bringing the generator on to the levers G and H of the side-switch, and thence (when in position 3) *via* the line wiper to the desired subscriber's line.

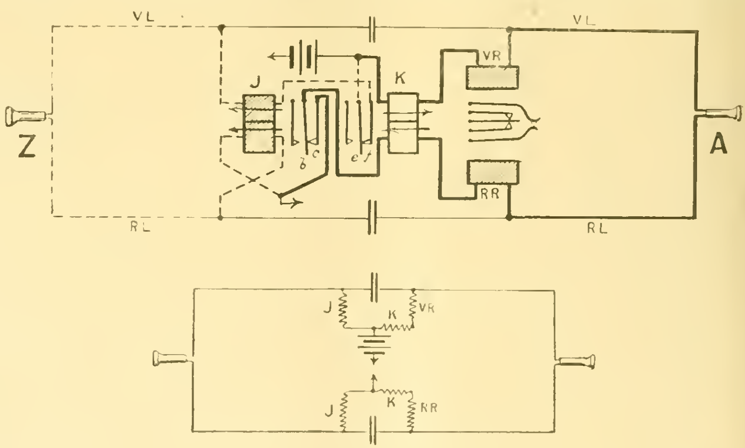

FIG. 6.—Two Subscribers "through."

We are now able to trace the results of the subscriber's call. He desired No. 58. By the first movement of his disc we saw that he earthed the vertical line five times and the rotary line once. Fig. 4 gives the result of this. By the earthing of the vertical line (as indicated by the arrow-head) a path, shown as a heavy line, is open to the battery from its positive pole through one coil of K and the vertical relay and line to earth. This current actuates both K and VR, as shown by the shading. The spring *r* being earthed at *s*, a second path, shown dotted, is open to the battery *via* VM and the lever E of the side-switch. The shaft L is therefore raised five teeth, corresponding to the number of current impulses passed over the vertical line. The earthing of the rotary line (once), as shown in Fig. 5 by the heavy line, actuates K by its lower coil and RR. The latter closes *s* and *u* and completes the circuit (shown dotted) of the switch magnet SM. This brings the side-switch into position 2.

The calling subscriber now inserts his finger in the eighth hole, brings the disc round, and then liberates it. The vertical line is then earthed eight times, and the rotary once. As the side-switch is in position 2 a circuit is open to the eight currents through the upper coil of K, VR, and the vertical line. K and VR are actuated, the latter connecting *r* and *s* and providing a second path from the battery through the rotary magnet, switch-lever E, and earth. The state of affairs is precisely as in Fig. 4, saving that RM is substituted for VM. The rotary magnet armature rotates the shaft (already on the level of the fifth row), and brings the wipers on to the eighth contact in that row. The final earthing of the rotary line repeats the operation shown in Fig. 5, and shifts BB another tooth in the escapement U, thus bringing the side-switch into position 3.

The wipers are now on the contacts of the desired loop and the calling subscriber depresses his push-button, which operation again earths the vertical line. VR is operated, and spring r making contact with s puts earth on the left-hand side of GM by way of switch-lever E (position 3). K also is operated by its upper coil, and the closing of its springs e and d brings the battery on the right-hand side of GM. The movement of GM's armature puts the generator (which is running continuously) on to the wipers, and thence to the required subscriber's (Z) loop, across which is placed his magneto bell, in series with a condenser. When Z replies, the current circulates through springs e, f, through the upper coil of J, round the loop, through J's lower coil, switch-lever F (position 3) to earth. J's two coils are now assisting each other, and spring b moves over to c. As b is joined to K's lower coil, this movement takes the battery from K's lower coil and puts on earth instead. The current now passes through K's upper coil, through VR, round A's loop, through RR and K's lower coil to earth *via* c. The currents in K, however, are opposing each other, so that the armature is not affected. The two subscribers are now "through," as in Fig. 6. The path traversed by the current on the left is shown by the dotted lines, and on the right by the heavy lines. The arrows through J and K show the direction through the separate coils, and the shading indicates the energised relays. The small skeleton diagram in Fig. 6 shows how the speaking circuit is made up. On Z's side the two coils

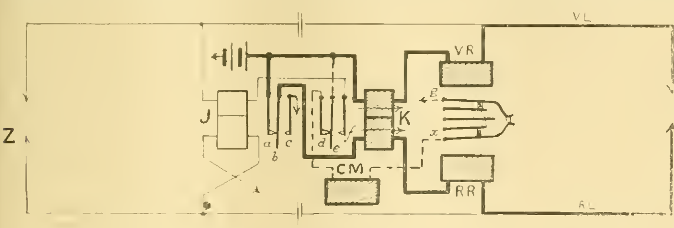

FIG. 7.—Clearing.

of J serve as impedance coils, whilst K's upper coil, plus VR and K's lower coil, plus RR, serve the same function on A's side.

On the conclusion of the conversation both subscribers hang up their receivers. In its passage downwards the switch-hook (momentarily) earths both the vertical and rotary lines simultaneously. The result of this action on A's part is that his rotary line is earthed at both ends. RR and the lower coil of K are thus short-circuited. K is then actuated by his upper coil, and by the movement of e from f to d current is cut off from J, which, ceasing to be energised, allows its armature to fall back. This causes b to leave c and return to a, substituting the battery for earth on the lower coil of K. Current now passes through both coils of K in the same direction, and thus continues to energise K, whilst both VR and RR being actuated, their outer springs make contact with each other and put earth on the right of the coils of CM, the clearing magnet. The other side of CM being connected with the battery through d e, the clearing magnet is energised. This is shown in Fig. 7, where the dotted line indicates the circuit of CM. The shaft is thus restored to its normal position and the circuits are cleared.

When a second caller attempts to get through to another subscriber who is already engaged, the following action takes place. As shown in Fig. 6 the earth on the left hand of J's lower coil is made by the lever F of side-switch in its third position. This puts earth on the "engaged" wiper, and through it on to all Z's contacts in the busy multiple. The new caller turns his disc twice in the usual way, thus getting on to Z's contacts in the line multiple. His (the newcomer's) side-switch, however, is still in position 2, so that, although his line wiper is on the required contacts, the wiper itself is still isolated. The final current over his rotary line causes RR and SM to be actuated. A contact on the latter (shown only in Fig. 3) is closed. The battery is already connected to the left hand of the newcomer's clearing magnet by means of his springs d and e. The closing of the contact on SM put the right-hand side of CM through to the earthed busy bank by way of lever F (position 2) of his own side-switch. His clearing magnet thus acts and his lever L returns to zero. By another contact (not shown) the busy signal from the generator is given over the newcomer's line, advising him that the required subscriber is engaged.

From the foregoing brief sketch it is hoped that the principle of working may be seen: the actual arrangements in practice involve large modification and extension. As only a certain percentage of the switches are in use at the same time, it is easily seen that it is unnecessary to provide one for every subscriber. A much simpler piece of apparatus, the "line switch," is therefore substituted, and only a comparatively small number of switches proper provided. The function of the first is simply to put a calling subscriber through to a disengaged switch—now slightly modified and called a "selector"—by which a certain group is selected. The subscriber having got through to the required group, now utilises a second switch, arranged practically as we have described and termed a "connector," through which he obtains access to the required correspondent. A still larger exchange will require a first selector, a second, &c., selector, and finally a connector. Taking the common case of an exchange with a maximum of 9999 subscribers: the line switch puts the caller through to a first selector, by which the thousands digit is selected. The hundreds figure is then picked out by the second selector, and the tens and units by the vertical and rotary movements of the connector.

ARTHUR CROTCH.

THE SUMMER OF 1911.

THE summer of 1911 has been remarkable in so many ways that without doubt it will receive the special attention of meteorologists, and will in course of time be dealt with very thoroughly, as it well deserves to be. Having for many years past kept touch with the published Greenwich weather records, a comparison of the present summer with the observations of the past seventy years, from 1841, may be of interest from one not officially attached to the Royal Observatory.

The exceptional character of June, July, and August lead naturally to the supposition that the summer proper, as limited to the three months, would beat all previous records in many ways, and this impression is amply supported by weather statistics.

The summer six months, April to September, can also claim a record so far as temperature is concerned. The mean temperature for the six months is

60·7°, which is the highest for any similar period since 1841. The next means are 60·6° in 1893, 60·4° in 1868, and 60·1° in 1865. These are the only summer six months with the mean temperature at Greenwich above 60°, and there has not been any summer with the mean temperature above 58° since 1901.

The following are the results for the several months:—

	Air Temperature			Rainfall		Sunshine
	Mean max.	Mean min.	Mean	Days	Total	Hours
	°	°	°		Inches	
April	55	39	47	13	1·75	150
May	69	47	58	9	1·88	212
June	71	51	61	12	2·11	224
July	81	56	68	3	0·26	335
Aug.	81	57	69	8	1·35	260
Sept.	72	50	61	8	1·34	234

The aggregate rainfall for the six summer months is 8·69 inches, which is more than 3·5 inches less than the average; there are several summers, comprised by the six months April to September as dry.

The mean temperature for the three summer months June, July, and August is 66·1°, which is 4·9° in excess of the average for the past seventy years; this is 1° warmer than any previous summer. The next warmest three summer months occurred in 1868, when the mean was 65·1°, and in both 1859 and 1899 the mean was 65·0°. August was the warmest summer month, the mean being 1° higher than in July.

The warmest days during the summer were as follows:—

Day	Temperature	Daily mean n excess of average
	°	°
July 21	94	15
,, 22	96	15
,, 28	92	14
Aug. 9	100	19
,, 13	91	14
Sept. 7	92	12
,, 8	94	13

There were in all during the summer seven days with a temperature above 90°, and the only other summer during the last seventy years with an equal number of warm days is 1868. In 1876 there were six days with the thermometer above 90°, whilst the only other years with as many as four such warm days were 1846, 1881, 1893, 1900, and 1906. There were forty-five days during the summer, from April to September, with the shade temperature at Greenwich above 80°, and previously the greatest number of such warm days was forty in 1868.

The absolute temperatures are very exceptional:—95·6° was recorded on July 22, which was the highest previously recorded at any period of the summer since 1841, with the exception of 97·1° on July 15, 1881, and 96·6° on July 22, 1868. The maximum reading of 100° at Greenwich on August 9 is 3° higher than any previous record at the Royal Observatory since 1841. On September 8 the shade temperature was 94·1°, which is higher than any previous reading in September, and the mean of the maximum readings from September 1 to 8 was warmer by 2° than the mean for any corresponding period since 1841. The mean maximum temperature for August is 81·1°, which is the first occasion of the mean of the highest day readings in August exceeding 80°.

The aggregate rainfall at Greenwich for June, July, and August is 3·72 inches, which is 2·80 inches less than the average. The only instances of a drier summer are 3·65 inches in 1849, 2·01 inches in 1869, and 2·50 inches in 1864. The driest month of the summer was July with 0·26 inch.

The periods of absolute drought were twenty-three days from July 1 to 23 and seventeen days from August 2 to 18.

There was an unusual amount of bright sunshine throughout the summer—the aggregate duration in the three months, June to August, was 819 hours, which is 189 hours more than the average for the last fifteen years.

The black-bulb thermometer exposed to the sun's rays exceeded 160° on July 22, August 4 and 9.

CHAS. HARDING.

A VULCANOLOGICAL INSTITUTE.

IN the *Nuova Antologia* of July 16, a copy of which has recently reached us, there is an interesting article by Mr. Immanuel Friedlander, in which he points out reasons which justify the attempt now being made to establish an International Vulcanological Institute. This is a matter to which we have already referred (see NATURE, April 6, 1911, p. 180). Among the many reasons why volcanoes should receive special attention is the fact that they bring to the surface fused silicates and other materials from the deeper parts of the crust of our earth which otherwise we should not be able to reach. Two lines of study are open to us. One is to investigate the phenomena presented by a given volcano, whilst the other is based upon the consideration of their geographical and geological distribution. In connection with this distribution we are told that the Atlantic and Pacific types of volcanoes differ in the chemical characters of their products. Attention is next directed to the fact that although many volcanoes follow faults or lines of weakness in the crust of the earth, examples are given of vents which seem to be independent of such lines.

The materials which have been erupted from selected volcanoes are enumerated in some detail. These fall under three heads, namely, materials which are Basaltic, Andesitic, and Trachitic, the quantities of silica in which are respectively 56, 60 and about 70 per cent. The volcanoes with the more acid lavas are the most irregular and violent in their activity. A curious feature connected with volcanic eruptions is that the nature of the material ejected is not necessarily constant. The first eruption from Panteleria was basaltic, after which materials which were andesitic together with acidic Liparites appeared. The last efforts at this island, like the first, revealed materials which are basic.

From the softening of glassware and the ignition of various materials, the temperature of the dust-cloud which was shot out laterally to destroy St. Pierre and its 30,000 inhabitants was estimated at about 600 or 800 degrees. The needle-like pinnacle which grew upwards from the crater of this mountain is compared with the one which in 1909 grew in the crater of Mount Tarumai in Yezo.

These, together with many other curious appearances and phenomena observed by the vulcanologist, suggest that much remains open for investigation.

One interesting section in the paper is a brief discussion of certain theories respecting the cause of volcanic action. It is pointed out that water could not pass to regions of heated rock through cracks or fissures. Suess considers that the aqueous vapour which escapes from volcanic vents represents water which reaches the surface of the earth for the first time, while Alfred Brun, of Geneva, denies the presence of water in volcanic eruptions. Stübel, who has worked amongst the volcanoes of Central America, holds the view that each volcano derives its materials from a special reservoir left in the crust of the earth during its solidification, but he does not explain why these reservoirs are arranged in chains or lines. With a few words respecting the part that radio-activity and the expansion of silicates in solidification may play in connection with volcanic action, the writer points to these various theories as indications of the uncertain and contradictory knowledge we possess respecting such phenomena. After a brief *résumé* of the investigations to be carried out at the new institute, the author tells his readers that the International Institute of Weights and Measures at Paris, that of Seismology at Strasburg, and that of Agriculture at Rome, have conferred upon those cities a great prestige. In like manner an International Institute of Vulcanology will be a new glory for Italy and for Naples.

J. M.

THE ARCHÆOLOGICAL DEPARTMENT OF INDIA.

LORD CURZON has done good service to the cause of archæology by his spirited protest published in *The Times* of October 7 against the change of system in regard to the ancient monuments of the country proposed by the Government of India. Up to the time when, as Governor-General, the attention of Lord Curzon was directed to this question, the State policy in connection with the excavation of sites of historical interest and the conservation of the Buddhist, Hindu, and Mahomedan religious and civil buildings was ill-considered and ineffectual. In the early days of our rule these buildings, which are due to the munificence of vanished dynasties or the religious devotion of their subjects, were usually neglected and often desecrated. Excavations were undertaken by unskilled workers in a haphazard way, and many objects of interest and value were lost or destroyed. Under General Cunningham as director, between 1870 and 1885, some useful excavations were carried out. But the result of the work as a whole was not commensurate with the expense which had been incurred.

When Lord Curzon took up the question in 1902, the department was reorganised under Mr. J. H. Marshall, a good scholar and competent archæologist, as director-general. Lord Curzon quotes many examples to show the urgent necessity of this course of action. At Lahore the exquisite Pearl Mosque had been converted into a Government treasury, the Audience Hall into a barrack, the Sleeping Hall of Shah Jahan into a church. The beautiful mosque at Ahmedabad was used as a revenue office; the pavilion at Selimgarh in the Agra Fort as a canteen; the marble pavilion of Shah Jahan at Ajmer as the Commissioner's dining-room; a fine mosque at Lahore as the office of the railway traffic superintendent; one at Mijapur as a dâk bungalow, another as a post-office; the gilded palace at Mandalay had been utilised partly as a church, partly as a clubhouse.

Under the new system such destruction and desecration were discontinued. Many beautiful buildings have been tenderly repaired. Museums have been opened at the chief historical cities, and whenever excavations have been conducted the scientific principles established by the work of Prof. Flinders Petrie in Egypt, the British School at Athens, and in many other places, have been followed. Mr. Marshall has published a series of progress reports which have been received with admiration by scholars in Europe and America.

Now it is proposed, from some petty considerations of economy, to bring to a close this admirable work, which costs 30,000*l.* *per annum* out of a revenue of eighty millions. The control of the head archæologist is to cease, and the provincial governments are to start again the inefficient methods of which we have had disastrous experience. These governments are habitually pressed for funds, and they neither possess nor can employ a staff competent to undertake the care of the ancient buildings or to conduct excavations.

Now that this proposed change of policy has been brought to the knowledge of the scientific world by the one man competent to express an opinion on such a subject, the result cannot be doubtful. The indignant protests of archæologists throughout Europe and America must compel the Indian Government to abandon these ill-considered proposals. It will be a bad omen for the future administration of India if, in the year when his Majesty the King-Emperor visits the country, a scheme which has commended itself not only to archæologists, but to the princes and rulers of India, is suddenly, without adequate reason, brought to an end, and the old system of neglect and maladministration re-established.

LOUIS JOSEPH TROOST.

BY the death of Troost, on September 30, at the ripe age of eighty-five, France loses the last surviving member of that group of workers—pupils of Henri Sainte-Claire Deville at the École Normale—who created, mainly under his inspiration and leadership, what was practically a new department of chemical science. Thermal chemistry, as we understand it to-day, may be said to have originated in mid-Victorian times. It may be urged that the relations of chemistry to heat are so intimate that the study of these relations is necessarily as old as the study of chemistry itself. But it was only at the beginning of the latter half of the last century that the subject of thermal chemistry was attacked. Systematically, and for the most part in France, at the instigation of Deville, who, with the aid of Troost, Debray, Isambert, Hautefeuille, and Ditte, laid the foundations of that imposing superstructure to which this special department of knowledge has now attained.

Troost, who was born in 1825, was educated at the Lycée Charlemagne. He entered the École Normale in 1848, becoming an assistant there in 1851, and receiving his doctorate of science in 1857. For some time he taught in the provinces, but ultimately took charge of the chair of chemistry at the Lycée Bonaparte at Paris, and then, in 1868, became Maître de Conférences at the École Normale. In 1874 he became a professor in the faculty of sciences of Paris, where he remained until 1900, when he retired. In 1884 he succeeded Wurtz at the Academy of Sciences. For many years he was a commander of the Legion of Honour.

Troost was an indefatigable experimentalist and a prolific writer. His published memoirs, either alone or in association with Deville, Marie-Davy, and Hautefeuille, number close upon a hundred. His earliest essays were in pure inorganic chemistry: he prepared and studied the salts of lithium, which, in the middle of the nineteenth century, was regarded as a rare element. By the student, however, Troost is mainly remembered by reason of his work with Deville on the determination of vapour densities at high temperatures, the study of which had received an enormous impetus on account of the applications of the doctrines of Avogadro and Ampère. The values so obtained have become classical and are to be found in practically every systematic treatise of chemistry. With Deville, he largely developed the conception of dissociation, and his memoir on the vapour density of chloral hydrate gave rise to a memorable controversy on the value of volumetric considerations in the determination of equivalents. In conjunction with Hautefeuille he followed Debray in elucidating the laws governing dissociation, the recognition of the fundamental phenomena of which we owe to Deville. In this connection we may cite the memoirs on the conditions determining the absorption of hydrogen by palladium, potassium, and sodium, the dissociation of the sesquichloride of silicon, and the transformations of cyanogen into paracyanogen, and of cyanic acid into cyanuric acid. With Deville he studied the porosity of metals at high temperatures, and with Hautefeuille the solubility of gases in metals.

Troost was a frequent contributor to metallurgical chemistry, and made important contributions to our knowledge of the parts played by silicon and manganese in determining the physical properties of the various forms of commercial iron. His treatise of chemistry, which originated out of his connection with the Sorbonne, has gone through innumerable editions, and for many years past has been a standard text-book to successive generations of pupils.

Troost, in spite of his advanced years, enjoyed excellent health up to a short time before his death. He preserved his faculties practically unimpaired, and was active and industrious to the last on the numerous commissions in which he took part, and more particularly on the Commission des Inventions at the Ministry of War, of which he had been president for some years past.

NOTES.

We notice with regret the announcement of the death, on October 7, of Dr. J. Hughlings Jackson, F.R.S., consulting physician to the London Hospital, at seventy-six years of age.

The Decimal Association announces that a weights and measures law, rendering the use of the metric system compulsory in Bosnia-Herzegovina, will come into force on September 1, 1912.

The Harveian oration will be delivered by Dr. C. Theodore Williams at the Royal College of Physicians of London on Wednesday next, October 18.

Recent progress in model or small-power engineering, both as a hobby and as a useful factor in technical education, will be demonstrated at the Model Engineer Exhibition—the third of its kind—to be held at the Royal Horticultural Hall, Westminster, on October 13–21.

We notice with regret that the death is announced, on September 25, in his sixty-eighth year, of Prof. Auguste Michel-Lévy, the distinguished geologist and member of the Paris Academy of Sciences.

The *Terra Nova* of Captain Scott's British Antarctic Expedition returned safely to Lyttelton, N.Z., on October 7. Lieut. Filchner, the leader of the German South Polar Expedition, left Buenos Aires a few days ago for the Antarctic in the *Deutschland*. It is announced from Sydney that the fund for Dr. Mawson's Antarctic Expedition now amounts to 43,000*l*.

Dr. J. H. H. Teall, F.R.S., director of H.M. Geological Survey, will take the chair at the first of the Selborne lectures of the season, to be held on Monday, October 16. The subject will be "The Evolution of Scenery," and the lecturer Mr. F. W. Rudler.

Dr. W. E. Adeney, of Dublin, who has devoted particular attention to questions of sewage pollution, has been invited by the Metropolitan Sewage Commission of New York to advise it in reference to the over-pollution of the waters of the harbour of that city. Dr. Adeney served as a member of the recent "Whisky Commission."

Dr. Wilhelm Dilthey, whose death is announced at the advanced age of seventy-seven, was professor of philosophy at the University of Berlin until 1905, when he resigned owing to ill-health. He held his chair as successor to Lotze, and had previously been professor of philosophy in Basel, Kiel, and Breslau. Although, perhaps, best known for his "Leben Schleiermachers," which brought him into notice in 1870, he published a number of other essays and books, some of which are of considerable philosophical importance.

In connection with the Exhibition of British Fisheries, &c., at Manchester, which was opened on Saturday, October 7, by his Excellency the Greek Minister, the Hull Museums Committee has an extensive exhibit of old whaling appliances, paintings, models, &c., of the old whaling ships. Mr. T. Sheppard, the curator, has issued an illustrated guide to the collection (32 pages, one penny) which is a useful account of the various weapons and tools used by the old Hull whalers. It is interesting to learn that both the present enormous fishing and oil industries at Hull have developed from the whaling trade.

The fifty-seventh report of the Postmaster-General on the Post Office, which has just been issued as a Blue-book (Cd. 5868), records that the number of radio-telegrams dealt with showed a satisfactory increase, the outward messages to ships reaching a total of 5640, as compared with 3266 in 1909–10, and inward messages from ships 34,161, as compared with 27,727, the total increase being 8808, or 28·4 per cent. During the year 97 licences, covering 107 land stations, were granted under the Wireless Telegraphy Act, and, with one exception, these were for experimental purposes. Connected with this subject, we notice the announcement in *The Morning Post* that the wireless telegraph station at Spitsbergen is now completed and ready for use. The machinery is working satisfactorily, and messages are received at Spitsbergen from Poldhu, in Cornwall, and communication is being established with the station at Ingö, in the north of Norway.

Coal is said to have been discovered on the estate of Sir Harry Verney, Bart., at Calvert, in Buckinghamshire, within fifty miles of London. It appears that exploratory work has been carried on intermittently for several years at this locality, and that a boring, which was sunk six years ago in quest of water, encountered coal-gas under pressure of about 60 lb. per square inch at a depth of 470 feet. Two bore-holes are now being sunk, and it is announced that one of them, after passing through an outburst of gas, reached coal at a depth of only 530 feet from the surface. Should this announcement be confirmed, it will justify the belief of those who hold that concealed coalfields may exist at workable depths between the Midland fields and those of Bristol and Somerset. So far back as 1877 a famous boring at Burford, in Oxfordshire, struck Coal-measures at a depth of 1184 feet, beneath a cover of Jurassic and Triassic rocks. At Batsford, in Gloucestershire, Coal-measures have likewise been found beneath Secondary strata.

At the monthly meeting of the Pharmaceutical Society, held on October 4, the president, Mr. C. B. Allen, handed the Hanbury gold medal and a cheque for 50*l*. to M. Eugène Léger, of Paris. The Hanbury gold medal is competed for every two years, and the winner receives also

50*l.* from a fund left by the late Sir T. Hanbury, brother of the late Mr. Daniel Hanbury, of whom the medal is a memorial. The council of the Pharmaceutical Society are the trustees of the fund, and the adjudicators the respective presidents of the Linnean, Chemical, and Pharmaceutical Societies and of the British Pharmaceutical Conference, together with Mr. Walter Hills. M. Léger is a member of the committee of revision of the French Pharmacopœia, and his work in connection with the chemistry of the active constituents of drugs is well known. A short time ago M. Léger was elected an honorary member of the Pharmaceutical Society.

THE trustees of Lake Forest University, Illinois, send particulars of the second decennial prize of 6000 dollars on the Bross Foundation. The prize was founded in 1879 by William Bross, of Chicago, as a permanent memorial of his son, Nathaniel Bross, who had died in 1856. Its object is to stimulate the production of the best books or treatises "on the connection, relation, and mutual bearing of any practical science, or the history of our race, or the facts in any department of knowledge, with and upon the Christian religion." The scope of the gift is so comprehensive that any phase of science, of literature, of human history, or of modern life that may throw light upon the Christian religion, or upon any phase of the same as it is received by the great body of Christian believers, would be a fitting theme for a book offered in the competition. The prize will be given to the author of the best book on any of the lines above indicated which may be presented on or before January 1, 1915. The manuscripts, accompanied by a sealed envelope containing the name of the writer, must be sent on or before the above date addressed to the President of Lake Forest College, Lake Forest, Illinois. It is requested that no manuscript be sent in before October 1, 1914. A copy of the circular containing all the essential conditions made by the deed of gift, or any further information desired as to this competition, may be obtained on application to President John S. Nollen, Lake Forest, Illinois.

A LECTURE on "Emotions and Morals" was delivered on October 4 by Dr. William Brown at the inauguration of the new session at King's College, London. In the course of his address, Dr. Brown said that modern theories of ethics are finding it more and more necessary to take account of the psychological nature of man in formulating their moral ideal. This is particularly the case with respect to the emotional side of consciousness, since it is in the emotions that all values reside. After rapidly reviewing the more important modern theories held as to the nature of the emotions, and their classification under the two main headings of simple and complex, and showing by a detailed analysis that love and hate are not emotions, but systems of emotional dispositions dominated by a fixed idea, he proceeded to sketch out the modern theory of *values* in its most general form, and to show (after Ribot) that the feelings have a logic of their own, distinct from, and not necessarily inferior to, that of pure reason, and that the logical primacy of pure reason over feeling, though generally held by the classical philosophers, is not by any means complete. In a digression on the psychology of music he discussed the intellectual "arabesque" theory of Hanslick and the more generally accepted emotional theory to which Schopenhauer and all the great creative musicians have subscribed, and stated his own view that music expresses a system of emotions *sui generis*, but in dynamic relation with the ordinary emotions, and is therefore of ethical importance. The imperative of duty may be expressed in the form, "Seek always the highest good," which would seem to be personality for ourselves and others.

The Times of October 4 announces the death, in September, at Bandra, a suburb of Bombay, of Lieut.-Colonel A. S. G. Jayakar, late of the Indian Medical Service, who when stationed at Muscat—latterly as surgeon-general—collected and presented to the British Museum during the last two decades of the nineteenth century a number of specimens of mammals, birds, reptiles, and fishes indigenous to the Oman district of south-eastern Arabia and the adjacent sea. When describing the mammals in 1894 (Proc. Zool. Soc.), Mr. Thomas remarked that Colonel Jayakar's collection was the first ever received from that district; it included a new and small species of thar (*Hemitragus jayakeri*), a genus of wild goats previously known only from India, and a new hare, while it also showed that the range of the Syrian hyrax extended to Oman. The birds included a new eagle-owl, described by Dr. Sharpe in *The Ibis* for 1886, and a new bee-eater, figured by Mr. Dresser in his monograph of that group. A fine skeleton of the short-beaked sword-fish (*Histiophorus brevirostris*), exhibited in the fish gallery at the British Museum (Natural History), was the gift of Colonel Jayakar, although there is no intimation of that fact on the descriptive label. Colonel Jayakar was born in Bombay in 1845, where he received the first part of his education; in 1867 he came to London, where, after taking the degrees of M.R.C.S. and L.R.C.P., he entered the Indian Medical Service, to which but few natives had been admitted up to that date. The greater part of his service was passed as residency surgeon at Muscat, where he remained for thirty years.

WE regret to announce the death of Dr. Joseph Bell, one of Edinburgh's distinguished surgeons. He was born in Edinburgh in 1837, educated at the Academy and University, and graduated M.D. in 1859, becoming soon afterwards resident house-surgeon under Prof. Syme. He thus followed the family tradition, for his father, grandfather, and great-grandfather had been surgeons. Dr. Bell became a Fellow of the Royal College of Surgeons of Edinburgh in 1863; in the same year he commenced to teach systematic surgery, and in the following year operative surgery. These courses were continued, with growing success, until 1878, when Dr. Bell was appointed senior acting surgeon in the Royal Infirmary. On his retirement he was made consulting surgeon, an appointment which he held to the last. Dr. Bell was one of the originators of the Royal Edinburgh Hospital for Incurables, and was surgeon to this, to the Eye Hospital, and the Royal Hospital for Sick Children, and consulting surgeon to many medical institutions in the city. He was the author of a manual of the operations of surgery, of useful notes on surgery for nurses, and of papers, describing some of his most interesting cases, published in *The Edinburgh Medical Journal*, of which he was editor for twenty-three years. For many years Dr. Bell was examiner in surgery in the Royal College of Surgeons, Edinburgh; for some time he was honorary treasurer, and later, for a period of six years, president, an office which his father had held twenty years previously. Dr. Bell was a man of strong and sympathetic personality, and was highly esteemed in the community in which he worked so zealously. He possessed to a remarkable degree the power of keen perception and of quick deductive reasoning; his surprising deductions from apparently trivial details suggested to Sir A. Conan Doyle, who was a student under Dr. Bell, the character of Sherlock Holmes.

Mr. R. Campbell Thompson, in *The Times* of October 9, has issued a further report on the excavations at Carchemish, which were started in the early part of the present year by Mr. D. G. Hogarth. The mound presents a record of continuous human occupation, beginning with that of a primitive race using flint knives, obsidian flakes, and hand-made pottery. These people were succeeded by the Hittites, who were enabled by the use of bronze weapons to overcome the primitive occupants of the site. Finally, in B.C. 717, the Assyrians captured the place, and bricks have been found inscribed with the title of "Palace of Sargon, King of Nations, King of Assyria." A remarkable result of these excavations is the discovery of numerous small pottery horses, which served some religious purpose or were used in some game. The Hittite sculptures already unearthed add considerably to our knowledge of the beliefs of that people, consisting of guardian door figures, winged lions, and protecting demons, like those of Assyria. A remarkable bas relief depicts the overthrow of an Assyrian, and proves that the latter race practised circumcision.

Prof. Boyd Dawkins, in *The Times* of October 6, remarks that the discovery of an ancient canoe on the edge of the Baddiley Mere, used for the water supply of Nantwich, reminds us that the recent drought offers an exceptional opportunity for the examination of the desiccated margins of all sheets of water in Great Britain. A similar protracted failure of rain in 1853–4 led to the discovery of numerous pile dwellings in Switzerland. Similar erections are found in considerable numbers in Ireland and in Scotland; but, so far, the discoveries of this kind in England and Wales are singularly poor. In the Lake District only one settlement of the Neolithic age, that on Ehenside Tarn, has been discovered. Wales has yielded one of doubtful age in the lake of Llangorse, Breconshire. There is one in the Vale of Pickering and the Marshes of Holderness, and in Norfolk one in Barton Mere and two near Thetford, all three of the Bronze age. If we add to these the three lake settlements at Glastonbury and Mere, the total amounts only to eight. Prof. Boyd Dawkins believes that careful search during this exceptional season, before the lake margins are covered by the autumn rains, would reveal prehistoric settlements in almost every county, and throw as much light on the daily life of the early inhabitants as the discoveries made elsewhere have done. It is not yet too late to seize the present unusually favourable opportunity for making these investigations.

The August issue of *The National Geographic Magazine* is largely and appropriately devoted to Morocco and Tunis. It includes an interesting article by Mr. G. E. Holt, American Vice-Consul General, describing two religious dances performed at Tangier. These displays are provided by two separate sects which have widespread influence, not only over Morocco, but in Algeria, Tunis, and even so far eastward as Egypt. One of these is the Aisawa, followers of the saint M' Hammed Bin Aisa; the second the Hamadsha, founded by Sidi Ali Bel Hamdush, a later and less influential body than the former. Each motion in these dances is a symbol of some phase of the Mohammedan religion or of one of the sectarian beliefs. One position, for instance, represents Islam on the defensive against Christianity; another the final triumph of the faith of the Prophet. Women share in these performances; and in one movement a male and female dancer bend down and tear the earth with their teeth, symbolising the Creation, when Adam and Eve lived on the fruits of the soil, an ideal of the simple life recommended to their descendants. These dances, well illustrated by photographs, describe an interesting phase of that active sectarian fanaticism which, in the near future, is likely to be a serious embarrassment to those European Powers which are at present engaged in adventures in North Africa.

We have received the September number (vol. i., No. 12) of *The Child*, a monthly journal devoted to child welfare, which completes the first year's issue. This number, which is well printed and illustrated, contains, among others, an excellent article by Dr. Mary Scharlieb on adolescent girls from the viewpoint of the physician. Valuable advice is given on diet, exercise, dress, and moral training for the adolescent girl.

Messrs. E. Leitz, Oxford House, London, W., have issued a circular respecting dark-ground illumination and ultra-microscopic vision. They direct attention to the fact that these methods of microscopical investigation, while often rendering visible objects which by ordinary illumination cannot be seen, do not enhance resolving power. The methods depend on the principle that brightly illuminated objects can be better seen on a black background than on one which is itself bright.

The *Bulletin de la Société d'Encouragement pour l'Industrie Nationale* for July (T. 115, No. 7) contains a report by M. F. Grenet on porous porcelain filters, particularly the form known as the Pasteur-Chamberland. By osmotic pressure determinations, it is calculated that the pores vary in size from $1{\cdot}08\,\mu$ to $2{\cdot}16\,\mu$ ($\mu=0{\cdot}001$ mm.) as minima and maxima. Collodion tubes also form extremely fine-pored filters, capable of retaining ultramicroscopic particles. By using a porous porcelain filter tube as a support for the collodion tube, the "life" of the latter may be much prolonged; M. Grenet has had one in use for a year, and it is still perfect.

The variation of micro-organisms, particularly bacteria, is at the present time attracting considerable attention. Mr. Cecil Revis describes the artificial production of a permanent variety of *Bacillus coli* (*Centr. f. Bakt.*, 2te Abt., Bd. xxxi., 1911). It was obtained by growing a strain of *B. coli* in broth containing 0·05 per cent. of malachite-green. After fifteen subcultivations, at intervals of about three days, its power to produce gas (formerly active) in lactose, dulcitol, mannitol, and glucose was completely lost, but the capacity to produce acid was retained. With salicin, at first acid was formed, but after the treatment this substance was no longer attacked. Acid-formation and curdling in milk remained practically unaltered, as well as the characters of the growth on gelatin. The new physiological condition of the organism is quite permanent, and all attempts to reproduce the power of gas-formation have been unavailing.

A form of paralysis, particularly attacking certain muscles of the lower limbs in children, and known as infantile paralysis, has been the subject of much research by Flexner, Levaditi, Landsteiner, and others during the last two or three years. The disease is sudden in onset, and sometimes occurs in epidemics, and is due to an inflammatory condition of the large motor cells in the anterior horns of the grey matter of the spinal cord. In the *Revue générale des Sciences* for September 15 Dr. Levaditi gives a good summary of our present knowledge of the causation, &c., of the disease. It is infective, *i.e.* is due to a micro-parasite, which is so minute that it passes through the pores of a porcelain filter, and is hence beyond the limit of visibility with the microscope. The disease can be transmitted to apes, injection of material from a human case reproducing the disease in these animals.

In No. 1860 (vol. xli., p. 297) of the Proceedings of the U.S. National Museum Mr. C. W. Gilmore describes, under the new generic and specific name of *Brachychampsa montana*, a crocodilian skull from the Cretaceous of Montana. The specimen indicates an alligator-like reptile, distinguished from all other members of the alligator-group by the absence of a posterior expansion of the hinder part of the premaxillæ to roof over the front of the nares. There are fourteen pairs of upper teeth, five of which are borne by the premaxillæ.

A new species (*B. tener*) of the stegocephalian genus Branchiosaurus, from the Rothliegendes of north-western Saxony, is described by Mr. G. Schönfeld in the *Abhandlungen Ges. Isis* for 1911, p. 19. It is characterised by the gills persisting at least to a late period of life, by the slenderness of the bones of the middle of the roof of the skull, the presence of teeth on the vomers and palatines, and in the young state on the pterygoids, and by the small scales being marked with a radiating sculpture and concentric growth-lines.

The "Bibliotheca Geographica" for 1907 has been published by the Gesellschaft für Erdkunde of Berlin, having been edited, as in the preceding years, by O. Baschin. In size this most useful volume of reference remains about the same; a few changes in the classification have been made as experience has shown to be desirable, and this sixteenth volume fully maintains the high reputation of its forerunners as a most convenient and comprehensive guide to geographical literature.

In the *Mitteilungen der k.k. Geographischen Gesellschaft* of Vienna (Heft 8) a detailed account is given of the construction of a map from the photographs taken by Dr. Pietschmann during a recent expedition in Mesopotamia. An ordinary camera and stand, slightly modified to enable him to take rounds of views suitable for cartographical purposes, enabled him, it is claimed, to obtain material sufficient for producing a far more complete and accurate map than he could otherwise have done, and that without too great interference with his other occupations.

In the August and September numbers of *The Geographical Journal* Mr. J. C. Brauner discusses at some length the geological structure of Bahia and the form and position of the principal mountain ranges of this part of Brazil, in which he spent eight months in 1907 when studying the geology. The paper contains a great deal of interesting geological material, but, as a geographical description, lacks that coordinating treatment which is needed to give a full and explanatory account of an area.

Prof. Otto Nordenskjöld, in the September number of *The Geographical Journal*, discusses some questions of general importance relating to the nature of the Antarctic regions. The general orography of the north-western portion, which faces the South American continent, is sketched out, and the Antarctic climate and the character of its glaciation is considered, especially with reference to the influence of land-ice. The great masses of it which collect lower the summer temperature and tend to make that of winter somewhat milder, so that the land is gradually wrapped in ice, and vegetable and animal life is extremely sparse. Full discussion of such matters will appear in the course of the year in the geographical part of the results of the Swedish South Polar Expedition.

The Meteorological Chart of the North Atlantic Ocean for October, published by the Deutsche Seewarte, shows that at the beginning of September icebergs were seen in the Belle Isle Strait, and were still met with to the eastward on the ocean routes. A useful series of synoptic charts illustrates the very stormy weather which occurred between the Azores and the European coast from April 18–22, 1909, inclusive. It rarely happens that storms of hurricane force travel eastwards from the Azores in April. The monthly charts show that at this period depressions originating to the west of those islands usually take a northerly course. The disturbance in question travelled in an E.N.E. direction until April 21 at the rate of 400–500 miles a day, then struck northwards, joined an area of low pressure coming from N.W., and arrived off the south of Ireland early on April 22. The sudden and unexpected appearance of this storm is referred to in the report of the Meteorological Committee for the year ended March 31, 1910.

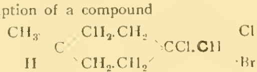
We have received the first four numbers of the Journal of the Washington Academy of Sciences, to be published semi-monthly except in July, August, and September, when monthly. The academy publishes a series of Memoirs, of which the first volume is dated 1866, the second 1884, the third 1885, and the remaining volumes at somewhat irregular intervals; these memoirs contain long papers. In 1899 a series of Proceedings was commenced containing papers shorter than those in the Memoirs, issued to members at intervals; at the end of each year these are collected into volumes, with indexes and title-pages. The present serial will replace the Proceedings, and is intended for shorter papers written or communicated by resident or non-resident members of the academy, for abstracts of scientific literature published in or emanating from Washington, for proceedings and programmes of the affiliated societies, and for notes of events connected with the scientific life of Washington. Parts i. and ii. (published together) contain 48 pages, and part iii. 56 pages. Many of the papers are of considerable interest, and extend over a wide range of subjects. The abstracts appear to be well done; the references give the name of the publication, the volume and pages of the beginning and end of the paper, and they are all from papers of the present year, indicating the desire to print the abstracts so soon as possible after the appearance of the originals. The Journal of the academy will be more useful both to residents and non-residents than the Proceedings of which it takes the place.

The July number of *Science Progress*, which was not received until last month, while particularly strong on the biological side, is sufficiently catholic in its articles to ensure that its readers have a wide and accurate knowledge outside their own special grooves. Dr. Waller, one of the advisory committee of the journal, proves that to Magendie rather than to Bell must be ascribed the discovery of the functions of motor and sensory nerves. Dr. Russell shows how the work of the Bureau of Soils of the United States Department of Agriculture has suffered materially owing to their neglect of the biological, as distinct from the chemical, processes going on in the soil. Prof. Bragg gives an outline of the facts of radio-activity, and shows that they force us to give up the idea of the impenetrability of matter.

Publication No. 149 of the Carnegie Institution of Washington consists partly of a reprint of a paper from *The Philosophical Magazine*, partly of new matter, and deals with a detailed investigation by Prof. C. Barus and his son of the conditions under which light produced by diffraction at a plane grating can be made to give interference fringes. The grating is mounted at one end and the eye-piece at the other end of a rod, the ends of which slide along tracks at right angles to each other, as in the

Rowland mounting for a concave grating. If a beam of parallel light from a collimator falls on a transmission grating, and is observed through a telescope after reflection, the spectrum is crossed by bands, which are due to the interference of rays diffracted at the grating surface and reflected from the back surface; rays transmitted through the grating surface without diffraction, then reflected and diffracted on their return; and, lastly, rays diffracted at the grating surface only. The authors develop the method, and produce an interferometer which is easily set up and possesses two degrees of sensitiveness, the higher corresponding to about half a wave-length of light.

AN interesting sequel to their observations on optically active substances containing no asymmetric carbon atom (NATURE, 1910, vol. lxxxvi., p. 93) is described by Profs. Perkin and Pope in the August number of the Journal of the Chemical Society. For this type of asymmetry they propose the name "centroasymmetric," and their last communication deals with the conversion of "centro-asymmetric" compounds into derivatives containing asymmetric carbon atoms, and *vice versa*. It is shown that, although two isomeric derivatives are sometimes produced, the optical activity of the compounds persists in all cases in which the molecule remains asymmetric. The models used by Prof. Pope in describing his observations to the Chemical Section of the British Association at Portsmouth are reproduced as photographs, the careful orientation of which makes them even easier to understand than the original solid figures. A point of considerable interest is the description of a compound



which owes its optical activity to an asymmetric atom linked to the three univalent radicles H, Cl, Br, the asymmetric carbon atoms of all active compounds described hitherto having been linked to at least two other carbon atoms.

A NUMBER of new uses of explosives in agriculture are described by Mr. F. H. Gunsolus in the Journal of the Franklin Institute for August. In the North-Western Pacific States dynamite is largely used for clearing land of tree-stumps; but a more novel application is to drill holes from 2 to 5 feet into the soil and to explode dynamite cartridges in them, in order to break up and loosen the subsoil. This process may be carried out on land where orchards have already been planted, the quantity of dynamite used varying from 25 to 100 lb. per acre. Explosives are also being used very largely in the Western States for digging ditches, especially in swampy clay ground. Slanting holes are punched at intervals of about 2 feet along the line of the proposed ditch; the middle hole is loaded with two or three cartridges, the explosion of which serves to detonate the charges in the other holes, with the result that a mile or more of ditch may be blasted simultaneously. The earth from the ditch is scattered evenly over the adjoining land, and the presence of stumps, trees, and underbrush interferes scarcely at all with the success of the operation.

A COPY of the October issue of the catalogue of second-hand instruments for sale or hire, by Mr. C. Baker, of High Holborn, London, has been received. The list contains particulars of more than 1500 pieces of apparatus, including a large selection of microscopes and astronomical telescopes. Customers unable to call at the showrooms to inspect pieces of apparatus can, on certain conditions, have them on approval for three days.

THE latest catalogue of general chemical apparatus and laboratory accessories issued by Messrs. A. Gallenkamp and Co., Ltd., of Sun Street, Finsbury Square, London, E.C., is likely to become a much consulted work of reference in chemical laboratories. The profusely illustrated volume runs to 800 pages, and provides full particulars, conveniently arranged, of all apparatus required for general use in the laboratories of every grade of educational institution, and those of industrial works where apparatus for research is employed.

OUR ASTRONOMICAL COLUMN.

BELJAWSKY'S COMET, 1911*g*.—From positions determined on September 29 and October 1 and 3, Dr. Kobold has calculated the following elements for the orbit of comet 1911*g*, which has now become an object for evening observations:—

$$T = 1911, \text{ October } 10{\cdot}196.$$
$$\left.\begin{array}{l}\omega = 71^\circ\ 39' \\ \Omega = 88^\circ\ 44' \\ i = 96^\circ\ 38'\end{array}\right\} 1911{\cdot}0$$
$$\log q = 9{\cdot}4823$$

From the ephemeris derived from these elements we give the following:—

Ephemeris 12h. Berlin Midnight.

1911	α (true) h. m.	δ (true) ° ′	log r	log Δ	mag.
Oct. 12 ...	13 37·6 ...	+8 59·1 ...	9·4931 ...	0·0051 ...	2·4
,, 14 ...	14 1·0 .	+6 30·3 ...	9·5190 ...	0·0201 ...	2·6
,, 16 ...	14 21·2 ...	+3 43·9 ...	9·5545 ...	0·0375 ...	2·9
,, 18 ...	14 38·5 ...	+0 54·3			
,, 20 ...	14 53·2 ...	−1 52·6 ...	9·6355 ...	0·0752 ...	3·4

The calculated magnitude at perihelion was about 2·3, but, owing to the rapid increase in distance, from both the sun and the earth, it is decreasing rapidly, and with the decreasing northerly declination the object is becoming a difficult one to observe; as the tail is approximately vertical, however, it may be possible to observe it, low down in the west, after the head has set, as was done in the case of comet 1910*a*.

Observations show that the tail, unlike that of Brooks's comet (1911*c*), is of the broad parabolic type often associated with great comets and small perihelion distances.

According to a *Times* communication, Mr. Hinks observed the comet between 16h. 30m. and 16h. 45m. on October 5, and estimated the magnitude of the nucleus as 3·5; only about 2° of the tail was visible. He also saw a strong zodiacal light just before dawn.

A tail 15° long was seen by Prof. Nijland, at Utrecht, on October 1.

QUÉNISSET'S COMET, 1911*f*.—The following is a further extract from Dr. Ebell's ephemeris for comet 1911*f*, which is still observable throughout the earlier part of the night:—

Ephemeris 12h. M.T. Berlin.

1911	α (true) h. m.	δ (true) ° ′	log r	log Δ	mag.
Oct. 12 ...	15 33·1 ...	+38 19·3 ...	9·9903 ...	0·0252 ...	6·7
,, 14 ...	15 35·2 .	+35 11·9			
,, 16 ...	15 37·0 ...	+32 14·4 ...	9·9707 ...	0·0499 ..	6·7
,, 18 ...	15 38·5 ...	+29 26·4			
,, 20 ...	15 39·8 ...	+26 47·5 ...	9·9519 ...	0·0754 ...	6·8

All these positions lie near to a line joining μ and δ Coronæ, the comet's apparent path lying almost due south.

BROOKS'S COMET, 1911*c*.—Brooks's comet passed the sun on October 12, and became a morning comet; as shown in the following abstract from Dr. Kobold's ephemeris, its apparent path now lies through Coma:—

Ephemeris 12h. M.T. Berlin.

1911	α (true) h. m.	δ (true) ° ′	log r	log Δ	mag.
Oct. 11 ...	13 10·8 ...	+30 2·5 ...	9·7970 ...	9·7899 ...	4·3
,, 13 ...	13 2·6 ...	+27 10·7			
,, 15 ...	12 55·4 ...	+24 14·5 ...	9·7583 ...	9·8178 ...	2·8
,, 17 ...	12 49·1 ...	+21 16·1			
,, 19 ..	12 43·9 ...	+18 15·5 ...	9·7241 ...	9·8498 ...	2·8
,, 21 ...	12 39·7 ...	+15 13·1			

The last four lines are taken from Dr. Ebell's continuation of the ephemeris, which appears in No. 4528 of the *Astronomische Nachrichten*.

THE SYDNEY OBSERVATORY.—In these columns on March 23 (vol. lxxxvi., p. 122) we expressed regret that the proposal to reorganise the New South Wales State observatory was not being taken up by the Government of that State. We now learn from a Sydney correspondent that at last the Government has agreed to the proposal, and has issued instructions for the appointment of a State astronomer, who is also to be professor of astronomy in the Sydney University; at present, we understand, there is no chair of astronomy in Australia.

In making this appointment, the Public Service Board is acting with the University authorities, and they have fixed the salary at 800*l*. per annum, with 100*l*. for quarters; the professorship will carry with it the usual pension allowance.

The first duty of the new State astronomer will be to organise the erection and equipment of a new observatory, for, as we pointed out previously, the present site is condemned; and since the death of Mr. H. C. Russell the work has, despite the untiring efforts of Mr. Raymond, fallen seriously into arrears.

The intended appointment is about to be advertised, and will, we understand, be dealt with by an influential committee in London. When this is done, and the Federal Government has organised its proposed Solar Physics Observatory at the new capital, it is hoped that astronomy will again flourish in Australia; meteorology has already been taken over by the Federal Government.

A NEW MINOR PLANET.—Advices from Vienna announce that Prof. Palisa has discovered a new minor planet which, having an increasing right ascension at opposition, may prove to be another object of the Eros type. The position on October 3 is given as

$$\text{R.A.} = 0\text{h. } 42\text{m. } 5\text{s., dec.} = +0^\circ\ 15'\ 38'',$$

and on October 4 was

$$\text{R.A.} = 0\text{h. } 43\text{m. } 59\text{s., dec.} = -0^\circ\ 17'\ 49''.$$

In No. 4528 of the *Astronomische Nachrichten* Prof. Palisa gives the daily motion as +2m. 8s., −32′, and the magnitude as 12·0. The advance in R.A. is greater than that of Eros at opposition, so that it may prove that the new planet, 1911 MT., approaches nearer than does Eros. It would appear that the orbit has a great eccentricity, and that the planet is near perihelion.

NEW WATER SUPPLY WORKS.

THE town of Birkenhead, containing a population of 120,000 inhabitants, at present depends for its supply of water on local sources; the wells in the Wirral Peninsula, however, are liable to salt water filtering from the sea and rendering the supply brackish. The Corporation of Birkenhead so far back as ten years ago realised that the condition of the water supply was not satisfactory, and appointed a committee to inquire as to a source from which a purer supply could be obtained. After a long inquiry, and acting on the advice of their consulting engineer, the late Mr. Deacon, a site was selected in Wales, fifty miles distant, which involved the construction of a large reservoir in the Denbighshire mountains on the River Alwen, a tributary of the Dee. In 1907 an Act was obtained conferring the necessary powers for carrying out the scheme and borrowing the money required. A few days ago these works were inaugurated with some ceremony by the Mayor and Corporation, a large granite block being fixed in one of the masonry piers of the dam now in course of construction, the contract for which has been placed in the hands of Messrs. McAlpine and Co. The amount of the contract for the reservoir is 186,153*l*. This dam is 1250 feet above sea-level; its length is 458 feet, and height 90 feet. The reservoir will be three miles long and about 350 yards wide, and will hold three thousand million gallons of water. The area of the ground from which it will be supplied covers 6300 acres, part of which is covered by peat, which in some places is 20 feet deep. This will all have to be removed. The average rainfall over the district is 51 inches, and the estimated average yield of water eleven million gallons a day. At the present time a large staff of men is employed on the works, about 400 being housed in wooden huts erected for the purpose. The water is to be conveyed to Birkenhead through steel and iron pipes varying in diameter from 20 to 30 inches. The estimated total cost is $1\frac{1}{4}$ million pounds. The works have been designed and are being carried out under the direction of Sir A. Binnie and Co., who took the matter up after the death of Mr. Deacon.

At Lincoln on October 4 was inaugurated with much ceremony, including a service at the Cathedral, the opening of the new waterworks which have been constructed for supplying the city with a pure supply of water. A few years ago Lincoln was afflicted with a very serious outbreak of typhus fever, the cause of which was traced to the pollution of the water in the River Witham, from which the supply was then obtained, and water for drinking purposes had for some time to be brought by railway in tanks. After much inquiry it was found that an entirely fresh source must be obtained. Boring in the locality was first tried, and, after sinking to a great depth and encountering considerable difficulties and delay, although a plentiful supply was reached, the quality of the water was not sufficiently good for use, and had to be abandoned. Parliamentary powers had then to be obtained for authorising the works now completed. The water is obtained from the pebble beds in Nottinghamshire at Eckersley, near the River Trent, at a depth of 500 feet below Sherwood Forest, the distance from Lincoln being twenty-three miles, the mains being carried across the river by a bridge built for the purpose. The water is raised from four boreholes 570 feet in depth, and pumped into 21-inch mains by engines of 500 horse-power, capable of raising 3,600,000 gallons a day. The machinery is all in duplicate, so as to provide against any accident that may occur. The total cost of the work is about 230,000*l*. The whole of the scheme has been carried out under the direction of Mr. McBarron, the city waterworks engineer.

PRECIOUS STONES.

THE chapter on precious stones which Dr. G. F. Kunz contributes to vol. xix. of *The Mineral Industry*, dealing with mining operations in 1910, contains, in addition to statistics of output, prices, and sales, much of general interest. Two-thirds of it is occupied with diamond. The main shaft of the Kimberley Mine has reached the considerable depth of 3527 feet. The extreme variation in the quality of the stones from the different mines is evinced by the average price per carat; thus 85*s*. is obtained for the stones from the Vaal River diggings, and 45*s*. from the De Beers group, while the Lüderitz Bay stones realise 26*s*. 6*d*., and the products of the Premier Mine only 14*s*. per carat. The occurrence of microscopic diamonds in decomposed olivine, with enclosed chromite, at Olivine Mountain, in the Tulameen River, Yale district, British Columbia, is of considerable scientific interest, though of no commercial importance. Students of political economy will be interested in the means whereby the powerful International Diamond-cutters' Union, with an income of about 3000*l*. a week, maintains a high level of wages. Apprentices are selected from sons of members of the union only, and their number is restricted to 5 per cent. of the whole. The great difference in price between manufactured and natural rubies calls for the note of warning that the qualifying term—scientific or artificial—demanded by law is sometimes inconspicuously written on the invoice. A specimen, weighing $98\frac{1}{2}$ carats, of the pink beryl, morganite, was discovered in Madagascar, and a magnificent aquamarine in Brazil; Madagascar is also supplying fine tourmalines. Unworked deposits of peridot have been found in the islands Rahamah and Kad-Ali, in the Red Sea. It is curious to learn that peridots have been dug up at Alexandria, where apparently they had been buried some 1500 years ago in the foundations of the houses in the belief that they would add to their stability. The best means for preserving the pearl-mussel is being studied at the station recently provided by Congress at Freeport, Iowa, U.S.A.

MATHEMATICS AND PHYSICS AT THE BRITISH ASSOCIATION.

The address of the president of Section A, Prof. H. H. Turner, has been already printed in this journal (August 31, p. 289).

Cosmical Physics and Astronomy.

The address was followed by a meteorological paper by Prof. W. J. Humphreys (of the U.S. Weather Bureau) on the earth as a radiator. Since our climates are not now perceptibly growing either colder or warmer, the total amount of heat received by the earth is substantially equal to the loss during the same time. But this statement does not apply to limited regions; and therefore to map the earth as a radiator it is necessary first to obtain temperature records within the isothermal region, where radiation alone is the controlling factor. From the experimental results the author deduces that the outward radiation is least near the equator, where the inward radiation is greatest, and greatest in temperate latitudes, a secondary minimum at the pole being indicated by the ascents in high latitudes. In the discussion it was pointed out that the results depend largely on the assumption that the atmosphere acts as a "grey" body. The values might be subject to considerable correction for irregularities in the absorbing power for different spectral regions. Dr. Shaw directed attention to the need for examining the influence of different thicknesses of water vapour in the atmosphere, and considered that reflection from cirrus clouds would introduce a considerable disturbing influence. A suggestion by Prof. Hicks that possibly the results were a consequence of the preponderating amount of ocean near the equator was met by Dr. Humphreys replying that the same results were obtained over ocean as over land.

Mr. L. Vegard, of Christiania, contributed a suggestive paper on the radiation producing aurora borealis, in which he starts from Birkeland's view that auroræ are caused by electric solar radiations, and endeavours to deduce the properties of these radiations. From the form and structure of the luminosity he infers that the electric radiations behave as though they are α rays. It is found, from the relation between range and velocity, that α rays will get down to heights varying between 70 and 300 km., which agrees with observations. Further, calculations show that α rays will strike the atmosphere at an angular distance from the magnetic axis of about 17°, which gives the right position of the auroral zone. The equidistant bands so characteristic of the draperies he explains by assuming groups of homogeneous rays, starting under the same initial conditions, such as would be provided by radium and its disintegration products in the sun. The author made a strong case for his explanation of these interesting phenomena.

Dr. W. N. Shaw communicated an account of the thunderstorms of July 28 and 29. The London storm on July 28 was accompanied by a squall of wind which reached fifty-four miles an hour at South Kensington, and the storms on July 29, which occurred over nearly the whole of England and Ireland, were preceded by violent squalls which raised clouds of dust, particularly noticeable in South Wales. At Watlington (Mr. W. H. Dines) the disturbance occurred while the passage of a depression was in progress, and the barograph curve took an M form instead of the usual ✓. The records of temperature, wind direction, and rainfall have still to be examined with the object of tracing the physical processes underlying the disturbance.

In the same department Commander Campbell Hepworth communicated a paper on the effect of the Labrador current upon the surface temperature of the North Atlantic, and of the latter upon the air temperature and barometric pressure over the British Isles. The purpose of the paper was to show the importance of the Labrador current in modifying the influence of the Gulf Stream.

Dr. Shaw showed models representing air currents up to heights of 10 kilometres which had been obtained from the observations of pilot balloons made at Ditcham Park by Mr. Cave. The models showed some of the types of motion which occur, and were very instructive to those unfamiliar with the details of upper-air observations.

Dr. Humphreys read a paper on the water vapour in the atmosphere on clear days, a quantity of great importance in the determination of the solar constant. He found a value of 87 per cent. of the value found by Hann from observations made in all kinds of weather.

Mr. Gold gave a brief account of the results obtained from the ascents in Ireland, undertaken by the committee for the investigation of the upper atmosphere. Three successful ascents had been made from Mungret College, Limerick, in the present year, and on July 6 values for the temperature had been obtained up to 21 km.

Dr. Dickson put forward the suggestion that the treatment of general atmospheric circulation might be simplified by taking the equatorial circulation to form a system by itself. It was pointed out in the discussion that general dynamical considerations rendered such an hypothesis untenable.

Mr. Craig read a paper by Dr. Ball and himself on the use of diagrams in the classification of climate. The diagrams dealt with temperature and humidity, and showed the annual course of these elements by a single closed figure for each of a selection of places from different parts of the world. The shape and orientation of the figure varied with the climate, and showed at once its principal features. Mr. Craig pointed out how they could be used not only by the man who was considering his health, but also in connection with such problems as cotton-growing.

Prof. J. Milne presented the sixteenth report of the committee on seismological investigations. Of the many interesting things in this report we may instance the observations on tidal load at Ryde in the Isle of Wight. By means of an instrument installed in a cellar in the Royal Victoria Yacht Club at Ryde and with its boom oriented east and west, a 10-foot tide in the Solent is found to produce an angular deflection of 0·85″. At Bidston a 10-foot tide gives at a distance of two miles a tilt of 0·2″. A curious feature of the Ryde photograms is the flatness of many of the crests and hollows of the deflections, which seems to indicate that from time to time the water remains high (or low) for several hours. When the boom was pointed north, or toward the advancing and retreating tide, the resulting photograms were practically straight lines.

Prof. H. H. Turner read a note on the periodogram of earthquake frequency from seven to twenty years, in which he investigated by Schuster's methods the possibility of periodicities in earthquakes, making use of the data in the "Catalogue of Large Earthquakes" recently edited by Prof. Milne. Within the range of periods examined, the only chance of a real periodicity is one of nineteen years, suggesting a nutational effect depending on the moon's nodes.

A paper by Mr. F. Napier Denison, on horizontal pendulum movements in relation to certain phenomena, was read by Prof. Milne, who also read one on the solar cycle, the Jamaica rainfall, and earthquakes cycles, by Mr. Maxwell Hall, dealing with observations extending from 1870 to 1910. Excepting a rainfall minimum in 1875, the minima for rainfall follow sun-spot maxima and minima by 1½ or 2 years. The rainfall maxima are more irregular. The earthquake maxima follow solar maxima by 2 years, while the minima follow solar minima by 2 or 3 years. Prof. O. Pettersson followed with a very interesting paper on parallactic tides set up in the bottom layers of the sea by the moon (see report of Section E).

Stellar Distribution.

The proceedings on Tuesday, September 5, commenced with a discussion on stellar distribution and movements, opened by Mr. A. S. Eddington, who stated that in attempting to form a conception of the structure of the universe as revealed by modern researches, we have to take into account the following principal phenomena. The great mass of the stars are distributed in a lens- or bun-shaped system, in which our sun occupies a nearly central position; round this, and in the same plane, are coiled the clusters, which make up the Milky Way. In the central parts of this the stars form two great streams moving in opposite directions; this is most easily explained as being the result of two more or less independent systems of stars having become intermixed. We have also to take note of "moving clusters," that is, groups of stars widely separated in space, which have almost identical motions, and are thus clearly connected in their origin. A whole class of stars, those of the helium type of spectrum, are exceptional, as they do not show the phenomenon of the two star-streams, and have very little motion of any sort, individual or systematic. This is perhaps due to the fact that they are extremely remote, and lie beyond the region through which the star-streams prevail. Finally, there is the recently discovered connection between spectral type and linear motion; the later the type of spectrum (as regards evolutionary development) the greater the average speed of the stars.

By considering the stars known to have a parallax greater than 0·2″ (seventeen in number), some important results are illustrated, notably the sparsity with which stars are distributed in space, the very heavy proportion of binary systems, the very different degrees of intrinsic brightness of stars, and the fact that the relative frequency of the different spectral types as seen in the sky is utterly misleading as an indication of their abundance in space. The publication by Prof. Boss last year of more than 6000 well-determined proper motions of stars distributed over the whole sky has greatly assisted investigations of the two star-streams. The bipolarity of the stellar motions is very clearly shown in the new data. Besides the theory of two star-drifts, an ellipsoidal theory, and more recently a three-drift theory, have been employed to represent the distribution of velocities. The theories have much in common, and it will be very difficult to distinguish between them. An attempt has been made to arrive at the law of velocities directly from the observations, without recourse to a particular theory; but the work, which involves an integral equation, has presented some difficulties, and is not yet completed.

The remarkable result that a star's motion appears to increase with its age, apparently implying that a star is born with practically no motion, leads us to inquire into the causes which produce stellar motions. From the consideration of the moving clusters it appears that the chance approaches of neighbouring stars have no appreciable effect, and the cause must be the resultant attraction of the whole mass of stars—a solution which, however, is not without its difficulties. Dr. Halm has suggested a law of equipartition of energy among the stars implying that the dependence of velocity is not really on the spectral type, but on the mass of the star; it seems that the stars of later types are progressively less heavy than those of early type. A third possibility is that distance from the centre of the stellar system is the determining cause. The hypothesis has recently been revived that the stellar system forms a spiral nebula similar to the thousands of spiral nebulæ in the sky. This theory, though highly speculative, appears to represent fairly well the observed distribution of the stars and the Milky Way, and the double-branched spiral form presumably involves motion in two opposite directions in the centre of the system similar to that presented by the two star-streams.

During the subsequent discussion Prof. Turner exhibited a model of the Ursa Major "moving cluster," specially showing that the component stars were nearly in one plane. Mr. A. R. Hinks emphasised that at present we are only getting at the central parts, and we do not know what fraction this part bears to the whole. In reference to the bun-shaped system, he considered that absorption of light had not been taken account of as it should be. He thought the spiral nebula conception was unnecessarily grandiose; he did not think that the star clouds of the Milky Way were well represented by the arms of a spiral nebula, as the latter seemed generally to be gaseous. He questioned whether anyone had yet explained the dynamics of the spiral motion in a nebula. He considered it premature to assume that there were not more than seventeen stars with parallax greater than 0·2″. He also criticised various points in nomenclature; in particular, the term star-cluster was being used in two senses.

The Astronomer Royal (Prof. F. W. Dyson) emphasised the value of the information given by measured parallaxes and the importance of making more determinations. The real difficulty is a lack of a knowledge of the actual distances of stars. He thought that the best way was to try to explain the velocities of stars gravitationally, and alluded to Lord Kelvin's satisfactory attempt in this direction to connect the total mass of the stars with the observed velocities. Prof. Turner and Mr. F. Bellamy explained the work done at Oxford in determining large proper motions; these were (unlike the stars as a whole) distributed nearly uniformly round the sky, the slight excess being in directions at right angles to the Milky Way. Father Cortie asked if there was not a contradiction in the fact that whereas the later-type stars had the larger velocities, yet they were relatively more abundant in the slow-moving drift than in the fast one. Mr. S. Stratton pointed out the anomalous position of the planetary nebulæ; their large velocities would place them at the end as the last stage of evolution. Mr. H. Hilton asked whether the velocity would not be least at the centre of a system of stars and increase outwards.

Mr. Eddington, replying to Prof. Turner, explained that the excess with large proper motions at right angles to the Milky Way was due to the solar motion coming in with greatest effect there in the Oxford zone. Replying to Mr. Hilton, he explained that he had regarded the stars not as moving in orbits, but as moving from outside to inside, and *vice versa*. Replying to Father Cortie, he explained that it is the individual motions of later-type stars that are greatest, as distinct from the drift motions.

Father Cortie and Mr. J. H. Worthington gave some particulars in regard to endeavours to view the recent eclipse.

The programme for Wednesday, September 6, contained two papers by Mr. S. Stratton, which in his enforced absence had to be taken as read. One of these, on an unusual meteor observed at Portsmouth on August 31, described a meteor with an apparent path in the form of a letter J, which probably arose from foreshortening accompanied by swerve. The swerve might be traced to spin and resistance or to unequal heating effects. The second paper, on the possible relations between sun-spots and the planets, contained a discussion of sun-spot material tabulated to show phase effects due to Venus and Jupiter. The conclusion is against the validity of conclusions come to recently by Prof. Schuster in connection with the influence of Venus and Mercury. A longer period of observation is apparently necessary before trustworthy results can be obtained.

Mathematics.

In the department of mathematics Lieut.-Colonel Allan Cunningham, R.E., read a paper on Mersenne's numbers. These numbers are of the form $M_q = 2^q - 1$, where q is a prime number. Since the appearance of Mr. W. W. Rouse Ball's paper in 1892 Prof. F. N. Cole has factorised M_{67}, Lieut.-Colonel Allan Cunningham has factorised M_{71}, M_{163}, and M_{197}, while H. J. Woodall has recently factorised M_{181}. This leaves still unverified (as composite) only fifteen out of the forty-four numbers (with $q<257$) originally affirmed by Mersenne to be composite, viz. when

$$q = 101, 103, 107, 109, 137, 139, 149, 157, 167, 173, 193, 199, 227, 229, 241.$$

A complete list of all the possible divisors <1 million of these fifteen numbers has been prepared by Mr. A. Gérardin (of Nancy, France) and Lieut.-Colonel Allan Cunningham, working independently. These trial divisors have been tested by the latter up to 500,000 without success (every "trial divisor" was tried twice).

Prof. J. C. Fields read a paper on relations between the double points and branch points of a plane algebraic curve $F(x,y) = y^n + F_{n-1}y^{n-1} +$, &c., which presents no singularities at infinity and the finite point singularities of which consist of nodes and ordinary cusps. On representing an arbitrary polynomial in (x,y) of degree $n-2$ by the notation $G(x,y) = \Sigma_{rs} d_{rs} x^r y^s$ a simple proof was given of the formula $\Sigma_\lambda c_\lambda \frac{G(a_\lambda, b_\lambda)}{F''_{b_\lambda}(a_\lambda b_\lambda)} = d_{o, n-2}$ where the summation is extended to all points (a_λ, b_λ) which are ordinary branch points, nodes, or cusps of the curve, the coefficient c_λ having as value either 1, 2, or 3, according as the corresponding point is an ordinary branch point, a node, or a cusp.

Mr. H. Bateman then contributed a note on the transformation of an electromagnetic field into itself. It is hoped that a discussion of the infinitesimal transformations will lead to equations of motion which will complete the electromagnetic scheme. Following the work of Mr. Hargreaves on the effect of an infinitesimal transformation on certain integral forms, it is assumed that these integral forms are invariants for the infinitesimal transformation. The analysis then indicates that two forms are exact differentials. Some types of infinitesimal transformations satisfying the conditions were obtained for particular electromagnetic fields, and the transformations were interpreted geometrically.

An account of the report of the committee for the further tabulation of Bessel and other functions was given by Mr. Nicholson. In the report tables are given (calculated by Mr. J. R. Airey) of the Neumann functions $G_n(x)$ and $Y_n(x)$ to seven decimal places for $n=0$ and $n=1$, and for values of the argument from 0·1 to 16·0 by intervals of 0·1. During the course of the year Sir G. Greenhill has brought forward a scheme for the rearrangement of the elliptic functions tables on a new basis. This scheme has now received the approval of the association, and a grant has been made towards the expenses of computation.

In this department Mr. H. Bateman contributed a paper on a geometrical theorem connected with six lines in space. PP′, QQ′, RR′ are three pairs of lines in space. LL′ are the common transversals of QQ′, RR′; MM′ the common transversals of RR′, PP′; and NN′ the common transversals of PP′, QQ′. If QQ′RR′ belong to a regulus, then MM′NN′ also belong to a regulus.

Mr. H. Hilton read a paper on the canonical form of an orthogonal substitution. After pointing out a short method of reducing a real orthogonal substitution to a canonical form, he discussed the analogous problem for an orthogonal substitution with complex coefficients. A canonical form was obtained in which the linear equations of the substitution were arranged in blocks, some of which contained two and others only one member. The leading coefficient occurring in one type of block was the reciprocal of the corresponding coefficient occurring in an associated block.

Prof. J. C. Fields read a paper on proof of certain theorems relating to adjoint orders of coincidence, viz.:—(1) In the reduced form of a rational function of (z, u), which is adjoint for the value $z=a$ (or $z=\infty$), the coefficient of u^{n-1} is integral with regard to the elements $z-a$ (or $\frac{1}{z}$). (2) If a rational function is adjoint for the value $z=\infty$, the degree of its reduced form is $\leqq N-1$. (3) The reduced form of a rational function adjoint for the value $z=a$ is integral with regard to the element $z-a$ if the equation $f(z, u)=(u-P_1) \ldots (u-P_n)=0$ (where $P_1 \ldots P_n$ are power-series in an element $z-a$ (or $\frac{1}{z}$) with exponents integral or fractional) is integral with regard to this element.

The Principle of Relativity.

The proceedings on Friday, September 1, opened with a discussion on the principle of relativity, led by Mr. E. Cunningham, who pointed out that the scope of the hypothesis of relativity is exactly coincident in extent with its scope in Newtonian dynamics. The acceleration of a point is not physically indeterminate as its velocity is. The theory of relativity is, for example, quite consistent with the magnetic effects apparent to terrestrial observers being explained as arising from the rotation of the earth with a nearly stationary distribution of charge. Within the limits indicated above and within the realm of phenomena in which the sole determinative laws are those of the electron theory, the hypothesis becomes a mathematically demonstrable fact in the sense that it is not possible to choose a unique frame of reference for which alone the laws will hold good. Mr. Cunningham then sketched the transformations connecting the measurements made according to two frames of reference, each of which is equally adequate to express known phenomena, and explained what deductions can be drawn.

In the subsequent discussion Dr. W. F. G. Swann pointed out that the compliance of a system with the electromagnetic scheme is by no means a sufficient criterion for the possibility of its existence; for instance, a system of two singularities, moving along at a constant distance apart, with the field at each point the sum of the ordinary fields due to the separate motions, is a system in accordance with the scheme, but it is one impossible of existence in practice. The explanation of the impossibility of the existence of such systems is to be found in the fact that they could never evolve out of any actually existing system. In fact, if we take the electromagnetic scheme as complete, those uniformities in nature which we call "laws" are to be looked upon as due in part to the compliance of the universe with the scheme and in part to the individuality of the initial system started. A complete knowledge of the field at every point in space, both inside and outside the molecules, would, in conjunction with the electromagnetic scheme, theoretically give us all that we should need to ascertain both the past and subsequent history of the universe. Since we cannot know the complete field at some instant, we are driven to make up for our incomplete knowledge by formulating certain "subsidiary laws," such as laws involving the conception of forces between the singularities, electrical surface conditions, gravitation, &c., the function of these laws being to *restrict those systems which satisfy the scheme, and are also to be considered as possible of existence, to those which can spontaneously evolve out of the actually existing universe.*

Mr. H. Bateman emphasised the mathematical interest attached to the principle, because it unites several branches of mathematics, such as geometry, partial differential equations, generalised vector analysis, continuous groups of transformations, differential and integral invariants, &c. He pointed out that there are two different types of transformations which can be used to transform one mathematical specification of an electromagnetic field into another. Those transformations which depend upon the electromagnetic fields which they can be used to transform form a much wider class than the spherical wave transformations, which can be applied to any electromagnetic field. The new transformations provide us with some very interesting analogues of mental phenomena.

Prof. P. Zeeman stated that the value of Fresnel's coefficient is easily deduced by means of the principle of relativity provided that no account is taken of dispersion. In that case the results of Fizeau's and Michelson and Morley's experiments on the propagation of light in flowing water agree with theory. The agreement is not so good if a dispersion term formally calculated by Lorentz be introduced. He asked whether the correction term would be the same if the principle of relativity were applied from the beginning to a dispersive medium. Prof. G. N. Lewis outlined some of the views which he has recently expressed in full in *The Philosophical Magazine*. Prof. A. E. H. Love warned one to be on the alert, because in the factor $K=(1-\beta^2)^{-\frac{1}{2}}$ we may be dealing only with a first approximation. Secondly, he suggested that it was conceivable that terrestrial magnetism might be only an apparent phenomenon due to the rotation of the earth. He had, however, tested whether by taking rotatory axes one could obtain effects of the magnitude of terrestrial magnetism; but they turn out to be very small, and it seems hopeless to think of magnetism as due solely to the rotation.

Dr. C. V. Burton, after expressing his satisfaction that none had confessed a disbelief in the æther, urged the importance of a search for residual phenomena not falling within the electromagnetic scheme. Conceivably gravitation is such a phenomenon. There is, further, a question as to whether neighbouring electrically neutral masses exert forces upon one another in virtue of their motion through the æther. Such forces would be non-electromagnetic; experiments designed to detect them are in progress, but have so far given a null result. The entire absence of such forces would imply that matter takes up no room (positive or negative) in the æther.

So much time had been taken up by the discussion that none was left to Mr. Cunningham to reply adequately to the numerous points raised. His scholarly paper introducing the discussion has been ordered to be printed *in extenso*; we look forward to perusing it in its extended form, and no doubt the answers to many of the questions will appear therein.

GENERAL PHYSICS.

In the department of general physics Mr. N. E. Dorsey gave an account of the work done at the Bureau of Standards on the absolute measurement of electric current. The measurements were made with a balance of the Rayleigh type; the coils were wound bifilarly, of enamel-insulated wire, upon brass forms. A novel feature of the fixed coils is the provision, in the forms and back of the windings, of a channel, through which water can be pumped so as to maintain the coils at a constant temperature. A double-walled jacket with water circulation surrounded the movable coils for the same purpose. The mean value obtained of the electromotive force of the mean Weston normal cell (as defined at the Washington conference) at 20° C. in terms of the international ohm and the Bureau balances is $1{\cdot}01822_4$ (with a mean deviation of 9×10^{-6}), which is 4 in 100,000 higher than the value obtained at the National Physical Laboratory. The cause of the discrepancy is not settled.

Prof. F. T. Trouton followed with a paper on peculiarities in the adsorption of salts by silica. Starting with very dilute solutions and gradually increasing their strengths, the amount of salt adsorbed first increases fast, then more slowly (or even decreases), then more quickly again. The thickness of the layer which exhibits the anomaly is calculated as being comparable with the usually given value for the range of molecular forces.

Dr. J. W. Nicholson contributed a paper on the atomic structure of the elements, with theoretical determinations of their atomic weights, in which an attempt was made to build up all the elementary atoms out of four protyles containing, respectively, 2, 3, 4, and 5 electrons in a volume distribution of positive electricity. Representing the protyles by the symbols Cn (coronium), H (hydrogen), Nu (nebulium), Pf (protofluorine), the accompanying table indicates the deductions of the author with regard to the composition of several elements, allowance being made for the mass both of the positive and negative electrons.

Gas	Formula	Atomic weight	
		Calc.	Obs.
Helium .. .	Nu. Pf.	3·99	3·99
Argon	$5He_2$	39·88	39·88
Krypton	$5\{Nu_4(Pf.H)_3\}$	83·0	82·9
Xenon	$5\{He_4(Pf.H)_3\}$	130·29	130·2
Neon	$2(Pf.H)_3$	20·21	20·2

The coincidence between the calculated and observed values is very great, but the general attitude of those present seemed to be one of judicial pause pending the fuller presentation of the paper, stress being laid on the fact that any true scheme must ultimately give a satisfactory account of spectra. The rest of the morning was occupied with the reading of the reports of the committee for establishing a solar observatory in Australia and the committee on magnetic observations at Falmouth Observatory.

Prof. F. R. Watson contributed the results of experiments undertaken in connection with curing the echoes and reverberations in the auditorium at the University of Illinois. In accordance with theory, it is found that a broad sheet of warm air drawn over the head of the speaker and out at the rear of the auditorium acts as a partition, and more or less reflects and refracts the speaker's utterances to the audience. In the absence of the author, a paper by Mr. J. W. Gordon describing an ingenious new micrometer was taken as read.

Mr. W. H. F. Murdoch gave an exhibition and description of a friction permeameter. This is a development of one previously designed by the author. In the new form the defects of the old form are removed. Dr. J. A. Harker followed with a paper (by himself and Mr. W. F. Higgins) on the methods and apparatus used in petroleum testing. He stated that it is well known that the Abel-Pensky apparatus gives a higher result for the same oil than the Abel. The results of experiments made at the National Physical Laboratory by the authors show that large differences of temperature exist throughout the oil cup and vapour space above it at any stage during an experiment amounting to 5° F. or more, and they are different in the different types of apparatus. The size of the test flame is also shown to be of importance. The difference of temperature in the two types is found to be due to the cover in the Abel-Pensky form containing much more metal, and therefore requiring longer to warm up.

The proceedings on Monday, September 4, began with a joint discussion with Section G on mechanical flight. A special article on this discussion has appeared elsewhere in this journal, and consequently it will not be further mentioned here.

Corpuscular Radiation.

A discussion was opened by an extremely lucid and persuasive paper by Prof. W. H. Bragg on corpuscular radiation. Such radiation he defined as consisting of entities or "quanta" each moving in a straight line with uniform velocity and unchanging properties unless impressed forces cause a change. The α and β rays are corpuscular, but not sound or light as ordinarily conceived. With regard to X (and γ) rays, it must be observed that the speed and direction of a β ray produced by an X-ray depend on the quality of the X-ray and not on the nature of the atom. The energy of the β ray, therefore, cannot come from the atom; nor yet can it be the result of the accumulation in the atom of energy extracted from many X-rays, for it can hardly be supposed that the accession of the last infinitesimal amount of energy required would determine so effectively the direction in which the β ray is ejected. Therefore one X-ray provides the energy for one β ray, and *vice versa*, and Whiddington's results show that very little energy is lost in the transformation. Again, since the speed of the secondary β ray is independent of the distance which the X-ray has travelled, the latter cannot diffuse its energy as it proceeds. Again, X-rays can excite X-rays of less, but not greater, penetrating power than themselves; and they must have arisen from β rays of energy exceeding a certain limit, viz. that characteristic of the X-corpuscle of that substance. The spreading pulse of Stokes and the kink in a tube of force (Thomson) fail to account for these facts; only a corpuscular theory will do this. Prof. Bragg's working model of such a corpuscle is a "neutral pair."

Sir Wm. Ramsay in the ensuing discussion asked whether a similar explanation might not account for the sun remaining hot so long, assuming it only sends out radiations in the directions for which a body exists to receive them. He also directed attention to experiments of his own in which radium enclosed in a glass tube surrounded by a second vessel gradually excited radio-activity in the latter. If the outer vessel is dissolved, an active substance can be chemically precipitated. His own theory is that the β rays shot out from the radium excite an actual chemical change in which a radio-active substance is produced.

Dr. Lindemann suggested that a crucial test between corpuscular and wave theory is supplied by the value of radiation pressure being twice as great on the corpuscular theory, but the reply came that the pressure is too small to be measured at present. Pulses of genuine delight ran through the meeting while Prof. Bragg expounded his views, and it was clear that many were impressed by the cogency of his arguments.

In a paper on the dependence of the spectrum of an element on its atomic weight, Prof. W. M. Hicks showed how to represent by formulæ the lines of a spectrum which are related to the well-known series in the same way as the second or third set of a doublet or triplet series depends on the first, or as the satellite lines of a D series depend on the more intense set. Examples were given from the sharp series of Mg, Ca, and Sr, but the other series show similar connections. In the absence of Major E. H. Hills a paper by him on the arc spectra of certain metals in the infra-red (λ 7600 to λ 10,000) was taken as read. This paper details the results of measurements made on photographic plates coated with a collodio-bromide emulsion, as originally used by Abney in 1880. Measurements by others have usually been made with a thermopile or bolometer.

Dr. Harker read a paper, on behalf of Mr. H. C. Greenwood, outlining an investigation on specific heats of metals, especially in the neighbourhood of their melting points, and determinations of the latent heat of fusion. The metals dealt with in this paper are aluminium and zinc.

The first paper read on Wednesday was by Mr. H. Davies, on the laws of solution. Mr. Davies showed how the formula of Rudolphi, which had been suggested to represent the cases where Ostwald's law of dilution breaks down, can be placed upon a theoretical basis. Hitherto it has been held as a purely empirical formula (see in relation to this subject the address of the president of Section B, NATURE, p. 297). Mr. Davies's contribution is of great importance to the physical chemist, inasmuch as it elucidates "the outstanding practical problem in the domain of electrolytic solutions."

Prof. P. V. Bevan contributed a paper on anomalous dispersion and solar phenomena. If light from a non-uniform source, such as an arc light, be sent through a tube containing non-homogeneous vapour of a metal which can show anomalous dispersion, and then an image of the source be focussed on the slit of a spectroscope, an apparent double reversal of certain lines may be produced. An explanation is given based upon the bright images of the two poles of the arc being formed on a darker background of light which has come from elsewhere through the vapour; the essence of the explanation is that the source shall be non-uniform. It was suggested that such apparent reversals might have a bearing upon solar phenomena.

LINKS WITH THE PAST IN THE PLANT WORLD.[1]

UNDER the heading "Links with the Past," several letters were published in *The Times* rather more than a year ago in which the writers gave instances of human longevity, showing how in certain cases a chain of a very few individuals suffices to connect the present with a comparatively remote past. One writer, for example, said that his grandmother, who died about forty years ago, used to boast that her grandfather was twelve years old when Charles I. was beheaded. Striking as such instances are when applied to man, on the other hand they serve to illustrate the relative insignificance of the length of time represented by human lives as contrasted with the duration of many forest trees. It is probably not an exaggeration to say that a single oak tree may form a link between the present day and the Norman Conquest; a very short series of ancestors suffices to carry us back to the days when the progress of the Roman invaders was seriously impeded by dense forests, which have long since disappeared, and farther back to the age of Neolithic man, whose flint implements are occasionally met with in the submerged forests round our coasts.

It would be interesting, if time permitted and my knowledge were adequate, to consider some of our forest trees from the point of view of their past history. The great majority of existing woods in Britain are the result of cultivation, and do not come within our purview in dealing with links with a remote past. Moreover, many of our familiar British trees, such as the common elm, the lime, the chestnuts, and others, have no claim to be classed as native, but were introduced in Roman or post-Roman days. In a few places in Inverness-shire and Perthshire patches of primæval forest survive; one of them is represented by the group of Scots pines growing in the Black Wood of Rannoch, in north-west Perthshire. Excavations in the Scotch peat-moors have revealed a succession of forests and wet moorland; in some places, *e.g.* in the Outer Hebrides, these buried forests occur in districts which are now almost treeless. As shown in sections recently published by Dr. Lewis, a cutting through 20 or 30 feet of Highland peat gives us an epitome of the changing physical and climatic conditions from the close of the Glacial period to the present day. The remains of Arctic willows, the crowberry (*Empetrum nigrum*), and other northern species immediately above the glacial deposits testify to the influence of the Ice age. The Arctic plants are succeeded by vegetation indicative of a milder climate; layers of bog-moss and stumps of pines point to an alternation of forests and wet moorland.

The spruce fir, one of our best known trees, affords an example of a species which was once a native, but is no longer found in a wild state. The cone of the spruce fir shown on the screen was recently recorded by Mr. and Mrs. Clement Reid, together with the seeds and fruits of many other plants, from deposits on the Norfolk and Suffolk coast which were formed shortly before the Glacial period. The plants of this pre-glacial flora indicate a temperate climate, but the nearer approach of more severe conditions is shown by the Arctic willow and dwarf birch which have been found in beds next above those containing the spruce fir.

The occurrence of the Glacial period is a fact of primary importance in relation to the antiquity of the present flora of this country. We know that Britain in comparatively recent times, speaking geologically, was in very much the same condition as Greenland is to-day. Over nearly the whole of Scotland, Ireland, Wales, and England, with the exception of a narrow strip in the south, there is clear evidence of ice action on a large scale and of the presence of ice-sheets and local glaciers. Under these Arctic conditions it can hardly be doubted that only a very small proportion of the vegetation could survive. Opinions differ as to the extent to which the Ice age proved fatal to the pre-glacial flora, but it is perhaps not too much to say that the present flora, as a whole, is of post-glacial date. The vegetation which grew in this part of Europe before the Glacial period reached its maximum must have been in great measure destroyed or driven south beyond the British area. The important point is that what we call our native flowering plants may safely be described in general terms as immigrants from other lands, aided, it may be, by land-connections across the North Sea and English Channel.

Special interest attaches to a few plants which occur in the west and south of Ireland, and to a less extent in Cornwall and elsewhere in the south-west of England. In Connemara in the west of Ireland, where hard frosts are unknown and winter snows rare, there are three kinds of heath, St. Dabeoc's heath (*Dabeocia polifolia*), the Mediterranean heath (*Erica mediterranea*), and *Erica Mackaii*, which are not found elsewhere in the British Isles or in the whole of northern Europe, but reappear in the Pyrenees. The London pride (*Saxifraga umbrosa*), another Pyrenean species, grows on the south and west coasts of Ireland from Waterford to Donegal. *Arbutus Unedo* (the strawberry tree), scattered through the Killarney woods, has a wide distribution in the Mediterranean region, its nearest continental station being in the south-west of France.

The presence of this small group of Mediterranean and Lusitanian plants in Ireland has long been a puzzle to naturalists. A few years ago I came across a solution to the problem of these southern plants in Ireland in a collection of stories entitled "A Child's Book of Saints." An Irish monk, Bresal, was sent to teach the brethren in a Spanish monastery the music of Irish choirs. In later years he longed for a sight of his native land, to which he at length returned; his thoughts reverted to Spain, and he saw once more the little white flowers of the Saxifrage and the strawberry tree from which he had gathered the orange-scarlet berries. With heavenly vision the prior of the Spanish monastery, seeing Bresal gazing at the flowers of Spain, commanded them to go and make real his dream. Thus, to gladden the heart of the monk, were these southern plants miraculously introduced into Ireland.

One view is that Arbutus and its companions are entitled to be regarded as a very old section of the British flora, survivals from a time, the so-called Tertiary period, when the climate was much milder than it is to-day. It is believed by some authorities that these plants migrated from Portugal to Ireland long before the Glacial period, and by means of a land-bridge, which afterwards sank below the waters of the Atlantic Ocean. This explanation is open to criticism; even granting the former existence of a land-connection, it is difficult to believe that the strawberry tree, which is restricted to one of the warmest districts in the British Isles, could have survived the rigours of the Glacial period. Moreover, as Mr. Clement

[1] Evening discourse delivered before the British Association at Portsmouth on September 4 by Prof. A. C. Seward, F.R.S.

Reid asks, why do we not also find in Ireland Portugal laurels and oaks, which are hardier than Arbutus? An alternative view is that Arbutus and its compatriots came to Ireland *after* the Glacial period, not by migration overland, but by natural means of dispersal, which would be favoured by the small size of their seeds as contrasted with the larger seeds of oaks and other southern plants, which never reached our shores.

The possibilities of plant dispersal by natural agencies have recently received a striking demonstration in the recolonisation of the island of Krakatau, in the Sunda Straits. In 1883 Krakatau, then covered with a dense tropical vegetation, was partially destroyed by a series of exceptionally violent volcanic explosions. It is believed that no vestige of life remained. In 1906, twenty-three years after the sterilisation of the island, 137 species of plants were collected, and the vegetation was in places so dense that a party of botanists penetrated with the greatest difficulty beyond the coastal belt. Some of the trees had reached a height of 50 feet. The nearest islands, except the small island of Sebesi, about twelve miles distant, are Java and Sumatra, separated from Krakatau by a stretch of water twenty-five miles in breadth. This new flora, introduced by ocean currents, by wind, and by the agency of birds, affords a useful object-lesson in regard to the efficiency of plant-dispersal without the aid of land-connections.

Before passing to the consideration of questions necessitating frequent reference to different periods of geological history, it is essential to direct attention to the sequence of chapters as revealed by the earth's crust. It is from the scanty records of plant life preserved in the sedimentary deposits of former ages that we obtain such evidence as we have in regard to the relative antiquity of different types. The crust of the earth, as Darwin wrote, "with its imbedded remains, must not be looked at as a well-filled museum, but as a poor collection made at hazard and at rare intervals."

The oldest rocks, largely composed of gneisses and other products of igneous action, throw no light on the nature of the organisms which existed in the earliest epochs of the earth's history. The complex structure of the oldest known animals and plants compels us to believe that they are the descendants of simpler forms of much greater antiquity. As the Cambridge professor of modern history has aptly said, "All the epochs of the Past are only a few of the front carriages, and probably the least wonderful, in the van of an interminable procession." The foundation-stones of the earth's crust have been so much folded and altered in the course of geological time that it is no wonder they have been searched in vain for records of primitive life. Passing higher up the series through the vast thickness of Cambrian, Ordovician, and Silurian strata, it is in the Devonian rocks of Ireland and elsewhere that we first discover the records of Palæozoic floras, and these bear a fairly close resemblance to the still richer floras of the succeeding Carboniferous epoch.

Turning, now, to the top of the geological series, the submerged forests round our coasts and the tree-stumps buried in peat form connecting links between existing plants and those of a prehistoric age. A little further down occur the Boulder Clay and other legacies from the Glacial period, and below these are the fragmentary relics of a pre-glacial vegetation. Further down the plants become less familiar and show a closer agreement with those of subtropical and tropical countries than with the recent vegetation of Britain. From the London Clay, a marine deposit, which underlies London and Portsmouth, and is exposed in the Isle of Wight, the Isle of Sheppey, and in other places, fossil seeds and fruits have been found practically identical with those of existing tropical species. One of the London Clay fruits may be mentioned as an especially interesting sample of the early Tertiary flora, namely, the genus Nipadites, so called because of the very close resemblance it bears to the fruits of the common tropical plant Nipa. *Nipa fruticans*, often described as a stemless palm, grows in the brackish estuaries of many tropical countries. The occurrence of fossil fruits of this type in Tertiary beds in England, Belgium, and France affords a striking instance of changes in the distribution of an ancient plant now restricted to warmer regions.

Below the Tertiary rocks we descend to the Chalk period, when a clear and comparatively deep sea covered the areas now occupied by chalk downs and cliffs. "During the Chalk period," as Huxley wrote, "not one of the present great physical features of the globe was in existence. Our great mountain ranges, Pyrenees, Alps, Himalayas, Andes, have all been upheaved since the Chalk was deposited." Below the Chalk in the Weald district of Kent and Sussex a rich Wealden flora has been discovered in sediments laid down in a shallow lake which occupied the south of England and extended across what is now the English Channel. The Wealden plant-beds have as yet furnished no satisfactory specimen of a flowering plant. It is one of the most interesting facts in the history of the vegetable kingdom that the highest class of plants which now overspreads almost the whole world did not come into prominence until after the close of the Wealden period. When, in the course of evolution, the flowering plant became a competitor in the struggle for existence, it spread with amazing rapidity.

The sandstones and shales in the Yorkshire cliffs and slightly older rocks on the Dorsetshire coast have supplied data which enable us to reconstruct in some measure the vegetation of that stage in the earth's history known as the Jurassic period. Below the Jurassic strata in some parts of the world, as in the south of Sweden, Germany, and elsewhere, from rocks of Rhætic age numerous fossil plants have been obtained. Descending further, the plant records from strata belonging to the early days of the Triassic period afford evidence of changes in the nature of the vegetation, which become more pronounced in the still older Permian and Carboniferous floras. It is, however, not my intention to deal with the vegetation of the coal forests and other Palæozoic floras; they are composed of plants for the most part much less closely related to existing types than those which I have selected as examples of links with the past.

Probably the human race made its entrance on to the world's stage at some time during the Tertiary period; but in Britain abundant evidence of man's presence is not met with until after the Glacial period. An additional illustration of the enormous antiquity of some of the plants to be described later is furnished by the absence of flowering plants in the rich floras below, or even including, those of Wealden age.

The widely distributed class of ferns supplies some notable instances of links with the past. It is not infrequently the case that plants which are now characterised by a restricted geographical range have a wide range in time, and, conversely, plants which are now more or less cosmopolitan may be of comparatively recent origin. Antiquity and restricted distribution often go together. The bracken fern, which we are apt to regard as essentially British, occurs also in Tasmania, in the Malay Peninsula, in British East Africa, in the Himalayas, and in many other countries; it is one of the most cosmopolitan of all living ferns. It would seem probable that this injurious species is one of the more modern members of its class. On the other hand, the family to which the royal fern (*Osmunda regalis*) belongs, though widely spread at the present day, has been traced into the Palæozoic era. The recent researches of Dr. Kidston and Prof. Gwynne Vaughan have demonstrated the existence in the Permian flora of Russia of ferns exhibiting a close relationship to existing members of the Osmunda family. The section shown on the screen was cut from a petrified fern stem of Permian age, which shows in its anatomical characters a remarkable resemblance to a stem of Osmunda. Some of the commonest fern leaves in the Jurassic rocks of Yorkshire and in many other parts of the world, both north and south of the equator, may be referred with a considerable degree of certainty to the Osmunda family, the relationship being indicated, not by mere external resemblance, but by the structure of the spore-capsules, and in a few cases by the occurrence of petrified stems. It is by no means improbable that the royal fern and other existing members of the family are entitled to the distinction of an ancestry which extends farther back into geological time than that of any other section of living ferns.

The next example of an old type of fern is one which is widely spread in the warmer regions of both the Old and New World. Gleichenia may, as a rule, be easily recognised by the regular forked branching of the fronds, as also by the structure of its spore-capsules and by the anatomy of its stem. Fragments of fronds hardly distinguishable from those of some surviving species have been found in Upper Jurassic rocks on the Sutherland coast and in Wealden strata on the Continent. In rocks of Wealden age near Brussels, pieces of stems have been discovered by Prof. Bommer sufficiently well preserved to be submitted to microscopic examination, and showing anatomical features exactly like those of the living species. The occurrence of numerous Gleichenia fronds in sedimentary rocks of Lower Cretaceous age near the edge of the Greenland ice-sheet on Disco Island, in lat. 70° N., points to climatic conditions very different from those which now prevail. This is one of many instances revealed by a study of ancient floras of remarkable changes in geographical distribution as in climate. Gleichenia, like many other plants which have long ceased to exist in Europe, was formerly a common northern genus, and may have had its origin in the far north, whence it was driven by adverse conditions to seek a home in more congenial surroundings.

The fern genus Matonia is now represented by two species in the Malay region; one of them was discovered a few years ago by Mr. Hose in a locality in Borneo, and has not been found elsewhere; the other and better known species, *Matonia pectinata*, occurs in the Malay Peninsula and on the mountains of Borneo. It is a fern with a creeping stem, from which are given off large spreading fronds borne on slender stalks reaching a height of 6 to 8 feet. It is recognised by the shape of the leaf and by other more important characters, notably by the structure of its stem, in which it differs from all other members of the fern class.

Its isolated position among the ferns and its limited geographical range are in themselves suggestive of antiquity. The records of the rocks abundantly confirm this inference. Fossil fern leaves closely resembling those of *Matonia pectinata* occur in strata of Rhætic age in Germany and in other parts of the world. In England this type has been found in the Jurassic beds on the Yorkshire coast and in Wealden strata not far from Hastings. From Wealden rocks in Belgium pieces of stems have been obtained exhibiting anatomical features identical with those of the recent species. Fronds practically identical with those of the Malayan fern are recorded from an Austrian locality from rocks higher in the Cretaceous series, but no satisfactory evidence is available of the persistence of the Matonia family in Europe or in the northern hemisphere during the latest phase of the Cretaceous or throughout the whole of the Tertiary period. The existing species of Matonia are the last survivors of a family which once flourished over a wide area in Europe and extended to the other side of the Atlantic. Exposed to unfavourable climatic conditions, and possibly affected by the revolution in the plant-world consequent on the appearance of the flowering plants, Matonia gradually retreated across the equator until this "living fossil" found a last retreat in Malaya, the home of not a few links with a remote past.

Brief reference may be made to another fern, the genus Dipteris, which grows in association with Matonia on Mt. Ophir and elsewhere in the Malay Peninsula. Dipteris is represented by more species and has a wider geographical range than Matonia; it occurs in northern India, central China, in New Caledonia, and other islands. The fronds are distinguished by their long, deeply cut segments, spreading from the top of a slender stalk. In the Rhætic plant-beds of northern and central Europe, North America, Tonkin, and elsewhere, numerous fossil leaves have been discovered which bear a close resemblance to existing species of Dipteris. Similar fronds have been found in the Jurassic rocks on the Yorkshire coast and in Sutherland. It is impossible to say with confidence how nearly these Jurassic ferns are related to the existing species, but there can be no reasonable doubt that Dipteris, like Matonia, is a fern which connects the present with a past too far off to be measured by ordinary standards of time.

The large class of plants known as the conifers—though the name is in certain cases a misnomer, as some members bear no cones—including the pines, larches, firs, and several other trees, has a very much longer past history than the flowering plants. In rocks of all ages down to the Upper Palæozoic strata the remains of leafy shoots, pieces of petrified wood, seeds, and cones are abundant fossils, but the difficulty is to piece together the *disjecta membra* and to determine the degree of relationship between the extinct and the living.

I will confine myself to two genera of conifers which are especially noteworthy as persistent types—plants, like the fern Matonia, which formerly played a much more conspicuous *rôle* in the world's vegetation than they do now. Everyone is familiar with the Californian trees known as Sequoia or Wellingtonia.

The redwood, *Sequoia sempervirens*, occupies a narrow belt of country, rarely more than twenty or thirty miles from the coast, 300 miles long from Monterey in the south to the frontiers of Oregon. The tapering trunk, rising to a height of more than 300 feet, gives off short horizontal branches thickly set with narrow leaves dispersed in two ranks, as in the yew. The female flowers have the form of oblong cones from three-quarters to one inch long, and each woody cone-scale bears several small seeds on its upper surface. The second and more familiar species, *S. gigantea*, the mammoth tree, which is commonly cultivated in this country, has an even more restricted range, being confined to groves on the western slopes of the Sierra Nevada between 3000 to 9000 feet above sea-level. This species is at once distinguished from the redwood by its stiff, sharply pointed and scale-like leaves, and by its rather larger cones.

In the British Museum there is a section of a mammoth tree which shows on its polished surface 1335 rings of growth. On the assumption that each ring marks a year's growth, the tree when felled in 1890 was 1335 years old, and when Charles the Great was crowned Emperor at Rome it had already flourished for more than 200 years. These two giant conifers, remarkable as being probably the tallest trees in the world, become even more impressive when we know something of their past. The investigation of the herbaria buried in the earth's crust reveals the occurrence of similar, and in some cases apparently identical, species in many parts of Europe and in American localities far from their present home. It has been demonstrated that the big trees of California are the survivors of a once vigorous family which formerly flourished in many parts of the Old World, but as the result of altered circumstances, changed physical conditions, or unequal competition with other types in the struggle for life, dwindled in numbers and narrowly escaped extinction.

At Bovey Tracey in Devonshire there is a basin-shaped depression in the granitic rocks of Dartmoor filled with clay, gravel, and sand—the flood-deposits of a Tertiary lake containing the waifs and strays of the vegetation from the surrounding hills. Among the commonest plants is one to which the late Oswald Heer gave the name *Sequoia Couttsiae*, and his reference of the specimens to Sequoia has recently been confirmed by the researches of Mr. and Mrs. Clement Reid. This Tertiary species is represented by slender twigs almost identical with those of *S. gigantea* and by well-preserved cone-scales and seeds. Moreover, it has been possible to examine microscopically the carbonised outer skin of the leaves, and to demonstrate its close agreement with that of the superficial tissue in the leaves of the Californian tree. With the Bovey Tracey Sequoia are associated fragments of Magnolia, Vitis, the swamp cypress of North America, as well as other types which have long ceased to exist in the British Isles. Twigs and cones identified as those of Sequoia are recorded from several continental districts from both Cretaceous and Tertiary strata. The genus occurs in abundance in Tertiary beds on Disco Island and in Spitsbergen. Dr. Nathorst has obtained specimens from the Arctic Ellesmere Land almost as perfect as herbarium specimens. Remains of Sequoia have been found also in Tertiary rocks on the banks of the Mackenzie River, in Alaska, Saghalien Island, Vancouver Island, and elsewhere.

One of the most remarkable instances of the preservation of trees of a bygone age is supplied by the volcanic strata of Lower Tertiary age exposed on the slopes of Amethyst Mountain, in the Yellowstone Park district. At different levels in the 2000 feet of strata as many as fifteen forests are represented by erect and prostrate trunks of petrified trees. The microscopical examination of some of these trees shows that they bear a close resemblance to *S. sempervirens.* In a photograph given to me by Dr. Knowlton, of Washington, one sees living conifers of other genera side by side with the lichen-covered and weathered trunks of the fossil Sequoia, contiguous but separated in time by millions of years. From Cretaceous rocks of South Nevada, not very far from the present home of Sequoia, petrified wood has been described possessing the anatomical characters of the mammoth tree. While there is little doubt that Sequoia formerly had its maximum distribution in the northern hemisphere, there is some evidence, though not conclusive, that the genus once existed in Madagascar and in New Zealand.

The Araucaria Family.

Another and even more venerable section of the conifers is represented by the Araucaria family, which includes two genera, Araucaria and Agathis. The best known species of Agathis, or Dammara as it is sometimes called, is the Kauri pine, probably the finest forest tree in New Zealand. The stems reach a height of 160 feet, terminating in tiers of spreading branches bearing thick and narrow leaves 2 to 3 inches long. The almost spherical cones consist of a central axis bearing overlapping, broadly triangular scales, each of which carries a single winged seed. Other species of Agathis occur in the Malay Archipelago, the Philippines, Queensland, and elsewhere. The genus Araucaria, with the exception of the familiar Monkey Puzzle (*Araucaria imbricata*) and a Brazilian species, is confined within the geographical area occupied by Agathis. In addition to the Monkey Puzzle, introduced into England in 1796 from Chile, the Norfolk Island pine (*A. excelsa*) is a commonly cultivated pot-plant in this country; it was introduced to Kew in 1793 by Sir Joseph Banks soon after its discovery by Captain Cook.

Before we consider the past history of the Araucaria family, a word must be added in regard to the characters which enable us to recognise Araucaria and Agathis in a fossil state. The wood of these two genera differs in certain minute structural features from that of other conifers; the examination of a radial longitudinal section of a branch of one of the Araucarias under a microscope shows on the walls of the elongated tubular elements of which the wood consists small polygonal areas technically known as bordered pits; these occur in one or more rows, and may be described as circles converted into polygons by mutual pressure. In pines and other conifers these bordered pits are circular or oval in form, and not, as a rule, contiguous. The foliage shoots of Araucaria, though fairly distinctive in the form and arrangement of the leaves, may be confused with branches of other genera, and are in themselves of secondary importance for diagnostic purposes. On the other hand, the seed-bearing scales of the large cones afford much more trustworthy means of identification; each scale bears a single seed either immersed in the scale or lying in the middle of its upper face. In other conifers two or more seeds occur on each scale. It is not possible as yet to give a definite answer to the question: How far into the past can we trace the direct ancestors of existing species of Araucaria and Agathis?

From Permian and Upper Carboniferous rocks foliage shoots have been obtained almost identical in form with those of the Norfolk Island pine, and there is other evidence of a more satisfactory kind pointing to the probable existence in Palæozoic floras of trees closely akin to Araucaria. Araucarian types are recorded from Triassic strata, but from rocks of Jurassic age Araucarian cones and seed-bearing seeds, together with wood and foliage shoots, have been found in greater abundance. Petrified wood practically identical with that of the living species is recorded from Lower Jurassic rocks at Whitby, and there is reason to believe that some of the Whitby jet owes its origin to Araucarian wood.

A good example of a cone agreeing closely in structure, as in size, with the cones of some species of Araucaria was described in 1866 by Mr. Carruthers from Jurassic rocks at Bruton, in Somersetshire. Cone-scales exhibiting the characteristic features of Araucaria have been found in the Middle Jurassic rocks of Yorkshire, in Jurassic rocks of north-east Scotland, Cape Colony, Australia, India, and in the eastern States of North America. In a collection of Jurassic plants obtained a few years ago by members of a Swedish Antarctic expedition in Graham's Land, Dr. Nathorst has recognised some seed-scales of the Araucarian type. As we ascend the geological series and pass into Cretaceous strata, evidence of the wide distribution of the Araucarieæ is still abundant. Araucarian wood has been discovered in Cretaceous rocks in Egypt, East Africa, Dakota, and elsewhere; and from beds of this age in New Jersey Prof. Jeffrey and Dr. Hollich have recently described several different types of fossils represented by petrified leafy shoots and cone-seeds, some of which are closely allied to Araucaria, while others are nearer to Agathis.

In Tertiary floras undoubted Araucarian species are less common; it is not improbable that some foliage shoots from the plant-beds of Bournemouth, described by Mr. Starkie Gardner as Araucaria, may belong to a species nearly related to the Norfolk Island pine. From the extreme south of South America Araucarian wood and branches have recently been recorded, and, at the other end of the world, Tertiary rocks on the west coast of Greenland have yielded fragments which, with some hesitation, may be classed as Araucarian.

One conclusion, which seems almost unavoidable, is that the species of Araucaria and Agathis which survive in South America and in the islands of the Pacific have in the course of successive ages wandered from the other end of the world. We can only speculate as to the causes which have contributed to the changes in the fortunes of the family; but one thing is certain, namely, that few existing plants are better entitled to veneration as survivors from the past than are the Monkey Puzzle and other species of Araucaria.

The Maiden-hair Tree.

In recent years the maiden-hair tree of China and Japan, introduced into Europe early in the eighteenth century, has become fairly well known in English gardens. There is probably no other existing tree with so strong a claim to be styled a "living fossil," to use one of Darwin's terms. In 1712 the traveller Kaempfer proposed for this plant the generic name Ginkgo, and Linnæus adopted this designation, adding the specific name *biloba* to denote the characteristic bisection of the wedge-shaped lamina of the leaf into two divergent segments. In 1777 the English botanist Sir J. E. Smith expressed his disapproval of what he called the uncouth name Ginkgo by substituting the title *Salisburia adiantifolia*; but the correct botanical name is *Ginkgo biloba*. In its pyramidal habit Ginkgo agrees generally with the larch and other conifers; its leaves, which are shed every year, are similar in form and venation to the large leaflets of some maiden-hair ferns. The seeds, borne on fairly long stalks, are enclosed in a thick green flesh, and in appearance resemble small plums. For many years Ginkgo has been recognised by botanists as an isolated and probably ancient type. It used to be placed near the yew among the conifers; but in 1896 a Japanese botanist, Hirase, made the important discovery that the male reproductive cells of the maiden-hair tree are characterised by the possession of innumerable cilia which enable them to swim in fluid like the male cells of ferns and many other plants. In the true conifers the male cells have entirely lost the power of independent movement. Without going into details, the important point is that Hirase's discovery confirmed suspicions based on other characters, that Ginkgo was not a true member of the conifers, and supplied a cogent reason for promoting it to a class of its own, the Ginkgoales.

Though some travellers in China have spoken of Ginkgo trees in a wild state, the balance of opinion is in favour of regarding the genus as represented at the present day solely by cultivated specimens. China was, no doubt, its last stronghold; in that country, as in Japan, it is regarded as a sacred tree, and planted in the groves of temples, and it would seem that the fact of its being held in veneration by the priests has saved it from extinction.

As in many other cases, so in regard to Ginkgo we cannot speak with certainty as to its first appearance in the world's vegetation. Leaves constructed on a similar plan have been found in Permian, Carboniferous, and Upper Devonian rocks in England, Germany, France, the Arctic regions, South Africa, Kashmir, the Ural Mountains, and elsewhere, but we still lack decisive evidence as to the systematic position of these plants.

It is, however, an undisputed fact that the maiden-hair tree is connected by a long line of ancestors with the earliest phase of the Mesozoic epoch. From many parts of the world large collections of fossil plants have been obtained from strata referred to the Rhætic period or to the upper divisions of the Triassic system. The vegetation in those far-off days, extending from Australia, Cape Colony, and South America to Tonkin, the south of Sweden and North America, was much more uniform in character than is the case with widely separated floras at the present day. One of the most widely spread plants in this vegetation is one known as Baiera, which possessed leaves differing only in the greater number and smaller breadth of their segments from those of the maiden-hair tree. In the later Jurassic rocks of Yorkshire true Ginkgo leaves, as well as those of Baiera, are fairly common, and a few fragments of flowers have also been found. Both genera are recorded from Jurassic rocks of Germany, France, Russia, Bornholm, and elsewhere in Europe; they occur abundantly in Siberia, and are represented in the Jurassic floras of Franz Josef Land, the east coast of Greenland, and Spitsbergen.

The abundance of fossil Ginkgo leaves and seeds in Jurassic strata in East Siberia has led to the suggestion that this region may have been a centre where the Gingkoales reached their maximum development in the Mesozoic period. The occurrence of fossil species in the Jurassic rocks of King Charles Land (78° N.) and in the New Siberian Islands (75° N.), in central China, Japan, Turkestan, California, South Africa, Australia, and Graham's Land, demonstrates the cosmopolitan nature of the group. During the Tertiary period Ginkgo flourished in North America, in Alaska, and in the Mackenzie River district, Greenland, Saghalien Island, and in several European regions. In the Island of Mull beautifully preserved leaves of Ginkgo, indistinguishable from those of the living tree, have been found in sediments deposited on the floor of a lake during a pause in the volcanic activity which in the early days of the Tertiary era produced the thick series of basaltic rocks to which is due the characteristic contour of the Inner Hebrides.

The recent cultivation in Britain of the maiden-hair tree is thus a reintroduction of a plant which formerly flourished in this part of Europe. Where and when this genus first appeared, and why a type once so vigorous has narrowly escaped extinction, are questions which we cannot answer with confidence; we are, however, certain that the maiden-hair tree links the present with a past inconceivably remote; it is a tree "sacred with many a mystery," antedating by millions of years the advent of man and far surpassing the flowering plants in antiquity.

As we search through the fragmentary records scattered through the sediments of former ages, we discover evidence of a shifting of the balance of power among different classes of plants. Plants now insignificant or few in number are found to be descendants of a long line of ancestors stretching back to remote antiquity. Others which flourished in a former period no longer survive. We can only speculate vaguely as to the cause of success or failure. As Darwin said, "We need not marvel at extinction; if we must marvel, let it be at our own presumption in imagining for a moment that we understand the many complex contingencies on which the existence of each species depends."

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—Dr. J. D. Falconer, late principal officer of the Mineral Survey of Northern Nigeria, and formerly assistant to Prof. James Geikie, has been appointed to the lectureship in geography, vacated by Captain Lyons, F.R.S.

Mr. J. S. Dunkerley has been appointed a university lecturer in zoology, with special reference to protozoology. Dr. Carl H. Browning, hitherto lecturer in bacteriology, has been appointed lecturer in clinical pathology and director of the new clinical laboratory at the Western Infirmary. Dr. A. Maitland Ramsay has been appointed university lecturer in ophthalmology. Principal Sir Donald MacAlister, K.C.B., has been appointed a member of the executive committee of the Carnegie Trust for the Universities of Scotland in succession to Prof. William Stewart, resigned.

His Majesty in Council has approved a new Ordinance, whereby geography is added to the subjects which may be offered in the final examination for the B.Sc. degree.

LONDON.—An appeal has been issued, with the authority of the Senate, for funds to build the Francis Galton Laboratory at an estimated cost of 15,000*l*. As stated in an article in NATURE of March 16, Sir Francis Galton in his will expressed a hope that his bequest for the promotion of eugenics, amounting to about 45,000*l*., would not be used for the provision of buildings, fittings, or library. The income is accordingly being used for the salaries of the professor (Karl Pearson, F.R.S.) and his staff. A site for the proposed laboratory has been allocated by the University at University College, and sketch plans, prepared by Prof. Simpson, are printed with the appeal showing adequate accommodation for lecture-room, museum, research laboratories for eugenics and biometry, together with a room for Galtoniana. The appeal directs attention to the importance of the work to be carried on in the laboratory in relation to future legislation dealing with social problems. "It is essential that the statistical facts on which such legislation may be based shall be analysed in a purely scientific manner by workers who can give time and energy to investigation, quite independently of any ulterior end or party bias." Already the laboratory, in spite of the difficulties due to inadequate accommodation, is carrying out on a considerable scale the founder's wish to "provide information, under appropriate restrictions, to private individuals and to public authorities." Contributions and promises of support will be gratefully received by Sir Edward Busk, chairman of the Galton Laboratory Committee, at the University.

SIX lectures on "The Causes and Economic Effects of Changes in the General Level of Prices" (illustrated from the history of the nineteenth century) are being delivered by Mr. W. T. Layton at University College (University of London) on Tuesdays at 5.30 p.m., the first having been given on October 10 The lectures are open to the public without fee or ticket.

A SPECIAL course of twelve lectures, dealing with illumination, will be delivered at Battersea Polytechnic during the coming session, the first six being delivered on Tuesday evenings, beginning on October 17, and the last six on Fridays, commencing January 12, 1912. The course will be open to students and all interested in the subject. The course will deal with all illuminants, including electric, gas, oil, and acetylene lighting, the effect of light on the eye and the hygienic aspects of illumination, the measurement of light and illumination, &c. Practical problems, such as the lighting of schools, streets, factories, &c., will also be treated. The lecturers will be Prof. J. T. Morris, Mr. J. G. Clark, Mr. E. Scott-Snell, Dr. W. J. Ettles, and Mr J. S. Dow.

ADDITIONAL buildings of the Royal Albert Memorial University College, Exeter, will be formally opened by the Lord-Lieutenant of Devon, the Earl Fortescue, on Friday, October 20. The buildings are the first instalment of an enlargement scheme which was approved by the governors in 1904. The steady development of the college work has necessitated periodical enlargement of the building accommodation. The last extension, in 1899, was formally opened by his Royal Highness the Duke of York (now King George V.), and the previous extension, in 1895, by the late Duke of Devonshire. The present addition has been erected on a site purchased at the rear of the main building of the Royal Albert Memorial at a cost of 8675*l*. for land and about 16,400*l*. for the building. This occupies only about half of the site acquired. The new buildings consist of two blocks, one for the University College and the other for the Day Training College.

THE opening lecture of the course of instruction on "Colloids" was given by Mr. E. Hatschek at the Sir John Cass Technical Institute on Friday, October 6, when the chair was taken by Dr. Rudolf Messel, president of the Society of Chemical Industry. Mr. Hatschek commenced his lecture by referring to the early work of Thomas Graham on colloids, and then dealt with the subsequent development of the subject as a borderland study between physics and chemistry. The characteristics of colloids were then examined, and an account given of laboratory products that have been prepared and of the large number of natural organic products which can be dissolved direct to form colloidal solutions such as starch, gelatine, agar, and the albumins. The importance of the subject in relation to industrial problems was next specified, reference being made to the tanning and dyeing industries, the photographic plate and paper industry, the fermentation industries, and the treatment of effluents and sewage. At the close of the lecture an experimental demonstration of the properties and methods of preparation of some colloidal solutions was given.

AMONG the scientific lectures arranged this term for advanced students, in connection with the University of London, we notice the following. A course of eight lectures on "Principles of Systematic Botany (Flowering Plants)" will be given by Dr. C. E. Moss, curator of the herbarium, University of Cambridge, in the botanical department, University College, on Thursdays, at 5 p.m., beginning on October 19. Informal meetings for the discussion of important contributions to current meteorological literature will be held at the Meteorological Office on alternate Mondays, at 5 p.m., beginning on October 23 and ending on March 25, 1912. Students who wish to attend are requested to communicate with the Reader at the Meteorological Office. A course of eight lectures on "The Manipulation and Theory of the Microscope" is being given by Mr. J. E. Barnard at King's College, on Wednesdays, at 5 p.m. A course of four lectures on "The History of Plague" will be given by Dr. C. Creighton at the University, South Kensington, on Fridays, October 20 and 27, and November 3 and 10, at 4 p.m. In all cases the lectures are addressed to advanced students of the University and to others interested in the subjects, and the admission is free, without ticket.

SOCIETIES AND ACADEMIES.

PARIS.

Academy of Sciences, October 2.—M. Armand Gautier in the chair.—The president announced the loss, by death, of Auguste Michel-Lévy and Joseph Louis Troost.—Émile **Picard**: Continuous solutions of integral equations of the third species.—Paul **Appell**: Functions of the fourth degree.—MM. **Esclangon** and **Courty**: Observations of the Quénisset comet and of the Brooks comet made with the large equatorial (38 cm.) of Bordeaux Observatory. Dates are given for September 26, 27, and 28. The Quénisset comet appeared as a circular nebulosity of 4′ to 5′ diameter, with a clear nucleus. The tail of the Brooks comet has been visible to the naked eye since September 17.—M. **Borrelly**: Observations of the Quénisset comet (1911*f*) made at the Marseilles Observatory with the comet finder. Positions of the comet are given for September 27 and 28. It appeared to be nearly circular, about 2′ diameter, with glimpses of a small nucleus of about the twelfth magnitude.—F. **Baldet** and F. **Quénisset**: Observation of the *gegenschein*. Attention is directed to the remarkable intensity now exhibited by the *gegenschein*, or zodiacal counterglow; it is pointed out that there is no satisfactory explanation for this phenomenon.—M. **Giacobini**: Observations of the Quénisset (1911*f*) and Beljawsky (1911*g*) comets made at the Observatory of Paris with the eastern tower equatorial of 40 cm. aperture. Positions are given for September 25, 27, and 30 for the Quénisset comet, which appears as a nebulosity of sensibly elliptical shape 45″ to 50″ in extent. The nucleus is well defined, and is of the eighth magnitude. The positions of the Beljawsky comet are given for September 30 and October 1. This comet is exceptionally bright, and has a nucleus of the third magnitude. The tail is about 15° long.—D. **Pompéiu**: The functions of complex variables.—Et. **Delassus**: Non-linear linkages.—G. **Reboul** and E. Grégoire **de Bollemont**: The transport of metallic particles under the action of heat. Sheets of copper or silver, near which is placed a sheet of porcelain or another metal, give deposits on the latter when heated. The amount of metal deposited is shown to depend to some extent upon the nature of the gas between the two plates.—Auguste **Marie** and L. **MacAuliffe**: The asymmetry of the Neanderthal, Cro-Magnon, and Spy No. 1 skulls. The application of the method proposed by M. Chervin to casts from these three skulls shows that all are asymmetrical. Three diagrams are given showing the deviations observed.—Paul **Marchal** and J. **Feytaud**: A parasite of the eggs of Cochylis and Eudemis.—E. **Roubaud**: New contribution to the biological study of Glossina. Some data on the biology of *G. morsitans* and *G. tachinoides* from the Nigerian Sudan.—L. **Boutan**: Some peculiarities relating to the mode of fixing of the crustacean *Gnathia halidaii.*

NEW SOUTH WALES.

Linnean Society, July 20. — Mr. W. W. Froggatt president, in the chair.—P. **Cameron**: Parasitic Hymenoptera from the Solomon Islands, collected by Mr. W. W. Froggatt. The parasitic Hymenoptera of the Solomon Islands are practically unknown. Mr. Froggatt's collection comprised representatives of seventeen undescribed species—Chalcididæ, 2; Braconidæ, 6; Evaniidæ, 1; and Ichneumonidæ, 8.—R. J. **Tillyard**: Further notes on some rare Australian Corduliinæ, with descriptions of new species. Seven new or rare Australian Corduliinæ are dealt with. Two new genera, Lathrocordulia and Hesperocordulia, are proposed, and four new species described. One of these is the beautiful yellow and black *Hemicordulia superba* from Pallal, New South Wales. From the same locality the female of *H. intermedia*, hitherto unknown, is also described. Two fine new species sent by Mr. G. F. Berthoud, of Waroona, West Australia, viz. *Lathrocordulia metallica* and *Hespercordulia berthoudi*, form the types of two new and interesting genera, which further bridge the gap between the two main groups of the subfamily. The latter species has a bright red and black coloration, unique amongst Corduliinæ. Lastly, a female of a magnificent new Macromia, *M. viridescens*, taken at Cape York, completes the list of new species.—R. J. **Tillyard**: The genus Cordulephya. This peculiar aberrant genus, originally monotypic and far removed from all existing forms, is enlarged by the addition of a new species, *C. montana*, from the Blue Mountains. The two species, *C. pygmaea*, Selys, and *C. montana*, are described and compared, and their full life-histories given. An interesting "theory of the two broods" is offered as a solution of the differentiation between the two, which occur at different seasons of the year.

August 30.—Mr. W. W. Froggatt, president, in the chair.—Dr. T. H. **Johnston** and Dr. J. Burton **Cleland**: The Hæmatozoa of Australian reptiles, No. 2.—A. M. **Lea**: Descriptions of new species of Australian Coleoptera, part ix. The paper contains notes on some of the types of King's and Macleay's Pselaphidæ; notes on *Xylopsocus bispinosus*, Macl., a species of Bostrychidæ, of which the male protects the female during her egg-laying period, and probably for some time afterwards; and descriptions of new species of Staphylinidæ (1), Pselaphidæ (23, including a new genus), Silphidæ (9), Byrrhidæ (1), Scarabæidæ (2), Lymexylonidæ (2), Ptinidæ (7), Tenebrionidæ (2, including a new genus, with one species of blind insects, the first blind beetle to be recorded from Queensland), and Erotylidæ (1).—Dr. R. **Greig-Smith**: Contributions to a knowledge of soil fertility. No. 2. The determination of Rhizobia in the soil. From a perusal of the literature upon the fixation of nitrogen by the bacteria in the soil, one is led to believe that Azotobacter is the most active. It is not known how many of these organisms may be contained in 1 gram of soil; and, from Löhms's work, we imagine that the members of nitrogen-fixing bacteria are small. By making use of a special medium described in the paper, the author has found as many as three millions of nitrogen-fixing Rhizobia in 1 gram of agricultural soil. The foremost place in the work of nitrogen fixation should, therefore, be given to Rhizobium rather than to Azotobacter, until it is found that the latter is at least half as numerous as the former. The numbers of Rhizobia in the soil afford an indication of its comparative fertility.

Cape Town.

Royal Society of South Africa, August 16.—Mr. S. S. Hough, F.R.S., president, in the chair.—L. **Péringuey**: A note on the Heidje Eibib, or stone mound of Namaqualand. The name Heidje Eibib is usually given to artificial mounds of stone occurring in certain places in Namaqualand and elsewhere, the formation of which is ascribed to the Hottentots, who whenever passing the spot add a stone to the cairn, taking great care, however, that in so doing their shadow is not projected on the mound. But so far there was nothing to prove that these cairns were really a kind of sepulture. Lately, however, one such mound was opened, and it was found that the accumulation of stones covered parts of a body; the skull is, to all appearances, that of a Bush. But the Rev. Mr. Kling informs the author that there are two kinds of Heidje Eibib. The one opened is known as Heidje Eibib Garedje, and would be the grave of a Bush witch doctor, erected by his people. But it is not yet proved that the Hottentot's Heidje Eibib is a grave.—E. **Nevill**: The secular acceleration of the orbital motion of the moon. The paper begins with a critical examination of the records of the principal ancient eclipses of the sun mentioned as being total, or very nearly total, by different Assyrian, Babylonian, Grecian, and Chinese records. The exact conditions of each eclipse have been calculated from the best modern theoretical data according to Hansen's method of computation. As a result, it is shown that with our present knowledge it is not possible by any system of data consistent with the modern observations of the sun and moon to bring all the principal eclipses recorded by ancient authorities as having been total into accord with the tables. The second portion of the paper assumes the existence of a secular acceleration in the motion of the earth around the sun, and proceeds to consider what might be the origin, and to what degree the existence of this cause will modify the motion of the different members of the solar system, and how far the deduced consequences are in harmony with observation. It is shown that the case of the terrestrial tidal effect due to the action of the sun and moon does not form a conservative system, and that the principle of conservation of angular momentum does not hold for any non-conservative system of forces. No other origin for a secular acceleration being apparent, the great difficulty in reconciling the consequences of such a secular acceleration with the known motion of the sun and moon render it preferable to look to one of the other permissible causes as a means of reconciling the existing theories of the sun and moon with the records of the ancient eclipses of the sun and moon.—A. **Theiler**: Some observations concerning the transmission of East Coast fever by ticks. In the experiments it has been proved:—(1) That brown tick imago which as larvæ had become infected with East Coast fever, and had transmitted the disease in their nymphal stage, were no longer infective for susceptible cattle. Four batches of ticks proved their infectivity in the nymphal stage on eight animals, but in their adult stage failed to transmit the disease to two susceptible animals. (2) Ticks belonging to the same batches which were feeding on two animals rendered immune to East Coast fever by inoculation, in the nymphal stage, did not transmit the disease in their adult stage to six animals, thus proving that the brown tick which has become infected in one stage cleans itself in the following stage by feeding on an immune or susceptible animal. (3) Ticks which became infected with East Coast fever in their larval stage, and passed their nymphal stage on a rabbit, did not prove to be infective in their adult stage for susceptible cattle. This conclusion bears out that given above (2), showing that a tick loses its infectivity the first time it feeds on an animal susceptible or immune to East Coast fever. (4) Clean or infective ticks feeding on an animal which has recovered from an attack of East Coast fever do not transmit the disease in their next stage. This conclusion is in support of experiments undertaken eight years ago (*vide* Annual Report of the Government Veterinary Bacteriologist, 1904–5). (5) It has been demonstrated that certain batches of ticks collected at the same time, and which fed under similar conditions, did not transmit the disease in their next stage, even when infected in great numbers and on numerous animals. Other batches of ticks reared in exactly the same way and under similar conditions only infected a few animals, whilst again other ticks proved infective in almost every instance, even when a minimum number were used. It is difficult to give an explanation of this fact, but it is quite likely that outside conditions have some influence. The ticks which did not transmit the disease were bred during the coldest time of the year.

DIARY OF SOCIETIES.

TUESDAY, October 17.

Faraday Society, at 8.—*Adjourned discussion*: The "Paragon" Electric Furnace and Recent Developments in Metallurgy: J. Härden.—Progress in the Electrometallurgy of Iron and Steel: Donald F. Campbell.—The Hering "Pinch Effect" Furnace: E. Kilburn Scott.

WEDNESDAY, October 18.

Royal Microscopical Society, at 8.—Structural Details of *Coscinodiscus asteromphalus*: T. W. Butcher.—Abstract of Paper on the Wheat Plant: A. Flatters.—New British Enchytræids: Rev. Hilderic Friend.—Instantaneous Exposure in Photomicrography: Walter Bagshaw.
Entomological Society, at 8.

FRIDAY, October 20.

A VOLUME OF KOHLRAUSCH'S COLLECTED PAPERS.

Gesammelte Abhandlungen von Friedrich Kohlrausch. Erster Band, Elastizität, Wärme, Optik, absolute elektrische Messungen und Verschiedenes. Pp. xxxv+1108. (Leipzig: J. A. Barth, 1910.) Price 25 marks.

THE first paper contained in this collection is dated 1863, the last is dated 1909, less than six months before the author's death. Together they fill more than one thousand pages, and each of them has its own value and interest. When it is considered that the present volume contains none of the work on the conductivity of electrolytes and mobility of ions, in connection with which it is probable that the author's name is best known (the papers on these subjects being reserved for a second volume), it must be admitted that here is remarkable evidence of sustained and well-directed labour.

The half-century that was nearly covered by Kohlrausch's scientific activity was, in relation especially to magnetism and electricity, the subjects at which he chiefly worked, a period of systematising and setting in order, rather than, until near the end, of the discovery of new phenomena leading to essentially new conceptions. Even the reconstruction of electrical theory by Maxwell was based, not on new discoveries, but on a revised interpretation of well-known facts. To those whose personal memory of such things goes back to Kohlrausch's student days, the greatest and most far-reaching of the changes they have lived through must seem to be the universal recognition of the principle of the conservation of energy, and, as essential for the definite statement of this principle, the introduction of the conception of "absolute" units of measurement.

At the time of which we speak, these ideas had been formulated, but they were far from familiar, and the instrumental appliances needed for their practical application scarcely existed. Gauss's method of measuring the absolute intensity of the earth's magnetic field was beginning to find a place in German text-books, but it might be sought in vain in English or French books. A tangent-galvanometer of accurately known dimensions was a rarity. "Resistance-boxes" did not exist. Kirchhoff had, as long ago as 1849, published the experiments that are commonly cited as constituting the earliest actual measurement of a resistance in absolute measure, but no concrete embodiment of his results existed. Wilhelm Weber had distributed a certain number of coils of which he had measured the resistance, but very few physicists possessed a coil, or wire of any kind, of which they knew the resistance, otherwise than by comparison with some accidental arbitrary standard. Though the fundamental principles of absolute measurement are due undoubtedly to Gauss and Wilhelm Weber, the general spread of the conception and the introduction of practical methods founded thereon was, in a great degree, promoted by the Committee on Standards of Electrical Resistance first appointed by the British Association in 1861. The committee's first experimental determination of the "B.A. unit," $10^7 \frac{\text{metres}}{\text{second}}$, was published in 1863. At the same time, Maxwell and Jenkin's memorable paper "On the Elementary Relations between Electrical Measurements" appeared. As the first connected and comprehensive statement of the matter, this paper contributed greatly to promote a more general understanding of absolute measurements.

It is significant of the condition of the current teaching of theoretical physics at this time that, when Tyndall published his "Heat as a Mode of Motion" in 1863, he introduced it as an attempt "to bring the rudiments of a new philosophy within the reach of a person of ordinary intelligence and culture," but he and other popular writers so completely neglected to deal with one-half of the new philosophy that Macquorn Rankine felt called upon, in 1867, to publish a paper, "De la nécessité de vulgariser la seconde loi de la thermodynamique." There was no such thing in those days as a physical laboratory in the modern sense of the word. As Kohlrausch says, conditions were "pinched and patriarchal," and it was quite appropriately that the whole instrumental outfit of a university was called the "physical cabinet."

The state of electrical knowledge at the outset of Kohlrausch's career is well brought out by him in speaking of the conditions under which Gustav Wiedemann wrote his magnificent "Lehre vom Galvanismus und Elektromagnetismus," first published from 1861 to 1863:—

"It is only right that we should call to mind some of the inherent difficulties which beset the production of this classical work, difficulties which increased the labour of the exposition to an extent that we can understand only by a distinct effort of the imagination.

"The thermodynamic basis for the connecting links which now bind all together to a coherent whole was then in course of development, and had not by any means become common property; and in the case of electricity especially a consistent system of measurement was still wanting in a practically accessible shape. It is true that Ohm and Kirchhoff had laid down the laws of the strength of currents, and the foundations of a system of measurement for current, tension, and resistance had been settled by Gauss and Weber, but hitherto very few measurements in definite units had been actually carried out. It is hardly too much to say that the subject of absolute electrical measurement was as yet familiar to but few physicists. The Daniell's cell was almost the only standard of measurement that was commonly accessible. Measuring instruments that gave the strength of a current in intelligible units were not introduced till much later. The measurements of resistance then in use were inconvenient and untrustworthy. I remember my own not very successful struggles with file and plane to construct a rheostat. The statements given in published papers in reference to the units of resistance employed were often uncertain to the extent of 50 per cent. or more."

As was befitting in a son of Rudolf Kohlrausch and a pupil of Wilhelm Weber, our author took an effective part in remedying this state of things, and the present volume forms the first part of a record of what he accomplished.

The contents are arranged by the editors in sections, the first of which, extending to nearly 200 pages, is headed "Elasticity and Capillarity," and contains the author's earliest published papers. The two papers on capillarity, however, belong to the years 1906 and 1907. In the first of them, the author reproduces the substance of a paper by Lord Rayleigh, on the formation of drops, because, as he says, it had been treated "etwas stiefmütterlich" by German periodicals, and he directs attention to the value of the "method of dimensions" used by Lord Rayleigh.

The second section, nearly 100 pages, relating to "Heat, Thermoelectricity, and Gaseous Mechanics," contains almost the only exclusively theoretical paper in the volume. In this paper, Kohlrausch starts from the fact that differences of temperature between neighbouring parts of continuous pieces of metal are an essential condition of the action of a thermoelectric couple. He points out that a thermoelectric current is therefore necessarily accompanied by a current of heat, and, assuming a mutual convective action between these two currents—that an electric current conveys heat and that a current of heat conveys electricity—and assuming further that the quantity of electricity conveyed by a given flow of heat depends on the temperature of the conductor, he arrives at the ordinary formula, which represents the electromotive force of a thermoelectric couple as being proportional to the difference of temperature of the junctions multiplied by the difference between their mean temperature and a fixed temperature depending on the nature of the couple.

The third section, fifty pages, devoted to "Optics," deals chiefly with a method of measuring indices of refraction founded on the phenomenon of total reflection.

The fourth section, more than 650 pages, "Electrical and Magnetic (absolute) Measurements and Methods of Measurement," is the most important in the book. We may mention specially a paper on the "Absolute Value of Siemens's Unit of Resistance," which contains an acute and interesting criticism of the experiments of the British Association Committee. Unfortunately, in his own experiments, Kohlrausch adopted, without personally verifying them, the dimensions of a coil that had been wound by Weber, although he carefully determined every other quantity involved, with the consequence that he obtained an erroneous result. A later determination of the "Absolute Resistance of Mercury" led almost exactly to the value now adopted as the most accurate. The same may be said of a determination of the "Electrochemical Equivalent of Silver," which he carried out in conjunction with his brother Wilhelm. These two investigations seem to have been conducted with the utmost care, and they afford striking examples of the multitude of minute precautions that must be observed when great accuracy is aimed at in the determination of a physical constant. These two papers are the most elaborate in the volume, but all go to show the author's love of exact measurement and furnish evidence that he was pre-eminently in his right place when he was appointed president of the Reichsanstalt.

A final section, 100 pages, is headed "Miscellaneous and Books." It contains some interesting addresses and reports and biographical notices, and the preface to the last (eleventh) edition of the author's "Lehrbuch der praktischen Physik," first published in 1870, under the title "Leitfaden der praktischen Physik."

It only remains to add that the volume is excellently printed and very carefully edited.

G. C. F.

A MODERN HISTORY OF CHEMISTRY.

A Concise History of Chemistry. By T. P. Hilditch. Pp. ix+263. (London: Methuen and Co., Ltd., n.d.) Price 2*s.* 6*d.*

IN this book an attempt is made to trace the development of chemistry from the point of view of its present-day position—that is, from the point of view, say, of a traveller who, having reached his goal, seeks to retrace his route, and to survey, as if from an eminence, the devious and dimly indicated wanderings by which he has attained the coign of vantage he has gained. There are, of course, two ways of writing history. The first, which is by far the more difficult, inasmuch as it presupposes profound knowledge and extensive research, combined with imagination and the faculty of detachment, is for the historian to seek to project himself, as it were, into the particular period with which he is dealing at the moment, and to attempt to elucidate it from the contemporary point of view. In this way he becomes a faithful chronicler of the epoch, reflecting its spirit, correcting its errors, supplementing its truths, and making manifest the gradual evolution and enlargement of the special phase of intellectual, moral, social, or political development with which he may be concerned. Or he may, as in the present case, view the whole course retrospectively. This, no doubt, has certain advantages. But when applied to chemistry it is apt to do an injustice to one's predecessors by belittling their successive contributions to the general knowledge: there is apparently so much chaff to be winnowed, and the kernels of good grain would seem to be so few and so small in comparison with the harvest of to-day. It is apt, too, to give false impressions of the course of reasoning—the movement of the time—by which the early speculators were led to formulate their attempts at a chemical system. It is impossible to do full justice to their efforts unless the historian has that complete sympathy with them which comes from trying to put himself in their place, and so appreciating the motives by which they were guided or impelled.

In a volume of some 250 small octavo pages, which seeks to trace, in the broadest possible outline, the growth of chemistry from the earliest times to the present epoch, there is not much room for dwelling on the philosophy of its history. Mr. Hilditch is chiefly concerned more with results than with motives —with the ordering in historical sequence—of the significant facts of the science, and it is quite remarkable what a number of such facts he has contrived to pack within the limited compass of his book. To the busy student who seeks to acquire merely an *aperçu* of the main current in the gradually broadening stream of chemical knowledge, and has but little interest in the personal aspects or human element in the story, the compilation, concise as it is, will be invaluable. Indeed, the author frankly confesses that his book "is designed more especially for those students whose interest in this aspect of the science is stimulated by the inclusion of 'historical chemistry' in the syllabus of examinations which concern them."

The examinee will certainly get a perfect plethora of the facts of chemical history if he steadily works his way through this volume. Even if he is unable to assimilate a moiety of them, he will at least have the satisfaction of knowing that he possesses in Mr. Hilditch's book a trustworthy and fairly comprehensive work of reference, and as such we warmly recommend it to every chemist, whether he be an examinee or not. The book is excellent in plan, and, in spite of its conciseness, eminently readable. Its arrangement readily enables the searcher to discover the origin and date of practically every fact of importance, even without the aid of the synoptical tables and very full index which are appended.

The book differs from all other works of the kind in its modernity. The author is more concerned, apparently, with the chemistry of our own times than with that of any preceding epoch. There are other works which deal more fully with the science of bygone ages, but there is certainly no book in our language which treats of the story of our own age with the same degree of fulness as the volume before us, and we hope that its sale will be such as to encourage the author to maintain it at its pretty high level of completeness.

THE ANOPHELINE MOSQUITOES OF INDIA.

A Monograph of the Anopheline Mosquitoes of India. By Dr. S. P. James and Dr. W. G. Liston. Second edition, rewritten and enlarged. Pp. viii + 128 + xv plates. (Calcutta: Thacker, Spink and Co.; London: W. Thacker and Co., 1911.) Price 16 rupees net (25*s*. net).

THE second edition of this work has been long looked for, and we now welcome it in much the same guise as before; for, although "enlarged," it has actually fewer pages than the first edition, the enlargement apparently referring to new plates, though the number of coloured plates remains the same as before. These coloured plates are so excellent that it is a pity that their number could not have been increased. In our opinion the outstanding merits of this book are the clearness of the descriptions and figures, and the provision of very good analytical tables.

We are glad in this edition to see Theobald's scale classification adopted as a first step in arranging the Indian anophelines in their proper zoological position. The authors are quite justified in their criticism of a good deal of scale nomenclature and their admirable plates of scales are a welcome addition, but their division of scales into "false" and "true" is hardly a happy one. In our opinion, "striate" and "non-striate" would have been better terms. In their attempts at revision of specific and generic names, the authors are a law unto themselves. It is not merely a question of nice judgment on the evidence for and against such a name, but there are violations of well-understood and accepted rules. We could give numerous examples of this, but one must suffice. Thus a certain African anopheline bears the name *Nyssorhynchus maculipalpis* (Giles). The authors accept Theobald's opinion that the so-called Indian *maculipalpis* is different; they therefore "change" the name of the Indian species to *maculipalpis* (James and Liston). This substitution of their name is, of course, no change at all, but it leaves us with two identical specific names in the same genus. A *new* name for the Indian species is imperative. We would appeal to the authors to consider this question of nomenclature, and to study carefully the laws governing it, and then publish a list of Indian anophelines with their synonyms. It is their duty to acquaint themselves with the matter fully, even down to the correct way of writing a specific name and its author.

We suppose the method advocated (p. 26) for mounting a collection of mosquitoes has advantages, or it would not have been adopted by the Central Malarial Bureau, but it certainly seems cumbersome, and to fasten nine different objects on to a board with *elastic bands* must sooner or later, in India of all places, spell certain disaster, *i.e.* loss of some of the objects.

Although the book contains an index of specific names, yet generic ones are omitted, and the general index of the first edition has disappeared—a distinct loss. We have noted several erroneous references to plates; *e.g.* three out of five on p. 7 are wrong. As is evident from reading the book, much work remains to be done on the male genitalia, larval stigmata, and eggs, and indeed on the whole bionomics of the Indian anophelines, but this will, we hope, now soon be remedied in India. The book has not, then, reached that ideal standard of excellence we had hoped for, but it must in justice be said, and this is a very practical point, that a worker with this book at his disposal will be able to find out with ease which of the some three dozen Indian anophelines his may be, although in several cases he will certainly be giving them erroneous names.

MINERALS OF RHODESIA.

The Mineral Industry of Rhodesia. By J. P. Johnson. Pp. iv + 90. (London: Longmans, Green and Co., 1911.) Price 8*s*. 6*d*. net.

THIS book is specially addressed to the prospector, and gives a good deal of information as to the occurrence of gold and minerals of economic value that have been worked in Rhodesia, the conditions under which they have been found, and mines of importance with their yields. It also gives an account of the occurrence of tin in other mines of South Africa outside Rhodesia, where minerals have been worked which the author thinks might reasonably be expected within the limits of the colony itself.

Gold has proved, up to now, the most important of the metals mined, a value of 2,508,200*l*. having been recovered in 1910. It occurs chiefly as free gold, but alloyed with a varying quantity of silver, and is found disseminated through various rocks, *e.g.* granite syenite, granulite, various schists, ironstone, and quartzite; but quartz veins traversing various rocks are the dominant gold carriers, all situated close to the granite contact. These veins vary greatly in width, and also in yield, the average yield for 1910 being 30*s*. 9*d*. per ton milled.

Nearly all the mines are situated on old native workings, and the quantity of gold taken from these workings, which sometimes attain a depth of over 200 feet, must have been considerable.

The blunders of pioneer mining companies and resultant financial difficulties have furnished a rich harvest for tributers, who have made handsome profits.

In a large number of the reefs a serious falling off in values is encountered at the water level, their payability down to that point apparently being due to secondary enrichment.

The conditions of Rhodesia are not favourable to the formation of extensive alluvial deposits, and very little gold has been derived from that source.

Other metals than gold are coming increasingly into prominence. Chromite has been mined continuously and with a progressive output since 1905 from a hill of the mineral at Selukwe, the output in 1910 being 44,000 tons, of a value of 98,130*l*., most of the mineral being shipped to America.

Wolfram and scheelite have been produced in the Buluwayo and Hartley districts of a total value of 10,930*l*.

Nickel and cobalt have not been found, but the author describes their mode of occurrence and the characters of the minerals at Sudbury and New Caledonia as a guide for prospectors.

Copper ores are very widespread in Rhodesia, and the author describes the Kansanshe, Bwana M'Kubwe, and Umkondo and Alaska deposits, on all of which there have been extensive old workings, those on the Alaska extending in an almost unbroken line for about 1700 feet with an extreme width of 660 feet, and have been proved to go down in some places to a depth of at least 70 feet. The copper so far exposed is mainly in the form of malachite, the sulphide zone not having yet been reached. It is disseminated through a crushed belt of limestone.

Lead and zinc are found as an enormous body in the well-known occurrence at Broken Hill, which is remarkable for the large development of phosphates of lead and zinc within the zone of oxidation. The Penhalonga Gold Mine has yielded lead as a by-product.

Molybdenite occurs on the farm Appingadam. Bismuth and antimony have only as yet been found in Rhodesia with the gold ores rendering them refractory. The output of silver is obtained mainly as a by-product in the treatment of gold ores, and partly from the argentiferous galena of the Penhalonga Mine, but no true silver minerals have as yet been found.

A chapter is also devoted to the non-metalliferous minerals of Rhodesia, which, while interesting, space does not permit us to notice, and the book concludes with a chapter giving hints to prospectors which they will find of interest.

Generally speaking, the book is clearly written, and contains a good deal of information; it should be in the hands of anyone who is devoting his attention to prospecting in Rhodesia.

THE FOUNDATIONS OF SCIENCE.

Die logischen Grundlagen der exakten Wissenschaften. By Prof. Paul Natorp. Pp. xx+416. (Leipzig and Berlin: B. G. Teubner, 1910.) Price 6.60 marks.

Probleme der Wissenschaft. By Federigo Enriques. Uebersetzt von Kurt Grelling. Erster Teil, Wirklichkeit und Logik. Pp. x+258+16. Price 4 marks. Zweiter Teil, Die Grundbegriffe. Pp. vi+259-599. Price 5 marks. (Leipzig and Berlin: B. G. Teubner, 1910.)

THE publication of these works, and, indeed, of the whole series to which they belong, furnishes further evidence for the revival of the interest in the ultimate problems of science, an interest which becomes very much alive so soon as an important branch of investigation reaches the borders of the knowable, and stands in danger of losing itself in unphilosophic disputations. Such an event is at present taking place in physics in connection with the relativity hypothesis, and before we reach the end of the controversy the logical foundations of science will have been thoroughly overhauled.

Prof. Natorp's work is practically a treatise on the fundamental principles of mathematics. It deals with such subjects as infinity and continuity, direction and dimension as determining pure number, time and space as mathematical structures, and the temporal and spatial arrangement of events. The treatment of the problems touched upon is detailed and thorough, and often leads to very decided (and, let us hope, decisive) pronouncements on present-day problems, as when the author declares it to be impossible to decide between the Euclidean or non-Euclidean structure of our space by means of any imaginable physical experiments. A brief summary of the new Principle of Relativity as formulated by Lorentz, Einstein, and Minkowski concludes a very informing and valuable work.

Prof. Enriques's two volumes are more practical and empirical, and will probably appeal to a wider circle of readers than Prof. Natorp's. The style is vigorous, and sometimes distinctly informal, and for that very reason the book is more readable than is the average work on these recondite subjects. His definition of "reality" is interesting. "Our belief in the reality of a thing," he says (p. 85), "supposes a totality of sensations which follow invariably upon certain conditions arbitrarily provided." This, as the author himself perceives, does not eliminate the possibility of a complex hallucination, unless we assume that the will is entirely in abeyance during hallucination. Those who prefer to regard reality as simply the "hallucination" common to the majority of mankind will scarcely be won over by the author's attempt to attain a definition more flattering to our self-esteem. A terse definition of reality as "an invariant in the relation between volition and sensations" (p. 100) expresses very aptly the author's point of view. The chapter on the physiological bases of logic brings out clearly the author's ultra-modern methods, and his treatment of non-Euclidean geometry shows that he is not greatly out of sympathy with Poincaré's demand to regard all postulates, not as fundamental verities, but as mere mutual agreements among philosophers.

The last chapters of the book deal with the root laws of mechanics and physics in a brilliant and entertaining manner, including, of course, the Principle of Relativity. In the treatment of the latter, it is regrettable that the author stopped at the Fitzgerald-Lorentz contraction without going on to Einstein's all-important work. His final *tour de force* is to show that freedom and necessity are not incompatible, inasmuch as there is a necessity for freedom in biological processes. That, at all events, seems the most concise way of putting his argument.

OUR BOOK SHELF.

The Book of Buchan: a Scientific Treatise, in Six Sections, on the Natural History of Buchan, Prehistoric Man in Aberdeenshire, and the History of the North-east in Ancient, Medieval, and Modern Times. By Twenty-nine Contributors. Edited and arranged by J. F. Tocher. Pp. xxi+508. (Peterhead: The Buchan Club, 1910.) Price 10s. 6*d*.

THIS is a compendium of essays, somewhat on the lines of the Victoria County Histories, dealing with the natural history, archæology, and history of a district of north-east Aberdeenshire, known from ancient times by the name of Buchan. The essays, which are published by the local Field Club and edited by its secretary, are of varying degrees of merit. There are excellent essays on the geology of the district by Mr. A. W. Gibb and Dr. T. F. Jamieson. Prof. J. A. Thomson gives an admirable sketch of the fauna of the district and their origin. Prof. Trail deals with the flora in an essay which is chiefly concerned with pointing out the imperfections of the present knowledge of the subject, and urging the local botanists to complete the survey which he himself has so well begun. A valuable essay on "Stone Cists in Aberdeenshire" is contributed by Prof. R. W. Reid, to which are added tables of measurements of the skulls and limbs of the remarkable race which inhabited east Aberdeenshire in the late Neolithic and early Bronze age. Important contributions also bearing on the prehistory of the district at the same epoch are "The Prehistoric Pottery of Buchan," by the Hon. John Abercromby, and "Some Notes on the Stone Circles of Aberdeenshire," by Sir Norman Lockyer. These essays represent the latest views on these interesting archæological questions by acknowledged authorities.

The remainder of the volume deals with the history of Buchan from the beginning of history up to modern times. Some of these contributions show evidence of considerable research and mastery of the subject, notably that on "Life in the Northern Burghs before the Reformation," by Dr. P. Giles, of Cambridge.

Many of the contributions are, however, not up to the above high standard. We have an essay on Gaelic place-names of a type which usually is produced by the Celtic scholar with insufficient knowledge of philology, who relies chiefly on picking out words of similar sounds from a Gaelic dictionary. It is not surprising either that the editor, who writes with an air of great authority on nearly all the various subjects dealt with in the volume, should sometimes be caught tripping. We find him waxing enthusiastic about the maps of Ptolemy, evidently ignorant of the fact that there is no evidence that Ptolemy ever drew any maps, all the so-called maps of Ptolemy having been drawn by modern geographers from Ptolemy's descriptions. He also ascribes the writings of Bede to the seventh instead of to the eighth century.

On the whole, however, the volume is a credit to the science and scholarship of Aberdeenshire.

The Senior Botany. By Prof. F. Cavers. Pp. vii+484. (London: University Tutorial Press, Ltd., 1910.) Price 4*s*. 6*d*.

LIKE the three earlier text-books which Prof. Cavers has prepared for this series, the present work is admirably designed to portray the plant as a living entity, to indicate how structure is subservient to function, and to show that conditions and purpose underlie the manifold variations which plants assume. Much of the earlier chapters has appeared in one or other of the former books; the broad bean plant is selected as the introductory type, and the same satisfactory arrangement of information supplemented by experiment is adopted. Although a chapter is devoted to the microscope and cell structure, evidence requiring microscopic examination is generally avoided.

Photosynthesis is taken as the starting point for explaining metabolism, and the attractive theory, for which, however, further proof is required, of a conversion from light to electrical energy as the crucial operating factor is definitely formulated. Incidentally it is suggested that carbon assimilation is a more suitable expression than photosynthesis, but this depends upon the application of the term assimilation. Here, too, it seems desirable to raise a protest against the use of the word "stomate" on the grounds that "stoma" is more correct, and used generally, if not universally, by the best authorities. Among the various forms of transpiration measuring instruments, the best and simplest is not given; also it is observed that the interesting subject of soil physics is omitted except to advise reference to agricultural books.

There is an extensive chapter on ecology, which, with the chapters on flowers, classification, fruits and seeds, deserve special praise, as they are all explicit, stimulating, and copiously packed with detail; a few minor points of criticism arise, notably the description of monocotyledons as a lower class than the dicotyledons.

It should be understood that the qualification "senior" refers to the local examinations of Oxford and Cambridge. The book is well adapted for its purpose, although there is more information than most pupils in schools could assimilate; in addition, it can be strongly recommended to students in the polytechnics as a sound guide to the study of plant-life.

Praktikum der experimentellen Mineralogie mit Berücksichtigung der kristallographischen und chemischen Grenzgebiete. By Prof. E. Sommerfeldt. Pp. xi+192. (Berlin: Gebrüder Borntraeger, 1911.) Price 4.80 marks.

THIS little book is a veritable *multum in parvo*. It is astonishing how much information Prof. Sommerfeldt has succeeded in compressing into so small a compass; he has covered practically the whole range of physics and chemistry so far as these subjects may be applied to the determination of the characters of minerals. He rightly believes that, while a careful study of the variety of specimens contained in a large mineral collection is most helpful towards acquiring facility in recognising mineral species, yet it is always desirable to be able to confirm a judgment by, or even to base it wholly upon, a few well-chosen tests, and this book is intended to assist students and others who may have occasion to identify mineral specimens in carrying out such tests.

The opening chapter deals with the goniometrical measurement and the perspective drawing of crystals, the calculation of the fundamental morphological data, and the measurement of refractive indices by the method of minimum deviation. In the next chapter the author passes on to the chemical examination by means of the blow-pipe, microchemical reactions, and the quantitative determination of the precious metals, coal, &c. The third chapter is concerned with crystal optics, and the fourth with the special application of these properties to use with the microscope. The last chapter includes the remaining physical characters, such as hardness, specific gravity, pyroelectricity, etching, melting point, and crystallisation, the phenomena presented by mixed crystals being considered at some length. In an appendix the author offers some hints on the kind of apparatus useful for prospectors and generally travellers interested in minerals, and considers the special case of precious stones.

The book has been carefully written, the hints given being evidently based upon the author's own experience, and it will be found to serve well the purpose for which it is intended.

Mikrographie des Holzes der auf Java vorkommenden Baumarten, im Auftrage des Kolonial-Ministeriums, unter Leitung von Prof. J. W. Moll, bearbeitet von H. H. Janssonius. Dritte Lieferung. Pp. 161–540. (Leiden: E. J. Brill, 1911.)

THIS is the third part of an extensive publication, designed to take advantage of a large number of Javanese wood specimens collected by Koorders with a view to the preparation of a forest flora for Buitenzorg. The collection is unique because corresponding herbarium material was gathered at the same time, so that the identity of each specimen can be accurately determined. The herbarium material was critically examined and described in the "Additamenta" noted in the title. The microscopic investigation is being conducted by Mr. H. H. Janssonius in great detail; a "topographical" or general description of the sections which would serve for most purposes is not considered sufficient, but copious details are supplied for each type of cell represented. Figures are only given for one species of each genus, and the scale of 1 : 25 is adopted; it would have expedited reference if a figure had been provided for each species on a scale of 1 : 10, enabling direct comparison to be made with illustrations provided in several standard works. The most valuable feature is the summary of anatomical characters drawn up for the analytical determination of genera and species. Prof. Moll suggested, in a notice of the earlier parts subscribed to the *Botanische Centralblatt* (vol. cxiii.), that it should be possible to determine not only the families but genera, and occasionally species, by the characters of the wood; the full consummation of this scheme is reserved for a final survey.

A book on these lines has long been a desideratum. Some estimation of the magnitude of the work can be formed when it is mentioned that this part completes a second volume of 540 pages, devoted entirely to the Disciflorae represented by 163 species or varieties.

When Should a Child Begin School? An Inquiry into the Relation between the Age of Entry and School Progress. By W. A. Winch. Pp. iii+98. (Baltimore: Warwick and York, Inc., 1911.)

MR. WINCH's book is an admirable example of educational inquiry as it should be pursued. Instead of arguing on *a priori* grounds that children under five are better at home than at school, he shows by careful statistical methods what the actual effect of early entrance upon school courses is. His research shows in a thoroughly convincing way that those who begin school about five years of age do quite as well—often very much better—than those who begin at an earlier age. Stated quite moderately, it is clear that it makes no actual difference to the future school record whether a child begins at three or at five, though incidentally the figures suggest that delay beyond the fifth year is actually disadvantageous—a point in favour of English as opposed to German practice. Of course, many school authorities have already ceased to provide for children so young, not because of Mr. Winch's work, but because the State has withdrawn the grants. Yet it does not follow, of course, that the social value of the babies' classes in the infants' schools is nil. It is something that overworked wives are relieved for a few hours a day of the strain which young children in a small house commonly bring. But it is abundantly clear that formal school lessons of any kind before the fifth year is completed are quite unnecessary. Hygienic surroundings and playful occupations with abundant opportunities for sleep are chiefly wanted. Trained nurses rather than trained teachers, crèches rather than schools, would perhaps meet the situation. J. A. G.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Orientation of the Great Temple of Amen-Ra at Karnak.

IN 1891 Sir Norman Lockyer made a magnetic survey of the axis of the great Temple of Amen-Ra, at Karnak, with the view of determining an astronomical date for the original building.

Since that time a great deal has been done in excavating and exposing the foundations of the older work along the temple axis, chiefly under the personal supervision of M. Legrain, of the Department of Antiquities, who for sixteen years has been the director of the explorations at Karnak.

On my recent visit to Karnak, where I spent some weeks, M. Legrain gave me the greatest assistance to enable me to make a resurvey of the axis in the light of the many new discoveries, and particularly in pointing out the parts of the original buildings still *in situ*, many of which he had himself uncovered, and all of which I afterwards measured and centred up.

Unfortunately, I arrived at a very unlucky time for carrying out this work, as the place was crowded with Arab workmen hauling out great stones from the excavations, and gangs of boys carrying baskets of earth from the diggings, all making as much noise as possible, that the place was more like a busy ant-hill than the eternal calm which might be expected in an Egyptian temple. In addition to this, the tourist season was at its height, and personally conducted parties were continually passing up and down, and naturally made a highway of the axis where I had set up my instruments. One soon forgets small inconveniences; but the torment of the insects, when both hands were occupied, is brought to mind by a remark made to me by a passing gentleman from the far West when he said, "Mr. Surveyor, I guess you're having a bully time with them flies."

In the end I managed to peg out a line, down as much of the axis as I could get at, 523 feet long, from the columns in front of the sanctuary down to the lower end of the Hypostyle Hall; unfortunately, both the extremities of the line are blocked up. The sanctuary itself is completely filled up with the huge stones of the fallen roof, and the last columns of the Great Hall at the other end are at present built round with stones and bags of sand on account of the repairs being carried out to the neighbouring pylon, while the pylon itself is timbered up to prevent its falling, so that the two important points for a survey of this part of the axis cannot be used at present.

The line at this end of the axis had to be continued by the theodolite alone, as no measures for centring were possible, as it had to be carried through the Rameses Pylon into the Outer Court so far as the standing pillar of Tirhakah in order to get the true bearing of the central line by observations of the Pole Star, that star not being visible from any place on the axis inside the buildings.

The result of the survey in general quite confirms the data used by Sir Norman Lockyer in fixing the date at which the original axis was laid down, viz. about 3700 B.C. —a date which M. Legrain fully accepts on the results of his excavations, as the building of the upper end of the temple has been assigned on archæological grounds to about this period; indeed, two statues have been dug out by him, both now in the Cairo Museum, which give direct evidence as to the date. One is a seated figure of Cheops with his cartouche (of the fourth dynasty), the date of which is given in the lists as B.C. 3733, and the other is a headless figure which has been assigned to the work of the third dynasty. These figures were, of course, dug up long after Sir Norman Lockyer's survey; no older work has been found.

The height of the hills behind which the sun used to set at the summer solstice, to which the temple was oriented, was taken at 2° 30′. From the spot I was able to climb up to on the stones filling the sanctuary, to what I thought was about the height of an altar, I made it a little more; but as I had to see the hills through the timbering of the Rameses Pylon, between the struts, I could only measure the small part which was not covered; if this is the correct height, as I believe it to be, it would make the date of the foundation a little earlier, possibly to the time of the headless statue, which M. Legrain has assigned to B.C. 4000.

There are a great many difficulties just now in carrying out such an accurate survey as is required to arrive at an astronomical date of any value on account of great work that is being carried on. It must be remembered that the temple is about 1200 feet long, and stands on an area about five times that of St. Paul's, and is divided into numerous halls, corridors, and gateways; but all these are connected by the axis which runs through the whole building from east to west. This axis, when originally laid down, pointed to the place on the hill at which the sun disappeared behind it on the longest day, and the difference between the place where the sun set then and where it sets now gives the date of the foundation of the temple, the rate of the sun's change in declination being known.

M. Legrain tells me that in about two years' time he will have cleared out the fallen roof of the sanctuary, and that by that time he hopes the repairs to the Rameses Pylon will be completed and the timbering removed. In that case a unique opportunity will present itself for a survey of the whole of the axis at once from the court behind the opened-out sanctuary right down to the Ptolemaic Pylon at the west; and this Mr. Dowson, the Director-General of the survey in Cairo, has very kindly undertaken to have done by the survey officers so soon as the work is completed.

A Possible Relation between Uranium and Actinium.

It is believed fairly generally that actinium has its source in the disintegration of uranium, although it is not a member of the direct line of descent through radium. This belief is based mainly on the fact that actinium and its products have a constant ratio to uranium in minerals, and since this ratio is very small actinium is supposed to be a branch-product.

In *The Philosophical Magazine* for September Mr. G. N. Antonoff describes some experiments in which a new product is obtained, called uranium Y, and gives strong reasons for the view that it is derived, not from uranium X, but directly from uranium. It is always in a small ratio to uranium X. Antonoff has shown that it is probably a branch-product, and a possible origin of the actinium series.

The following considerations may indicate how such a branch-product could be formed. They were not thought worthy of mention until the starting point of a branch-series had been found experimentally. If a single atom of uranium begins to disintegrate, it ordinarily leads to the whole radium series, without disturbance from other atoms. But the molecule of uranium will contain at least two atoms chemically combined, and perhaps a large number. An instability arising in one atom may frequently produce a similar instability in a contiguous atom, or even a projection of one atom into another, so that two atoms may break up together and form new combinations.

The scheduled atomic weight of uranium is 238·5. Two such atoms have a weight 477. If they break up together and form only one substance, it might have a molecular weight equal to that of uranium, or $\frac{1}{2}$, $\frac{1}{3}$, . . . of that of the combined atoms. On the assumption that three atoms of a substance are formed, its atomic or molecular weight is 159.

The experiments of Russ appear to give the most trustworthy value of the atomic weight of actinium emanation. They showed that the thorium emanation is 1·42 times as heavy as that of actinium. If thorium emits two α particles, both helium atoms, its emanation should have an atomic weight about 224. The atomic weight of actinium emanation thus becomes about 156.

On a theory of the constitution of the elements given to the British Association by the writer at Portsmouth, it is more likely that the emanation from thorium has the same atomic weight as that from radium, and that actinium emanation has an atomic weight of 152·5. Russ's experiments would then lead to a value very close to this for actinium emanation. It is, of course, difficult in most cases to obtain satisfactory conclusions from such experiments on diffusion, but there are strong grounds for thinking that in this special case the usual sources of error have been minimised.

If uranium Y be formed in this way, with an atomic weight 159, it may well be the parent of actinium, whether the suggested atomic weight of the emanation be correct or not, and it is not unlikely that at certain stages in the radium series a similar series of branch-products of low atomic weight may be produced. There is evidence of this in the complex product radium C.

Hot Days in 1911.

Mr. MacDowall's letter in Nature of October 12 (p. 485), in which he directs attention to certain features in the sequence of annual number of hot days at Greenwich, is interesting. Nevertheless, I think he himself will acknowledge that his example, viz. the summer of 1911, is a happy one. What his diagram would lead one to expect if one were making a forecast, and not a retrospect, is that the number of hot days in 1911 would lie between his lower limit of 90 days and an upper limit of about 90+130, or 220 days; the value half-way between the two, *i.e.* 155 days, being the "most probable." Clearly in this case the upper limit, and also the most probable value, may be disregarded, and the lower limit is sufficiently high to be worthy of note.

The fact is that the dot for 1909, the ordinate of which is sought, lies on the lower edge of the boundary of the area of dots, so that in this case the lower limit gives a close approximation to the truth. If a dot happens to lie near the upper edge of the area of dots, the upper limit of its range along the vertical of the diagram becomes a close approximation. But since the difference between the upper and lower limits is no fewer than about 130 days, that is, 53 days more than the average number of hot days per year, it is evident that the method will seldom give results that are useful.

I think the most striking fact brought out by the diagram is that a distinct relationship exists between the total number of hot days in five consecutive years and the difference between that number and the corresponding one for the next five years. I have used the diagram to find the coefficient of correlation between these quantities, and I find that its value is as high as -0.725 ± 0.059.

Five hot years are thus usually followed by five cold years, and *vice versa*. This may be accounted for by supposing that the number of hot days at Greenwich is subject to a regular fluctuation with period not far from 10 years. If the period were exactly 10 years the coefficient of correlation would be nearly -1, and all the dots would practically lie on a straight line passing through the origin of the diagram. The fact that they do not lie on a straight line means either that there is another period or periods superposed, or that 10 years is nearly, but not quite, the true period.

It would be interesting to learn whether the directions of the lines joining successive points (chronologically) on the diagram show any sort of regularity. If they proceed generally in a clockwise direction they indicate that the period is slightly greater than 10 years; if in a counter-clockwise direction the period is less than 10 years. The whole arrangement is similar in some respects to Dr. Schuster's well-known periodogram. R. CORLESS.

October 14.

Insects Feeding on "Slime Flux" of Trees

MY attention has been directed to three elm trees at Ettington, near Stratford-on-Avon, which it is said have been "killed by wasps." It appears that the wasps were attracted by the sweetness of the sap, and attacked the trees in such swarms, and so drained them of sap, that the death of the trees seems imminent, all the leaves having gone yellow long before the usual time.

I should be glad to know if others have noticed similar attacks on elm trees, and whether the averred sweetness of the sap is due to some previous degenerative change in the tissues of the tree, or whether wasps would attack a normal tree if they could get access to the sap.

The elms are all three comparatively young trees, and belong to the common variety. My informant tells me that he has previously noticed the same thing happen with an elm tree in one of his fields, which died the next winter.

JOSEPH A. GILLETT.

Woodgreen, Banbury, October 9.

A SIMILAR phenomenon may be seen at the present time in the collection of elms at Kew. The trunk of a fine specimen of *Ulmus parvifolia* has for some weeks past—but more especially during August and September—been the daily rendezvous of hundreds of wasps and bluebottles. As is the case with the trees at Ettington, the attraction is the sweet sap that exudes from the trunk. It is a mistake, however, to blame the wasps for the damage that is being done to the trees. They do not cause the outflow of sap, but are merely there feeding on it. A piece of bark has been removed from the tree at Kew and microscopically examined. It was found to be suffering from what is commonly known as "slime flux," the bark being saturated with sugary moisture. The primary cause of this somewhat obscure disease appears to be a yeast, which finds its way to the cambium layer by means of a wound. Often, as in the Kew instance, ingress has been facilitated by the borings of an elm beetle. The yeast sets up a decomposition of the cells, and starchy, ultimately sugary, products are formed, which exude from the trunk in solution. It is this which attracts the multitude of wasps, bluebottles, and other insects. It is evident from the odour of the bark that a certain amount of fermentation is going on, and the presence of alcohol is further indicated by the behaviour of the wasps, which, after feeding for some time, become stupid and lethargic.

Although "slime flux" is not an uncommon disease of trees in Britain (it is much more prevalent on the Continent), it is not one of the most troublesome. Still, where it attacks it is nearly always ultimately fatal. The Kew tree is evidently suffering from severe debility. Unfortunately, the disease, as a rule, has become firmly established before there are any outward indications of its existence. When noticed on a branch the part attacked can be removed, but when the trunk is badly affected there seems to be no means of curing it. W. J. B.

Meteor Showers.

THE following meteor showers become due about the time when the Orionids may be expected to put in an appearance:—

Epoch October 18 22h. (G.M.T.), approximately twenty-ninth order of magnitude. Principal maximum, October 20 12h. 45m.; secondary maxima, October 20 11h. 15m. and October 22 8h. 10m.

Epoch October 20 9h. 30m., approximately fifth order of magnitude. Principal maximum, October 21 11h. 15m.; secondary maxima, October 20 9h. 30m. and October 22 10h. 35m.

From the foregoing it may be seen that there is likely to be a considerable amount of meteoric activity on the nights of October 20–22. These three nights seem well favoured as regards maxima, which occur at times very suitable for observations.

Other radiants besides that in Orion may be found active on the nights mentioned, but Orionids ought to prove most numerous on the night of October 20, as it is on this night that the general Orionid maximum becomes due. JOHN R. HENRY.

October 16.

The Possible Identity of the Kiess Comet.

IT is well known that the aphelia of many comets are grouped at distances which are nearly the same as those of the larger planets, and astronomers have sometimes attempted to use this fact to demonstrate the existence of a planet beyond Neptune. M. Flammarion mentions two cases—a comet which appeared in 1532 and 1661, and Tuttle's 1862 comet, which is related to the Perseid meteors, and has a period of $121\frac{1}{2}$ years. These are taken as indications of a planet at a mean distance of about 48 astronomical units. The evidence is obviously insufficient; and special interest therefore attaches to the statement that the Kiess comet (1911*b*) is possibly the same as 1790 I. If the identity can be established, this comet must belong to the same group as the other two, and may be regarded as strengthening their evidence as to the hypothetical planet. P. H. LING.

7 Chandos Road, Redland, Bristol, October 2.

Standard Time in New Zealand.

I NOTE that in NATURE of March 16, in an article headed "Standard Time in France," it is stated on the authority of "Hazell's Annual" that the standard time adopted in New Zealand is 11 hours fast on Greenwich.

This is not correct. New Zealand standard time is the time of the meridian $172\frac{1}{2}°$ E., that is, $11\frac{1}{2}$ hours in advance of Greenwich civil time. This is correctly stated in "Whitaker's Almanac," 1911, p. 89.

G. HOGBEN.

Seismological Observatory, Wellington, New Zealand, September 4.

Habits of Dogs.

MR. VENABLES's reference to formic acid (NATURE, September 21, p. 382) reminds me that once, in the pine-woods at Potsdam, I came upon a forester performing some curious evolutions, apparently patting something on the ground and then holding his hands to his face. He explained that it was an ant-hill, and the smell was "very good for the nerves." A. EVERETT.

ARCHÆOLOGY IN EGYPT AND GREECE.

NO great discovery has marked the progress of archæological excavation in the Near East during the past season. The fierce heat of summer has now, at the time of writing (August), stopped all excavation by us northerners in the lands of the eastern Mediterranean, and probably only the Cretan archæologists at Tylissos (and possibly the Italians, also in Crete) are still in the field. The work of winter and spring is over, and we may now sum up the more important results of it.

In the Nile-basin the most sensational find has been that of Profs. Garstang and Sayce, working for the Sudan Excavations Committee of the University of Liverpool, at Meroë, in the Sudan, the ancient seat of the kingdom of the Kandake queens. The splendid bronze head (Fig. 1) of an imperial Roman of the first century A.D. (no doubt Augustus himself), which was on view in June in the rooms of the Society of Antiquaries at Burlington House, and has now been acquired by the British Museum, was alone sufficient to "make the fortune" of any excavator; while the nuggets and cakes of gold which a lucky chance revealed to Prof. Garstang's spade are no doubt a very unusual sensation in archæology. To the Sudani, and not less to the Egyptian and the Nilote Greek, it must have seemed that one antîka-hunter, at any rate, had at last obtained what all must really be seeking—gold.

Gold, far more than iron nowadays, "doth of itself attract a man"; and for its gold alone the Meroë excavation would be remarkable to the vulgar, while the head of Augustus renders it remarkable to the *cognoscenti*. But we cannot dignify either the finding of a heap of ancient dross, though intrinsically valuable and useful on account of its value, or that of a fine Roman bronze head, as a great discovery. The great discovery was made last year, when the Meroë of the Kandakes was found, and the temple of Amen mentioned by Herodotus was identified. The smaller finds this year are less interesting than those of last year. There is more of the remarkable African-looking, hand-made pottery which to our eyes unmistakably stamps the Meroïtes as pure negroes of central Africa, Nilotes perhaps, but certainly negroes; as, indeed, we see in their rude pseudo-Egyptian representations of themselves and of the Egyptian gods whose worship they caricatured.

Of the history of the Roman head and how it got to Meroë, we can only conjecture that in some raid northwards into Upper Egypt the head of an imperial statue of heroic size, set up possibly at Syene, was struck off and carried by the barbarians back to Meroë. Though in the reign of Augustus the Roman general Petronius took Napata (Gebel Barkal) from one of the Kandakes (in punishment for just such an incursion as has been postulated), the place was not retained, and there is no likely place for a big public statue of an emperor anywhere south of Syene: it is not at all probable that so fine a figure as this must have been would be set up at the southern frontier station of Primis (Ibrîm). From Syene then we must suppose that the head originally came, and it is most like a young Augustus, of all the imperial family: perhaps one may almost call it an Octavian. Germanicus it certainly is not, nor is a statue of Germanicus in Egypt in any way probable, or even possible, in spite of the honour with which he was received: he was there illegally, in violation of the law of Augustus which forbade those of senatorial rank to visit that country. The head has now been placed in the British Museum through the generosity of the Sudan Excavations Committee, in consideration of a gift of a thousand guineas towards the committee's further excavations by the National Art Collections Fund. The photograph here shown was kindly lent by Prof. Bosanquet.

As for the gold, one might well wish that it could be coined into sovereigns, each with the word Meroë stamped upon it in the manner of the Vigo money, coined of the silver captured out of Spanish galleons at Vigo, of Queen Anne. But it is to be feared that the "Meroë" sovereigns would as soon pass out of circulation as did those of President Kruger!

Generally speaking, the Liverpool excavations have been of great interest as showing us more of the life of this curious Egyptianised negro kingdom of Meroë, whose Queen Kandake sent the eunuch to Jerusalem who was converted to Christianity and baptised by St. Philip on the way to Gaza (Acts viii. 27). There is no proof that he perpetuated his new religion at Meroë, though long afterwards the Ethio-

FIG. 1.—The Meroë Head of Augustus.

pians were strong Christians and handed their faith on to the non-negro Abyssinians, who (absurdly) like to call themselves "Ethiopians" to-day.

Passing northward to the modern border of Egypt and the Sudan, the scene of many an Ethiopian foray in old Roman days and many an Egyptian razzia in days then ancient, we find that at Farrâs, north of Wadi Halfa and just on Sudanese territory, Mr. F. Ll. Griffith, reader of Egyptology in the University of Oxford, has, assisted by Mr. Blackman, excavated a large number of tombs of late period, ranging from Ptolemaic to Christian days. Very interesting pottery has been found, linking up that of Meroë with that of Nubia exemplified by Mr. Randall-MacIver's finds at Areika (see NATURE, April 28, 1910), but at the same time presenting constant points of difference and originality. Additions have also been made to our store of inscriptions in the

"Meroitic" demotic script, of which Mr. Griffith is the first to begin the decipherment.

One cannot describe in detail all the various excavations, some regular, others ephemeral, that are set on foot every year in Egypt. The season has not been remarkable for discoveries. The Egypt Exploration Fund, premier and pioneer of modern scientific excavation-societies in Egypt, has dug with success at Atfih in Middle Egypt (this work was carried out by Mr. de M. Johnson), and has steadily gone on with the thorough exploration of Abydos which it resumed two years ago. The Fund's expedition at Abydos was directed by Prof. Naville, assisted by Mr. T. E. Peet and Mr. James Dixon. The work of supplementing Prof. Petrie's former excavations of the royal tombs of the first dynasty at Umm el-Qa'ab by further investigations has been brought, at any rate temporarily, to a conclusion, the previously unexplored portion of the Mound having been thoroughly excavated. Last year interesting discoveries had been made, including a fragment of a crystal bowl with the name of an early king (well known from the former discoveries of Amélineau on the same site), which has been the subject of scientific discussion and is now in the British Museum.

The results of this year's work from the tombs explored in the necropolis of Abydos (not Umm el-Qa'ab) have been exhibited, not in England, but at Boston. The Egypt Exploration Fund is an Anglo-American society, and it is fitting that the yearly exhibition should occasionally, at least, be held in the United States.

Next year Prof. Naville proposes to proceed to the complete exploration of the "Osireion," an extraordinary subterranean (or apparently subterranean) sanctuary of Osiris, close to the great temple of Seti I. This Osireion has already been attacked by the Egyptian Research Account, several years ago, and the results of this work were published by Miss M. A. Murray. But various reasons did not allow of the heavy work of emptying this tunnel being concluded, and it now remains for the excavators of the Exploration Fund, directed by a veteran whose speciality has always been precisely this kind of work, to discover the hidden secrets of the Osireion. But for a big work of this kind money is necessary. Subscriptions for the Fund are urgently required, and the office of the secretary is 37 Great Russell Street, W.C. Among recent subscribers to this work may be mentioned, as an instance of Japanese interest in all branches of science, the University of Kyoto, which has already received from the Fund many interesting relics of ancient Egypt to be studied by the youth of new Japan.

The other British society at work in Egypt, the Egyptian Research Account, has, under the direction of Prof. Flinders Petrie, continued its work at Memphis and elsewhere. An interesting series of Græco-Roman portraits from Hawara, similar to those discovered by Prof. Petrie at the same place many years ago, has been exhibited at University College, Gower Street, this summer, together with sculptures from the Egyptian Labyrinth and from Memphis, and prehistoric vases and flints from a site explored during the season's work.

Turning to Crete, we find a sterility of results this year comparable to that in Egypt. Sir Arthur Evans (whom we congratulate most heartily on his richly deserved knighthood) has not put spade to earth at Knossos this year, or continued the works of conservation which he carried out in the "Queen's Megaron" last year. Nor has Mr. Seager dug in the country round the Isthmus of Hierapetra, which he has earmarked as his own special hunting-ground. But he has located, and reserved for future excavation, possibly next year, an extraordinary village-site of the Geometric period, on a ledge, almost inaccessible to all but Cretans and Mr. Seager, high up on the vertical side of the great cleft in the mountains above the village of Monasteraki, near Kavousi (Fig. 2). This ledge, at first barely three feet wide, turns the corner of the cleft, and there, well within the gorge, broadens into a platform some ten feet across, on which people of the Geometrical period had found a hidden and secure refuge from the attacks of the Ægean pirates of their degenerate and barbarous times. The cliff rises sheer above, and falls sheer below for hundreds of feet to the untrodden floor of the gorge. Another work reserved by Mr. Seager until next year is the continued exploration of the hill-village of Vrokastro, begun last year by Miss Edith Hall, which yielded interesting antiquities of the transition period from Geometric to classical times.

FIG. 2.—The great Cleft of Kavousi.

The Italian work of recent years has resulted in the addition of a pillared "agora" to the palace of Agia Triada (Fig. 3): the results of this year's explorations, which were not yet begun when the writer visited Phaistos and Agia Triada in May, have not yet come to hand.

An interesting feature of Cretan work is now the participation in it of the Cretans themselves, who are keenly interested in the antiquities and past history of their splendid but sorely tried and oppressed island. In Drs. Hatzidakis and Xanthoudidis, Crete possesses archæologists of whom England, France, Germany, or any other country might be proud. Dr. Xanthoudidis has for several years past made important discoveries, and now Dr. Hatzidakis has discovered and is excavating an important Minoan palace at Tylissos, not far from Knossos, at the base of Ida. Great brazen bowls, the largest vase of obsidian (a single piece twelve inches high) yet discovered, and a remarkably bold and fine bronze statuette of a man in the Minoan saluting attitude of adoration, are only a few of the fine trophies that have come from Tylissos to the shelves of the really magnificent museum of Candia. The work at Tylissos continues under the direction of Dr. Hatzidakis.

The Museum of Candia may be described as the Mecca of students of the Greek Bronze age, though the Ashmolean at Oxford, thanks to the unremitting care of Sir Arthur Evans, is a very good second to it, so far as Cretan antiquities are concerned, and the first vase room at the British Museum now contains a "Mycenæan" collection which, thanks chiefly to the results of past excavations of Minoan tombs in Cyprus, makes the British Museum by no means a bad third, while its Cretan collection also has now become quite important. The Museum of Athens proudly exhibits its trophies from "golden" Mycenæ and elsewhere in Greece, but of Cretan and Cypriote antiquities it has none.

FIG. 3.—Agia Triada: the new Agora.

The British School at Athens has again turned its attention to a Mycenæan site this year, having resumed its interrupted excavations at Phylakopi in the island of Melos. Interesting discoveries, especially of pottery, have been made. The German work at Tiryns last year produced most important results, especially remarkable being the remains of a fresco depicting a boar-hunt, in which figure two women (or, more probably, in the writer's view, noble youths) riding to the hunt in a chariot. A fine representation of a woman in splendid robes has also been found. Reproductions of this fresco, from the accomplished hand of M. Gilliéron, junr., will soon be given to the world.

Elsewhere in Greece, though interesting results have been obtained by the French at Delos, the most remarkable discovery has been made this year at Corfu, where the Greek Archæological Society has discovered an archaic temple, with sculptures resembling the metopes of Selinus in Sicily. In view of the fact that ancient Kerkyra was a colony of Corinth, and Selinus of the neighbouring Megara, this resemblance is interesting. At the time of the discovery the German Emperor was in residence at his Corfiote palace of the Achilleion, and, thanks to his active interest in it, the excavation is to be continued under the distinguished direction of the leader of German archæology in the Levant, Prof. Dörpfeld (see NATURE, vol. lxxxvii., p. 149).

I bring this account to an end with a mention of the explorations of Messrs. Wace and Thompson for the English Macedonian Exploration Fund in the Elassona district of Turkish Thessaly, which will no doubt add much to our knowledge of the remarkable Neolithic culture of northern Greece, which has upset so many preconceived notions of the early history of Greek civilisation. It may be noted, in this connection, that Mr. F. W. Hasluck has just discovered a Minoan "bee-hive" tomb at Kirk-kilisse in the vilayet of Adrianople.

H. R. HALL.

PROGRESS IN ELECTRIC LIGHTING, HEATING AND COOKING.

ELECTRICAL engineers are claiming—and are claiming with justice—that great advances from the industrial and commercial point of view have been made during the last year or two in electric lighting, heating and cooking; but the average man of science, who probably concerns himself more with general principles than with the detailed applications of physics, may wonder in what these great advantages really consist. He will remember that the employment of tungsten in place of carbon for the filaments of incandescent lamps, and the consequent improvement in efficiency from 4 to $1\frac{1}{4}$ watts per candle-power, dates back to five years ago, and will point out that in the present form of this lamp a tungsten filament is still used, heated to the same temperature, and consequently having the same light efficiency. As to electric heating, he may even be still more sceptical, for, when at school or college, he may have learnt that the energy of an electric current flowing continuously through a resistance is transformed into heat, and that no invention can make the heat generated greater than is represented by the square of the current multiplied by the resistance of the wire. It will, therefore, not be out of place to pass in review the actual improvements in detail which enable the electrical engineer to substantiate his claim that great progress has been made.

Taking the case of electric lighting first. The efficiency of the incandescent lamp depends entirely upon the temperature of the filament, if we neglect for our present purpose the hypothesis of selective emissivity of certain substances, which, although advanced from time to time, has never been completely established, and in any case would only slightly affect the accuracy of the above general statement. Tungsten, being more refractory than carbon, can be kept continuously at a higher temperature without volatilising, and a tungsten filament would give three times the light of a carbon filament for the same consumption of power and the same life. But as the specific resistance of tungsten is lower than that of carbon it was necessary to produce a finer filament than the carbon one, and to find a means of supporting a greater length of this fine filament in the lamp. These difficulties were at first only partly overcome. The filament of a 25-c.p. 220-volt carbon lamp has a diameter of about 0·16 mm., and a length of about 350 mm., while the filament of a tungsten lamp of the same candle-power and voltage is about 0·02 mm. in diameter and 830 mm. long.

To produce pure tungsten in the form of a rod with a diameter in the order of a few hundredths of a mm. it was necessary to mix it with other materials, to press or "squirt" a filament of the required diameter, and to eliminate the foreign substances by various processes, at the same time "forming" and strengthening the pure tungsten filament which was left. This resultant filament was exceedingly brittle, especially when cold, and it could only be made in short lengths, so that several separate loops had to be independently supported and joined in series in each lamp; obviously a delicate operation in view of the fragility of the filament and the difficulty of welding tungsten to other metals.

At first, therefore, the filament could only be made of small enough diameter and high enough resistance for comparatively high candle-powers, and for voltages not greater than 110 volts; and, in fact, when the first tungsten lamps were put on the market as articles of commerce only one diameter of filament was used, and the length varied according to the voltage, so that the buyer had to be satisfied with one particular candle-power of lamp suited to his voltage. Month by month and year by year, however, the manufacturing processes were improved, the filaments were made stronger, finer filaments were pressed and formed, and the methods of mounting them were bettered. The range of sizes and voltages was gradually increased, and during the first half of 1909 16-c.p. 100-volt lamps and 32-c.p. 200-volt lamps with tungsten filaments were placed on the market, followed in the autumn of that year by a 25-c.p. 200-volt 32-watt lamp.

With this, the limiting size of a squirted filament seemed to have been reached, but in the meantime painstaking research work had been carried on in the laboratories of the chief lamp manufacturers, with the object of finding a process for actually drawing tungsten in the form of a wire. This has now been finally accomplished on a commercial scale, and during the last two months three of the leading incandescent lamp manufacturers in this country have already practically "scrapped" their comparatively new filament presses used for the squirting process, and are making their lamps with filaments of tungsten wires. The new wire filament has an enormously greater strength, and as in addition it can be used in the lamps in one continuous length without joints, the robustness of the lamp has been so improved that it is as great as that of one with an ordinary carbon filament. Finally, it has been already found possible to produce finer filaments of drawn wire than by the squirting process, and, as has already been announced in our columns (September 28, p. 420), at the opening of the Electrical Exhibition at Olympia on September 23, a 16-c.p. 220-volt 20-watt Osram lamp was shown, as an article of commerce, with a filament only about 0·015 mm. in diameter.

During the various stages of the introduction of the metal filament lamp, the electrical engineer set himself the task of making the utmost use of the economy which it occasioned in the consumption of electrical energy. For equal light, one-third of the energy was being consumed as with the carbon filament lamp, and the consequent cheapening of electric light opened a much wider field, and brought it within reach of the smaller householder. There were, however, two obstacles to overcome: first, the fact that the metal filament lamps for the usual town-lighting voltages were only to be obtained in comparatively large sizes, so that although the consumer obtained three times the light at the same cost, he could not light a small room at one-third of the cost; and, secondly, the expense of wiring a house for electric light acted as a deterrent to the small householder.

The first of these difficulties was overcome, in alternating-current systems, by the interposition of a small transformer or "auto-transformer" between the consumer's main switch and his lamps. A voltage of 25 or 50 could thus be obtained, for which pressures metal filament lamps down to the smallest candle-powers have been obtainable during the past four years. A wastage of electrical energy is, however, liable to occur when no lamps are on, unless the consumer then turns off the supply at his main switch, for otherwise magnetising current is passing through the primary of the transformer all day long, whether lamps are switched on or not. To prevent this waste automatic switches have sometimes been employed to disconnect the transformer when all lamps are extinguished, and to reconnect it as soon as a lamp is turned on.

One of the latest types of these (made by Messrs. Muirhead and Co.) is shown in Figs. 1 and 2. In this case an auto-transformer is employed; that is to say, a coil connected across the mains with a tapping at a point corresponding to the pressure required for the secondary circuit. The construction of the switch is clear from the general view and diagram. When no lights are on, the main circuit of the auto-transformer is open at the mercury cup 1. As soon as one lamp is switched on, a circuit is established through the coil marked starting coil, and the "auxiliary" coil and "main" coil in series, and the core seen in the two illustrations is sucked into the coil, making contacts 1 and 2. This connects the auto-transformer to the mains at contact 1, and also short-circuits the starting coil at contact 2. When a few more lamps are in circuit, bringing the current up to 2·2 amperes, the core has been sucked in further, and contact 3 is made, short-circuiting the "auxiliary" coil and leaving the main or retaining coil only in circuit. The object of successively short-circuiting the first two coils is to diminish the voltage drop. On the lamps all being switched off, the arm falls by gravity, and the auto-transformer is out of circuit.

One of the largest items in the wiring of houses is the cost of fixing the steel tubing or wooden casing in which the wires are placed. In those houses where surface work is not objected to, use is now frequently made of metal-encased wires, which are simply fixed on the walls by metal saddles. The metal casing is in the form of a tube of thin tinned copper or a lead alloy pressed round the insulated wire, and forming an integral part of it. When low-voltage wiring is supplied through a double-wound transformer, the outer metal sheathing of the wire is used as a return conductor; in the case of the lead-covered wire there is a thin copper tape under the lead to improve the conductance. For continuous current and houses supplied through an auto-transformer, a twin wire is usually employed, the two wires being under one sheath. In both cases it is essential that the outer sheath shall be mechanically continuous; in the concentric system this is obvious, and in the twin system the continuity of the casing, which is then earthed at one end, is necessary to secure immunity from shock or fire in case of leakage. The necessary "bonding" of the sheathing, therefore, forms part of the "system," and various simple arrangements are used for connecting the wires to the fittings, which effectually prevent this bonding from being omitted.

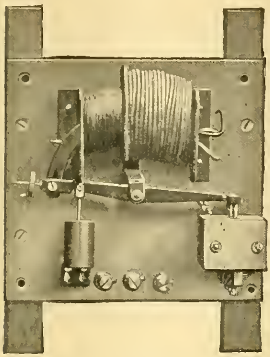

FIG. 1.—Automatic Transformer Switch (cover removed).

In comparison with the triumphs that have been accomplished in the laboratory and works in connection with lamp manufacture, the improvements in heating and cooking apparatus will appear slight. They are largely pure improvements in constructional details. The success of electric cooking has been almost entirely due to the possibility of bringing the actual heating element in the closest possible proximity to the object to be heated, so as to heat nothing else than the actual surfaces required for the cooking operation; this is, of course, not possible to such a degree either with coal or gas cooking. To illustrate this two of the simplest examples may be taken. Fig. 3 is a "table toaster" shown open. The heating element is a ribbon of high-resistance alloy wound spirally on strips of mica. This glows with a dull-red heat when current is turned on. The bread is placed in the removable sides (one only is seen in the illustration), a piece on either side of the heater, and these are closed up so that the bread is held vertically, and parallel to the surface of the heater, with only a very short space between. As a result the bread is toasted absolutely evenly, and with no loss of heat at all. Fig. 4 is a section of the lower part of an electric kettle, and it is seen that the heating element projects into the bottom of the kettle, and is practically surrounded by the water.

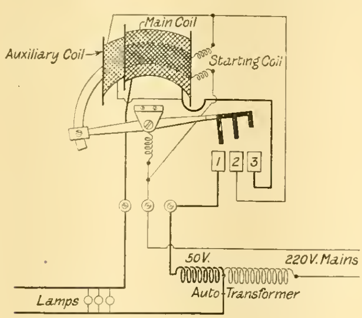

FIG. 2.—Diagram of Automatic Transformer Switch

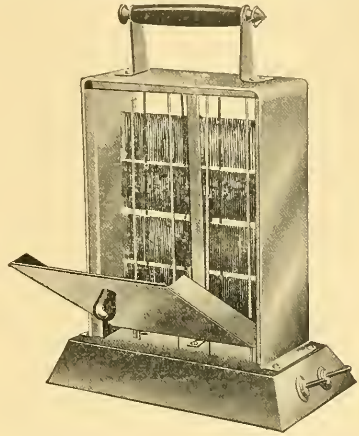

FIG. 3.—Electric "Table Toaster." (Simplex Conduits, Ltd.)

In the larger cooking apparatus similar means are taken to bring the heating elements exactly where they are wanted, and to reduce the amount of heat lost by radiation and convection to a minimum. For instance, in most forms of electric oven at least three of the sides contain heating elements quite close to the interior surface; in nearly all makes the lagging is very thoroughly carried out, while others rely to some extent on giving the outside of the apparatus a bright surface to reduce radiation. It has also been proved by experiment that in roasting a joint in an electric oven, owing to the more even distribution of the heat there is less shrinkage of the meat, so that it retains its gravy; it appears that the smallest possible diminution of weight in a joint during cooking is an object aimed at by cooks and housewives, and that in this respect the electric oven has the same superiority over the gas oven as the gas oven has over the ordinary coal-fired kitchen range. The precision with which the heat can be regulated by switching on or off the heating elements as required is also a great advantage both as regards good cooking and absence of waste, and several makers adopt a series-parallel arrangement of connections and switching, so that all the elements are utilised, whether at full, half, or quarter heat, and there is absolute uniformity of temperature over the whole of the heating surface.

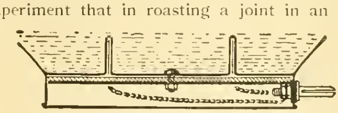

FIG. 4.—Arrangements of heating elements in Kettle. (Simplex Conduits, Ltd.)

Great improvements have also been effected in the heating elements themselves. In the earlier apparatus it was customary to use coils of wire coated with or embedded in enamel, but trouble was experienced owing to the different coefficients of expansion of the wire and the enamel, and consequent cracking and gradual disintegration of the latter, due to unequal expansion. Enamel insulation has been considerably improved in this respect now, and some makers employ it with success, but the favourite method is to wind the high-resistance metal in the form of ribbon on mica strips, or to use flat strips of metal wound edgewise and separated by mica. One maker employs spirals of wire in quartz tubes, and another has for long been particularly successful with strips of mica upon which very thin films of metal have been deposited.

An interesting attachment to a water-boiler (made by the Bastian Electric Heating Syndicate) is shown diagrammatically in Fig. 5. Above the chamber containing the heater is a light, hinged metal flap, upon which bears the end of a rod connected to a catch lever holding the switch in the "on" position. The bubbling of the water when boiling causes the flap to rise, releasing the switch and thus turning off the current.

MANKIND—FROM THE PLIOCENE TO THE PRESENT.[1]

DURING the last forty years the opening period of mankind has receded further and further into the past. At first we were content to count the years in thousands, then in tens of thousands, and now nothing less than hundreds of thousands is regarded as sufficient to cover the known period of man's existence on the earth.

The three works noticed here cover the whole of the human period so far as it is yet known. Dr. H. v. Buttel-Reepen deals with the Europeans of the Pleistocene or Glacial period, to which, following the teaching of Dr. A. Penck, he assigns a round half-million of years. Dr. Franz Schwerz takes up the story where Dr. H. v. Buttel-Reepen leaves off, and describes the various races which have inhabited his native canton of Schaffhausen since the Neolithic period began—one which he regards as commencing about 25,000 years ago. The third work, by Prof. Niederle, of the University (Tchéque) of Prague, is concerned with events which lie within the Christian period—the expansion and fate of the Slavonic race into south and central Europe and into Asia.

The three works are very different in nature; Dr. v. Buttel-Reepen's small monograph is a concise and excellent summary of the facts and theories relating to mankind in Europe during the Glacial period; it is the best of the many books that have lately appeared in Germany to supply a popular demand for information concerning early man, and is richly illustrated. Dr. Scherwz's monograph represents the results of personal research, and reflects the exact, elaborate, and painstaking methods of the Zurich school of anthropologists. Prof. Niederle's book is a stock-taking of the Slavonic race; he estimates that there were 139,000,000 Slavs at the commencement of the present century, more than 20,000,000 of whom occupy territories outside Russia, and are a continual cause of political unrest in central and eastern Europe.

It is the anthropological rather than the political data of Prof. Niederle's writings which interest us here. He appears to supply the answer to a problem which has puzzled Dr. Schwerz and has been an enigma to anthropologists in every country, especially in England. The problem concerns the source and supply of the brachycephalic races of central Europe and their sporadic appearance in Britain. The oldest human remains yet found in Schaffhausen—a canton almost surrounded by German territory—are those of Schweizersbild—remains which supplied Prof. Kollman, of Basle, with the basis for his famous theory of a pygmy prehistoric race in Europe. There can be absolutely no doubt that the Schweizersbild Neolithic men are identical with the Neolithic English described by Huxley as the "river-bed type"—people of rather low stature and with small heads, somewhat compressed from side to side and falling in the dolichocephalic group. The inhabitants of Schaffhausen soon after the beginning of the Christian era were also a long-headed people, which Dr. Schwerz associates with the Reihengräber of south Germany. The modern inhabitants of Schaffhausen are eminently short-headed, but as to how and when the short-headed people replaced the long-headed Dr. Schwerz can give no answer.

The change in head form in Schaffhausen is most probably due to a Slavonic permeation. In colouring and head-form the modern inhabitants of Schaffhausen are Slavonic. As far back as history and tradition can take us Russia has been the home of the greatest and most homogeneous mass of brachycephalic humanity. Prof. Niederle paints a picture of the exodus of the Bulgarians, Servians, Slovenes, Slovoques, Tschéques, Lusaciens, and Poles, from the parent stock in Russia, and their absorption in the German-speaking peoples.

We may be certain that what has taken place in historical times—a continuous exodus and absorption of the round-headed Slavonic stock—had been at work during the greater part of the Neolithic period, if not earlier. A round-headed race is not known to occur in western Europe until the latter part of the Palcolithic period. There is every reason to regard the short-headed races of mankind as comparatively recent products of evolution; every known example of Glacial and early post-Glacial man, with the possible exception of some Krapina people, is of the long-headed

[1] "Aus dem Werdegang der Menschheit. Der Urmensch vor und während der Eiszeit in Europa." Von Dr. H. v. Buttel-Reepen. Pp. vi+139+109 figures in text+3 tables. (Jena: Gustav Fischer, 1911.)

"Versuch einer anthropologischen Monographie des Kantons Schaffhausen speziell des Klettgaues." Von Franz Schwerz. Neue Denkschriften der schweizerischen naturforschenden Gesellschaft, Bd. xlv., pp. 83–292+80 figures+1 map+87 tables. (Zürich: Zürcher & Furrer, 1910.)

"La Race Slave, Statistique, Démographie, Anthropologie." Par Prof. Lubos Niederle. Traduit du Tchéque par Louis Léger. Pp. xii+231+1 map. Paris: Félix Alcan, 1911.) Price 2.50 francs type. From the present distribution of the short-headed races we may regard Russia as the most probable cradle of this race. The brachycephalic fair-haired European may be regarded as the latest and perhaps highest product in evolving humanity. Time will show that the brachycephalic peoples of Europe are essentially of Slavonic origin, and that brachycephaly will prove to be a Mendelian dominant in the fusion of long- and short-headed peoples.

Dr. v. Buttel-Reepen adopts Dr. Penck's three intermissions of the Glacial period—a first, second, and third; and in the tentative condition of our knowledge that division is as good as another. To the beginning of this period he assigns *Homo Heidelbergensis*, known from his mandible only and by the Eoliths ascribed to him. A minute study of this mandible leaves no doubt that *Homo Heidelbergensis* must be assigned to the Neanderthal race. Remains of this race are also ascribed to the second interval and the third succeeding Ice age—a period estimated at 200,000 to 400,000 years. If such a period is approximately correct, then it is wonderful that the type remained so constant throughout such a vast interval of time. We know of only nine crania of the race, and the limb bones of only five or six individuals, and in all of them the state of preservation is incomplete.

The rarity of such specimens probably explains the extraordinary sum paid by the Museum für Völkerkunde, in Berlin, for the skeleton discovered by Herr O. Hauser near Le Moustier in 1908—a price, according to Dr. Buttel-Reepen, amounting to 160,000 marks. The skull of this skeleton, like that found at Chapelle-aux-Saints, was so broken that in neither case has an approximately accurate reconstruction been made. Indeed, the only cranium which is nearly complete and intact is that found at Gibraltar so long ago as 1848—nine years before the discovery of the Neanderthal calvaria. This cranium, which Dr. Buttel-Reepen regards as of little scientific value, is, in the opinion of the writer, the most primitive and therefore probably the oldest of all the remains yet found of the remarkable Neanderthal race. It is the only one which shows a cranial capacity decidedly below the average of modern Europeans; the palate, and especially the teeth, are of the most primitive form known in this race. In such a long period of time as that ascribed to the Ice age, there must have been a succession of many races, and in the remains found at Krapina (Croatia), and at Spy (Belgium), we see what is apparently a mixture of older and more recent forms.

In the third interval of the Ice age the Neanderthal race apparently disappeared; his successor at present is supposed to be the type of man found at Gally Hill in Kent, and at Brünn in Moravia—a long- and narrow-headed race, so unlike the Neanderthal that Prof. Klaatch propounded the theory of a multiple simian origin for human races—a theory which Dr. v. Buttel-Reepen says must be taken *cum grano salis*. The remains found in the Grimaldi cave, near Mentone, and the Cro-Magnon race are also assigned to the close of the Glacial period. The Cro-Magnon race, which thus early appeared in Europe, is from a physical point of view, and also as regards the cranial capacity, one of the finest races of mankind ever evolved. The bearing of all recent discoveries of ancient man in Europe, both as regards his physical structure and his culture, is to remove the beginning of humanity into a more remote past—one which reaches into the Pliocene period at least.

Dr. Buttel-Reepen, like of many of his German colleagues, is inclined to assign the skull discovered in Gough's cavern, Cheddar, and described by Mr. H. N. Davies in 1904, to the Palæolithic period. There can be no doubt this is an error, for the cranium in question is an example of the "river-bed" type—the characteristic form in England during the early Neolithic period. The Tilbury skull, and one recently found in a Derbyshire cave by the Rev. E. H. Mullins, are also of this type.

A. KEITH.

COAL DISCOVERIES IN BRITISH COLUMBIA.

THE announcement, made in a special article in *The Times* of October 14, on "Coal in British Columbia," that an "immense body of anthracite coal exists at the head-waters of the Skeena . . ." to quote the words used in the telegram from the Minister of Mines of that province, need cause no surprise when it is considered how little is yet known about the mineral resources of the vast territories comprised within the Dominion of Canada. If the figures given by Reuter may be taken as trustworthy, 2100 square miles and 43,000,000 tons per square mile, the estimated coal resources of the province leap up in a single bound from 40,225,000,000 tons, as estimated in 1910, to 130,525,000,000 tons, the addition amounting to about three times the quantity estimated to be contained in our own South Wales coalfield.

Very little information appears to have been allowed to leak out regarding this immense coalfield almost up to the moment when publicity was given to the foregoing statements. All that is said about it in the annual report of the Minister of Mines for the year ending December 31, 1910, is that "the anthracite district around the head-waters of the Skeena continues to attract attention" (p. K88). Again, on p. K176 of the same document a summary is given in the form of a table of the estimated coal-content of the various known coal areas in British Columbia, extracted from a paper read by Mr. D. W. Dowling, of the Geological Survey, before the Canadian Mining Institute at the Quebec meeting in March, 1911, in which the Skeena River is credited with sixteen square miles and 61,000,000 tons of anthracite. Lastly, when the present writer had the pleasure of meeting Mr. McEvoy (mentioned in the telegram of the Minister of Mines) in Toronto on March 7 last, nothing that he can recollect was said to give him any clue to the vastness of the coalfield which Mr. McEvoy was then about to re-visit.

In the table referred to above the names of twelve separate coalfields are given, probably all of Cretaceous age, containing 39,674 million tons of bituminous coal; three, probably of Tertiary age, containing 490 million tons of lignite; and one, the Skeena River coalfield, the geological age of which is not mentioned, containing sixty-one million tons of anthracite. The largest areas are those of Comox, 300 squares miles; Nanaimo, 350; Elk River, 230; Elk River north, 140; Graham Island, 60, all containing bituminous coal; and Graham Island, 100, lignite. Although the areas of Comox and Nanaimo fields are the greatest, the assumed thickness of coal in each, namely, six feet, puts their estimated reserves far behind those of the two Elk River fields, each with 100 feet of coal distributed in a number of separate seams. As stated in the article in *The Times*, the two first are in Vancouver Island. The seams of coal, Douglas and Wellington, with a rider from two to three feet thick under the first, and a similar rider from two to four feet thick above the second, crop out at a greater or less distance from the shore, not exceeding six or seven miles perhaps at most, and dip under the sea in the Strait of Georgia and under the small islands near the shore. The two last, Elk River and Elk River north, are cut through by the defiles in, and not far from, the watershed of the Rocky Mountains, and consequently many of the seams of coal are accessible by means of day-levels. The present writer would have thought that a greater thickness than six feet of coal could have been attributed, at any rate to the seams in the Nanaimo coalfield, as the Douglas seam occurs in the form of lenticular masses, the maximum thickness of which attains as much as twenty-six and twenty-eight feet at some points, and as the Wellington seam, which underlies it at a depth of seven hundred to one thousand feet, is from three to six feet thick.

The following analyses will serve to show the character of the bituminous coals referred to above :—

	Comox per cent.	Nanaimo per cent.	Elk River per cent.
Moisture	1·47	4·60	0·87
Volatile combustible matter	28·19	33·70	23·11
Fixed carbon	64·05	54·70	70·70
Ash	6·29	7·00	5·32

The proportions of all these constituents vary in each of the coalfields, the moisture attaining in some cases as much as 7 per cent., volatile combustible matter more than 40 per cent., and ash 10 per cent. and more. Some of the seams make good coke, when the proportion of moisture is low enough (not exceeding 2 per cent.).

The produce of the Vancouver Island Collieries is in demand along the western coast of America; that of the Elk River Collieries supplies smelting works in the United States, railways, and so on.

The produce of the Skeena River Collieries will have about 180 miles to travel to the coast at Prince Rupert, and will thereafter have to compete with the bituminous coals of Vancouver and some of the other islands along the coast, which can ship their coal directly into the holds of the ships which use it.

It is to be hoped that in the great field the existence of which has been foreshadowed, some of the supposed anthracite will be found to contain at least 12 per cent. volatile combustible matter, as "drier" coals and true anthracites, containing from 3 per cent. to 6 per cent., are not considered suitable for steam-raising purposes in European countries, on account of their slow rate of combustion, although Pennsylvanian anthracite seems to be quite acceptable in some parts of the United States.

DR. HUGHLINGS JACKSON, F.R.S.

THE recent death of Dr. Hughlings Jackson has called forth that widespread recognition amongst men of science which his modesty and retiring nature rendered impossible during his lifetime. To many, and particularly to workers in scientific fields remote from medicine, his name is unknown, and yet, although he never performed an experiment, no one man has so profoundly influenced the growth of our knowledge of the functions of the nervous system.

John Hughlings Jackson was born in 1835, at Green Hamerton, in Yorkshire, and began the study of medicine at York. After a short period as a student at St. Bartholomew's Hospital, he became qualified to practise medicine in 1856, and then returned to York for two years as house-surgeon to the dispensary. In 1862 he was appointed assistant physician to the National Hospital for the Paralysed and Epileptic, and in 1863 he became assistant physician to the London Hospital. These are the material facts in Dr. Jackson's outwardly uneventful life.

At the National Hospital he came in contact with two men who influenced the direction of his thoughts. Brown-Séquard, from whom he acquired a knowledge of the recent work of French physiologists, and Lockhart Clarke, whose beautiful microscopic preparations taught him the minute anatomy of the nervous system. But in his early lectures, delivered between 1864 and 1868, he showed how quickly he had found that path which was to lead him by consecutive steps to his greatest generalisations. In 1864 he had already shown that paralysis of the right half of the body was associated, in most cases, with loss of speech, and characteristically gave the whole credit to Broca, whose work had appeared shortly before his lecture. Broca's observations were essentially anatomical, and are still the subject of dispute, but Jackson described forms of disturbed speech associated with hemiplegia, which stand untouched to-day. In 1866, he formulated the condition now known as apraxia, and repeatedly demonstrated cases of this disturbance to his pupils in the wards of the hospital. But he was forty years before his time, and apraxia was not generally recognised until its rediscovery by Continental observers.

At that time all work on the functions of the nervous system was dominated by the brilliant discoveries of the French School of Physiology, and Jackson's idea that convulsions arose from some change in the cerebrum and usually from a focus within the territory of the Sylvian artery was passed over in contemptuous silence. But when Hitzig and Fritsch showed, in 1870, that stimulation of the cortex could produce movements, Jackson's views came to the front, and local convulsions are now called by his name.

Step by step we can watch the growth of his great generalisation put forward in the Croonian lectures of 1884 on "Evolution and Dissolution of the Nervous System." He showed that in hemiplegia movements and not muscles were affected, for the brain is not dealing with tools but with functions. Thence he passed to the idea of "levels" in the nervous system, each of which represented a higher evolution; passage from one level to that above it was always from the general to the special in function, and from the simple to the complex in structure. Dissolution produced by disease or by experiment occurred in the inverse order, and the removal of the highest level set free the activities of those below. To this view Jackson gave the widest application, and explained the rigidity of limbs paralysed from cerebral disease by the over-action of uncontrolled centres in the cerebellum and spinal cord. So far back as 1877, he laid down that "the cerebellum is the centre for continuous movements and the cerebrum for changing movements," and so formulated the modern doctrine of the tonic nature of cerebellar activity.

These wide-reaching generalisations have not yet received their full application, but they permeate modern neurology; and the position of the English School is due largely to Dr. Jackson's stimulating influence and generous self-effacement. H. H.

AUGUSTE MICHEL LÉVY.

ON September 25, Auguste Michel Lévy, director of the Geological Survey of France, and Inspector-General of Mines, died in his sixty-eighth year. His work, which has had so wide an influence, covered the whole period of the rise of modern petrology. The systematic grouping of rocks was largely a French study at the opening of the nineteenth century; Michel Lévy carried on the tradition into far broader fields by concerning himself with their natural relationships and modes of origin. The great memoir entitled "Minéralogie micrographique; Roches éruptives françaises," in which he was associated with his master Fouqué, appeared in 1879, and showed how the methods of Sorby had been appreciated in

France, simultaneously with their development by Vogelsang, von Lasaulx, and Rosenbusch in Germany. A dual nomenclature, indeed, grew up, for certain structures in igneous rocks, of which traces are still clear when we compare works produced on opposite banks of that great factor in literature, the Rhine.

Lévy, in his desire to understand, and not merely to describe, set himself to construct igneous rocks by fusion in the laboratory, as Ste.-Claire Deville and others had constructed rock-forming minerals. In the domain of lavas the results, produced in collaboration with A. Lacroix, were especially successful, and surpassed the expectations of petrologists, who had previously been content with glassy slags. Carrying the study of the optical properties of minerals in thin sections to a high degree of refinement, Lévy and Lacroix issued their book on "Les Minéraux des Roches" in 1888, and the details there given have formed the basis for a long series of researches by their followers in many lands.

The separation of the members of the felspar family, those halting-points in the continuous series indicated, on chemical grounds, by Tschermak, received special attention in Lévy's memoir on the "Détermination des Feldspaths" in 1894. But those who have watched the development of the French Geological Survey will also recognise how much is due to Lévy as an organiser in the field. The gneisses of the Morvan occupied his attention twenty-four years ago, and in 1887, in a modest paper entitled "Sur l'origine des Terrains cristallins primitifs," published by the Socété géologique de France, he set forth his belief that dynamic metamorphism had been overrated as a cause of the crystallisation of minerals in schists. His official memoir on the "Granite de Flamanville" (1893) shows how far he was prepared to go in urging the potency of contact metamorphism and mutual absorption in the production of types of crystalline rock; and his views, associated as they were with the parallel work of Barrois, laid the foundation for many later observations, such as those of Lacroix, Sederholm, and Daly.

Lévy's official work extended to an investigation of the water supply of his country, a research of immense public importance, which is still in progress. His secure position as one of the foremost of scientific men earned him his election as a member of the Institute of France. For those who wish to have before them, and for future generations of their students, the record of the firm and noble features of Lévy as he lived, it may be well to mention the fine photogravure portrait now included in the series by Eckstein, of Berlin.

DR. F. AMEGHINO.

A CIRCULAR letter recently received at the British Museum (Natural History) from the president of the Sociedad Cientifica Argentina, Buenos Aires, announces the death of Dr. Florentino Ameghino, the well-known palæontologist, as having taken place at La Plata, on August 6. We believe that the cause of death was neglect of a limb that had been wounded in an accident, the deceased refusing to call in medical assistance. For many years Dr. Ameghino kept a small stationer's shop in La Plata, and it was there that much of his palæontological work was carried on. When and how his attention was first directed to this subject we have no information, but it must evidently have been during the 'seventies, as he published a paper entitled "L'homme préhistorique dans la Plata" in the second volume of the *Revue d'Anthropologie*, 1879. This was followed by a number of papers in various local journals on the Tertiary mammals of Patagonia, the materials of which were collected by his brother, Carlos Ameghino, who for many years afterwards continued to make collecting journeys to that country; but whether on his own account or at the instance of others we are unaware.

Figures and fuller descriptions of the, frequently fragmentary, specimens upon which scores of species and genera were founded in these preliminary papers were given in a quarto two-volume work, published at Buenos Aires in 1889, under the title of "Contribucion al conocimento de los Mamiferos fosiles de la República Argentina." This was followed by a perfect stream of memoirs and papers on the fossil mammals and birds of Patagonia and other parts of the Argentine Republic, in all of which the author insisted that the Santa Cruz beds are Lower Eocene, and some of the other mammaliferous horizons of Patagonia Cretaceous, whereas most palæontologists consider them to be not older than Oligocene.

In 1895 Dr. Ameghino published in Buenos Aires an important memoir entitled "Sur les Oiseaux fossiles de Patagonie," in which appeared a full account of the gigantic seriema-like Phororhachis. The discovery and description of this wonderful bird were alone quite sufficient to have made Ameghino's name celebrated in palæontological annals; another great discovery being that of the development of a monodactyle type of foot in an animal far below the grade of the horse. That Ameghino, out of the redundance of his material, should have been profuse in naming species and genera, is, although a matter for regret, scarcely to be wondered at, and must not be allowed to obscure our view of the value of his work in bringing to notice the marvels of the ancient fauna of Patagonia.

On the death of Dr. Carlos Berg, Dr. Ameghino was appointed director of the Museum at Buenos Aires, a post he held until his death.

NOTES.

Reuter's agency states that the British Government is sending out a further commission to Central Africa in connection with sleeping sickness. This will be in charge of Colonel Sir David Bruce, who will be accompanied by Lady Bruce, and assisted by Captain Hamerton, R.A.M.C., Prof. Newstead, of the Liverpool School of Tropical Medicine, Major Harvey, R.A.M.C., Staff-Sergeant Gibbons, and Mr. James Wilson. The work of the commission will on this occasion be confined to Nyasaland, where more than forty cases of sleeping sickness have occurred since 1909. The commission, which is also under the auspices of the Royal Society, is expected to be absent from England for three years. Sir David and Lady Bruce will leave Marseilles on November 10, and will proceed up the Zambezi and the Shire Rivers to Blantyre and Zomba, the capital of Nyasaland. One of the principal objects of the commission is to endeavour to ascertain whether the existence of the fly supposed to be responsible for sleeping sickness in Nyasaland depends upon the presence of big game.

All artists and chemists will learn with regret that Sir Arthur Church has decided to retire from his position as professor of chemistry to the Royal Academy, where he has for so many years not only acted as guide to the young art student through the intricate subject of chemistry as applied to the painting of pictures, but has also performed invaluable services both in advising and assisting artists in their work, and on many occasions helping the Government in the preservation of works of art. His careful investigations and restorations of the frescoes in the Houses of Parliament, and his invaluable work in the preservation of ancient stone buildings, such as Westminster Abbey, are well known to all who are acquainted with these subjects. While on one hand Sir Arthur Church was for many years professor of chemistry at the Royal Agricultural College at Cirencester, and has done invaluable work in connection with the application of chemistry to agriculture, on the other hand he may be said to be one of the few living chemists who have applied their scientific knowledge to the problems connected with the applied arts; and he has done this not only in the department of chemistry, but also in the scientific theory of colour as applied to decoration. He is also known as an authority on precious stones, porcelain, and earthenware, and has shown all his life that interesting combination of the scientific and artistic temperament which is rarely found. It is to be hoped that his retirement from the professorship will mean merely that he will have greater leisure to continue his many researches on the application of chemistry to painting, researches upon which the permanency of some of our greatest works of art must ultimately depend.

REUTER reports that a slight earthquake shock was felt at Catania on October 15. The shock was more severe at Giarre, Macchia, Guardia, Rondinella, and Santa Venerina.

THE South African Branch of the Royal Sanitary Institute is arranging to hold a congress in Cape Town on November 9–11. This is the first sanitary congress to be held in British South Africa.

THE death is announced, on October 10, of Dr. W. R. Huggard, the British Consul at Davos, Switzerland. Dr. Huggard was an authority on mental diseases and tuberculosis. He was not a prolific writer, but was known as the author of a "Handbook of Climatic Treatment, including Balneology," and a few papers in medical periodicals. Dr. Huggard had been a resident at Davos for twenty-five years.

THE death is announced of the Rev. Mariam Balcells, S.J., professor of mathematics at Boston College, Mass. A native of Tarragona, he was for a time connected with the Spanish Geological Survey. He became director of the Ebro Observatory of Cosmical Physics, which he had himself built during his earlier career as an engineer. He introduced into Spain the study of the solar chromosphere by means of the spectroheliograph, and in collaboration with Father Cirera, now the director of the observatory, made various investigations of the relation between solar activity and terrestrial magnetism.

FROM the Abor expedition, which is about to start, we have a good prospect of learning more about this little-known region. Besides the surveying work which is always carried out on such mountain expeditions, the Government of India has arranged for as much scientific investigation to be carried out as the circumstances will admit. According to *The Morning Post*, Mr. J. H. Burkill will be the botanist, and Mr. S. Kamps and Mr. R. Hodgirt will take charge of zoology and anthropology respectively. A geologist will accompany the expedition, but the definite appointment has not been announced. Captain Trenchard and Lieut. Oakes are in charge of the survey operations. An interesting experiment is being made with various forms of rations, and especially with compressed tea, which has been made up into small cases of 45 lb. each for handy transport.

AT the present time Mr. Chas. Urban, who has done so much to correct our geographical impressions, is exhibiting at the Scala Theatre a "kinemacolor" representation of the recent eruption of Etna. It is not an exciting show, though possibly the photographer got uncomfortably hot, for the most interesting feature of the film is the portion depicting the slowly advancing front of a lava stream. This is well worth seeing by any geologist who has not actually witnessed this type of flow. There is a peculiar fascination in watching the deliberate fragmentation of the cooling lava-crust, with the continuous detachment of solidified blocks, each with its attendant puff of white steam. Sitting in the comfortable seats of the Scala, the visitor would like more of this portion; but no doubt there were difficulties.

THE eighteenth International Congress of Americanists is to be held in London from May 27 to June 1, 1912. This will be the first time the congress will have visited Great Britain. The main subjects to be considered at next year's meeting are:—(*a*) the aboriginal races of America, their origin, distribution, history, physical characteristics, languages, customs, and religions; (*b*) the monuments and archæology of America; and (*c*) the history of the discovery and occupation of the New World. H.R.H. the Duke of Connaught is the patron and Sir Clements Markham president. The organising committee includes Sir Richard Martin, Sir T. Holland, Dr. C. H. Read, Profs. Gowland and J. L. Myres, Mr. H. Balfour, and others, with Mr. Alfred Maudslay as chairman. Titles of papers to be presented at the meeting of the congress should be sent immediately to the secretary, c/o the Royal Anthropological Institute, 50 Great Russell Street, London, W.C.; and it is further requested that synopses of the papers may be sent in by March 31, 1912. Communications may be oral or written, and the languages admitted are English, German, French, Italian, and Spanish.

MR. E. A. GAIT, Census Commissioner for India, has collected into a single volume the detailed instructions issued to the provincial superintendents describing the subjects on which it is desired that information should be collected and embodied in their reports now in course of preparation. Of particular interest are the inquiries into the internal working of the caste system and the extent to which the rulers of independent States exercise their traditional prerogative of interfering in such matters; the investigation whether the existence of the Mendelian law can be traced in the crosses between different races; birth and marriage customs; and numerous other subjects which have been discussed only in a summary way during the last and previous enumerations of the people. If the provincial superintendents, in addition to the task of compiling and explaining the statistics, can find time and opportunity for undertaking this investigation, the forthcoming reports of the census of 1911 are sure to furnish materials of much interest to students of anthropology and sociology.

THE committee appointed to investigate ancient earthworks and fortified enclosures has prepared a report for presentation to the Congress of Archæological Societies. The committee reports steady progress in the investigation of these monuments, in particular in Hampshire, where Dr. J. P. Williams is engaged in cataloguing the barrows of that county after the completion of his list of earthworks. Measures of preservation have been adopted in the case of the Stokeleigh Camp in Somerset, the Scambridge Dykes in Yorkshire, and at Skipsea in the same county. The committee regrets to announce grievous destruction at the earthworks of Willington in Bedfordshire, Penmaenmawr in Carnarvonshire, Uley Bury in Gloucestershire, Stainton in Westmorland, and of the ditch round the top of Windmill Hill at Avebury, in Wilts. Excavations have been carried out on several sites, the most important being those at Avebury under the control of Mr. St. George Gray, and some preliminary investigations of Stokeleigh Camp, in Somersetshire, by Prof. C. Lloyd Morgan and Mr. A. E. Hudd, but nothing was found to throw further light on the origin and construction of the camp. At Old Sarum the work of the Society of Antiquaries was practically confined to the uncovering of masonry structures.

IN 1878 ("Cat. Chiroptera Brit. Mus.") Dr. Dobson gave the name *Kerivoula brunnea* to a bat collected by Sir Andrew Smith years previously, leaving it open whether the habitat was South Africa or Madras. Until a short time ago that specimen remained the only known representative of the species; but it is announced in the Annals of the Transvaal Museum for April that a second example has been obtained in Portuguese East Africa, thus fixing the habitat.

IN an article on a new species of Hipparion (*H. proboscideum*) from the Upper Tertiary of Samos, published in *Verh. Deutsch. Zool. Ges.*, 1910–11, p. 192, Prof. Studer expresses the opinion that the preorbital depression or pit found in the skull of many members of the horse group is not for the reception of a lacrymal gland, but is for the purpose of muscular attachment, and attains its maximum development in species like Onohippidium and *Hipparion proboscideum*, which were probably furnished with a proboscis. The position of the pit, it is stated, differs somewhat from that of a true larmier, and the inframaxillary foramen is always some distance from the pit. This accords, in some degree, with the views of Mr. R. I. Pocock, who has pointed out that in Onohippidium the pit is divided into two moieties, one of which may have contained a gland, and that the pit in Hipparion is probably also glandular. From the fact that a preorbital pit occurs in Merychippus, as well as in the above-mentioned genera, Dr. Studer is inclined to think that a proboscis may have been developed in most or all of the forerunners of the horse group.

A THIRD part of the publication "Illustrations of New South Wales Plants," for which Mr. J. H. Maiden is responsible, contains descriptions of seven species of Callistemon, the bottle-brushes, and four species of Swainsona; all except *Callistemon lanceolatus* are illustrated. A key to the species of Callistemon, prepared by Mr. E. Cheel, separates a large section having anthers with free filaments from a small section displaying coherent filaments. Certain species are cultivated, notably *C. rigidus* and *C. pinifolius*, here described. Swainsona, belonging to the Papilionatæ, includes some fodder plants and a few that are poisonous to stock.

A PUZZLING fossil organism, named Traquairia by Mr. Carruthers, forms the subject of a short article contributed by Mrs. D. H. Scott to the *Annals of Botany* (April), a separate copy of which has just reached us. The chief feature in the organism is the complicated structure of the outer envelope, with an elaborate system of anastomosing tubes connected with prominent spines. It was originally referred by Mr. Carruthers to the radiolarians, but subsequent botanical investigators have regarded it as a possible reproductive organ of a cryptogamic plant. Without expressing a definite opinion, the author inclines towards the original suggestion. The chief object of the paper is to identify and describe four species that differ primarily in the nature of the spines.

ARISING out of an investigation into the sources of the Ignatius beans of commerce, furnished by species of Strychnos, Mr. A. W. Hill has prepared a revision of East Indian and Philippine species of the genus, and it is published in *The Kew Bulletin* (No. 7). The section, characterised by long corolla tubes and large fruits containing strychnine, forms a very natural group, ranging in distribution throughout the area, although the individual species conform to the general rule of localised distribution. Types of seven new species are described. Another systematic article is provided by the list of new African plants, which includes two new genera, Discoglypremna and Sclerodactylon. Also a new genus, Dipentodon, showing unique floral characters, is discussed by Mr. S. T. Dunn, who places it provisionally in the Celastraceæ.

THE United States Geological Survey has published ten bulletins (Nos. 457–464, 469, 472, 473) dealing with the results of spirit-levelling during the last ten or fifteen years in various parts of the country. A plate showing the form of bench-mark used is now included to facilitate recognition of the bronze or aluminium plate on which the altitude to the nearest foot, before the final corrections are applied in the office, is stamped.

THE Canadian Department of Mines has published a summary of the triangulation and spirit-levelling carried out in Vancouver Island, B.C., in 1909. Descriptions of the stations are given, and the azimuths, back-azimuths, and distances of points observed from each station are tabulated; but the method of observing is not stated, nor is the accuracy attained anywhere indicated. An 8-inch theodolite, with two micrometer microscopes reading to two seconds, was used. The levelling was carried out with a 14-inch Dampy level, each line being run at least twice; altitudes are tabulated to 0·001 foot, but here again there is no indication of the precision aimed at or attained.

THE mining town of Burketown is in the north-western corner of Queensland. Its ore deposits were first discovered by Mr. F. H. Hann in 1887, but mining was only begun in 1897; since then several of the ore deposits have been worked, and concentrates carted to the coast at Burketown, one hundred miles distant. The leading mining company of the district, the Queensland Silver Lead Mines, Ltd., recently arranged for an inspection of the field by one of the officers of the Queensland Geological Survey. The work was entrusted to Mr. Lionel C. Ball, whose report, illustrated by five maps, twenty-three plates, and forty plans, has now been issued by the Geological Survey of Queensland (Publication No. 232). Mr. Ball is impressed by the widespread distribution of the ores; but the quantity of high grade is small, and the success of the field will depend upon the large low-grade ore bodies. The ore deposits are mainly brecciated lodes in a series of silicified sandstones and indurated shales. The report contains not only a precise account of the chief mineral deposits, but includes some important contributions to the geology of north-western Queensland.

THE U.S. Weather Bureau has issued a special bulletin relating to the destructive hurricane which visited the South Carolina-Georgia coast on August 27–28. Synoptic weather charts are drawn for the Atlantic Ocean for August 25–28, giving the position of the hurricane; reports from vessels show that the storm was in process of formation on August 23 in about latitude 24° and longitude 67° 30′. Its course was far north of the normal path of tropical disturbances at this season of the year, and its influence was not felt at any stations in the West Indies; the first signs of its approach were felt at the land stations that suffered most, viz. Charleston and Savannah, on the morning of August 27, and warnings of its approach were fortunately sent by the Central Bureau to both those stations and to shipping at various ports, thus minimising the danger so far as possible. The centre of the hurricane reached the coast near Savannah at 8h. a.m. of August 28, passed through eastern Georgia, recurved over North Carolina to E.N.E., and passed to sea off the New Jersey coast. Immense damage was wrought, both to houses and shipping, the velocity of the wind at places exceeding 100 miles an hour (factor 3?). Prof. Moore remarks that, had wireless reports been at hand, it would have been possible to give warning of the approach of the storm several days previously; but this would not have saved the hundreds of houses unroofed, the destruction of telegraph wires, and the like.

As stated in NATURE of September 28 (p. 417), at the Turin meeting of the International Electrochemical Commission the committee on international symbols agreed provisionally to the proposals made at the Brussels meeting. These were to represent mass, length, and time by M*m*, L*l*, and T*t*; electric current, electromotive force, and resistance by I, E, and R; quantity of electricity by Q*q*; magnetic field and induction by H and B; inductance by L; the last three symbols to be printed in special type not yet settled. The maximum value of any quantity to be indicated by the subscript *m*.

THE *Verhandlungen* of the German Physical Society for September 15 contains a paper by Dr. A. R. Meyer, of the University of Greifswald, on the change of the electrical resistivity of pure iron from 0° to 1000° C. The iron is in the form of a wire, and is enclosed in an evacuated glass bulb. Its resistance is measured by the fall of potential down the central portion of it, due to the passage of the heating current. Its temperature is measured thermoelectrically by means of a fine platinum platinum-rhodium junction in contact with it, or by means of a radiation pyrometer. For each of three specimens of iron the resistance increases more rapidly with temperature as the temperature rises until 700° C. is reached. Above this temperature the rate of increase is smaller and more nearly uniform. Up to 700° C. the watts spent in the wire, the current through it, the electromotive force at its ends, and its resistance are all proportional to powers of the absolute temperature.

THE September issue of the Journal of the Chemical Society contains obituary notices of Profs. Beilstein, Erlenmeyer, Fittig, Landolt, and Menschutkin. In addition to the biographic and scientific narrative, an admirable series of portraits is given. In the case of Prof. Beilstein, the notice is signed by Prof. Otto N. Witt.

THE forty-second volume of the *Sitzungsberichte* of the Physikalisch-medizinischen Sozietät in Erlangen has recently come to hand. In addition to five papers by Prof. E. Wiedemann on the history of science, the volume includes chemical papers on the halogenaurates of ethylene- and propylene-diammonium, by A. Gutbier and C. J. Obermaier on the copper salts of ferro- and ferri-cyanic acid, and by D. Hovermann on the atomic weight of iridium. The values deduced for this atomic weight by four different methods from the analysis of the salt K_2IrCl_6, were 192·942, 192·881, 192·956, and 193·116, whilst the analysis of the salt $(NH_4)_2IrCl_6$ gave the value 193·403.

The Scientific American of September 16 is devoted specially to industrial chemistry. It contains articles on "How Electricity is Aiding the Chemist," by Prof. W. H. Walker, of Massachusetts; on "Artificial Rubber," by Prof. Ira Remsen; on "Testing before Buying," by Dr. C. F. McKenna; on "Catalysis," by A. J. Lotka; on "The Industrial Chemist," by Prof. R. K. Duncan; and on "The Technically Trained Foreman," by Dr. Allen Rogers. The magazine is attractively produced, and contains a number of interesting and unfamiliar illustrations, but suffers from the disagreeable characteristic of American journalism whereby each article is interrupted at the conclusion of its first or second page and continued in fragments amongst the advertisements.

DEALING with the destruction of the Austin dam, Pennsylvania, *The Engineer* for October 13 states that, shortly before the actual disaster, the condition of the structure had aroused fears among the residents of the towns below, and that these, being expressed, had the effect of inducing the owners to undertake certain minor protective measures. It is questionable whether anything short of complete reconstruction could have saved the dam. Owing to the upward overturning pressures caused by leakages below the foundations, the alignment of the upper edge had last summer already become a slight arc. That this was the real cause of the disaster is the opinion of the engineer who designed the dam, and reported on the defects discovered in January, 1910. He and another engineer reported the dam to be safe, notwithstanding these defects, but made certain recommendations for the repair and reinforcement of the structure. These, however, he was not engaged to supervise, and he has no knowledge that they were ever carried out. That Austin will be rebuilt, or the lumber industry of the district survive the calamity, seem improbable. The local timber supply was rapidly nearing exhaustion, and at the best could have held out but five years longer. To these circumstances, perhaps, in some degree, may be attributed the comparatively few and ineffectual measures taken to safeguard public interests.

Engineering for October 13 contains an account of the demolition of the Bridlington railway bridge on the North-Eastern Railway, an operation which was carried out by the Ammonal Explosives, Ltd., of London. The bridge was composed of five arches, each arch having a span of 18 feet, with a width of 37½ feet. The arches were built of four courses of hard ringing bricks set in cement, forming a hard, tenacious mass of masonry requiring to be pulverised completely and instantaneously. To facilitate the operation, the surface of the bridge had been stripped, leaving simply the crowns of the arches and the buttresses to be blown down. As the bridge was separated from the station and buildings by only about 8 or 10 feet, the crowns of the arches only were blown down at the first operation. The total quantity of ammonal No. 5 explosive used was 39·5 lb., distributed in 139 holes. A feature of the operation rendering it more than usually interesting was the employment, for the first time in England, of an entirely new kind of detonating fuse, called Bickford's toluene fuse or "Cordeau" detonant. With this fuse, detonators in each cartridge are dispensed with. The fuse may be either laid alongside or simply inserted into each cartridge, and one detonator, attached to the firing end of the fuse, alone is necessary to cause the instantaneous detonation of the whole mined structure. The whole operation was conducted in a most successful manner.

MESSRS. H. F. ANGUS AND CO., of Wigmore Street, London, W., have issued their second catalogue of second-hand scientific apparatus and accessories. All the instruments listed have been tested, adjusted where necessary, and, unless otherwise stated, are capable of work of equal precision as when new. The catalogue gives particulars of microscopes and accessories, various other optical instruments, and sundry apparatus.

THE second part of vol. iv. of the Proceedings of the University of Durham Philosophical Society can now be obtained from Messrs. A. Reid and Co., Ltd., of Newcastle-upon-Tyne. It includes a selection of the papers read to the society between December 8, 1910, and May 11, 1911. These papers include a description of a new steam trap, by Mr. E. M. Eden; one by Prof. Henry Louis on the mutual development of metallurgy and engineering; and others by Dr. T. H. Havelock, on the displacement of the particles in a case of fluid motion; by Dr. J. A. Smythe, on benzylorthothioformate; and by Dr. A. A. Hall, on the relationship between the chemical composition and the position of some North Country clays. In addition there is a report of the Boulders Committee on the boulders and pebbles collected or determined since the last report of the committee.

ERRATUM.—In line 9 of Mr. Rollo Appleyard's letter in NATURE of October 12, for $A=e$ read $A=e^{U}$. The expression was correctly given by Mr. Appleyard in his letter, and the ^{U} was in place in the page passed for press, but it fell out in the course of printing last week's issue.

OUR ASTRONOMICAL COLUMN.

CHANGES ON MARS.—An observation made by M. Jarry Desloges at the Massegros Observatory, and published in Circular No. 133 from the Kiel Centralstelle, records a change on the Martian feature Libya. Previous observations had shown this area to be of a dull greyish hue, but on October 12 it was seen to be very bright; changes in the intensity of these white areas are by no means uncommon, and Libya, for example, was recorded as intensely white by the Rev. T. E. R. Phillips on May 22, 1903.

COLOUR PHOTOGRAPHY OF MARS.—In No. 42 of the *Mitteilungen der Nikolai-Hauptsternwarte zu Pulkowo* M. Tikhoff describes some results he has secured by taking photographs of Mars through coloured screens. These screens transmitted light of wave-lengths 690–655 $\mu\mu$ (red), 680–600 $\mu\mu$ (red and orange), 620–545 $\mu\mu$ (orange and yellow) and 550–495 $\mu\mu$ (green), respectively, and were used in conjunction with the 30-inch equatorial telescope. Taken at the focus, the images of Mars were about 1·5 mm. diameter.

Excellent photographs of Mars were secured, and a comparison of those taken with the red and with the green filters shows some remarkable differences. For example, on the "red" photographs the "continents" (Hellas, Elysium, Ausonia, &c.) are very bright, much brighter than the south polar cap; the latter is the most intense feature on the "green" photographs.

The seas are very dark on the "red" plates and greyish on the "green"; the canals (such as Xanthus, Scamander, Cerberus, &c.) are best seen on the "red" and "orange-red" photographs, their colour apparently resembling that of the seas.

The study of the polar cap led to the conclusion that it was of a greenish colour rather than white, and this suggested ice rather than snow, so experiments on the absorption spectrum of ice were carried out. These, and photographic experiments on sand, snow, and ice made by M. Kalitine, confirmed the conclusion that during August 4–30, 1909, the south polar cap of Mars exhibited the optical properties of ice rather than of snow.

BROOKS'S COMET, 1911c.—Below we give a further extract from the ephemeris for comet 1911c, published by Dr. Ebell in No. 4528 of the *Astronomische Nachrichten*. The cloudy and hazy skies of the past week have rendered observations difficult, and, apart from these local conditions, the difficulty will now increase owing to the decreasing northerly declination and magnitude.

Ephemeris 12h. M.T. Berlin.

This path lies nearly due south through Coma and Virgo, and the comet will be quite near to γ Virginis on November 1.

THE SOLAR ECLIPSE OF APRIL 17, 1912.—From the *Gazette Astronomique* (Nos. 45–46) we learn that preparations are to be made by the Uccle Observatory to organise two stations for the observation of the solar eclipse of April next. According to the *Connaissance des Temps* data, the eclipse should be total for six seconds in Spain, for two seconds in the neighbourhood north of Paris, and should cease to be total in Belgium. But the Nautical Almanac data would make it not a total eclipse anywhere in Europe, although the greatest duration of annular eclipse, six seconds, would then take place in Belgium.

AN ENORMOUS BOLIDE.—On April 10 a great noise was heard at Catania following, by about three minutes, a brilliant flash of bluish-green light; the microseismograph also registered slight movements. These phenomena and their relation to a bolide are discussed very fully by Prof. Ricco in No. 7, vol. xl., of the *Memorie di Astrofisica ed Astronomia*, who finds that the meteor probably exploded at a height of 30 km. above a point some 52 km. N.N.E. of Catania. A careful search in the indicated region has, however, revealed no traces of the fragments as yet. From the tabulated summary of communicated observations it would appear that a most extraordinary phenomenon was very generally observed.

MICROMETER MEASURES OF ENGELHARDT-STUMPE STARS.—During the winter of 1910–11 Dr. Lau employed the 10-inch refractor of the Urania Observatory for micrometer measures of faint stars measured by Engelhardt in the neighbourhood of stars given in Stumpe's catalogue. From these measures and Engelhardt's he has derived the proper motions, which he now publishes in No. 4523 of the *Astronomische Nachrichten*, with notes as to the colour and magnitudes of the pairs; of the fifty-four systems given, about two-thirds are optical, and one-third physical, systems.

PHOTOGRAPHS OF THE 1898 TOTAL SOLAR ECLIPSE.—From the Tokio Observatory we have received a copy of the report of their 1898 eclipse observations, published in 1910. The volume contains some excellent reproductions of photographs of the corona, which were taken at Jeur, in western India, and are described and discussed by Mr. H. Terao and Prof. S. Hirayama.

COOPERATION IN OBSERVING VARIABLE STARS.—The observation of variable stars is one that calls for only a modest equipment, and so can readily be undertaken by amateurs. In No. 166 of the Harvard College Observatory Circulars Prof. Pickering prints a list of 372 variables of long period, and asks for cooperation in the observation of them. Many are already being regularly observed, but more help is required, and, if desired, the results would be incorporated in the Harvard publications.

THE SCIENCE SECTION OF THE TURIN INTERNATIONAL EXHIBITION.

When the scope of the Franco-British Exhibition was under consideration, the British Science Guild approached the organisers and suggested that a science section should be arranged. The suggestion was agreed to; and it will be remembered how successful the exhibit was, and what a large amount of interest it aroused. Since then similar exhibits have been arranged at the Japan-British Exhibition and the present Coronation Exhibition, and still continue to attract attention.

The Exhibitions Branch of the Board of Trade has, at the instance of the Physical Instruments and the Chemical Committees of the Royal Commission appointed to deal with the exhibitions at Brussels, Rome, and Turin, organised an exhibit on somewhat similar lines. It was realised that at international and other exhibitions physical and chemical instruments and apparatus are not shown to advantage. The facilities for examination of the instruments are inadequate, owing to the fact that they are usually shut up in cases. Generally speaking, also, there is no one there to take them out and explain them to those who may be interested. It was therefore decided to instal working chemical and physical laboratories, in which exhibitors would have, for the first time in international exhibitions, an opportunity of having their instruments explained and demonstrated. The educational value of such a system of exhibiting is obvious, not only from the point of view of the manufacturers, but also to the public. The average person has no idea of what goes on in a physical or chemical laboratory, or what the apparatus, generally seen in a case, is employed for. In these laboratories actual experimental work can be seen in operation, and the demonstrators are there to give explanations to those seeking information. It should be mentioned here that professors and students from the universities and polytechnics on the Continent have taken great interest in the laboratories, in many cases spending several hours, and coming not once, but several times.

A Joint Committee of Mathematical and Scientific Instruments and Chemical Industries Committees was appointed to deal with the matter and to appoint competent scientific representatives to act as demonstrators in the laboratories.

The laboratory fittings were constructed by Messrs. Baird and Tatlock, Ltd., under the directions of the joint committee and personal supervision of Dr. F. Mollwo Perkin.

In the physical laboratory a dark-room has been set apart, where demonstrations are given with the well-known optical lantern of Messrs. Reynolds and Branson. The lantern employed is a special one fitted with a movable stage, so that it can be used for ordinary optical work and for illustrating practical experiments in science teaching. It is also fitted with a polariser, which, by moving the stage, can be brought into position, and by a further movement of the stage a microscope of special design can be used. Thus bacteriological, physiological, and natural-history specimens can be shown.

On the bench adjoining the dark-room Messrs. Reynolds and Branson exhibit other types of lanterns, and the Barr and Stroud lantern-slide apparatus. This very convenient piece of apparatus is fitted with graduated scales, which enable the operator without calculations or focussing on the screen, rapidly to prepare a lantern-slide.

Beyond this is an interesting exhibit by Robert Paul of electrical apparatus, including the Irwin oscillograph, on which are shown both the current and pressure curves of the alternating current, supplied by a small alternator of the Crypto Electrical Company, and complete apparatus for making measurements of self-induction by means of the Campbell variable mutual inductance, the alternating current being obtained by a microphone hummer.

On the next bench Messrs. J. J. Griffin and Sons show Sand's apparatus for the electro-deposition of metals, and their separation by means of an auxiliary electrode, the potentiometer box containing a capillary electrometer of special design. On the opposite bench Messrs. Townson and Mercer exhibit apparatus for the demonstration of the laws of mechanics, and also certain laboratory electrical instruments.

Messrs. Adam Hilger show their wave-length spectroscope. Other apparatus on this bench consists of a collection of electrical and magnetic testing instruments by Messrs. Baird and Tatlock, Negretti and Zambra, the well-known "Tintometer" for colour estimation, two mathematical models in plaster by Prof. Crum Brown, F.R.S., and a "Geryk" vacuum pump by the Pulsometer Engineering Co., Ltd.

On a separate bench Messrs. T. Oertling have a splendid collection of assay and chemical balances and accessories.

The central bench contains some interesting examples of modern electrical instruments made by the Cambridge Scientific Instrument Company, amongst which are the "Duddell" oscillograph, with camera outfit, for use on circuits up to 50,000 volts, shown in operation; a "Callendar" recorder connected to an open-wound thermometer, by means of which a continuous record of the laboratory air temperature is obtained; the "Thread" recorder, connected to a copper couple, arranged so that its extreme sensibility can be shown; a laboratory type pyrometer with a platinum platinum-iridium couple (this is used for showing the temperature of an electrically heated laboratory furnace).

Fig. 1.—General View of Chemical Laboratory.

Most of the firms showing in the laboratory also have good exhibits in the Physical Instruments Court.

On entering the chemical laboratory, the first bench on the left-hand side is a furnace bench of Yorkshire stone with a uralite hood. On this bench various furnaces by Messrs. Fletcher Russell and Co., Ltd., are exhibited, such as are employed in metallurgical and assay work; also laboratory burners of various design.

On the opposite side is a bench which is in part fitted up for electrochemical analysis, and here actual analytical operations are from time to time carried out by the laboratory demonstrator. On another part of the same bench the method of assaying gold in order to test its fineness is illustrated in a series of twelve operations by Messrs. Johnson and Matthey, who have also supplied the platinum electrodes for analysis. First a gold link taken from a watch chain is shown, (2) the hammered gold, (3) the rolled gold, (4) a weighed quantity ready for assay, (5) the gold with a piece of silver wrapped in lead, (6) the same in a cupel, (7) the gold-silver alloy hammered and rolled after cupelation, (9) the rolled and coiled alloy in the parting flask, (10) the gold after parting with nitric acid, (11) the gold annealed, (12) the assayist's report. The assay balance and muffle employed in such operations are also shown. In still another part of the same bench various crucibles and other apparatus used in assay work are shown by the Morgan Crucible Co.

At another bench Messrs. Townson and Mercer show a large assortment of apparatus employed in various operations. Thus there is a centrifuge operated by means of an electromotor which is shown in operation. There is also apparatus for the analysis of explosives, and general apparatus, such as the Lewis Thompson calorimeter, hot-air ovens, vacuum drying apparatus, &c. A portion of this bench, which is provided with water and electrical heating, is reserved for general demonstrations, such as operations of filtration, crystallisation, precipitation, and so on. Demonstrations in dyeing are also given here, and the action of dyes on mordanted and unmordanted cotton, silk, &c., illustrated. The apparatus for dyeing and material for these experiments are supplied by Messrs. Read Holliday, of Huddersfield.

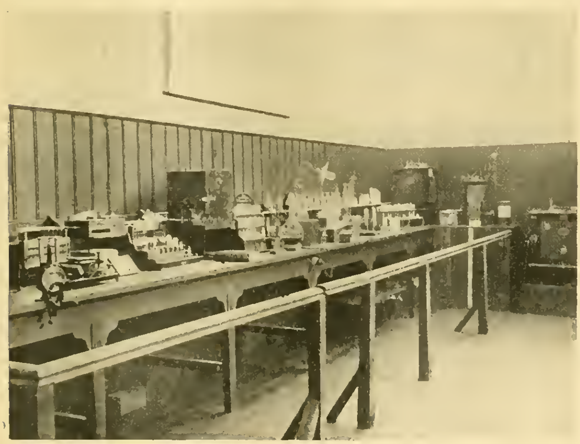

FIG. 2.—Bacteriological Bench where demonstrations were given.

Following this bench is a draught cupboard, which contains apparatus for the generation of sulphuretted hydrogen, carbon dioxide, and so on.

On the next bench the various apparatus employed in the analysis and examination of mineral oils is exhibited; for example, the method of estimating the viscosity by means of the viscometer is shown in operation, and also the taking of flash-points. Most of this apparatus is exhibited by Messrs. Baird and Tatlock, but the Mahler-Cook bomb calorimeter is shown by Messrs. J. J. Griffin and Sons, Ltd. There is also on the shelves a fine display of reagents and pharmaceutical products exhibited by Messrs. T. Morson and Son. On the opposite side of the bench the various apparatus employed in gas analysis is shown. There is also a good display of silica apparatus by the Silica Syndicate and the Thermal Syndicate. This apparatus has attracted a very great amount of attention, as in Italy it was generally not known that silica apparatus was manufactured in England.

At the end of the laboratory a long bench is devoted to bacteriology, where Messrs. Baird and Tatlock make a display of the various apparatus used in bacteriological work, and also show cultures on solmedia, a powdered form of bacteriological culture. At another portion of the demonstration bench Messrs. Edward Cook and Co., the well-known soap-makers, have a demonstrator who shows the methods employed in the standardisation of disinfectants by the Rideal-Walker method and by the Lancet method.

On the next bench there is a working laboratory apparatus exhibited by Ozonair, Ltd., showing the formation of ozone. On another part of the bench there is a most interesting exhibit of old chemical apparatus used in the eighteenth century, kindly lent by the Society of Apothecaries, London.

In the centre of one side of the room Messrs. Burroughs, Wellcome and Co. have an exhibit showing the results obtained by the firm in research work, and in the manufacture of substances of pharmacological importance. Thus the formation of ernutin from ergot is graphically displayed. Investigations in the Wellcome Physiological Research Laboratories have shown that ergot contains at least three active principles, and the exhibit is intended to show the production of these. This exhibit is of great interest, and demonstrates the high value of chemical research in technical operations.

There is also a lead-covered distillation bench, on which are shown the processes of distillation, fractionation, and extraction in operation.

This part of the British exhibit has attracted great attention, and the Board of Trade has been highly commended by other nations upon the new departure. At the same time, it must be mentioned that the whole of the British Section is most creditable to the Exhibitions Branch of the Board of Trade, without which it would not have been possible. Thus there is a splendid exhibit of textiles, and the exhibit of British motor-cars has attracted a large amount of interest. There is also a good exhibit of agricultural machinery and implements.

Most excellent catalogues have been drawn up to explain the various exhibits. The catalogue for the Mathematical and Scientific Instrument Section is in French and is splendidly illustrated. The apparatus is most carefully and fully described both from the theoretical and practical aspect, and Mr. E. H. Rayner, who edited the catalogue, is to be congratulated upon its excellence.

The Catalogue of Chemical Industries, of which there is an English and French edition, commences with articles descriptive of the following industries, which have been written or revised by the persons whose names accompany the articles:—The alkali industry, J. F. L. Brunner and J. I. Watts; sulphuric acid and nitric acid, Dr. F. Mollwo Perkin; the gas industry and coal-tar products, Prof. Vivian Lewes, cyanides and prussiates, A. Gordon Salamon and Dr. G. T. Beilby; electricity, Dr. G. T. Beilby; explosives, Walter F. Reid; nickel, J. F. L. Brunner; oils, fats and waxes, soaps and candles, Dr. J. Lewowitsch; petroleum and shale oil, Sir Boverton Redwood, Bart.; pharmacy, Thomas Tyrer and N. H. Martin; salt, J. F. L. Brunner and J. I. Watts; disinfectants and antiseptics, Dr. D. Somerville; rare metals, Dr. F. Mollwo Perkin. The catalogue is thus a small treatise on technical chemistry. The second part of the catalogue deals with the actual exhibits.

THE FOURTH INTERNATIONAL CONFERENCE ON GENETICS.

THE fourth International Conference on Genetics is the latest of a series of conferences which was inaugurated with the "Conference on Hybridisation" convened in 1899 by the Royal Horticultural Society. The Horticultural Society of New York undertook the organisation of the second conference, held in that city in 1902; the third "Conference on Plant-breeding" took place in London in 1906, again under the auspices of the Royal Horticultural Society; the fourth conference of the series, and the first to receive the title of "Conference on Genetics," has recently been held in Paris under the control of the Société Nationale d'Horticulture de France, which is to be very heartily congratulated on the success which attended all its arrangements.

As M. Ph. de Vilmorin has pointed out, genetics, though born of the studies provoked by the rediscovery of Mendelism, is itself of wider scope, and includes all that appertains to the physiology of heredity, the problems of fluctuating variation, selection, mutation, the transmission of acquired characters, cytology, &c. Most of the subjects were represented among the communications brought before the recent conference. There were, indeed, no papers dealing purely with cytology, though Dr. Swingle brought forward the tentative suggestion that the diverse types encountered in certain F_1 families might be due to different groupings within the cell of a given set of determinants; but the absence of cytological papers no more than reflects the present difficulty of producing any satisfactory cytological "explanation" of the phenomena of heredity, and we can only hope for better things in the future. Appended are short notes on a few of the communications made to the conference.

Messrs. Bateson and Punnett described some results of very great interest in regard to the special relations which have been found to exist in certain cases between distinct factors. Those who have followed recent progress in this work will remember that in not a few crosses, between plants differing from one another in respect of two characters, the phenomenon known as "partial coupling" between the factors for these characters has been exhibited; that is to say, the F_1 produces the four possible types of gamete, not in the approximately equal numbers which would result from a chance distribution of the factors, but in proportions represented by the general expression

$$(n-1)AB : 1Ab : 1aB : (n-1)ab,$$

where n is any power of 2 and is equal to one-half the total number of gametes produced.

Other crosses, on the other hand, gave results which suggested that, in certain circumstances, the same two factors were repelled from one another in gametogenesis. Unlike the phenomena of coupling, the repulsion appeared to be complete, so that no germ-cell received both factors, and consequently no germ-cell was without one of them.

This year, however, Punnett has discovered a case in which repulsion is not complete, but the gametes containing one or other of the two factors (but not both) are produced in greater numbers than the other types of gamete. That is to say, the middle terms of the gametic series are large, the end terms small—the converse to what occurs in "partial coupling"—and the gametic series is represented by the expression

$$1AB : (n-1)Ab : (n-1)aB : 1ab.$$

In Punnett's case the gametic series was of the form 1 : 3 : 3 : 1; even in this case, where n has its lowest value, only one plant having both recessive characters is to be expected in every sixty-four F_2 plants. With higher values of n, the proportion of double-recessives in F_2 will be smaller still, and it can scarcely be doubted that this is the explanation of the cases hitherto regarded as representing complete repulsion; at the same time, the isolated occurrence of double-recessives in families exhibiting repulsion is explained.

The di-hybrid F_1 may therefore produce the four types of gametes in proportions ranging from

$$(n-1) : 1 : 1 : (n-1)$$

through

$$1 : 1 : 1 : 1$$

to

$$1 : (n-1) : (n-1) : 1$$

Bateson and Punnett point out that the conception underlying the terms "partial coupling" and "repulsion" is no longer justified, and they substitute the phrase "reduplication of terms" in a series of gametes.

Profs. Baür and Lotsy described experiments in crossing different species of snap-dragon. *Antirrhinum majus* (in the normal and peloric forms) was crossed reciprocally with *A. molle*, with *A. latifolium*, *A. sempervivum*, &c. The characters of the hybrids and of the very numerous forms obtained in F_2 were illustrated by means of coloured drawings. The experiments showed conclusively that segregation takes place in these species-crosses; how numerous are the factors to be considered may be judged from the fact that, of the 500 F_2 plants raised, scarcely any two were alike. Among these plants there appeared an interesting new type resembling the flowers of the yellow-rattle (Rhinanthus) in the shape of the corolla.

Several papers dealing with cereals were presented, some of them of no little importance from the economic point of view. Dr. Nilsson-Ehle described experiments indicating that precocity and resistance to cold depend upon combinations of Mendelian factors. Dr. Surface described the results of selection for such characters as protein-content, &c. He showed that in one case of successful selection for high protein-content, the plants raised after the ninth generation were all the descendants of a single progenitor, that is to say, selection had resulted in the isolation of a pure line possessing the desired quality. This result agrees with much that has been done since Johannsen first clearly presented the idea of pure lines, and agrees, too, with the new results which Prof. Boeuf communicated on the present occasion.

Dr. Orton described some work of the highest economic importance in the raising of varieties of agricultural plants resistant to the attacks of disease. Many varieties of cotton, the cow-pea (Vigna), and the water-melon are susceptible to the attacks of species of Fusarium; the cow-pea, in addition, is liable to the attacks of the nematode *Heterodora radicicola*. Immune or highly resistant varieties of all these plants have now been obtained, in the case of the water-melon, however, only after crossing with a non-edible but resistant wild type.

At the session devoted to papers dealing with animals, Prof. Federley described an interesting case in Pygæra of the transmission of a disease through females, themselves unaffected by the disease, to their male offspring, all of which died of the disease. Dr. Walther, of Vienna, gave an account of his investigations into the inheritance of coat-colour in horses, a subject with regard to which he has secured a great wealth of material.

Finally, mention must be made of a new case of brachydactyly in man, described by Dr. Drinkwater. This case differs from the previous one in that there is no ankylosis of the short median phalange with the terminal phalange, and the fingers are intermediate in length between the extreme brachydactylous and the normal types. The abnormality is present in about one-half of the members of the affected family.

Much as there was of interest in the proceedings of the conference, not the least memorable of its features was the visit which the members were privileged to pay to the establishment of MM. Vilmorin, Andrieux et Cie. at Verrières-le-Buisson. One's only regret was that the time at our disposal was all too short for even the most cursory inspection of the wonderful collection of plants which has been gathered together here, and of the experiments in breeding and selection which are being carried on by M. Ph. de Vilmorin himself and by the firm of which he is the head. It is useless to attempt in a limited space to give any detailed description of Verrières; it need only be said that the whole establishment, gardens and museum alike, admirably reflects the enthusiasm which M. Ph. de Vilmorin, like the members of his family who have preceded him, has always shown for the scientific as well as the more obviously practical aspects of horticulture and plant-breeding.

PHYSIOLOGY AT THE BRITISH ASSOCIATION.

THE presidential address in Physiology has appeared in full in NATURE (September 14), and the remainder of the sectional proceedings can be summarised under three heads: reports of committees and papers related to them, discussions, and other communications.

Reports of Committees.

Committee on Anaesthetics.—The report contains four appendices. The first describes the installation of a chloroform-balance for daily use in hospital practice. The detailed instructions by Prof. Waller will be extremely useful for anyone who wishes to establish one of Prof. Waller's instruments. The second appendix contains some estimations of the probable percentage of ether inhaled by the "open" method of ether administration. The third appendix relates the experience gained by the use of a chloroform-balance in the out-patient department of St. George's Hospital, and the fourth is a recapitulation of the effect of recent advances on the practice of anæsthesia.

This report was followed by a paper by Dr. A. Vernon Harcourt, F.R.S., on additions to the use of a chloroform inhaler. As objection had been made to the vacuum principle of the author's chloroform inhaler, he has adapted his ingenious apparatus to work by the plenum system, and also for use with oxygen.

Committee on Dissociation of Oxyhaemoglobin at High Altitudes.—The hydrogen ion concentration of blood can be determined by the percentage saturation of hæmoglobin with oxygen at low pressures of oxygen. Using this method, it was found that at high altitudes the hydrogen ion concentration of the blood was increased.

The remainder of the reports contained information of such detailed nature that it is not possible to give a summary of their contents, but in some cases the work has already been published elsewhere.

Discussions.

Discussion on Inhibition.—Prof. C. S. Sherrington, F.R.S., opened the discussion by pointing out that it would be of great importance to discover the intimate nature of inhibition. The processes of inhibition are fundamentally the same whether they occur in the central nervous system or in apparently muscular organs such as the heart. He then described many of the phenomena of inhibition as exhibited by rhythmical reflex movements of the limbs. In dealing with the reciprocal action of muscles, it seems necessary to assume, as suggested by Macdonald, that there is an intercalated neurone in the inhibition path. Any after discharge from the muscle, which ought to have finished contracting, would lead to clumsiness in the alternating movements of flexion and extension; but inhibition removes all after discharge. In the same way inhibition diminishes the tonus in muscles antagonistic to those that are contracting. The utility of a common final path is evident, because there cannot be more than one movement going on at the same time; and so long as a path is held by inhibition contraction cannot occur, and *vice versa.* Examples were shown of double stimulation and algebraical summation of excitation and inhibition in both flexors and extensors. Two antagonists may be in action together, but their activity increases and decreases in reciprocal proportions; hence the smoothness and accuracy of trained movements. The conditions favourable to inhibition are fatigue and administration of chloroform, and those favourable to excitation are increase in the "background" stimulation and administration of strychnine and tetano-toxin. According to circumstances, the same stimulus may give either excitation or inhibition.

Dr. John Tait, rhythmical stimulation of cooled frog's nerve. The Wedensky effect was described, and Frohlich's explanation of the phenomenon was stated. By cooling the nerve a result was obtained similar to that of Wedensky. The effect is greater the greater the degree of cooling, the longer the piece of nerve cooled, and the more rapid the rate of stimulation. Conduction by the nerve is entirely blocked at $-2°$ C., and the phenomenon is present near this point. Fatigue favours the effect. Wedensky effect is shown by well-fed, but not by under-fed, animals.

Dr. Keith Lucas, conduction between muscle and nerve with special reference to inhibition. Frohlich's explanation of the Wedensky effect does not hold in homogeneous tissues, as a second stimulus within the refractory period does not prolong the refractory phase. By indirect stimulation it was found that the blocking occurs at the junction between muscle and nerve. The refractory period of nerve is less than that of muscle, and a stimulus sent into the nerve shortly after the end of the refractory period causes a second refractory period. A stimulus to the nerve just after the end of the refractory period is so diminished in strength that it cannot pass the motor end plate. The explanation is that each stimulus to the nerve reduces the response to the succeeding stimulus, and thus all except the first are too weak to pass the resistance of the junction between muscle and nerve; thus there is a single contraction of the muscle with the first stimulus, and no further response as the stimulation continues. By applying the same processes to the synapses of the central nervous system, an explanation of central inhibition was given. Prof. Waller then spoke, and Prof. Sherrington replied.

Discussion on ventilation in confined quarters, especially in relation to ships. Dr. Leonard Hill, F.R.S., introduced the subject by explaining that under ordinary conditions the percentage of oxygen is never reduced to a dangerous extent, nor is the carbon dioxide increased beyond reasonable limits. The great factor in ventilation is to provide air under suitable conditions to promote evaporation from the skin and stimulate the nerve endings in the skin. He then described experiments showing that circulation of air in a closed chamber produced the same effect as admitting fresh air in promoting a feeling of well-being. A draught is dangerous, as it causes a local cooling, but cooling of the whole surface by evaporation from the skin is beneficial. He described some of the special difficulties met with on board ships, and advocated the wet- and dry-bulb thermometers as a test of the efficiency of ventilation. Fresh air is beneficial, as it dilutes harmful products, such as bacteria.

An abstract furnished by Prof. N. Zuntz, of Berlin, was read. He agreed with Dr. Hill that oxygen and carbon dioxide are not the predominating factors in ventilation, but he pointed out that there might be poisonous gases given off under some conditions. He then showed that unless the carbon dioxide be kept down to the limit usually given as the maximum allowable, the air becomes almost saturated with the moisture given off from the lungs. Therefore the moisture must be kept down by dilution with fresh air or by condensation on cold surfaces. The use of fans will not entirely remove the need for fresh air, but they will improve the working efficiency of the men.

Dr. C. J. Martin, F.R.S., spoke in support of Dr. Hill's view by referring to the conditions in Australian gold mines.

Fleet-Surgeon Whitelegg gave instances of the difficulties encountered on board battleships, where, of course, the fighting efficiency was the first consideration. He then described some of the precautions taken before men were allowed to enter unventilated spaces. Dr. Hill then replied.

Other Communications.

Prof. H. J. Hamburger, on the influence of iodoform, chloroform, and other substances dissoluble in fats on phagocytosis. In the absence of the author an abstract of this paper was read. In high dilutions the substances used promoted phagocytosis. This effect is the result of the substances dissolving in the lipoids of the cell wall, whereby the surface tension is lowered. When the surface tension is lowered there is less resistance to an increase of surface, and hence amœboid movements occur more easily.

Dr. J. Tait and Mr. J. A. Hewitt, certain physical questions regarding blood vessels and blood cells. Blood does not adhere to the endothelium of blood vessels. This is associated with a large amount of ether soluble material in the endothelial cells. Coating glass vessels with oil delays coagulation, as it prevents the adhesion to the glass of certain blood cells. Possibly the high blood-blood-vessel surface tension, as shown by non-adherence of the blood to the vessel wall, is a factor in preventing coagulation of blood in the vessels. Contact of amœboid corpuscles with particles of carmine or Indian ink causes phagocytosis if the surface tension between corpuscle contents and particle is less than that between the plasma and particle. When a corpuscle adheres to the wall of a blood vessel it is driven outwards if the surface tension between corpuscle and blood-vessel wall is less than that between corpuscle and plasma, and hence diapedesis occurs. The association of hæmolytic and hæmorrhagic poisons may be due to a lowering of the surface tension causing both processes.

Mr. W. W. Waller, an attempt to obtain photographic records of the emigration of leucocytes. This was illustrated by a number of photographs showing blood vessels with white corpuscles escaping from them. Several interesting points were mentioned, such as a tendency for several corpuscles to escape at the same point, and apparently to form colonies after their escape.

Dr. Hariette Chick and Dr. C. J. Martin, F.R.S., the chemistry of heat coagulation of proteins. Coagulation takes place in two stages, denaturation and agglutination. Denaturation is due to the presence of water, depends on the temperature, and is an exponential function of the concentration. The temperature coefficient is remarkably high. Egg albumin differs from hæmoglobin owing to a change in reaction during coagulation, but by using boric acid to keep the hydrogen ion concentration constant the egg albumin then behaves like hæmoglobin. Increase of acidity favours denaturation. Agglutination depends on the concentration of hydrogen ions. Three factors, namely, surface tension, electrical charge, and velocity of Brownian movement seem to regulate the agglutination.

Prof. Freundlich spoke on this communication, referring to the importance of such investigations into the processes of coagulation.

Dr. W. N. F. Woodland, recent views concerning the physiology of gas production in connection with the gas bladder of bony fishes. The structure of the rete mirabile duplex is concerned with the secretion of oxygen. The composition of the gas varies in different species. The pressure of any particular gas may be greater than that in the blood stream, and hence there must be some process of secretion. Fish which change their depth rapidly secrete oxygen to compensate for the effects of pressure. A weighted fish rises after some time, mainly due to increase of oxygen in the swim bladder. It has been stated that a toxin is formed which causes hæmolysis of the red blood corpuscles, but none was found as the result of activity, nor, as previously stated, were gas bubbles found in the secreting cells. The author urged physiologists to undertake the study of the process of oxygen secretion.

Prof. J. S. Macdonald and Dr. J. E. Chapman, heat production and body temperature during rest and work. By means of the calorimeter at Sheffield the heat production of a fasting man was determined at rest and then during the performance of work. Heat output lags behind heat production owing to a rise of body temperature, which stores a certain amount of heat. The lighter the clothing the more nearly the heat output keeps pace with the heat production. Fatigue is not shown in the record of heat output, but it is shown in the rate of cycling.

Dr. H. E. Roaf, carbon dioxide output during decerebrate rigidity. The carbon dioxide output was measured during decerebrate rigidity, and then after abolishing the rigidity. Abolishing the rigidity by curare or by cutting the motor nerves did not lower the carbon dioxide output. Hence decerebrate rigidity differs from ordinary muscular contraction, as there is no increased production of carbon dioxide during rigidity.

Dr. F. W. Edridge-Green, the frequency of colour-blindness in males. The percentage of colour-blind men has been underestimated. The author finds at last 6 per cent. are colour-blind, and that 25 per cent. have diminished colour-vision.

Prof. G. J. Stokes, paramnesia. The author suggests that the same idea may reach the brain by two different routes, one passing through a greater number of synapses, and thus arriving after the other. Hence in certain cases a feeling that the incident is not new, although it could not possibly have happened before.

Miss May Yates, the nutritive value of whole meal and white bread. This was a correction of some statements made in a recent Local Government Board report. It was claimed that the report did not correctly compare the nutritive value of white flour and flour without removal of the germ and bran.

Prof. A. D. Waller, F.R.S., read an interesting historical paper reviewing the documentary evidence of the discovery of the distinction between motor and sensory nerves.

It was an unfortunate coincidence that the two foreign guests who had accepted invitations as representatives of physiology should at the last moment have been prevented from attending the meeting. Apart from this, the meeting was an agreeable and interesting one for physiologists.

AGRICULTURE AT THE BRITISH ASSOCIATION.

THE outstanding event this year was the elevation of agriculture to the position of a full section; henceforward agriculture comes definitely within the purview of the British Association, and permanently figures as Section M. The increasing output of work by investigators in this country fully justifies this step, while the great interest always shown in agricultural matters by the members of the association encourages the hope that the new section will at least contribute its share to the attractiveness of the meetings.

The problems presented by soils, crops, and animals are so complex that agricultural investigators are bound to keep in close touch with workers in pure science in order that their methods and conclusions may be critically examined. At the British Association meetings more than anywhere else such critical discussions are possible, and in permanently arranging for them the association is fulfilling the first of its declared objects—"to give a stronger impulse and a more systematic direction to scientific inquiry."

The president's address dealt broadly with the application of genetics to the problems of agriculture and horticulture (see NATURE, September 21), and several of the papers dealt with special aspects of this subject. In an interesting communication Mr. C. C. Hurst discussed the genetics of horse-breeding. Chestnut coat colour is recessive to bay and brown; consequently chestnut horses always breed true when mated together, notwithstanding their bay and brown ancestors. Bays and browns, however, are of two kinds, one throwing chestnuts, the other not. Grey is dominant to bay, brown, and chestnut, but since grey × grey matings are rare in England, English grey thoroughbreds are nearly all heterozygous, throwing bays, browns, or chestnuts; a homozygous grey is, however, known in Germany which throws nothing but greys. In certain strains a partial coupling is observed between coat colour and racing power, bay and brown descendants of St. Simon being much better racers than the chestnuts. There is apparently a partial tripling of brown coat colour, high racing power, and female sex in St. Simon's own offspring.

Prof. Wilson described his studies of the inheritance of milk yield in cattle, the earlier accounts of which have attracted a good deal of attention. After eliminating abnormalities due to time of calving, period of lactation, food, shelter, and age of the animal, it is found that full-sized mature cows fall into three grades, giving, respectively, 500 to 600, 650 to 850, and about 1000 gallons of milk a year. The two extreme grades are approximately pure, while the middle grade is a hybrid.

A different type of problem was dealt with by Mr. W. J. Backhouse. A systematic inquiry was undertaken into the gametic composition of our common plums with the view of putting the raising of new plums on a scientific basis. At the height of the flowering period the flowers of certain plums were carefully hand-pollinated with their own pollen. Some varieties proved remarkably self-fertile, the flowers setting very well to fruit. Other varieties, however, proved self-sterile, and set absolutely nothing. It is understood that these interesting observations are being followed up.

A useful day was spent in discussing the bacterial diseases of plants. Prof. Potter opened with a summary of our present knowledge of the subject. The old idea that the plant was not susceptible to the attacks of bacteria is now known to be erroneous; indeed, certain bacterial diseases can be faithfully reproduced with absolute certainty by inoculation in healthy tissues. The plant possesses many vulnerable points of attack; infection may take place through the water pores, the stomata, the floral nectaries, and wounds, the vessels of the xylem affording a suitable channel for the dispersion of the invading bacilli. Further, certain bacteria secrete a toxin and cytolitic enzyme which destroy the protoplasm and rapidly dissolve cellulose. The actual penetration of the bacterium through the cell-wall has been observed. A complete homology has been established between the parasitism of bacteria and that of various fungi. Saprophytic bacteria, like fungi, develop under certain conditions into virulent parasites, and their aptitude as parasites may be increased or suppressed by variations in nutrition. The nature of the soil, manurial treatment, and other factors materially affect the constitution of the host and its predisposition to infection. Mr. Brooks followed with an account of the gum disease of the sugar-cane, caused, as Irwin F. Smith has shown, by a specific bacterium, *Pseudomonas vascularum*. A disease of cherry trees, accompanied by profuse gumming, has been traced by Aderhold and Ruhland to *Bacillus spongiosus*. On the other hand, the mosaic disease of the tobacco plant, formerly attributed to bacteria, is now regarded as the result of some physiological disturbance within the plant.

Dr. Pethybridge described his investigations on the bacterial diseases of the potato plant in the west of Ireland. From a confused group of diseases formerly known as "yellow blight" he has disentangled a definite disease, "black stalk rot," resembling the "black leg" of other authors, and caused by an organism which he names *Bacillus melanogenes*. The organism not only brings about the untimely death of plants in the fields, but also causes a most serious rot in stored potatoes, even healthy unwounded tubers being capable of infection through their lenticels.

Mr. A. S. Horne emphasised the effect of external conditions on the incidence of disease. The probability that a plant will thrive in a given spot depends upon certain combinations of factors relating, respectively, to (1) the structure and internal constitution of the plant and the organisms associated with it; (2) the soil and soil organisms; (3) the climate, season, and aërially-borne organisms. Disease may occur if the optimum arrangements of the factors be disturbed.

Another day was spent in considering how best the university agricultural departments can come into contact with the practical farmer. Mr. R. Hart-Synnot opened with a description of the Irish system and a modification that seemed suitable to English conditions. It is admitted that the English system has not been entirely successful; indeed, it became evident in the discussion that some of the most successful departments have broken altogether from the conventional lines. Principal Ainsworth Davies considered that the universities should not only undertake research work and the training of experts, but should also disseminate the results obtained among the farmers, and act as bureaus of information generally. Mr. Burton dealt with the place of the agricultural instructor, whose title, he thought, ought to be changed to that of agricultural adviser.

A group of papers came in from the Cambridge Agricultural Department. Prof. Wood and Mr. Harvey described a very ingenious method of determining the baking strength of single ears of wheat. Hitherto it has been necessary to work with large quantities of flour, which can only be obtained with difficulty in plant-breeding experiments. The method suggested simply requires one gram of flour. On shaking with water an opalescent extract is obtained, the humidity of which affords a measure of the strength of the wheat. The sensitiveness of the method is increased by addition of iodine to the turbid extract. Mr. H. A. D. Neville gave a preliminary description of the mucilage of linseed. On hydrolysis with sulphuric acid, mucilage yields dextrose, galactose, arabinose, xylose, and small amounts of a cellulose-like substance and of an acid which forms a soluble barium salt. It appears to be completely digested by the animal, but is neither acted upon by saliva nor by pancreatic juice; it is rapidly decomposed, however, by the bacteria of the cæcum. Messrs. Marshall and Mackenzie introduced a technical subject of very great importance—the question of ovariotomy in pigs. This practice has been known for many years, but has not hitherto received the scientific attention it deserves. If the ovaries are removed after sexual maturity is reached, the uterus undergoes a gradual atrophy; on the other hand, the removal of the uterus has no effect on the development or functional activity of the ovaries. Further, if the ovaries are only incompletely removed, a fragment left behind may in the course of a few months regenerate into an ovary of considerable size. Ovariotomy frequently results in a deposition of fat in various parts of the body; hence its commercial value. In a second paper the same authors dealt with the temperature variations during the œstrous cycle in cows. The rise may be as much as 5°, whilst on the approach of heat a rise of 2° or 3° was usual. These results have special importance in connection with the tuberculin test, in which an animal is supposed to react if the temperature rises 2°.

Mr. H. W. Elwes gave an account of aboriginal races and little-known breeds of domestic sheep, which elicited an interesting discussion, in which Profs. Ridgeway and Wilson, the chairman, and others took part. Domesticated animals seem to have been curiously neglected by zoologists, and Mr. Elwes could find only few references to them in zoological literature. By dint of much inquiry in remote and comparatively inaccessible regions of the British Islands and elsewhere, he has succeeded in finding a number of aboriginal breeds interesting not only in their relationship to our present breeds, but because of their potential value to the practical man, inasmuch as they are extremely hardy and might be used to restore to some of our present breeds the constitution that has been partially lost. Another livestock subject was dealt with by Mr. J. Hendrick in his discussion of the effects of ventilation on the temperature and carbon dioxide content of the air of byres. The amount of pollution is sometimes extraordinary, more than 100 parts of carbonic acid per 10,000 having been recorded, whilst the average CO_2 content was 30 parts where ventilation was restricted and 12 to 15 where it was freer. In spite of the low temperature resulting from free ventilation, the health of the cows was better and their yield of milk was as good as in the warm, badly ventilated byres.

Messrs. Barker and Hillier described a disease known as cider sickness that causes a loss probably amounting to several thousand pounds sterling each year in the west of England alone. It is brought about by a bacterium capable of fermenting dextrose and lævulose with production of alcohol and carbon dioxide, together with a small amount of hydrogen, an unrecognised acid, and an odour resembling that of decaying lemons. It does not appear to attack saccharose, maltose, or lactose. Prof. Priestley and Miss Lee described an ingenious method of measuring the effects of various factors on the growth of micro-organisms. The rate of production of the metabolic products as measured by the change in electrical conductivity of the culture solution is taken as an index of growth, and is found to give results in accordance with the much more tedious process of counting. The particular factor investigated was the influence of electricity. Currents up to about 60 micro-amperes had a favourable effect on the rate of growth of *Bacillus bulgaricus*, whilst currents of greater strength inhibited their activity. No difference could be detected between the effects of direct and alternating currents. In a paper with Mr. Knight, Prof. Priestley dealt with the influence of electricity on the respiration of germinating seeds; a direct current was found to be harmful; a rapidly alternating current at low strength stimulated respiration, but had no effect at 150 micro-amperes; whilst stronger currents caused a decrease; the overhead discharge gave irregular results until some turpentine was introduced to absorb the ozone produced, and then an increase was observed in the amount of carbonic acid produced.

After a suggestion for the reform of the British system of weights and measures had been put forward by Mr. J. Porter, two papers, that brought the meeting to a close, were read by Prof. Bottomley. In the first he adduced further evidence in support of his contention that the bacteria Azotobacter and Pseudomonas fix more nitrogen per unit of carbohydrate consumed when grown together than when grown separately. In the second he claimed to have obtained evidence of the existence of bacteriotoxins in the soil.

A new feature introduced this year was a semi-popular lecture, by Mr. Hall, on the local soils and farming practices. So great was its success that a semi-popular lecture is likely to become a regular part of the programme of the Agricultural Section.

THE EAST AFRICAN NATURAL HISTORY SOCIETY.[1]

THERE has been no falling off in the East African Journal of Natural History: No. 3 of vol. ii. is as interesting as its predecessors. The scientific student of Africa welcomes these genuine, first-hand studies, these notes and records without the flim-flam, facetiousness, and vague inaccuracy which so often characterise the articles contributed to similar societies in young colonies.

In the part under review the most noteworthy articles, perhaps, are:—"Notes on the Common Pathogenic Protozoa in British East Africa," by R. Eustace Montgomery; "Some East African Pigs," by C. W. Woodhouse; and "Mendel's Principles of Heredity," by Dr. A. H. Marsh (this last with reference to the crosses between *Bos taurus* and *B. indicus*).

Mr. Montgomery is the veterinary bacteriologist for British East Africa. In his paper he devotes himself chiefly to describing the protozoa of the groups Mastigophora and Sporozoa. Of the first-named, the Spirochætæ—causing diseases among cattle and domestic poultry—are transmitted mainly or entirely by ticks of the genera Boophilus, Argas, and Ornithodorus, and another tick seems to be the introducer into the human system of the *Spirochaeta duttoni*, which is the cause of human relapsing fever. (The closely allied flagellate, *Treponema pallida*, is the cause of syphilis. We are all aware of the ordinary and normal manner of conveying the infection of syphilis, but the question arises whether in Uganda and similar countries where it rages infection may not also be conveyed by the agency of a tick.) There are four recognised trypanosomes in British East Africa and Uganda: *T. gambiense*, the deadly germ of sleeping sickness; *T. dimorphon*, which may produce disease in horses, cattle, dogs, &c., but does nothing to man; *T. vivax*, of which the same may be said; and *T. lewisi*, a parasite in rats. The transmitting agencies of the trypanosomes appear to be not only the notorious *Glossina palpalis*, or tsetse-fly, of equatorial Africa, but possibly also other Glossinæ, a gad-fly, Tabanus, and a mosquito, Stomoxys.

Among the East African Sporozoa, the genera Babesia, Nuttallia, Theileria, and Anaplasma are pathogenic among cattle and dogs. The transmitting agency for all these sporozoa of the suborder Acystosporea is a tick—Boophilus, Rhipicephalus, or Hæmaphysalis. Babesia is the cause of red-water, or Texas fever, and also of tick fever in the dog; Nuttallia creates biliary fever in horses, asses, and mules; Theileria is the parasite of East Coast fever in cattle; and Anaplasma produces a form of gall sickness in cattle.

With regard to the article on East African pigs (in which there is much fresh material concerning the appearance and habits of the giant forest pig), a puzzling mistake occurs in the first paragraph, wherein reference is made to an Abyssinian type of "wart-hog," *Phacochoerus johnstoni*. This should be *Potamochoerus johnstoni* (the East African river-hog); and it is not, we believe, Abyssinian in range, but equatorial East African.

A question is raised on p. 76 as to the attitudes of marabou storks during flight. It has always seemed to the present writer that in the normal attitudes of this bird when flying the neck was stretched out like that of other storks, or slightly curved and retracted, especially when wheeling. Others have asserted that the marabou drew back its neck into the ruff of shoulder feathers as a heron would do. It is a point which could best be decided by instantaneous photographs. As a general rule, storks, Balæniceps, and Scopus (besides ibises) stretch out their necks when flying; herons and pelicans retract them.

This No. 3 contains as a frontispiece a remarkable photograph of a record head of a Cape buffalo from Uganda—a splendid specimen almost recalling in length and curve of horns the extinct *Bos antiquus*. There is also an interesting article on birds in Uganda forests, another on anthropometry, and a third on the seasonal variation of the Junonia genus of butterflies.

H. H. JOHNSTON.

WHELKS AND THE VALUATION OF THE SEA.[1]

IN the first of these reports Dr. Petersen discusses the possibility of combating the harmful animals of the fisheries, especially the whelks (Buccinum and Nassa), in the Limfjord. It appears that these animals are exceedingly troublesome in the Limfjord owing to their great abundance and rapacity. They feed on the plaice caught in the nets (gill-nets), and Dr. Petersen estimates the loss to the fishermen at a third of the year's total catch, a very considerable amount. The process of deliberate extermination is not recommended, however, as being too costly and uncertain, nor does it appear possible to make any economical use of the whelks; but it is suggested that the fishermen should clear their nets at more frequent intervals, and for the rest hope for an epidemic among the whelks. The possibility of the latter seems by no means remote.

In the twentieth report Dr. Petersen displays the foundations of an extensive and notable work on the quantitative determination of the animal life on the bottom of the sea. The investigation is stated to be a logical extension of Hensen's ideas; but, as a matter of fact, the "census of the sea" of Hensen, Brandt, and Herdman is widely different from the "valuation of the sea" of Petersen. Where the former lay stress on the plankton, and ignore the part played by the organic matter dissolved in sea water and in the bottom soil, the latter rather discredits the plankton, pointing out, in agreement with Lohmann, that its "producers" are not always able to supply sufficient food for its own "consumers," and lays stress on the organic matter. In the first part of this report Dr. Boysen Jensen discusses the results of his chemical analysis of the bottom soil and sea water, and concludes, *inter alia*, that the organic matter must come essentially from the benthos flora (algæ, and especially Zostera) in the Limfjord. The benthos animals—*e.g.* the oyster—are dependent on this organic matter, and not on the plankton.

It follows from this that the methods of investigation used by Dr. Petersen are entirely different from those of the planktologists. The basal idea is to determine the quantity of animal life on a fixed unit of surface (0·1 $m.^2$) at as many different stations as possible, and at all seasons of the year. For this purpose Dr. Petersen has designed a special apparatus, which is simple in construction and can be used at any depth. To count the animals, after sifting, from such a unit of surface is obviously a much easier matter than the enumeration of the plankton. But Dr. Petersen goes much further, and, with the assistance of Dr. Boysen Jensen, gives the equivalents for each species in grams of organic matter. This common denominator thus serves as a basis of comparison of the value, not only of the different species, but also of different areas or fishing grounds. From this basis also it is possible to compare the amount of nourishment available and the amount consumed, as by the fishes. Even the fishes are reduced

[1] Nineteenth Report from the Danish Biological Station. Some Experiments on the Possibility of combating the harmful Animals of the Fisheries, especially the Whelks in the Limfjord. By C. G. Joh. Petersen. Pp. 20. (1911.)

Twentieth Report from the Danish Biological Station. Valuation of the Sea. I. Animal Life of the Sea-bottom, its Food and Quantity (Quantitative Studies). By C. G. Joh. Petersen and P. Boysen Jensen. Pp. 81; with 6 tables, 3 charts and 6 plates. (1911.)

to the common denominator; and it is shown, for example, that in the Limfjord the annual increase in weight of the plaice is only about one-sixth of the amount of organic matter consumed, and that the annual consumption of the plaice and eel together is only about one-ninth of the nourishment available.

The work is stated to be in its beginning, and this report is to be regarded as the introduction only; even so, it is remarkable for its broad and philosophic insight into fisheries problems and its wealth of ideas and practical suggestions. It can be strongly recommended to the planktologists—as an antidote. K.

SCIENTIFIC WORK OF THE IMPERIAL INSTITUTE.

WE have received a copy of the "Report on the Work of the Imperial Institute, 1910" (Cd. 5467–23), which contains a prefatory statement describing the organisation and objects of the institute, and includes summaries of the investigations carried out by the scientific and technical staff during the year. These comprised the examination of various minerals; of vegetable products such as cotton, rubber, oils, tobacco, foodstuffs, and so forth; and of a few animal products, including sponges, shells, feathers, and hair. Among the minerals mention is made of thorianite from Ceylon, containing 51·1 per cent. of thoria and 24·9 per cent. of uranoso-uranic oxide, the case being of special interest as indicating the kind of rock with which thorianite may be expected to occur in other localities.

Deposits of lignite from Southern Nigeria have been found to yield briquettes of excellent quality, and it is now clear that the use of local fuel, by obviating the heavy expenditure on imported coal, will materially assist the development of the West African colonies.

In the East African Protectorate an immense deposit of "soda" is to be worked; it consists essentially of sodium sesquicarbonate, and merely requires heating to furnish commercial "soda" of good quality. Numerous samples of rubber were examined, though only one actual consignment of any magnitude is described; this consisted of about 650 lb. of Landolphia rubber from the Bahr-el-Ghazal, which was of good chemical quality and realised fair prices.

In connection with the production of lemon-grass oil, the report states that the cultivation and distillation of lemon-grass in Uganda is now securely established. Samples of wheat from the East African Protectorate and from Northern Nigeria were found to be of excellent quality, and some "Turkish" tobacco from the Cape Province was regarded by experts as very promising. During the year three papers on geological and mineralogical questions, and one on the synthesis of caoutchouc, were contributed to scientific journals by members of the staff of the institute.

EXHIBITION OF MODEL AND EXPERIMENTAL ENGINEERING.

MR. PERCIVAL MARSHALL and those who are acting with him are to be congratulated on the success of the third biennial exhibition of model and experimental engineering. As before, this is held at the Royal Horticultural Hall, and it closes next Saturday. Model engines and boats, both sailing and steam, and kites, have always supplied an unfailing attraction to the younger generation; but now the amateur mechanic and experimentalist has a wider and more attractive field, largely dependent on the gas or petrol engine, a field in which in the last two years enormous strides have been made. Aëroplanes and hydroplanes of model size are doing wonders, though, of course, in most cases the engine of the aëroplane is made of elastic. The gyroscope and electricity afford more subject-matter for the experimentalist, as the model engineer now so often becomes, to work upon. Even wireless telegraphy is not outside his reach. When it is realised that a speed of more than twenty miles an hour has now been reached by a model "speed boat," and about half a mile has been traversed by a model aëroplane, it must be felt that the model engineering and experimental art as fostered by the society for which Mr. Marshall is doing so much is more than mere toy-making—it has a valuable educational influence.

It may be said that there are two types of small machine or model, one the faithful copy on a small scale of the big machine, and the other the small machine made so as itself to be as good as possible as a working machine. The two ideals are wholly distinct; each has its attractive side, each is well represented at the exhibition; but it is the second that is the most instructive, and this appeals most to the scientific imagination. While the visitor cannot help admiring the model of an engineering workshop with its steam engine, shafting, travelling crane, lathes, shapers, and planing machines, all beautifully made, and with leg vices, spanners, and small tools all in keeping, and while so beautifully made a model is quite instructive, model machines made not a bit like their large prototypes, but with their proportions altered so as to make them work as well as possible, are more interesting. They may fail in appealing to the æsthetic sense, if that be the sense which makes scale models so attractive, but if so they satisfy the reasoning faculty and experimental sense, and to the writer they appear the more important. Of course, at times proportions become so wildly inverted as to lead to a ludicrous appearance; but that only indicates the triumph of reason over the imitative art. For instance, there is a model petrol engine with pressure tank, carburettor, and engine in which the proportion of carburettor and cylinder irresistibly remind one of Lear's "young bird in that bush."

The only regret, and this is expressed not for the first time, is that Mr. Marshall so far has been unable to organise his exhibition at a time of year when boys are having their holidays.

FORTHCOMING BOOKS OF SCIENCE.

IN addition to the books announced in NATURE of October 5, the following works may be expected:—

AGRICULTURE.

W. H. and L. Collingridge.—Manures for Garden and Farm Crops, W. Dyke. *John Murray.*—A new edition of Elements of Agriculture: a Text-book Prepared under the Authority of the Royal Agricultural Society of England, by the late Dr. W. Fream, edited by Prof. J. R. Ainsworth-Davis, illustrated.

ARCHÆOLOGY.

Cambridge University Press.—The Thunderweapon in Religion and Folklore: a Study in Comparative Archæology, Dr. C. Blinkenberg, illustrated. *Oxford University Press.*—Four Years' Excavations at Thebes, the Earl of Carnarvon and Mr. Howard Carter, with chapters by Mr. F. L. Griffith, M. George Legrain, Dr. Moller, Prof. Newberry, and Prof. Spiegelberg, illustrated.

BIOLOGY.

Blackie and Son, Ltd.—Methodical Nature Study, W. J. Claxton, illustrated. *Gebrüder Borntraeger (Berlin).*—Die Wirbeltiere, Prof. O. Jaekel, illustrated; Symbolae Antillanae seu fundamenta florae Indiae Occidentalis, edited by I. Urban, Band iv., fasc. 4; Flora von Steiermark, Dr. A. von Hayek, Band ii., Heft 1; Handbuch der systematischen Botanik, Prof. E. Warming, new edition by Prof. M. Möbius; Kulturpflanzen und Haustiere in ihrem Übergange aus Asien nach Griechenland und Italien sowie in das übrige Europa, V. Hehn, new edition, edited by Prof. O. Schrader. *Cambridge University Press.*—Types of British Vegetation, by members of the Central Committee for the Survey and Study of British Vegetation, edited by A. G Tansley, illustrated; The Vegetation of the Peak District, Dr. C. E. Moss; Life in the Sea, J. Johnstone; Heredity and Eugenics, edited by J. M. Coulter; American Permian Vertebrates, S. W. Williston, illustrated. *W. H. and L. Collingridge.*—Orchids for Amateurs, C. A. Harrison, illustrated; Rock Gardens and Alpine Plants,

E. H. Jenkins, illustrated. *Herbert and Daniel.*—Evolution in the Past, H. W. Knipe, illustrated. *Hutchinson and Co.*—The Flower Fields of Alpine Switzerland, G. Flemwell, illustrated; The Story of Evolution, J. McCabe, illustrated. *Jarrold and Sons, Ltd.*—Horses and Practical Horse Keeping, F. T. Barton, illustrated; Farther Afield in Birdland, O. G. Pike, illustrated; Wild Animals and the Camera, W. P. Dando, illustrated; My Book of Little Dogs, G. V. Stokes and F. T. Barton, illustrated; Our Dogs and All About Them, F. T. Barton, new edition, illustrated. *John Murray.*—Further Researches into Induced Cell-reproduction and Cancer, H. C. Ross, illustrated; The Genus Rosa, E. Willmott, drawings by A. Parsons, in parts, continued; Science of the Sea: an Elementary Handbook of Practical Oceanography for Travellers, Sailors, and Yachtsmen, prepared by the Challenger Society for the Promotion of the Study of Oceanography, and edited by Dr. G. H. Fowler, illustrated; and a new edition of Recent Advances in the Study of Variation, Heredity, and Evolution, R. H. Lock, illustrated. *Williams and Norgate.*—Introduction to Science, Prof. J. A. Thomson. *Grant Richards, Ltd.*—The Complete Wildfowler Ashore and Afloat, S. Duncan and G. Thorne, illustrated; The Birds of the British Islands, C. Stonham, parts 19 and 20, completing the work. *Seeley, Service and Co., Ltd.*—The Wonders of Bird Life, J. Lea. *Whitcombe and Tombs, Ltd.*—An Australian Bird Book, J. A. Leach, illustrated.

CHEMISTRY.

Gebrüder Borntraeger (Berlin).—Chemisch-technisches Praktikum, Dr. W. Moldenhauer; Die Chemie der Cellulose, Prof. C. G. Schwalbe; Magnetochemie, Prof. E. Wedekind, illustrated.

ENGINEERING.

Cassell and Co., Ltd.—Electrical Engineering, by H. H. Simmons, in 14 parts, illustrated. *Seeley, Service and Co., Ltd.*—The Wonders of Modern Engineering, A. Williams.

GEOGRAPHY.

Cambridge University Press.—The Climate of the Continent of Africa, A. Knox, illustrated; The Physical Geography of South Africa, A. L. Dutoit; Cambridge County Geographies, illustrated: Buckinghamshire, Dr. A. M. Davies; East London, G. F. Bosworth; West London, G. F. Bosworth; Northamptonshire, Rev. M. W. Brown; North Lancashire, Dr. J. E. Marr, F.R.S.; Monmouthshire, H. A. Evans; The Isle of Man, Rev. J. Quine; Oxfordshire, Rev. P. H. Ditchfield; Dumfriesshire, Rev. Dr. J. K. Hewison; Midlothian, A. McCallum; Perthshire, P. Macnair. *John Murray.*—Rambles in the Pyrenees and the Adjacent Districts—Gascony, Pays de Foix and Rousillon, F. H. Jackson, illustrated. *G. Philip and Son, Ltd.*—Philips' New Historical Atlas for Students, Prof. R. Muir; Philips' Chamber of Commerce Atlas: a Graphic Survey of the World's Trade, with a Commercial Compendium and Gazetteer Index; Philips' Modern School Atlas of Comparative Geography, edited by G. Philip, new edition; The Imperial Stations from Gibraltar to the Far East, prepared for the Visual Instruction Committee of the Colonial Office. *Whitcombe and Tombs, Ltd.*—The Geography of New South Wales, Historical, Physical, Political, and Commercial, Dr. Woolnough, assisted by A. W. Jose, G. Taylor, with introduction by Prof. T. W. David, illustrated.

GEOLOGY.

Gebrüder Borntraeger (Berlin). Geologischer Führer durch das Mainzer Tertiärbecken, Dr. E. Mordziol, illustrated; Geologische Charakterbilder, edited by Prof. Stille: Heft 7, Westgrönland, Basalt- und Sedimentgebirge, by A. Heim; Heft 8, Der Odenwald bei Heidelberg und sein Abbruch zur Rheinebene, by W. Spitz and W. Salomon, illustrated.

MATHEMATICAL AND PHYSICAL SCIENCE.

Cambridge University Press.—An Elementary Treatise on Cross-ratio Geometry, with Historical Notes, Rev. J. J. Milne; and new editions of A Primer of Astronomy, Sir R. Ball, F.R.S., illustrated; The Mathematical Theory of Electricity and Magnetism, J. H. Jeans, F.R.S. *Hutchinson and Co.*—Photography, edited by H. P. Maskel. *John Murray.*—A New Geometry, A. E. Layng. *G. P. Putnam's Sons.*—Star Lore of all Ages, W. T. Olcott, illustrated. *Williams and Norgate.*—Astronomy, A. R. Hinks.

MEDICAL SCIENCE.

D. Appleton and Co.—A Text-book of Bacteriology: a Practical Treatise for Students and Practitioners of Medicine, P. H. Hiss, jun., and H. Zinsser; Treatise on Tuberculosis, edited by A. C. Klebs; Plastic and Cosmetic Surgery, F. S. Kolle; Clinical Symptomatology, with Reference to the Life-threatening Symptoms and their Treatment, A. Pick and A. Hecht; A Text-book of Medicine for Practitioners and Students, Dr. A. V. Strumpell; A Text-book in Psychotherapy, including the History of the Use of Mental Influence, directly and indirectly, in Healing, and in the Principles for the Application of Energies derived from the Mind to the Treatment of Disease, J. J. Walsh. *Gebruder Borntraeger (Berlin).*—Pharmakognostischer Atlas, Zweiter Teil der mikroskopischen Analyse der Drogenpulver, Prof. L. Koch, Band i., illustrated. *Herbert and Daniel.*—The Romance of Modern Surgery and its Making: a Tribute to Listerism, Dr. C. W. Saleeby. *J. Nisbet and Co., Ltd.*—Tuberculin in the Diagnosis and Treatment of Tuberculosis, Dr. W. C. Wilkinson; The Intensive Irradiation and Wave Current Treatment of Rheumatism, Sciatica, Lumbago, Neuritis, and Painful Joints, L. E. Creasy.

TECHNOLOGY.

Gebrüder Borntraeger (Berlin).—Internationale Zeitschrift für Metallographie, edited by Dr. W. Guertler, Band i., illustrated; Handbuch der bautechnischen Gesteinsprüfung, Prof. J. Hirschwald, illustrated. *C. Arthur Pearson, Ltd.*—Wires and Wireless, T. W. Corbin. *Seeley, Service and Co., Ltd.*—Mechanical Inventions of To-day, T. W. Corbin, illustrated; The Romance of Aëronautics, C. C. Turner. *John Hogg.*—A new edition of Silverwork and Jewellery, H. Wilson, with notes by Prof. U. Bisei, illustrated.

MISCELLANEOUS.

Gebruder Borntraeger (Berlin).—Gedanken und Vorschläge zur Naturdenkmalpflege in Hohenzollern; Die Gefährdung der Naturdenkmäler und Vorschläge zu ihrer Erhaltung, Prof. H. Conwentz, new edition. *Cambridge University Press.*—Byways in British Archæology, W. Johnson, illustrated; Assyrian and Babylonian Letters Belonging to the Kouyunjik Collections of the British Museum, edited by R. F. Harper, parts x. and xi. *John Murray.*—Early Norman Castles in the British Isles, E. Armitage, illustrated; The Excavation of Gezer, 1902–5 and 1907–9, Prof. R. A. Stewart MacAlister, 3 vols., illustrated.—*Scott Publishing Company, Ltd.*—The Composition of Matter and the Evolution of Mind, D. Taylor. *Williams and Norgate.*—Psychical Research, Prof. W. F. Barrett, F.R.S.; The Dawn of History, Prof. J. L. Myres.

THE SCIENTIFIC MISAPPROPRIATION OF POPULAR TERMS.[1]

ONE of the main functions of the British Association is to prevent the development of a scientific caste in this country. The essential ideas of caste and science are diametrically opposed; nevertheless, the spirit of caste has in times past invaded the spirit of science, with the natural consequence that the eager explorers of knowledge became the academic guardians of tradition; and the same invasion now would deprive science of the popular sympathy and support which are more than ever necessary for its steady development. The members of the corresponding societies have special opportunities for helping that part of the Association's mission, for their personal intercourse with all sections of the community enables them to do much "to obtain a more general attention to the objects of science." Their influence must be exerted mainly through words, and the proper use of words is a matter of vital importance to the welfare of science. The recent appeals

[1] Address to the Conference of Delegates at the Portsmouth meeting of the British Association, by Prof. J. W. Gregory, F.R.S., chairman.

for the improvement of the language of scientific literature are therefore direct contributions to scientific method; and as the societies represented at this conference are the strongest link between the technical specialist and those who take a friendly interest in science, special sympathy may be expected here with the complaints against the unintelligibility of some scientific writings owing to the excessive use of technical terms. I wish this afternoon, without denying that technical terms are sometimes used unnecessarily, to direct attention to a more neglected and insidious evil—the use of well-known English words with a technical meaning. The temptation to adopt an old word for a new idea, instead of inventing a fresh term, is often strong. It saves trouble—at the time. The old word is probably shorter than a new one would have to be, and its use avoids burdening a passage with an unknown and perhaps uncouth term. A sentence in which all the words are familiar appears to present no difficulties; a reader skims lightly over it pleased with the lucidity of the author and ignorant of the fact that it has been misunderstood, as the leading word conveyed to him a meaning different from that intended by the writer. The danger of a passage being misunderstood is more serious than that of its being not understood. It is worse to be misled by a plausible phrase than to be startled or repelled by a correct technical statement. A new word compels a conscientious reader to determine its true meaning, and should help him to a clear conception of the fresh idea; whereas the use of an old word with a new meaning discourages inquiry and encourages slovenliness in work and thought. The use of popular phraseology may render scientific literature apparently less strange; but if that phraseology be incorrectly used, the ultimate effect is to increase the divergence between the scientific and popular languages, and the estrangement between science and public opinion. For the scientific use of terms inconsistently with their ordinary meanings is apt to persuade the layman that the language of science is so different from his own that it is no use attempting to understand it.

Most sciences have adopted popular terms with new and restricted meanings; and if the origin of such a word be forgotten, scientific writers are apt to treat any use of it in its original sense as a popular blunder. For example, zoologists not only now reject spiders from the class of Insecta, but treat the idea that a spider is an insect as a mistake due to simple ignorance. Thus, to quote a recent standard work, J. H. and A. B. Comstock, in their "Manual for the Study of Insects" (1909, p. 12), remark that spiders "are often mistaken for insects," although the authors have abandoned "Insecta" as the name of the class in favour of Hexapoda. The word insect is much older than modern systematic zoology and the class Insecta. The word insect is derived from the Latin *insectum*, which is based on the verb *insecare*, "to cut into"; and it was used for animals the bodies of which are notched or incised into sections. This meaning of the word is well expressed in the definition by Philemon Holland, who is the earliest English author quoted in the "New English Dictionary" as having used the word insect. In his book, "The Historie of the World, commonly called the Naturall Historie of C. Plinius Secundus" (1601), he says, "Well may they all be called Insecta, by reason of those cuts and divisions, which some have about the necke, and others in the breast and belly; the which do go round and part the members of the bodie, hanging together only by a little pipe and fistulous conveiance."

The class Insecta was based by its founder, Linnæus, on the segmentation of the body, and not on the number of legs; it therefore included scorpions, millipedes, and spiders. It was not until half a century later that Lamarck excluded spiders from the class Insecta; and as late as 1864 we find so distinguished a naturalist as Bates[1] remarking that the spiders "Mygales are quite common insects." Even such a recent standard modern cyclopædia as the "Jewish Encyclopædia"[2] retains the millipedes as insects. The term insect should not, however, be applied to a coral polyp; "coral insect" is justly denounced as a misleading blunder, due to ignorance of the nature of the coral animal. The terms *insectum* and insect according to their original usage no doubt included worms, and

[1] "A Naturalist on the Amazon," p. 96. [2] 1906, vol. vi., p. 105.

Holland expressly mentioned earth-worms as insects. In many worms, however, the body is not divided into segments, and worms were therefore early and appropriately excluded from insects; so Milton writes[1] in his description of the bower in Eden:—

> "Other creature here,
> Beast, bird, insect, or worm, durst enter none."

Johnson's Dictionary (first edition, 1755) accepted a definition restricting insects to animals whose body is nearly divided in the middle into two parts. "Insects may be considered together as one great tribe of animals; they are called insects from a separation in the middle of their bodies whereby they are cut into two parts, which are joined together by a small ligature, as we see in wasps and common flies." This definition, while admitting spiders, excluded worms. The present zoological separation of insects from other air-breathing arthropods is based mainly on the presence of six legs. The term Hexapoda is therefore more suitable for the class as now defined than Insecta; and the restriction of Insecta in systematic zoology to a group based not on the insection of the body, but on the number of legs, is less accurate and appropriate than its previous use in zoology and in popular English. It would seem better to admit that the spider is an insect, but insist that it is not a hexapod.

The term worm, on the other hand, illustrates cases in which a restriction of popular meaning is both appropriate and convenient. A worm was originally not necessarily one of the Vermes of the zoologist. Thus the worms mentioned in the Old Testament included various insect larvæ. Dr. Ridewood tells me that the manna collected by the Israelites in the desert was probably a small lichen, and that the worms bred in it[2] were probably fly grubs; and the references by Job and Isaiah to worms that cover the dead may include both insect grubs and nematodes. When Job reminds the sinner of the worm that "shall feed sweetly upon him,"[3] he had in mind the larvæ of blowflies; and though the worms that ate Herod[4] may have been an endoparasitic worm or fluke, the worm that caused the withering of Jonah's gourd[5] was probably a beetle larva.

In popular English, moreover, worms always included snakes, as shown both by Dr. Johnson's definition of a worm, "A small, harmless serpent that lives in the earth," and by Shakespeare in Cleopatra's inquiry:—

> "Hast thou the pretty worm of Nilus there,
> That kills and pains not?"[6]

Uniformity between popular and zoological terminology can best be secured in regard to the term worm by inducing the public to use it only for one of the Vermes, for it is less necessary to have one term for all creeping things than to distinguish noxious snakes and centipedes from the lowly and useful worm.

The word fish illustrates how a popular word may become unduly extended and then be again restricted with fuller knowledge. The word is of very ancient origin, and was probably originally limited to what the zoologist accepts as fish. The term fish is not derived from the primitive Aryan language, and it was not introduced until the Latin-Teutonic section had separated from the Indian and the Greek; and as the term was invented by people who apparently had no knowledge of the sea, they doubtless used it for fresh-water fish.[7] The primitive hunters who went to the coast may have extended it to shellfish, and it was adopted in the English crayfish by a corruption of the French *écrevisse*. When whales and dolphins were discovered, they were accepted as fish in ignorance of their affinities, for such aquatic animals as seals and otters were never included among fish, since their mammalian characters were obvious. That whales, porpoises, and their allies are not fish is now admitted in current language, though the old usage survives among whalers. The terms whale-fishery and seal-fishery are firmly established; but they are unobjectionable, because those industries have so many important features in common with the capture of fish. The general current limitation of fish to the fish

[1] "Paradise Lost," iv. [2] Exodus, xv. 20. [3] Job, xxiv. 20.
[4] Acts, xii. 23. [5] Jonah, iv. 7. [6] "Antony and Cleopatra," v. 2.
[7] See O. Schrader, "Prehistoric Antiquities of the Aryan Peoples," 1890, pp. 117–118, 127–128, 353–354.

of the zoologist is only a return to the primary meaning of the word.

Chemistry supplies an excellent illustration of the justifiable adoption of an old term with a revised meaning. Element is used in its later classical meaning, and Chaucer in 1386 shows that it was used in Early English in a similar sense. He says in the Frere's Tale (line 206):—

> "Make ye yow newe bodies alway
> Of elementz."

Its modern chemical use means the resurrection of the word element to a new period of usefulness.

The chemical adoption of the terms metal and non-metal for the two classes of elements is, on the other hand, an example of the inconvenience that results when a new definition is only approximately coincident with a well-established current meaning. The word metal appears to be derived from the Greek *μεταλλον*, connected with *μεταλλάω*, "to seek after," through the Latin *metallum*, a mine or quarry, or substance obtained by mining. Hence road metal for stone is correct.

By the time of Johnson the word metal was usually restricted to those products from mines which have metallic as distinct from earthy or stony properties. Johnson's definition—"We understand by the term metal a firm, heavy, and hard substance, opake, fusible by fire, and concreting again when cold into a solid body such as it was before, which is malleable under the hammer, and is of a bright, glossy, and glittering substance where newly cut or broken"—states the general idea of a metal.

The chemical adoption of the word for the larger of the two classes of elements has resulted in the use of the word metal in science with two contradictory senses; thus in elementary geology the word is used with its chemical meaning; but in economic geology metal is used in its commercial sense.

Sodium and potassium are therefore metals in elementary geology and academic mineralogy; but they are not metals in advanced economic geology. This double use of the word is an occasional source of confusion and discounts any good advice that may be given to students as to precision in the use of terms. It is perhaps too late to change, but it would have been better if the chemists had adopted technical terms for the two groups of elements instead of applying the term metal to a material so unlike the ordinary idea of a metal as is sodium.

Geology has been a particularly flagrant sinner in the misuse of popular terms. Its nomenclature has not only unconsciously absorbed and modified many English words, but committees of experts have deliberately committed such wholesale piracy that our language has been left bankrupt in some departments. Thus terms are needed in stratigraphy for the various subdivisions of the sedimentary rocks and for the lengths of time occupied in their deposition. The International Geological Congress proposed the following series of terms, beginning with the larger divisions:—

Formation	Equivalent Time
Group.	Era.
System.	Period.
Series.	Epoch.
Stage.	Age.

Although a systematic nomenclature would be very useful, this scheme has not been generally adopted; and I think the reason is that, by assigning definite meanings to all the indefinite terms available, there is nothing left for use in an indefinite sense. Thus a number of beds, which together may be either more or less than a subdivision of a system, cannot be called a series without risk of misunderstanding. All the above eight terms are required for use in geology with their current English meanings. The scheme proposed by the International Geological Congress involves using these words sometimes in a technical and sometimes in a non-technical sense. In literature the difficulty may be overcome by printing the words with capital letters when they are used as the names of definite divisions; but that is impossible in speech. The principle recommended by the International Geological Congress was excellent, but the scheme proposed has proved impracticable owing to its application of old words to new things.

Buckman adopted a sounder policy when he introduced the term Hemera for the time equivalent to a zone.

Geologists have adopted some common words with meanings which render geological phraseology unintelligible or even ludicrous to the man who has not been warned that they require special interpretation. Thus the need in elementary teaching for emphasising the difference between mineral species and mineral aggregates has led to the frequent use of the term mineral as an abbreviation for mineral species. Some authors have been led by this practice to deny that mineral aggregates are minerals, and therefore assert that coal, most iron ores, oil shale, mineral oil, &c., are not minerals. According to that view the mineral industry has little concern with minerals; and the mineral resources of the British Isles, which are generally regarded as extensive, are reduced according to this nomenclature to practically nothing.

Another triumph of dauntless logic is the use of the word rock. It is no doubt convenient, when speaking of the crust of the earth, to have one term to cover all its materials; and rock is used in this way just as the dust in the atmosphere and the salts in the sea may be included with the air and the water. Hence has arisen the geological convention of calling any large constituent of the earth's crust a rock, quite regardless of the cohesion of its particles. G. H. Kinahan, for example, in his "A Handy Book of Rock Names" (1873), says, "Thus loose sand, clay, peat, and even vegetable mould, geologically speaking, are rocks" (p. 1); and on p. 131 he includes ice among rocks.

Now this use of the term ignores the very essence of the popular idea of a rock. The term appears to be derived from the same word as crag, and the essential quality of a rock is firmness. The parable of the man who built his house upon a rock would need to be retranslated, and Shakespeare's "He's the rock, the oak not to be wind-shaken,"[1] loses its meaning if rock may be loose, drifting sand. The conventional use of the word rock in geology has been so widely adopted that objection to it may appear pedantic. Rosenbusch,[2] however, has defined "Rocks as the geologically independent constituents, of more or less constant chemical and mineralogical composition, of which the firm ('feste') crust of our earth is built." Hence such definitions as that in my "Structural Geography" (p. 21) of rocks as the firm coherent masses which form the main part of the lithosphere may shelter behind the high authority of Rosenbusch.

Reference to the paradox of calling clay and sand rocks reminds me that the word clay is now used in two very different senses in two sections of geology. In mineralogy the clays are a group of mineral species which are hydrous silicates of alumina. To the merchant, the farmer, and the economic geologist the essential quality of clay depends on texture and not on chemical composition. The [illegible]d clay appears to be based on the same root as clog and cleave, while the Russian glina and the Greek *γλία* connect it with glue and glutin. The root of the word clearly refers to the adhesiveness which clay owes to its plasticity.

The essential property of clay is that it becomes plastic when wet. In England this property is chiefly found in material, which, being formed from decomposed felspars, is a hydrous silicate of alumina; but other common materials have the same property, if ground to the requisite fineness. Quartz flour is a common clay-forming material in many parts of the world, and much of the material called clay by the farmer is pure silica. Hence the definition of economic and agricultural geologists that clay is earthy material, which is plastic when wet, its particles being no more than 0·05 mm. in diameter, is a more common-sense definition than any based on chemical composition.[3]

If a name be wanted to distinguish clays which are silicate of alumina from clays of different composition,

[1] Coriolanus, v. 2, 117. Cf. also Zangwill "Feeling solid-based upon eternal rock."

[2] H. Rosenbusch, "Elemente der Gesteinslehre," Stuttgart, 1910, third edition, p. 1.

[3] Ries's definition—"Clay is the term applied to those earthy materials occurring in nature whose most prominent property is that of plasticity when wet" (H. Ries, "Clays, Their Occurrence, Prooerties, and Uses, with especial reference to those of the United States," 1906, p. 1)—is an example of those based on texture and not on composition.

then a new name should be invented, instead of adopting a definition which refuses to accept as clay the slime of the quartz miner, much of the Scottish boulder clay, and any one of the nine brick-clays in the table of brick-clay analyses given by Ries.[1]

I have referred to a few instances to illustrate the frequent misappropriation of current terms by various branches of science, in the hope that the members of the corresponding societies will use their influence to discourage this practice. It should be remembered, however, that there are many cases in which it is a wise policy to transform a current popular term. It may be even justifiable, as in the case of minium and cinnabar, to use a word with the very opposite of its original meaning. A term may be adopted and redefined where, as in the cases of fish and worm, the popular meaning involves a wrong idea, which it is advisable to correct, or overlooks a distinction which is practically important. Change and growth in nomenclature must be allowed. A dead language is very good for fixed ideas; but rigid adherence to original meanings is a bondage from which it is to be hoped scientific terminology will be always free. It is useless to suggest rules as to when popular terms may be revised; each case should be judged on its merits.

The casual adoption of current words with new meanings is often an attempt to secure specious simplicity at the price of subsequent confusion. Deissmann's recent book, "Light from the Ancient East" (1910), directs attention to the misconceptions that have similarly arisen in theology, for he urges that words used in the New Testament are now understood, in what the authors of that volume would decidedly call a non-natural sense. The idea that science is being driven into an intellectual wilderness owing to its technical terminology is an idle bogie. Reference to the sporting or business columns of any daily paper will show that all specialised pursuits have their own special language. The language of golf is as technical as that of geology, and I venture to urge that science will lose more by the misuse of current English than by the invention of new terms for new ideas and new materials. A rose by any other name may smell as sweet, but we cannot get sweet-smelling roses if we order them under the name of dandelions. In short, to put new meanings into standard English words appears as unjustifiable as to put home-brewed beer into Bass-labelled bottles.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The next combined examination for sixty-eight entrance scholarships and a large number of exhibitions, at Pembroke, Gonville and Caius, King's, Jesus, Christ's, St. John's, and Emmanuel Colleges, will be held on Tuesday, December 5, and following days. Mathematics, classics, and natural sciences will be the subjects of examination at all the above-mentioned colleges. Most of the colleges allow candidates who intend to study mechanical sciences to compete for scholarships and exhibitions by taking the papers set in mathematics or natural sciences. A candidate for a scholarship or exhibition at any of the seven colleges must not be more than nineteen years of age on October 1, 1911. Forms of application for admission to the examination at the respective colleges may be obtained as follows:—Pembroke College, W. S. Hadley; Gonville and Caius College, The Master; King's College, W. H. Macaulay; Jesus College, A. Gray; Christ's College, The Master; St. John's College, The Master; Emmanuel College, The Master; from any of whom further information respecting the scholarships and other matters connected with the several colleges may be obtained. The forms of application must be sent in on or before Saturday, November 25.

The syndicate appointed to consider the question of providing pensions for professors and others in the service of the University has considered the desirability of framing a contributory scheme. The stipends, however, which the University is at present able to pay do not seem to the syndicate sufficiently large to justify a tax for providing pensions. The syndicate has also considered whether the University should enter into an arrangement with an assurance company or should form its own pension fund; but it recommends that the University should establish its own pension fund. In its scheme the syndicate has aimed at providing pensions for professors (with certain exceptions), readers, and certain officers on the basis of compulsory retirement at a given age; the maximum pension to be 500*l.* a year or five-sixths of the stipend, whichever is the less; and the actual pension to be in a proportion, varying with the length of service, to the maximum pension. The amount of pension is further limited to 500*l.* a year, inclusive of any college pension, stipend, or emolument. The syndicate proposes that in the first instance the pension scheme should apply only to professors, readers, and officers appointed in the future, in which case the annual contribution for pensions would for many years probably be small. But it is hoped that the University may be able in due course to provide pensions for some of the present staff if they are willing to place themselves under the scheme. There are nineteen professors, twelve readers, and nine university officers of the present staff who would be under the age of sixty on January 1, 1911, and entitled to pensions according to the scheme.

The syndicate appointed to consider the financial administration of the various scientific departments of the University, and the financial relations between these departments and the museums and lecture-rooms syndicate, has issued a revised report, in which the following rules are formulated, among others:—(1) That the responsibility for the working and superintendence of each of the scientific departments and for the administration of the departmental fund rest with the professor who is the head of the department. (2) That, subject to any subsisting agreement for the retention of fees by individuals, all fees received for lectures and practical courses be paid into the departmental fund. (3) That a university buildings syndicate be established in substitution for the museums and lecture-rooms syndicate, and that all university buildings be placed under its charge except the University Press and any other buildings specially committed by the Senate to any special board or syndicate. (4) That a general maintenance fund for university buildings be established in substitution for the museums and lecture-rooms maintenance fund, and that it be referred to the financial board to advise the Senate what annual payment should be made to this fund.

The financial board has reported on the college contributions for 1911. In its opinion the sum of 30,071*l.* should be raised in the present year by contributions from the colleges for university purposes. This report has been accepted by the Senate.

It is proposed to establish a post of demonstrator in medical etymology in connection with the Quick Laboratory. The appointment will be made by the Quick professor of biology with the consent of the Vice-Chancellor, and the office will terminate with the current period of the tenure of the Quick professorship.

THE governing body of the Lister Institute has made the following appointments:—Drs. E. E. Atkin and W. Ray to be assistant bacteriologists, Mr. A. W. Bacot to be entomologist, and Dr. Casimir Funk to be a research scholar.

AN international exhibition is being arranged by the Imperial Russian Technical Society to illustrate the organisation and equipment of schools. The exhibition is to be opened on April 15, 1912, and will last until the following July 15. This will be the first exhibition of its kind to be held in Russia. Full particulars and the conditions for exhibitors can be obtained from the executive committee of the International Exhibition "Organisation and Equipment of Schools," St. Petersburg, Panteleimonskaia, 2.

REUTER'S correspondent at Simla states that about 30 lakhs of rupees (200,000*l.*) have been collected for establishing a residential Hindu university at Benares with an adequate European staff. Mr. Butler, of the Viceroy's Council, in writing to the Maharaja of Darbhanga, indicated the conditions upon which the Government would recognise the university, and these conditions have been accepted by the promoters of the scheme. The Maharaja of Darbhanga has given five lakhs of rupees (about 33,330*l.*) towards the university.

It is announced in *Science* that the late Dr. William Flynn, of Marion, has bequeathed his entire estate, valued at about 6000*l.*, to the Indiana Medical College, in which he was a member of the faculty for many years. From the same source we learn that among the public bequests made by Mr. G. M. Pullman was that of 240,000*l.* for founding and endowing the Pullman Free School of Manual Training at Pullman, Ill. This fund has increased to more than 500,000*l.* The first step towards founding the school was the purchase, in 1908, of forty acres within the limits of the town of Pullman at a cost of 20,000*l.* Mr. Laenas Gifford Weld, until recently professor of mathematics and dean of the faculty of liberal arts in the Iowa State University, was appointed principal in May, and entered upon his new duties on September 1. He will visit the leading technical and trade schools in this country and in Europe before the preparation of definite plans is undertaken.

SOCIETIES AND ACADEMIES.

MANCHESTER.

Literary and Philosophical Society, October 3.—The president, Prof. F. E. Weiss, gave an address on recent researches on heredity in plants. After mentioning the work of earlier investigators, Prof. Weiss referred to the experiments of Mendel on the crossing of different strains of peas. From the results Mendel deduced the two fundamental laws of heredity: first, the dominance of certain unit characters in the first hybrid generation, and, secondly, the segregation of the dominant and recessive characters in the second hybrid generation. This latter law, though not its numerical ratios, was independently discovered by Naudin. These discoveries remained almost unnoticed for half a century, until de Vries, Correns, Bateson, and others brought them prominently before biologists at the beginning of the century. Confining himself to the phenomena of heredity in plants, Prof. Weiss dwelt upon some of the investigations of Correns and Bateson on colour inheritance in *Mirabilis jalapica* and sweet peas, and referred also to his own experiments in crossing the scarlet and blue forms of the common Pimpernel. The resultant cross was completely scarlet, like one of the parents, but in the subsequent generation 25 per cent. of the offspring were pure blues. The same result was obtained by crossing the blue form with pollen from a pink variety of Pimpernel, blue being recessive in the first hybrid generation. Prof. Weiss also dealt with the numerical ratios exhibited in the inheritance of paired characters, and with some of the more complex manifestations, such as the appearance of coloured flowers as the offspring of two white parents. Dealing with the analysis of hybrid plants, he referred to his experiments with *Geum intermedium*, the cross between the common and water avens, a hybrid not uncommonly met with in the limestone dales of Derbyshire. This plant exhibits in the size, colour, and shape of its flowers an intermediate condition between its two parents, and is thus easily distinguished from either. The flowers of the hybrid possess both the yellow plastids of the common avens and the red sap (anthocyanin) of the water avens. When pollinated with its own pollen, this very fertile hybrid gives rise to plants some of which have red flowers with no trace of yellow, while others are yellow with no red sap, and, in addition, a number of plants with pure white flowers were obtained. A similar "throwing" of white flowers was observed in the offspring of the hybrid between the primrose and the oxlip. The question of the determination of sex has also been attacked from the botanical point of view by Correns with some success, and his results, on the whole, tend to confirm the view that this problem may yet be satisfactorily solved on Mendelian lines.

DIARY OF SOCIETIES.

THURSDAY, OCTOBER 19.

INSTITUTION OF MINING AND METALLURGY, at 8.—The Economics of Tube-milling: H. Standish Ball—Fallacies in the Theory of the Organic Origin of Petroleum: Eugene Coste.

CONTENTS.

THURSDAY, OCTOBER 26, 1911.

AGRICULTURE IN DRY COUNTRIES.

Dry Farming: a System of Agriculture for Countries under a Low Rainfall. By Dr. J. A. Widtsoe. Pp. xxii+445. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 6*s.* 6*d.* net.

ACCORDING to the author's calculations, nearly six-tenths of the land surface of the earth receives less than twenty inches of rain per annum, and therefore requires the adoption of special agricultural methods differing from those in use in moister regions. In the strict historical sense it may be that the "dry farming" methods are really the older, for some of the ancient civilisations—Babylon and Egypt—flourished in "dry" regions. But to-day the dry farming methods are new, and are rapidly being extended over the regions of deficient rainfall that are now coming into cultivation.

Dry farming is different from irrigation, which is not touched upon in the present book. It consists in cultivation methods that reduce the loss of water from the soil by evaporation, and thus leave a maximum amount for the crop. Hence it implies a certain rainfall; at least ten inches a year are wanted, and success is not certain with less than fifteen inches.

A clear account is given of the differences between the soils of semi-arid and of humid regions, so far as these can be connected with the differences in rainfall. In humid regions the fertility of the soil is largely bound up with the clay fraction; a good deal of washing has gone on, and there is a tendency for the clay to wash into the subsoil, thus limiting the distance to which air can penetrate. A sharp distinction therefore arises between the surface and the subsoil, the latter being unsuited to plant growth. In semi-arid regions, on the other hand, the washing is reduced to a minimum; clay does not wash into the subsoil (it is said that clay does not even form to any great extent, but no evidence is set forth), and the difference between surface and subsoil does not arise; hence all parts of the soil are adapted to plant growth. Two deductions are drawn: the semi-arid soils are richer in plant food and stand in less need of fertilisers than humid soils; and recourse can be had more freely to deep ploughing.

Dry farming in the States, in its modern sense, is said to have been begun by Brigham Young and his followers when, in 1847, they went into the Great Salt Lake Valley. In this arid region starvation seemed to be the only possible ending to the colony, but suitable methods of farming were gradually evolved, and the results are matters of history. But the methods were not put together until H. W. Campbell, in 1895, published his "Soil Culture and Farm Journal." Then a boom began. The railway companies, with true commercial instinct, set up demonstration farms in dry regions for the benefit of intending settlers, and glowing accounts were given of what dry farming methods would do. The question aroused great interest in the British colonies, where large semi-arid tracts occur, and commissions and deputations were sent to study the methods on the spot. It is unfortunate that commercial interests were ever involved, because for a time the whole system was looked on with considerable suspicion by agriculturists, but Mr. Widtsoe's book will go far to satisfy the most sceptical that the methods are really effective.

Naturally there has been a good deal of change in methods, but the general conclusions to which Mr. Widtsoe is led are as follows. The soil should be a clay loam, uniform to a depth of at least eight feet. After the land has been cleared and broken it should lie fallow for one year, all weeds being rigorously hoed down; it should then be ploughed deeply in autumn. If crops are to be sown immediately (as they should be if the winter season is not too cold) the plough is followed by the disk cultivator and the harrow; if not, the land should lie up rough during winter, be further ploughed in spring, disk cultivated and harrowed. After every shower of rain the land is to be cultivated; the hoe or the harrow must be kept going all the season, and directly after harvest the land must be disked. Two great principles are that a fine layer of dry soil is to be maintained on the surface; and every weed must be killed.

It was originally thought necessary to compress the soil below this surface layer, but later experience shows this operation to be superfluous. A recent development, however, is the summer-cultivated fallow, adopted every third or fourth year in regions of fifteen to twenty inches rainfall, and every alternate year in regions of less than fifteen inches rainfall. By constant cultivation a large proportion of the rainfall can be kept in the soil for the next crop.

Wheat is the best crop, maize the second best; but a rotation is desirable, including a leguminous crop. As cattle cannot be kept the straw is not wanted; the grain is therefore cut off with a "header" and the straw ploughed in. Up to the present fertilisers have not been used, and the soil, so far from showing signs of impoverishment, is said actually to increase in fertility. However, the author does not counsel disuse of fertilisers, but insists that the soil must give out unless manure is added.

The necessity for a summer fallow arises from the fact that crop production is only possible where sufficient moisture is present. It is particularly to be noticed that no economy is attempted so far as the plant itself is concerned: extraneous sources of loss only are cut off.

As in other branches of agriculture, the facts are ahead of the hypothesis. The distribution of water over a complex mass of particles like the soil has not been worked out, but it is clearly regulated by the surface attractions between the particles and the water. Further, it is supposed that evaporation takes place only at the surface, and scarcely at all—only about 0·2 inch per annum—from the layers below, but this supposition is a little difficult to reconcile with the phenomena of diffusion of air into the soil.

Soil students and agriculturists will welcome the book as a useful summary by a man on the spot of what has been achieved so far, and they will be put in a position better than before to disentangle the real from the imaginary in the accounts of dry farming they come across.

E. J. R.

THE GROUSE AND ITS AILMENTS.

The Grouse in Health and in Disease: being the Final Report of the Committee of Inquiry on Grouse Disease. Two vols. Vol. i., pp. xxiii+512. Vol. ii., appendices, pp. vii+140+11 plates (41 maps). (London: Smith, Elder, and Co., 1911.) Price 2*l.* 2*s.* net.

ALTHOUGH, as its name implies, the Grouse Disease Inquiry Committee was formed to investigate the nature and causes of the mortality which has been so prevalent of late years in the one species of game bird peculiar to the British Isles, it has accomplished a great deal more than this. For in the handsome volumes before us we have the life-history and organisation of the grouse, coupled with those of the various parasites by which it is infested, described in a manner never before attempted in the case of any other wild bird. This magnificent piece of work, it should be added, has been carried out from start to finish by private effort and enterprise; for although the committee was officially appointed by the Board of Agriculture and Fisheries in the spring of 1905, its funds have been entirely furnished by private subscriptions. The whole investigation is, indeed, a striking, and we believe, a unique example of what can be done by the combined efforts of sportsmen, gamekeepers, field-observers, and biological experts; and to Lord Lovat, the chairman, and all those who have worked with him are due the gratitude of naturalists and sportsmen, not only in the British Islands, but throughout the world.

The first volume opens with an introduction by Lord Lovat, in which are recorded the formation of the committee, the scope of the inquiry, and a general summary of the results of the investigation. Then follow six chapters by various experts dealing with the natural history of the grouse in its normal condition, among which special reference may be made to Mr. E. A. Wilson's elaborate and careful account of the changes of the plumage, both in health and in disease. Since, however, much of this has already appeared in the Zoological Society's Proceedings, it will be familiar to many of our readers. Part ii., containing ten chapters, is devoted to the diseases of the grouse; while the third part, with the remaining seven chapters, treats of the management and economic aspects of grouse-moors. The second volume, containing only 150 pages, is devoted to lists of the names of the committee, correspondents, and subscribers, together with a number of statistical tables.

Since various notices of the progress of the inquiry have appeared from time to time in NATURE, the present review must be short. It will accordingly suffice to mention that grouse suffer chiefly from two diseases, namely, strongylosis, due to a thread-worm, *Trichostrongylus pergracilis,* and the so-called coccidiosis, caused by the sporozoon now known as *Eimeria avium.* The former attacks adult birds, and may accordingly be regarded as the chief cause of the great epidemics of "grouse disease" which have in past years wrought such destruction. The latter, on the other hand, as has been recently mentioned in our "Notes" columns, in connection with a paper by Dr. Fantham on coccidiosis in poultry, confines its attacks to young birds, which are either killed outright or recover; this disease, which was discovered during the investigation, can, therefore, have little or nothing to do with the great epidemics among adult birds. In the report the parasite of coccidiosis is referred to as *Eimeria* (*Coccidium*) *avium.* This, we may point out, is misleading, since to the systematist it would indicate that Coccidium is a subgenus of Eimeria, whereas it is really a synonym of the latter which has been discarded on grounds of priority. If this rejection be definitely accepted, we may suggest that it would be advisable to rename the disease eimeriosis, since it is obvious that if there be no such genus as Coccidium the retention of the name coccidiosis is illogical. There would, moreover, be the further advantage that we should have but one name to remember in place of two. For a somewhat similar reason, Dr. Shipley suggests on p. 207 of the first volume that strongylosis should be renamed trichostrongylosis, although there is the genus Strongylus.

The account of the life-history of the thread-worm of the grouse is written by Dr. R. T. Leiper; Dr. Shipley communicating a general account of the group (Nematoda) to which it belongs. The sporozoon (Eimeria) is discussed by Dr. Fantham, whose article appeared previously in the Proceedings of the Zoological Society. As mentioned in the "Notes" columns of NATURE some time ago, this intestinal parasite especially affects the duodenum and cæca (unusually long in the grouse), and has two developmental phases, namely, an asexual schizogony, and a sexual form in which cysts and spores, suited to a life outside the host, are produced.

Of less importance, from the point of view of the sportsman, are the tapeworms of the grouse, which are described by Dr. Shipley. Although the birds are attacked by three species of these organisms, two only need be mentioned here, namely, the large *Davainea urogalli* and the small *Hymenolepis microps,* of which the latter is by far the more dangerous to the life of its victims.

As regards future prospects, the great hope appears to lie in the proper method of managing the moors. "To put it briefly and in practical language," writes Lord Lovat, "moor-management is the science of distributing the stock of birds over the moor, so that at no period of the year can any area be so infested by the strongyle worm as to make it a source of danger to the least well-nourished bird in that area."

R. L.

CLIMATIC CHANGE.

Palestine and its Transformation. By Prof. E. Huntington. Pp. xvii+443. (London: Constable and Co., Ltd.; Boston and New York: Houghton, Mifflin and Co., 1911.) Price 8*s.* 6*d.* net.

SEVERAL years of travel in Asia Minor, Persia, India, and central Asia, and a prolonged study of the arid and semi-arid regions of those lands, have furnished Prof. Huntington with special qualifications for investigating the effect of physical environment on human distribution and modes of life and thought in Palestine, where history reaches back to a far remoter period than in most lands. Eight months of the spring and summer of 1909 were spent in traversing the country in many directions; and since the rainfall was exceptionally deficient in the early months of that year, the struggle for subsistence on the margins of the more arid portions was strongly emphasised.

The first half of the book deals with the form of the different parts of Palestine, and its relation to the geological structure on one hand, and the distribution, occupation, and past history of the inhabitants on the other. It is this physical basis that distinguishes the present volume from many descriptions of the same region. The isolated plateau of Judæa is indicated as the heart of the land from its isolated and uplifted position, in which it stood apart from the great highways of trade which passed to the north and to the south of it, while the moisture from the Mediterranean gave it a moderate fertility. On the west the broken foothills of the plateau form a transition zone, the Shephelah, between the plateau and the coastal plain alternately controlled by the Hebrews of the highland and the Philistines of the sea margin. But on the west, facing the valley of the Jordan on the leeside of the plateau, rainfall rapidly diminishes, and the desert conditions are sharply contrasted with the comparative fertility of the Shephelah but five and twenty miles away. Similarly the present form of Samaria, due to original folding worn down by erosion to a peneplain which has since been elevated and partially dissected, has opened this portion of the land to the peoples of the East, the coast-dwellers, and traders from Africa, so that the great trade routes and the routes of armies passed through it. The peculiar characteristics of Phœnicia, of Bashan, of Galilee, of the Dead Sea depression and the neighbouring deserts, are in like manner brought out and illustrated by the author's own travels through them and the incidents therein noted, presenting a most vivid picture of the land and the influence of its form on the history of its inhabitants.

In the second half of the book Prof. Huntington treats more especially of the climate of Palestine and reviews the present-day conditions, which he contrasts with the more favourable ones which existed, in his opinion, at an earlier date. He has put forward the same hypothesis in relation to central Asia, Greece, and Asia Minor, on previous occasions, giving numerous data in support of a modification of climatic conditions during the past twenty or thirty centuries. The lines of evidence reviewed are (1) the density of the population of Palestine at various periods; (2) the distribution of woodland; (3) ancient migrations, trade routes, and lines of invasion; (4) the distribution, location, and water-supply of abandoned sites; (5) the fluctuations of the Dead Sea.

Under the semi-arid conditions which prevail over the greater part of the country, and the strictly seasonal character of the rainfall, even small departures from the normal amount react powerfully on the economic conditions throughout the area, so that there must always be a strong inclination to postulate definite deterioration of climate where signs of former occupation now abandoned are to be seen. Some of the caravan routes in northern Africa, now but little used, give little sign of their practicability for the great caravans which we know used them a few decades ago, but which altered economic conditions have suppressed. Human settlements cannot always furnish evidence that all in a given spot were occupied at the same time, and the preservation of perishable objects affords some testimony that past rainfall was not of great abundance. The author argues that there have been pulsations in the rainfall, dry periods succeeding others of greater humidity; and that, on the whole, in Palestine a diminution of rainfall from the earliest historical times to the present era has been in progress, while the pulsations within these periods often coincide with great race movements.

The importance of these alternations of dry and humid periods of moderate intensity will be generally admitted, and on the margins of desert regions the effects will be most strongly marked; but while their reality is beyond question, and the evidence for a certain decrease in the average total rainfall from the earlier historic times to the present day is obtainable in certain areas, the direct connection of race movements with such climatic variations at certain periods of history seems to be scarcely established as yet. But in any case, a most valuable summary of the subject as it relates to Palestine is given, and a survey of the history of it and the surrounding lands furnishes occasion for indicating race movements and events which apparently coincide with more or less favourable conditions of climate. An orographical map, as well as a photograph of a model of Palestine, enables the form of the land to be appreciated, and the photographs are most instructive, though the geographer will wish they had been larger. The diagrams in the text suffer from the paper being unsuited to this form of illustration.

H. G. L.

A GUIDE TO ELECTRICAL TESTING.

Testing of Electromagnetic Machinery and other Apparatus. By B. V. Swenson and B. Frankenfield, assisted by J. M. Bryant. Vol. ii., Alternating Currents. Pp. xxvi+324. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1911.) Price 11*s*. net.

"THE efficient direction of any industry to-day demands a very large amount of technical knowledge which cannot be learned at the bench or in the shops."

With this quotation, taken from the writings of Prof. J. B. Johnson, the authors dedicate their work to his memory, and this also gives the keynote to the book. It is essentially a guide to electrical testing, so that the reader may be fitted for that particular technical knowledge which is required in the test-room of a modern electrical engineering works. The reader must, however, not be a beginner; on the contrary, he must be familiar with the scientific side of electrical engineering generally, so that all he needs is a kind of finishing-touch in his technical education which will make his work in a particular direction more efficient.

In the book under review this finishing-touch is given in the matter of testing alternating-current machinery and apparatus. In all there are 127 tests described. In each case the description begins with references to the literature on the subject; then is stated the object of the test, and after that comes a short dissertation on "theory and method." In some cases the authors add suggestions as to the collection of data, the plotting of curves, the extension of the test to somewhat different cases, and questions as to the effect of varying some of the conditions of the standard test. All this is extremely useful to the advanced student, but only to him. A beginner could only blindly follow instructions, and could not grasp the true scientific meaning of the thing he is doing.

It is perhaps natural that in a book written, in the first instance, for the students of an American university, methods and tests devised by American engineers should receive more attention than equally good work done in Europe; but when the authors christen old and well-known methods by American names, they go a little further in the direction of local patriotism than is warranted. As an instance, I take the Joubert method of taking the E.M.F. and current curves of an alternator. After describing the original method (by the way, the authors spell the name Jobert), where a ballistic galvanometer is used, they describe a "Bedell method" and a "Mershon method." Both these are nothing else than the Joubert method as it has been used for a generation in Europe. In the former, the ballistic galvanometer is replaced by a condenser and electrostatic voltmeter, and in the other by the well-known device of a potential slide and D.C. voltmeter.

Again, some methods which originated in Europe are either ignored or mentioned without reference to the inventor. Thus the well-known Sumpner method of testing transformer efficiency under full load whilst only the lost power need be supplied from outside, is given without Dr. Sumpner's name being mentioned. These are, however, minor blemishes; the important thing is that the authors have given us a valuable collection of accurate tests which can be carried out with such apparatus as may reasonably be supposed to be available in the test-room of a modern electrical engineering works.

GISBERT KAPP.

EDIBLE FATS.

Edible Fats and Oils: their Composition, Manufacture, and Analysis. By W. H. Simmons and C. A. Mitchell. Pp. viii+150. (London: Scott, Greenwood and Son, 1911.) Price 7s. 6d. net.

FAT enters into human food in a considerable variety of forms, and the modern tendency is to increase the variety. Whilst in earlier days the animal products—butter, lard, and dripping—were the principal fats consumed as foodstuffs, in recent times a large number of vegetable oils and fats have also been brought into use for the same purpose. New oils and "butters" have been found; improved processes of purification have been introduced; and the industry has become one of notable magnitude. It has greatly augmented, and therefore cheapened, the supply of fat available for human consumption.

What the authors have done in the volume before us is to collect from various sources particulars of the edible fats and oils now in use, and arrange them in a convenient form for reference. These particulars include short descriptions of the origin, manufacture, physical and chemical characters, and methods for the analysis of the various products dealt with, which fall into the four main classes: butter, lard, butter-substitutes, and salad-oils. From the scope of the book, however, the descriptions are necessarily often meagre. They would serve well as an introduction to the subject, or for easy routine work in examining the various articles, but would require to be supplemented in the more difficult cases which are met with in practice.

A somewhat curious analogy is recalled by the name of Mège-Mouries, mentioned in connection with the origin of butter-substitutes. The production of beet sugar, which has now reached very large dimensions, is said to owe its early development to the encouragement given it by Napoleon I. in his policy of making France independent of foreign supplies. Now, just as this variety of sugar has supplemented and partly ousted cane sugar, so margarine has supplemented and partly supplanted butter; and the introduction of margarine we owe to investigations fostered by Napoleon III.

M. Mège-Mouries was commissioned by this monarch to find, if he could, a cheap but wholesome substitute for butter, to be used by the French poor. He eventually succeeded in doing this, utilising the softer portions of beef suet for the purpose. Later, owing to scarcity of this ingredient, it became necessary to include a proportion of vegetable oils, and this has led to a greatly extended consumption of such oils. The margarine industry is now quite a considerable one, the annual importations into this country alone being valued at more than two millions sterling.

If we consider the effect which the production of beet sugar and of margarine has had, first in augmenting the supply of foodstuffs for the human race in general, and secondly in benefiting the agriculture of the particular countries engaged in the production; and if we further remember that this effect, so far as can be foreseen, is destined to continue, from year to year and generation to generation, is it altogether paradoxical to suggest that the two Napoleons' claims to remembrance might justly be based less upon their military operations than upon their vicarious attentions to sugar and margarine? If the swords have not been beaten into ploughshares, they have perhaps been beaten by them.

C. S.

ELEMENTARY PHYSICS.

(1) *An Elementary Text-book of Physics.* Part i., General Physics. By Dr. R. Wallace Stewart. Pp. v+414. (London: C. Griffin and Co., Ltd., 1910.) Price 4*s*. 6*d*. net.

(2) *Magnetismo e Elettricità.* Principi ed Applicazioni Esposti Elementarmente da Francesco Grassi. Quarta edizione. Pp. xxiii+878. (Milano: Ulrico Hoepli, 1911.) Price 7.50 lire.

(3) *Intermediate Physics.* Prepared in accordance with the new regulations of Indian Universities. By Prof. P. L. Narasu. Pp. xii+637. (Madras: Srinivasa Varadachari and Co., 1911.)

(4) *Elementary Light: Theoretical and Practical.* By W. H. Topham. Pp. vii+212. (London: Edward Arnold, n.d.) Price 2*s*. 6*d*.

(5) *Practical Physics: an Elementary Course for Schools.* By J. Talbot. Pp. viii+112. (London: Edward Arnold, n.d.) Price 2*s*.

(6) *A College Text-book of Physics.* By Prof. A. L. Kimball. Pp. ix+692. (New York: Henry Holt and Co., 1911.) Price $2.75.

(7) *Die Elektrizität.* By Prof. F. Adami. Erster Teil. Pp. 127. Bücher der Naturwissenschaft, herausgegeben von Prof. S. Günther. 9. Band. (Leipzig: Philipp Reclam, junr., n.d.) Price 40 pfennig.

(1) THIS volume is presented as part i. of the series by the late Dr. Stewart, although the volumes on sound, light, and heat have already appeared, and publication occurs subsequently to the unfortunate death of the author. It may be said at once that as regards mode of treatment, type, and diagrams, this part is uniform with those which have preceded it, and deserves the same praise as has been given to them. There are one or two points, however, which call for criticism, and the first is with reference to the title. Actually, the contents are chiefly concerned with what is usually termed mechanics, and only a comparatively small portion is devoted to the ordinary physical properties of matter. Strictly speaking, of course, mechanics is a section of physics, and its inclusion, especially if treated experimentally rather than mathematically, is desirable in every elementary physical text-book. It is unfortunate, however, when, as in this case, such inclusion has secured the exclusion of several essentially physical properties of matter and the inadequate treatment of many others. Thus we find, for example, the viscosity of liquids only briefly referred to, and no mention at all of the same property in gases. The second criticism is in connection with two definitions in the mechanics which are vague and even misleading. In common with so many other text-books on this subject, this book lacks the fundamental definition of "mass." The author introduces the term "mass" without definition in order to define force, and then uses this definition for the purpose of defining mass. Few writers on mechanics appear to realise that a definition of mass *apart from force* is the essential first step from the point of view of absolute measurement. The other definition to which exception may be taken is that of simple harmonic motion in terms of the uniform motion in a circle of a second particle. The effect of this is to suggest to students that this second particle *really exists* in all cases of simple harmonic motion.

(2) The fourth edition of this book has been produced in order to include the numerous and important advances in this subject which have been made since 1902, particularly those which have practical applications. The subject is treated in considerable detail, but essentially from a non-mathematical point of view, and it should be possible for a novice to obtain considerable insight into the fundamental principles of magnetism and electricity, and the many useful devices depending upon them. The earlier chapters are devoted to the usual descriptions of phenomena and statements of laws in electrostatics, magnetism, and current electricity, but, owing to the absence of mathematics, exact treatment is impossible, and the absolute units of potential, current, &c., are not defined. Although the obvious intention of the author is to lead up to what is practically electrical engineering, some space is devoted to descriptions of radio-active phenomena and the electronic theory of conduction through gases. The final chapters on telegraphy and telephony—both wireless and otherwise—and the applications of electricity to traction are the most detailed in the book. Good diagrams are given, but some of the photographic reproductions leave much to be desired.

(3) Whatever may be said of the merits of this book in other respects, there can be no two opinions concerning its chief failings. These are the obvious carelessness both in correcting the proofs and in producing the very numerous diagrams. Upon opening the book we are met at once by two pages of *errata*, containing some sixty or seventy corrections to the text. That these are, nevertheless, incomplete is indicated by a rather amusing mistake on p. 30, where we are told that "the direction of gravity is shown by the 'plum-bline.'" It may also be mentioned that the diagram illustrating this instrument is a typically poor one. Many of the figures, besides being badly printed, follow the old style of depicting hands, or even complete persons, performing certain experiments. The book is specially designed to meet the requirements of students preparing for the intermediate examinations of the various Indian universities, but the author claims that it is suitable for the initial stage of any college course. For some reason it is not divided into chapters, nor even into distinct sections dealing with the various parts of the subject—an arrangement which may tend to confuse the student. With regard to the subject-matter, here again we find the same vagueness in defining "mass" as has been mentioned above in the criticism of Dr. Stewart's book. This inexactness occurs in several other places, notably in the following statement:—

"The absolute unit of potential is too large. Hence $\frac{1}{300}$ of the electrostatic absolute unit of potential *is taken* as the practical unit of potential and is termed a volt."

A similar erroneous description of the "coulomb" is also given.

(4) The author has prepared a book comprising the

theory and laboratory work suitable for various examinations of the standard of London matriculation. The general arrangement of the work is very neat and methodical, descriptions of the experiments in connection with the theory being appended to each chapter. There are also numerous examples collected, principally from papers set in the London matriculation. The author has adopted the "ray" method, since he regards it as easier to understand than the "wave" method; but he is careful to proceed in such a manner as to admit of the development of the wave theory at a later stage without apparent contradiction, and, in the final chapter, introduces the student to the elements of this theory. To those who need the information it supplies this book may be in all respects thoroughly recommended.

(5) This consists of a series of simple experiments in heat, light, electricity, and sound. The procedure is to give the boy exact instructions of what to do, and to tell him to observe and record his results. Occasional questions bearing on the experiments are also asked. This method is certainly preferable to that which is sometimes adopted, viz. to allow the student to invent his own experiments. As the author points out, the ordinary schoolboy is usually incapable of originality in a subject which is new to him, and should at first, at any rate, follow instructions implicitly. In schools this collection of experiments should be found useful.

(6) The leading feature of this text-book is the extraordinary amount of ground covered in relation to the size of the volume. Attention is devoted to all the usual branches of physics, and many details are found which seldom occur in elementary treatises; indeed, from a purely descriptive point of view the work should suffice, not merely for preparation for intermediate, but also for final examinations. This condensation of material has been made possible, however, only at the expense of that mathematical treatment which is essential for both examinations. That this is no oversight is clearly indicated by the author's preface, in which it is asserted that mathematical reasoning, even of a simple sort, is found a stumbling-block by many students. This may be true, but we cannot agree that it forms a justification for overlooking the fact that an exact knowledge of physics is impossible without frequent recourse to mathematical processes. From the author's point of view, however, consistency demands that no unproved formulæ should be quoted, but this is by no means the case. The result of this avoidance of exact treatment has been to render the book very unequal, the descriptive portions being distinctly adequate and good, but the equally essential mathematics is looked for in vain. In fact, the contents may be described as insufficient for the serious student, and at the same time much too detailed to be useful as a popular treatment of the subject. The type and diagrams are good, and the more important statements are either in heavy type or in italics.

(7) There is no subject in which there is a greater demand for books on popular lines than electricity. This pamphlet forms the first part of such a book, and is devoted to electrostatics and magnetism.

OUR BOOK SHELF.

Geologischer Führer durch das Mainzer Tertiärbecken. By Dr. C. Mordziol. I. Teil, Allgemeine Übersicht und Exkursionsführer in die Umgebung von Mainz und Wiesbaden. Pp. xii+168, with 39 figures in the text. (Berlin: Gebrüder Borntraeger, 1911.) Price 5.60 marks.

IN view of the increasing interest taken in Germany in field geology, it is to be regretted that this small guide to a very accessible district should be issued at so high a price. Schubert's Dalmatia in the same series is, in fact, slightly cheaper, and students at Bonn, Giessen, and Heidelberg may feel that they have a right to more liberal treatment. Dr. Mordziol, of Aachen, indicates at the outset the limits of the basin of Mainz, a region of subsidence, in which the youngest deposits lie in the centre, while the older Cainozoic strata appear upon the margins. The gravels laid down by the Rhine in glacial times actually lie below the present level of the sea (p. 2). On the south, the basin merges into the sunken valley-floor of the upper Rhine, as is apparent on any orographic map of southern Germany.

The hilly ground bordering on the basin includes a great variety of rocks, and the problem of the gneisses on the south side of the Taunus, which may be of Devonian age, is regarded as still undecided. The true interest of the basin itself lies in its Cainozoic strata. The author (p. 15) supports Sandberger's division of Oligocene from Miocene at the base of the Cerithium limestones, in opposition to Dollfus and Steuer, who include this limestone and the whole brackish water series above it as Miocene. These strata are clearly described and illustrated, and the terrestrial sands and gravels (p. 65), derived from the decay of earlier Cainozoic and still older rocks, are held to be of Lower Pliocene age. We may remember that the Deinotherium beds of Eppelsheim, north-west of Worms, containing Mastodon, Machairodus, and Hipparion, are included in this interesting area.

The author, in tracing characteristic siliceous pebbles onward from the Hipparion-sands into Holland, makes out a case for the existence of a pre-glacial northward-flowing Rhine (p. 68). He then proceeds to illustrate the basin by a series of excursions, in which the underlying Permian strata are not overlooked. An index of places is much needed, but will probably accompany the second part.

G. A. J. C.

Evolution. By Prof. Patrick Geddes and Prof. J. Arthur Thomson. Pp. 248. (Home University Library of Modern Knowledge.) (London: Williams and Norgate, n.d.) Price 1s. net.

PROFS. GEDDES and J. Arthur Thomson have added yet another to the large number of books already existing which are designed to deal with evolution in a manner suited to the needs both of the beginner in serious study and of the general reader. The reputation of the authors will have led us to expect at least accuracy in the statement of facts, and this anticipation is certainly fulfilled in the little volume before us. Apart from the region of fact, we seem to discern a twofold influence at work, leading, on one hand, to a caution in interpretation so extreme as sometimes, we fear, to confuse the inquirer; and admitting, on the other, a boldness of speculation which is somewhat likely to disconcert him.

As an example of the former tendency may be mentioned the authors' manner of dealing with the crucial question of the inheritance of somatic modifications. No uncertain sound should be given on a point like this, but it is doubtful whether the student with only the present book before him would be as much impressed as he ought to be with the importance of the issue. The use of the word "saturating" (p. 197) does not make for clearness. The working of the second tendency is to be seen chiefly in those parts of the book which deal with social analogies and applications. These appear to us, although interesting and unconventional, to be somewhat far-fetched. But the book is a good one, and will make a strong appeal to the thoughtful. F. A. D.

The Evolution of Kingston-upon-Hull, as shown by its Plans. By Thomas Sheppard. Pp. 203. (Hull: A. Brown and Sons, Ltd., 1911.) Price 3*s*. 6*d*. net.

WHEN this island first became the home of man the site of the city of Kingston-upon-Hull bore an aspect very different from that which it assumes at present. The North Sea washed a long line of cliffs extending from Hessle to Bridlington, and the Humber, even then a mighty river, ran straight out to sea. Then followed the great Ice age, which left behind it masses of glacial drift, the foundation of the present city. The milder climate which succeeded produced abundant vegetation, which gave rise to the bed of peat which covered the site. A single bronze axe found in it was probably dropped by some visitor from a canoe, and supplies the only record of prehistoric man. Then the water encroached on the land and laid down great deposits of silt along the present valley. The Romans do not appear to have occupied the place, and the first attempt to embank it is attributed to the Danes, who have left marks of their occupation in the plan of the older parts of the city. In time the place gained increased importance by the absorption of the adjoining villages, and in the fourteenth century the site was surrounded by a wall, of which, and of the old manor and palace of the King, whence the name of the city was derived, only a few stones remain. The later development of the city can be traced in the fine series of reproductions of old maps and drawings which illustrate this useful contribution to local history.

Proceedings of the American Society for Psychical Research. Vol. v., part i., April: A Case of Hysteria. By Dr. W. H. Hamilton, Dr. J. S. Smyth, Dr. Louis Millard, and James H. Hyslop. Pp. 672. (New York: The Society, 1911.) Price 6 dollars.

Is it worth while? Here is a tome of 660 pages devoted to the investigation of an apparently healthy young woman, Miss Burton (pseudonym), aged twenty-two, who is supposed to be able to pass into a trance-like state at will in order to become a "medium" in communication with the spirit world. There are the usual stories of raps, touchings, whistling, singing, combined whistling and singing, whispering, tambourine-playing, table levitation, &c., all by the spirits. The investigations show that the whole thing is trickery; but the investigators concede that this young damsel was perfectly honest so far as her phenomenal consciousness is concerned, but that her subconscious self was deceitful.

A Revised Catalogue of the Indigenous Flowering Plants and Ferns of Ceylon. By Dr. J. C. Willis. (Peradeniya Manuals of Botany, Entomology, Agriculture, and Horticulture, No. 2.) Pp. 188. (Colombo: H. C. Cottle, Government Printer, 1911.)

A CATALOGUE of Ceylon plants was prepared by Dr. Trimen, and published in the Journal of the Ceylon Branch of the Royal Asiatic Society in 1885; this has long been out of print; hence the necessity for the new catalogue now issued by Dr. Willis. The book is divided into two sections, enumerating respectively native and introduced plants; the latter section includes nearly all the valuable economic pants. The catalogue supplies Sinhalese and Tamil names, also references to the pages in Trimen's "Flora of Ceylon," where descriptions of the species can be found. It is noticeable that very few new species have been discovered recently. The total numbers amount to 1095 genera and 3074 species in the first section, and in the second to 285 genera and 387 species. About twenty genera and very many species are endemic.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Scientific Misappropriation of Popular Terms.

IN his interesting address to the Conference of Delegates at the Portsmouth meeting of the British Association, as reported in NATURE of October 19, Prof. J. W. Gregory makes certain remarks to which I venture to take exception. I comment on them partly because they push the principle of priority further than it need be pushed, and partly because I am afraid that Prof. Gregory's advice "to admit that the spider is an insect" may be taken to heart by some of his audience at Portsmouth or by some of his readers in NATURE.

Zoologists will not be surprised to learn that the word "insect" formerly had a wider application than at present. Many of them will feel that Messrs. J. H. and A. B. Comstock are not fairly treated by being taken to task for telling their readers, in a general manual, that a spider is not an insect. So far as the account of the use of the word "insect" is intended to be a historical account of the subject, and no more, criticism is unnecessary. But if it is a serious attempt to reinstate "insect" in its former meaning, I think it should be resisted on the ground that this procedure would introduce confusion where everything is at present clear, and that it has no compensating advantages to recommend it.

We are, fortunately, not obliged to apply the rules of priority to zoological names of higher value than genera. There is no compulsion to substitute Insecta for Arthropoda on nomenclatorial grounds; and it cannot be disputed that to do so would be productive of endless confusion. I am prepared to follow Prof. Gregory in thinking that it may be inconvenient to employ a familiar popular term in an altered signification in scientific writings. But in the present instance the wider use of "insect" has been so long abandoned in literature that even in popular works the majority of authors understand "insect" exactly as it is understood by a zoologist.

For one reason or another it is not unusual for a word in popular use to change its meaning during the gradual evolution of a language. It would be simply pedantic, in many of these cases, to attempt to go back to what is supposed to be the original meaning. Would Prof. Gregory recommend us to use the last word in "mice and rats, and such small deer," in its earlier signification in preference to the meaning it has acquired in modern times?

Prof. D'Arcy Thompson has put zoologists under a deep debt of gratitude by the recent publication of his translation of the "Historia Animalium" of Aristotle. Those of us to whom the original has hitherto been practically a sealed book may learn from this translation that Aristotle, in a professedly zoological work, used γένος in practically the sense in which we use "class." I will conclude by asking whether the principles of priority are to be held to give any countenance to the substitution of "genus" for "class" in systematic zoology.

SIDNEY F. HARMER.

58 Albemarle Road, Beckenham, October 21.

Iron Bort.

We have been getting occasional pieces of a curious material from the diamond mines, which may prove to have a relation to the mineral described in NATURE of September 7 (J. R. Sutton, "A New Mineral?"), and also may throw some light ultimately upon the origin of the diamond. To outside appearance, in extreme cases, the material has a cindery look; in less extreme cases its diamond affinities are fairly evident. It can be readily disintegrated with a mineralogical file, but it has hard corners which will scratch corundum. The specific gravity is 3·3 to 3·5, *i.e.* slightly lighter than diamond. It is insoluble in acid, is feebly magnetic, and when suspended by a light thread or floated on water (on a cork) shows distinct polarity under the influence of an ordinary large steel horse-shoe magnet. When it is crushed a small bar magnet will readily take up small specks of it. (The mineral previously described in NATURE, by the way, shows no polarity.)

Some months ago I casually examined some pieces of this material, and concluded that they were diamond (bort) with enclosed impurities. Some of the impurity is now proved to be iron, which shows that the statement sometimes made that diamond is not found in association with iron is not quite correct.

Some pieces of this material which had been extracted by the electromagnets at the pulsator were brought in by Mr. Stewart (the manager of the pulsator) a few days ago. They were very unlike the stuff readily recognisable as diamond, but the chain of gradation from these to something more nearly approaching true bort is fairly complete. Whether a diamond buyer would put the same commercial value upon them as he would upon bort is quite another question. Up to the present time I have not come upon any true bort which shows the same magnetic properties. Like true bort, however, this material is a good conductor of electricity.

As a distinctive name for this variety of bort, or iron bort—if bort it may strictly be called—Stewartite would be suitable.

A Starling's Deception.

THREE weeks ago, or, to be quite correct, on September 22, I was considerably startled and surprised, on going into the garden at 9.30 a.m., at hearing what I thought was a wryneck's call in a tree not many yards off. I listened, and in a few minutes the cry came again clear and distinct as one hears it in the spring and early summer. I was astonished, knowing it to be a rare thing to hear the wryneck after the middle of July. I approached the tree (in which two or three starlings were chattering and whistling) and tried to get a sight of the supposed wryneck, but did not, although the call was repeated several times. I put down my failure to the thickness of the foliage and the ivy-grown trunk, somewhere in the midst of which the bird was doubtless in hiding.

Well, the next morning, and on several days following, the unseasonable, but otherwise very pleasant, note continued to be heard, and always from the same tree and, apparently, in association with the starlings, for I noticed that the cry invariably came after one of the starlings had whistled. The whistle, in fact, seemed to be the signal for the wryneck to sing.

It struck me as being altogether very curious, and I determined to find out, if possible, more about it. So one morning (September 27) I resolved to investigate the matter more closely. Standing under the tree, and after a little patient waiting, I got a starling well into view and watched him carefully. Wagging his head from side to side he chattered and cackled for all he was worth; then came the whistle, and immediately afterwards the wryneck's note, in uttering which I quite distinctly saw the quick movement of the beak. And so the mystery was solved! I waited, hoping to see a repetition of the performance, but the bird, I fancy, caught sight of me and flew away. On two or three of the following days I tried to catch him in the act again, but was not successful. In the early days of October the cry was not heard (at any rate by myself), but it fell on my ear once more, and for the last time, on October 6, and from the same tree.

Starlings are great mimics, I believe, and I am wondering if this particular bird has been reared in the immediate vicinity of a wryneck's nest, and so caught the note from the parent wryneck. However this may be, I thought the incident would interest your readers, and perhaps elicit additional facts of a similar nature from some of them.

I may add that in 1901, from August 19 to September 10, a friend and myself heard almost daily what we firmly believed to be a wryneck's cry. It surprised us, certainly, but, other than being very interested in hearing the unseasonable note, we never investigated the matter properly. The question now arises, were we and the neighbours deceived by a starling in 1901 as I was so nearly deceived by one this autumn?

BASIL T. ROWSWELL.

Hot Days in 1911.

MR. MACDOWALL's dot diagram in NATURE of October 12 certainly shows high correlation between the number of hot days in a quinquennium and the difference between this and the number of hot days in the next quinquennium, and Mr. Corless in NATURE of October 19 finds the value of the correlation coefficient to be $-0{\cdot}725$; but the conclusion is not that the number in one quinquennium is correlated with the number in the next.

If x_1 is the departure from mean value of the number of hot days in one five-year period, and x_2 that in the next succeeding, then, if these are wholly independent variables, sum $x_1x_2=0$, the minus values neutralising the plus, and the coefficient of correlation between x_1 and x_2-x_1, which is

$$\text{sum } x_1(x_2-x_1)/\sqrt{\text{sum } x_1^2}\times\sqrt{\text{sum }(x_2-x_1)^2},$$

becomes

$$-\text{sum } x_1^2/\sqrt{\text{sum } x_1^2}\times\sqrt{\text{sum }(x_2^2+x_1^2)},$$

or $-1/\sqrt{2}$, since sum $x_2^2=$ sum x_1^2 in a long series.

The value $-1/\sqrt{2}$, or $-0{\cdot}707$, is within the limits $-0{\cdot}725\pm0{\cdot}059$ given, and the conclusion is that the correlation between successive quinquennia is nil.

This conclusion, based on the figures of Mr. Corless, must render ineffectual Mr. MacDowall's endeavours to make long-range forecasts of weather by correlations at five years' distance, and will disappoint any hopes that the new method may have raised in the minds of "official meteorologists."

H. E. SOPER.

University College, London, October 23.

MR. MACDOWALL, in dealing with the number of "hot" days in a year (NATURE, October 12, p. 485), compares two series of numbers which are not independent, and uses the comparison in an attempt to make seasonal forecasts. His method does not appear to be statistically legitimate. He obtains a series of numbers $N+n_1$, $N+n_{11}$, . . . $N+n_{m-4}$, representing the total number of "hot" days for periods of five years, 1, 2, 3, 4, 5; 2, 3, 4, 5, 6, &c., and plots a diagram showing the relation between $N+n_r$ and $n_{r+5}-n_r$, N being the mean of the five-year totals. If the scales of ordinates and abscissæ were the same, and the series of numbers $N+n_3$, &c., represented a random selection, we should expect to find in the diagram a number of dots distributed more or less symmetrically about a line bisecting externally the angle between the axes. This is what Mr. MacDowall obtains in his diagram on p. 485, allowance being made for his difference of scale. The diagram, as it stands, cannot therefore help the forecaster.

We should expect also to find a large correlation coefficient between $N+n$ and $n_{r+5}-n_r$. For a long series of numbers in which there was *no correlation* between $N+n_r$ and $N+n_{r+5}$ the value of the coefficient between $N+n_r$, $n_{r+5}-n_r$ would be $-\frac{1}{2}\sqrt{2}$, or $-0{\cdot}71$, say. Mr. Corless finds from Mr. MacDowall's figures a value $-0{\cdot}73$. Clearly, therefore, this cannot be taken to prove periodicity.

The total number of "hot" days in the nine years preceding 1911 is, according to Mr. MacDowall, 586, compared with an average of $9\times77=693$, so that unless there is a variation of very long period or a secular change we must in the next few years experience a preponderance of summers with more than the average number of "hot" days.

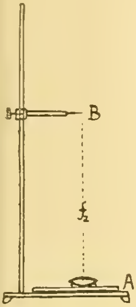
Determination of Refractive Index of a Liquid.

THE following simple method of finding the refractive index of a liquid available in small quantities may be of interest.

A plane mirror A is placed on the base of the stand, and on it is put the double convex lens in such a position that its centre is beneath the needle point B. With the eye directly above B, the observer adjusts the sliding arm until the needle point and its image just coincide, as found by parallax. The distance from B to the centre of the lens is then accurately found—let it be f_1. The experiment is then repeated, after first placing a drop of the liquid upon the mirror, when it will be spread out to a plano-convex lens between the glass lens and the mirror—let the new focal distance be f_2; then evidently the focal length f of the liquid lens will be given by $1/f = 1/f_2 - 1/f_1$.



But since the focal length of the liquid lens is also given by the relation $1/f = (\mu - 1)/r$, where r is the radius of curvature of the surface of the glass lens, it is evident that from a knowledge of r the index of refraction of the liquid can be at once found.

If r is not known it can be found by putting a sheet of paper between the lens and mirror, and again obtaining an image of B coincident with itself by reflection in the lower surface of the lens. If this new distance from the lens be called d, we have, since reflection is now only at the upper surface of the lens, $\mu\ r - 1/d = (\mu - 1)/-r$, or $r = (2\mu - 1)d$, where μ now, of course, refers to the glass, and can, if necessary, be calculated.

The apparatus is thus complete in itself, and three readings of the position of B give all the data required.

G. N. PINGRIFF.

Market Bosworth Grammar School.

The Nematodes of the Thames.

IN a recent letter to NATURE on the "Ooze of the Thames," I alluded to the number of nematodes which I had observed. I found as I continued my researches at least three different species were present. I have since been working on some ooze from near the Tower Bridge, and again find three different species, some of which are quite distinct from the forms taken at Kew. Thus the two localities yield at least four, if not five, different kinds. They range from about 3 mm. to 20 mm. or more in length. Considering the important part which some of these lowly creatures play in human and animal pathology, it would seem that the Thames mud offers a wide field for investigation. May we hope that this note will direct the attention of London naturalists to a subject of great importance lying close to hand?

Swadlincote. HILDERIC FRIEND.

Miniature Rainbows.

WITH reference to the recent correspondence on miniature rainbows, there is, or was, a most perfect example at the beautiful waterfall known as "Stock Gill Force," situate half a mile outside the little town of Ambleside, near the head of Lake Windermere, County Westmorland.

About five o'clock in the evening is the best time to see it, and, of course, the sun must be shining.

RICHD. COULSON.

4 Waltham Terrace, Blackrock, Co. Dublin, October 15.

Olive Trees.

IN this part of the world when an olive plantation is being made trees of more than 6 inches in diameter in the stem are put in, with all roots cut off short. In the hole where they are planted about two handfuls of barley are also put in.

Considering the age of the trees and the way the roots are cut away, it would seem impossible that the tree would ever grow.

These facts may be of interest; and I should like to know what useful purpose is served by the barley.

Smyrna, Asia Minor. DORA BARFIELD.

EXPLOSIVES ON BOARD BATTLESHIPS.

SOME people have been tempted of late to look back to the old days when black powder held its sway, indifferent to the effects of temperature, and always to be trusted so long as it was kept dry. "Villainous saltpetre" it was called, with a rough affection, and after storing it on shore in magazines plumed with lightning conductors, or comfortably near the boilers on board ship, we never gave it a thought until it was fed, in its flannel bag, into the gun. Then came armour and the long and hard contested duel between protection and penetration. The velocity of the projectile had to be increased. The old black powder, treat it as we would, could only deliver its rather clumsy blow which, while it imparted but a low velocity to the shell, gave an unpleasant, percussive strain to the gun. It was a push that these heavier projectiles required, not a blow.

This state of things led to the introduction of slow-burning powders, and they progressed very slowly. First, the size of grain of black powder was increased until it attained the dimensions of a two-inch cube. The improvement, however, was slight, and the internal stresses on the bore of the gun were still too great. The next step towards real progress was the introduction of what was known as cocoa, or brown powder, in which materials other than dogwood or alder furnished the carbon. This had but a short reign, its place being taken by various propellants which were frankly chemical compounds. To give a list of all this class of propellant, with which experiments and lengthy trials have been carried out with more or less success, would be far beyond the scope of this article; but the interest of the scientific world gradually focussed itself on compounds having nitro-cellulose as their chief constituent, especially after the wonderful discovery that two high explosives, gun-cotton and nitroglycerine, when chemically compounded, tamed and restrained each other, so that a propellant resulted of which the speed of burning could be regulated at will by increasing or diminishing the size of the grain or cord, and also by adjusting the proportions of its constituents. Thus came to man's hand a propellant which far outstripped black powder even in its improved forms, and threw into shade the cocoa powder which, after all, remained in the category to which the French artillerists contemptuously alluded as *poudre brutale*.

"Now," triumphantly exclaimed the gunmakers, "here is a propellant which will enable us to increase the striking velocity of our armour-piercing projectiles, and also to flatten our trajectories to an extent never before contemplated. The cemented steel plates will no longer confer invulnerability on the battleship, and our chances of hitting her will be vastly enhanced." So, to suit the new powders, guns were lengthened and charges increased, and the muzzle velocities rose by leaps and bounds, while the destructive stresses on chamber and bore were minimised by the employment of a propellant the characteristics of which may be summed up in the one word "suitable." Every nation adopted a powder in which nitrocellulose played the leading part, the variants being the proportions of nitroglycerine and the quantities and qualities of additional restrainers.

For a time all went well; but we, as a nation, were pointed at as being behind the times because our cordite, since it contained rather a large proportion of nitroglycerine, developed more heat, and produced more bore-erosion than powders of what had become practically pure nitrocellulose. But soon a cloud, no bigger than a man's hand, appeared above the horizon, and it was found that this class of propellant exhibited an almost sentient dislike to extremes of temperature. Not being a mechanical mixture, like the old black powder, it proclaimed itself a chemical compound with a marked tendency to instability, in a somewhat disconcerting manner. Great heat disorganised it altogether; extreme cold brought the nitroglycerine, if there were any used in the manufacture, to the surface, and this did not add to the gunner's confidence in it. The tendency to deterioration from exposure to undue heat, however, was seen to be the more to be feared of the two, and it was a drawback with which it was exceedingly difficult to deal. So far as cordite was concerned, it was found to remain stable at temperatures under 80° Fahr., but in some of the older ships, owing to steam pipes being led near, and even in some cases through, the magazines, temperatures as high as 140° were recorded, and these were equalled by those in limber boxes in some stations in India.

To keep a check on this deterioration the heat test, invented by the late Sir Frederick Abel, has always been used in this country and in the Colonies, and to its frequent application is most certainly due our immunity from explosions on board battleships. One is almost tempted to write *unberufen* before stating that we are exceptional among the larger navies in having *not* lost a ship by the explosion of its own powder. We have had our warning and have profited by it. Some ten years ago a cordite cartridge ignited on board one of our battleships, but did not fire those around it. Up to 1906, when spontaneous ignition of cordite took place with what might have been disastrous results at Haiderabad and Ferozepore, cordite, with the exception of the one cartridge mentioned above, had not given rise to an accident in thirteen years. Catastrophes were averted at both these places by conspicuous acts of daring on the part of officers and men, in the first-named by drenching boxes of cordite set smouldering by one in which the cartridges had fired, and in the other by the removal of nine tons of black powder from a burning magazine within a few feet of which were stored 135 tons of black powder.

There is now little doubt that the destruction of the United States ship, the *Maine*, was due to the spontaneous explosion of her own defective powder, and also of other ships which have since been similarly lost; the Japanese have lost two, the French two (including the *Liberté*), and the Brazilians one ship. About four years ago we began to set our house in order by installing cooling apparatus in the vicinity of the magazines, by which the temperature is kept below 80° Fahr., and the ventilation system gives the charges what may be described as an atmospheric washing, as the surrounding air is being constantly cooled and changed. Great care is taken, moreover, in the construction of our ships to protect the magazines from heat given off from boilers and steam pipes. It is natural that both magazines and boilers should be placed below the water-line, and in the least vulnerable part of the ship, and that, therefore, they should find themselves fairly close together; but a good thickness of insulating material can be interposed, and the lagging of steam pipes, purposely added to ensure the retention of heat, much diminishes radiation in their vicinity. Such precautions as these serve to reduce risk of spontaneous ignition to a minimum, and they are well worth the initial cost; but alone they are insufficient, and to them must be added periodical examinations of the propellant, the heat test being then the detective.

It would appear that gelatinised nitrocellulose is liable to be attacked by an organism which rapidly brings about its deterioration, and that nitroglycerine acts to a certain extent as an antiseptic. Another theory is that the nitroglycerine hardens the substance, and renders it less susceptible to climatic influences. The net result, however, is that pure nitrocellulose is undoubtedly less stable than nitroglycerine compounds such as cordite, and that the measure of immunity of the latter from effects of extremes of temperature varies directly with the proportion of nitroglycerine. The main difficulty, therefore, with which the authorities have to contend is the natural leaning towards a propellant which will be proof against baneful climatic influences, even though it may have a greater erosive effect on the gun. For naval services these considerations have to be nicely balanced, but the preponderance must ever be on the side of safety. Guns can be changed when worn out, and their cost, when compared with that of a ship and its crew, is negligible; hence the absolute necessity for cooling apparatus, the insulation of the magazines, effective drowning arrangements, and periodical inspections of the powder.

Nitro-compounds have one great advantage over black powder—they do not explode with nearly the same violence unless very closely confined. Even when, as in the case of the Ferozepore conflagration, the cordite is confined in metal-lined cases, it only burns with great vehemence, and, with effective flooding arrangements, there should be time to prevent disastrous explosions on board ship. At Ferozepore the removal of the black powder, as described above, averted what might have been a terrible disaster. On board battleships the gases evolved by a large conflagration of any nitro-compound would be confined, more or less, by the protective steel deck, bulkheads, and watertight doors, but it is difficult to account for the terrible disruptive effects manifested in the explosion in the ill-fated *Liberté*. It is probable, however, that she had on board her full complement of high explosive (Mélinite) shells. The intense heat of burning cartridges would probably fire one of these, and this would certainly detonate those in the same shell-room. This, of course, is only conjecture, but the curious tearing of steel plates, and the projection of large pieces of heavy armour to great distances, would seem to point to something more in the nature of the detonation of a high explosive than the upheaval that would be caused by the imprisoned gases of a propellant. The inquiry into the cause of the catastrophe will no doubt throw light on this point, but its fatal consequences will tend to make all nations redouble their precautions, not only as regards the storage in battleships, but also in the direction of extreme care in the selection of a propellant which shall not only meet ordinary Service requirements, but on the stability of which they may place absolute trust.

DESMOND O'CALLAGHAN.

THE SHARMAN SYSTEM OF WIRELESS TELEPHONY AND TELEGRAPHY.

WIRELESS telephony by induction and conduction has of late years occupied an insignificant position, owing to the efforts that have been made to obtain satisfactory transmission of speech by means of undamped oscillations, such as are produced with the "singing arc." But provided that a reasonable distance can be overcome, the conduction system is one which demands serious attention on account of the small amount of power required and the simplicity of the apparatus.

The system on which Mr. A. W. Sharman has been at work for some time is based on the earlier experiments of Preece, but its essential feature is the "impulse coil," with which the microphonic currents are intensified before transmission through the conductive medium.

During the past twelve months the writer has had various opportunities of working with Mr. Sharman's apparatus, both on land and sea, and there has been ample proof of the possibilities of the system, as with of twenty feet between the extreme ends; the ends are attached to plates or rods—stair-rods proving eminently practical for placing in the earth.

The receiving circuit consists of two similar electrodes, which are placed in series with the telephone receiver. A change-over switch in the instrument enables one to speak or listen at will.

There appear to be several factors upon which the limit of clear speech transmission depends. Thus with a wider base line, *i.e.* a greater distance between the electrodes, longer distances can be covered, while with an increase in the battery power used with the microphone a similar result is obtained. There is a serious limit, of course, to increasing the primary energy, as the microphone will not admit of the use of more than eight or ten volts in practice; various forms of microphone have been tried, and those permitting of the use of the highest voltage and largest amount of current have proved the most successful.

A number of experiments have been made with the earth as the conducting medium, and distances of a mile have been covered without difficulty; the nature

Fig. 1.—Motor Boat fitted with the Sharman Apparatus for Wireless Telephony.

a primary energy of only a few watts clear telephonic communication has been established at distances ranging between half a mile and a mile and a half.

The speaking apparatus consists of a microphone, battery, and impulse coil, all of which are in series; tappings are taken off the coil, the two wires leading to metal electrodes, which are either stuck in the ground or submerged in the water, as the case may be. The impulse coil consists of a comparatively low number of turns of thick copper wire, wound round a soft iron composite core of special construction, and the result is that with every variation in resistance of the microphone, when someone is talking, a momentary current of great intensity is induced. This is "transformed down" by the portion of the coil used for transmitting the impulse to the conductive medium, the coil thus serving additionally as an auto-transformer. The wires leading from the impulse coil may be from ten feet in length upwards; thus with two ten-foot wires there would be a possible distance

of the ground does not appear to be a very important factor, as good speech has been transmitted through chalk, gravel, and various other soils, also from the interior of coal mines at a depth below the surface of nearly one thousand feet; in the latter case a number of different strata separated the two instruments, without any apparent detriment to the speech.

The electrodes appear to act as the foci of an elliptical disturbance, which travels chiefly in the direction at right angles to the major axis, and not at all in the line joining the two points. It is thus desirable to have the two base lines parallel, and the necessity for this provides a means of directing the energy, so that with a flexible base line, speech will only be carried in certain desired directions, and cannot readily be "tapped" in other directions. The directional effect was very noticeable in experiments recently carried out on the sea at Pegwell Bay, near Ramsgate, even when the distance between the water "plates" was a hundred feet and more.

A particular feature of the conduction system is that it is not superficial, as was at one time suspected. The clear telephonic conversation carried out between the low level in a mine and the surface dispelled the idea altogether, and hence no difficulty would be experienced in speaking from a battleship to a submarine, even when the latter was submerged to a very considerable depth.

In the experiments recently carried out by Mr. Sharman, a motor-boat was employed as the floating station, and two plates of iron buried in the sand led up to a shore station situated in a room in an inn on the cliff. Speech was carried on very distinctly on some occasions over a distance of a mile and a quarter, but there were some apparent variable factors, possibly water temperature, which prevented an absolute uniformity of results. An interesting point is that, when the tide was some distance out, there being half sand, half water, between the two stations, the speech was quite perfect, so that it is improbable that

FIG. 2—The Wireless Telephone Apparatus in use.

there is any refraction of the waves at the separating surface. It is possible that the currents were transmitted through the sand right up to the position immediately under the motor-boat, selecting the shortest path through the water, for, in the writer's opinion, increase in the conductivity of the separating medium does not by any means agree with increase in the loudness of the transmitted speech.

Considering the very small amount of primary energy used, the results so far obtained have been surprisingly good, and it is to be hoped that efforts to find a microphone capable of withstanding heavier currents will meet with success. The extreme simplicity of the system and insignificant bulk of the apparatus used are in themselves points which place it at once on a level with commercial telephony over wires. A great advantage of the system is that telephony or telegraphy are available at will, as impulses can be generated by means of a Morse key and low-resistance tuned buzzer, and signals transmitted over at least double the distances at present possible for speech. There is undoubtedly the prospect of considerable development in a system based on such simple foundations, and Mr. Sharman's future work in this direction will be watched with interest.

T. THORNE BAKER.

FORESTRY IN INDIA.

IN the issue of NATURE of October 12, attention was directed to Lord Curzon's spirited protest against the change of system in regard to the preservation of the ancient monuments of India. In a letter published in *The Times* of October 11, Sir W. Schlich enters a similar protest against the proposed abolition of the post of Inspector-General of Forests, the technical adviser of the Government of India on all questions referring to the administration of the forests of India. He points out the immense progress made during the last forty-seven years in the systematic management of the forests covering one-fourth of the total area of British India, a progress chiefly due to the initiative of successive inspectors-general of forests. He believes that the contemplated abolition, if carried out, for the sake of the possible saving of a few thousand rupees, if any, will have a disastrous effect upon the further progress of forest conservancy in India. This view is supported in a letter from Sir Herbert Maxwell, published in *The Times* of October 18.

Systematic forest management on scientific lines is of vital importance to the Indian community, not only in the British part of the country, but also in the Native States. Important questions must continue to be dealt with by the supreme Government, and serious mistakes can scarcely be avoided, if that Government has not its own expert at hand to advise it. Lord Lamington, in a letter published in *The Times* of October 20, though not attacking Sir W. Schlich's views, says that no one man can by any possibility be able to give trustworthy guidance "on the multitudinous points connected with forest administration over such a vast area as that of India and Burma." No Inspector-General would attempt to guide the details of the administration. His duty would be to advise on general policy, and that he would be able to do, because no sensible Government would think of appointing to the post a man who had not a sufficient knowledge of the conditions prevailing in the several provinces. Moreover, he would visit the different parts, just as heads of other departments do. At any rate, the same objection could be raised in the case of any other branch of the administration.

Decentralisation is desirable in such a large country as India, but it must not go so far as to deprive the supreme Government of the necessary technical advice. The Government of India will still have to deal with numerous questions, such as the establishment of further reserved State forests, legislation in connection with it, the general lines on which the management of the forests is to proceed, the control of the Imperial Forest College at Dehra Dun, the Research Bureau and its labours, extending over the several provinces, advice to Native States as regards forest administration, the education of the Imperial forest staff, as well as of the superior provincial staff, the organisation and reorganisation of the superior and subordinate staff, and last, but not least, the control of forest finance. Without a duly qualified technical adviser at headquarters, these questions cannot possibly be dealt with in a satisfactory manner. No doubt, the Secretary of State for India will take all these matters into consideration when dealing with the proposals now before him.

AN ALBUM OF GEOLOGICAL TYPES.[1]

THE success of the British Association series of photographs of geological interest has encouraged the issue of several further collections. Prof. Stille, of Hanover, has arranged for the publication of a series of pictorial monographs illustrating various geological and physiographic phenomena which are confined to special regions, and of areas which especially well illustrate geological principles. The parts announced deal especially with glacial geology, mountain structures, and physiographic types, such as the Karst.

FIG. 1.—Inland Ice seen from the Gaussberg. Reduced from "Geologische Charakterbilder."

The first of this series is a collection of six plates of Antarctic icebergs and land-ice, from photographs contributed and explained by E. Philippi, the geologist of the German Antarctic Expedition. The photographs are each $8\frac{1}{2}$ by 6 inches in size; they are excellently reproduced in appropriate tones of black, blue, and green.

The first photograph gives a general view of the inland-ice seen from the Gaussberg, near the headquarters of the German Antarctic Expedition. It is described as a vast ice sheet, now 300 metres thick, but in recent geological times at least 400 metres thicker. Its surface is free from moraines, but the ice contains bands of rock débris, showing that it has passed over or is resting on an uneven rocky surface.

The Antarctic floebergs are illustrated by a view of a large berg floating in Posadowsky Bay; its height varies from thirty to forty metres above the sea, and rarely exceeds fifty metres; but only one-sixth or one-seventh of the ice is above sea level. Herr Philippi refers to some of the bergs met with on the expedition as sixty miles long. The details of the composition of this berg are shown in a view of one part of its face, and its evidence is consistent with the belief in the snow-fed origin of the upper layers of these bergs. The presence of included bands of moraine material shows, however, that they have been either formed on land or have grounded at some time during their voyage.

The author contributes an interesting note on the characters of the included stones, which are described as usually angular; many have been flattened on one or more sides, like the facetted stones of some ancient glacial deposits. Stones which are ice-scratched on all sides are rare in these Antarctic icebergs.

FIG. 2.—Vertical wall about 40 metres high of an Iceberg with distinct stratification planes and fissures, Posadowsky Bay, Antarctic. Reduced from "Geologische Charakterbilder."

These photographs promise to be of great value to

[1] "Geologische Charakterbilder." Herausgegeben von Prof. Dr. H. Stille. Heft i., Eisberge und Inlandeis in der Antarktis, by E. Philippi-Jena. 6 plates. (Berlin: Gebrüder Borntraeger, 1910.) Price 3.60 marks.

teachers of both geology and geography; and their value would be much greater to British students if the titles of the plates were repeated in English, for which there is abundant space on the explanatory sheets. The titles are short and necessarily technical, and their translation, unaided by context, would be often too difficult for the students to whom these photographs should be of most value. J. W. G.

THREE-COLOUR KINEMATOGRAPHY.

IN spite of the large amount of work which has been done upon three-colour photography, it is doubtful whether the results obtained by the newer methods are in any way superior to those obtainable by the original three-colour projection process used by Maxwell in his classic lecture.

In three-colour photography, three negatives are taken, one through a red, a second through a green, and a third through a blue-violet filter. Having secured the negatives, we may then proceed to produce a three-colour photograph by one of two methods: either we may prepare black positives from our negatives and project the three positives by means of the three primary colours, or we may prepare from each negative a print in some substance such as bichromated gelatine, which can be dyed in the colour complementary to the taking filter. The superposition of these three-coloured positives will then give a coloured picture. It is found, however, in practice, that the first method, which is known as the additive process, gives results appreciably superior to the second or subtractive process. The cause of this lies in the fact that the dyes used for preparing the prints cannot completely absorb the colours which they are required to absorb, and, at the same time, completely transmit that portion of the spectrum which they should transmit. While the yellow dye is fairly satisfactory in this respect, and the red dye efficiently transmits red light, the red dye always fails to transmit sufficient blue light, and the light blue dye, used for the prints from the red negative, never transmits either sufficient blue light or sufficient green light, the deficiency in the transmission of green being usually very marked, and resulting in the reproduction of all dark green objects as browns, or at best, blacks.

For the first method or additive process it is, of course, necessary to use three separate projection systems, and owing to the great loss of light through the filters these are advisedly supplied from three separate light sources. Unfortunately the unsteadiness of arcs makes it very difficult, if not impossible, to use three separate arcs, and consequently the best system is probably that arranged to use three large Nernst burners, the triple lantern being arranged so that the three projection systems stand vertically one above the other, and the three positives, printed on one plate, can be inserted together and focussed simultaneously, the adjustments for register being made once for all upon the lantern, so that subsequent slides register automatically. If an arc lamp is used, as in Mr. Ives's apparatus, only one lamp can be used, and the light from this must be divided into three by means of a system of reflectors, a procedure which unfortunately is frequently very wasteful of light and leads only to unsatisfactory results.

Attempts to apply triple projection methods to kinematography have frequently been made, but have not yet come before the public, except in the "Kinemacolor" method, which uses only two colours, abandoning the third, and so eliminating much complication. A two-colour method can, of course, at best be only a compromise, but it would seem at present to be the most satisfactory for kinematograph work.

In kinematograph work it is not necessary to project the colours to be combined simultaneously, as in the ordinary projection method. The colours can be successively projected, the observer combining them by persistence of vision. The three negatives are taken in turn on one film, a rotating shutter being arranged behind the lens of the camera carrying the three filters; but if the image is not to flicker strongly on the screen, it will be necessary for all three filters to be exposed within the ordinary period of exposure of a single kinematograph picture, which involves an exposure for each filter of about one-fiftieth of a second, a rate of work which is not only a great strain on the film and apparatus, but represents very brief exposures when it is remembered that the negatives must be taken through strongly absorbing red and green filters.

Attempts have been made to project the three images simultaneously by means of three separate optical systems, as in ordinary three-colour work, but the difficulties of register have been found very serious, although it is not at all clear why this should be so if both positive and negative sets of pictures are handled simultaneously on films of three times the normal width.

In the "Kinemacolor" method, the spectrum is divided into two, one taking-filter being orange-red and the other blue-green. In order to get a satisfactory rendering of greens, the latter taking-filter must be rather greener than a true blue-green filter would be, and in the resulting picture blue is little distinguishable from blue-green, while a yellow is rendered rather as an orange than a true yellow. The results are, however, surprisingly good considering the theoretical difficulties of the method and the extreme badness of ordinary two-colour work, and they will doubtless be even better when the promoters of the process have learned that above all things they must avoid in their pictures the two colours which they are using for projecting. These two colours are a pure red and a very bright blue-green, or minus-red colour, and in some of the pictures at present there is a tendency to use these two colours in the composition of the original scene, so that one gets little girls dressed in red blouses and blue-green skirts, which colours the process renders with only too distressing fidelity. Considering the excellent way in which the process reproduces subdued colours, such as browns, there really seems no need for this. A much less serious defect in the process, and one which is, of course, unavoidable, is that when anything moves rapidly it is projected as a series of coloured images, so that a horse's leg on the screen may appear as a series of alternately red and blue-green legs.

There is no doubt, however, that kinemacolour is a success, and is a striking testimony to the good practical results which may sometimes be obtained from a theoretically inaccurate system.

In a recent patent it has been suggested that the successive and synchronous methods of projection might be combined, two projecting systems being used with two sets of pictures, one set representing only one-colour element, such, for instance, as red, while the other is composed alternately of pictures of the other two-colour elements, blue and green. A stationary red filter is used in front of one projecting lens, while the second film is projected through a rotating filter, part green and part violet. This would appear to be somewhat more complicated than the two-colour system, while the colour rendering should undoubtedly be superior; but the method does not appear to have, at present, reached the stage of practical use.

C. E. KENNETH MEES.

PROPOSED REFORM OF THE CALENDAR.

IN the issue of NATURE for April 27 a concise account was given of the various proposals which have recently been put forward for the reform of the calendar. There is no reason to think that the subject has gained any serious general attention in England, if the fixing of Easter and the dependent festivals be regarded as a distinct question. But it has received a certain recognition in the discussions of some public bodies of an international character, such as the Congress of Chambers of Commerce; and the Swiss Government has invited a conference for its formal consideration. In order to bring a definite scheme before the public a Calendar Reform Bill was presented to Parliament by Mr. Robert Pearce. The main features of the Bill were briefly described in the article quoted. The first day of the year is called New Year Day, and is placed outside the reckoning of the week and the month. In leap years a day called Leap Day is intercalated between the end of June and the beginning of July, and is equally excluded from the week and the month. By this device there are left 364 days in every year, which are divided into four equal quarters of 91 days. Each quarter is subdivided into three months containing respectively 30, 30, and 31 days. Since 364 is exactly divisible by seven, the first of January always falls on the same day of the week, and the result of making this day Monday is to give 26 weekdays in every month, the four longer months containing five Sundays. Every calendar date corresponds to a particular day of the week (*e.g.* Christmas Day always falls on a Monday), and the calendar is fixed, no longer changing as at present from year to year.

No doubt such a system possesses slight advantages from the point of view of simplicity over our present calendar. Apart from the objections which must be urged against any disturbance of conventions to which we have grown accustomed on anything less than adequate grounds, the great disadvantage attaches to the scheme that it interrupts the continuity of the weeks. The practical effect of this is seen where two or more calendars are in use side by side. Thus inconvenience must arise even now from the Jewish Sabbath falling on our Saturday. Under the provisions of the Calendar Reform Bill the case would be worse, for it would no longer hold a fixed place in the Christian week.

A second Bill has now been presented to Parliament, this time by Sir Henry Dalziel. While differing from Mr. Pearce's Bill, the new proposals contain nothing of importance which will be novel to readers of our previous article. For the Bill merely embodies the suggestions made by Mr. John C. Robertson at the fourth International Congress of Chambers of Commerce held in London in June, 1910. The differences arise in the treatment of the four quarters of 91 days. These are divided into three months containing respectively 28, 28, and 35 days. Thus each month contains an exact number of weeks, and is made to begin with a Sunday. Incidentally it is necessary to move Easter Sunday from April 14, as before proposed, to April 15. Also Christmas Day will fall automatically on a Wednesday instead of on a Monday. The advantage of the whole scheme is to obtain commensurability between the month and the week, but it is an advantage dearly bought at the sacrifice of even approximate equality between the months. This necessitates special legal provision for payments in the case of monthly contracts to be made proportional to the length of the month concerned. Moreover, it requires legal definition for the duration of a "month" from any given date. Thus we understand that a month beginning on any day of the last week of a long month (containing 35 days) will close on the last day of the following month. At least, this is the interpretation which, after careful thought, we have placed upon the following interesting example of Parliamentary draughtsmanship:—

"8. In calculating monthly periods the following rule shall apply:—In any period beginning in a long month and ending in a short month, the last day of the short month shall be held to be the corresponding day to any of the days in the last week of the long month."

If this interpretation be correct, a month may mean any period from 28 to 35 days in length. Surely the clause comes perilously near to a *reductio ad absurdum* to the whole scheme. We can imagine the following simple problem:—"A domestic servant is engaged on March 32 at 22*l*. a year. What is the amount of the first monthly payment, and when will it fall due?" We are utterly at a loss to solve the question, and suggest it for the consideration of the framers of the Fixed Calendar Bill.

The fundamental feature common to both the Bills alluded to is the use of the *dies non*. Mr. Alexander Philip, who was responsible for reviving the idea of this fiction and advocating its practical convenience, appears to have become impressed with the extent of the opposition likely to be encountered before it can be adopted. Accordingly, in a paper before the section of Economic Science and Statistics, read at the recent meeting of the British Association, and in a pamphlet with which we have been favoured, he seems to have abandoned those who are seeking to give legislative form to his ideas, and to advance a totally different suggestion. This requires that February shall gain two days, that July and October shall each lose one day, and that the extra day in leap-year shall be placed at the end of June. Then in each quarter (now containing three calendar months) a period of twelve weeks (always beginning on a Sunday) can be found, two such successive periods being separated by a week. The idea is that public engagements can be more conveniently fixed by reference to the proposed twelve-week period, while the correspondence between this reckoning and the ordinary calendar can be very simply exhibited by a "perpetual adjustable" arrangement. But this practically means that we should have two calendars side by side, and no further criticism seems to be necessary.

It is fairly evident that the group of people who are bent on introducing a change in our present calendar are not agreed as to the precise form which that change should take. In the meantime it is probable that public opinion in this country is not ripe for any reform. It would welcome a fixed Easter, but it is more than likely that any radical alteration of the calendar would be resented. Since the reformers adhere to the yearly divisions of the Gregorian system, no scientific question is involved at any point, and the public convenience and public feeling are alone concerned with the issue. H. C. P.

NOTES.

A SOMEWHAT tardy recognition of the service rendered by Amedeo Avogadro to systematic chemistry was made by the unveiling at Turin of a bronze monument to his memory on September 24, erected, as the result of an international subscription, under the auspices of the Royal Academy of Sciences of Turin. The King of Italy presided at the inauguration ceremony, which was attended by nearly all the more eminent Italian chemists and physicists, as well as by a number of representatives of foreign academies, including M. Haller, of the Paris Academy of

Sciences; M. Moureu, of the Chemical Society of France; Prof. Nernst, of the Chemical Society of Berlin; and M. Guye, of the Geneva Society. No representative of the Royal Society or of the Chemical Society was, unfortunately, able to be present. The date selected was the centenary of the publication of Avogadro's celebrated memoir.

Sir William E. Smith, C.B., Superintendent of Construction Accounts and Contract Work, has been appointed to succeed Sir Philip Watts, K.C.B., F.R.S., as Director of Naval Construction. Sir William E. Smith was born in 1850, and joined the Portsmouth Dockyard in 1861, when only eleven years of age. In 1865 he was apprenticed as a shipwright at Woolwich. In 1866 he was transferred to Portsmouth Dockyard, and, having spent four years' apprenticeship, joined the South Kensington School of Naval Architecture. He entered the Royal Corps of Naval Constructors in 1873, and succeeded Sir William White as an instructor of naval architects at the Royal College at Greenwich in the early eighties. Sir William E. Smith is the Admiralty representative on the Committee of Shipbuilding Materials, in connection with engineering standards. He represents the Institution of Naval Architects, of which he is a vice-president, on the executive council of the National Physical Laboratory.

At the annual statutory meeting of the Royal Society of Edinburgh, held on October 23, the following office-bearers were elected:—*President*, Sir William Turner, K.C.B., F.R.S.; *vice-presidents*, Prof. J. C. Ewart, F.R.S., Dr. J. Horne, F.R.S., Dr. J. Burgess, Prof. T. Hudson Beare, Prof. F. O. Bower, F.R.S., Sir Thomas R. Fraser, F.R.S.; *general secretary*, Prof. George Chrystal; *secretaries to ordinary meetings*, Dr. C. G. Knott, Dr. R. Kidston, F.R.S.; *treasurer*, Mr. J. Currie; *curator of library and museum*, Dr. J. S. Black; *councillors*, Prof. D. Noël Paton, Dr. W. S. Bruce, Prof. F. G. Baily, Dr. J. G. Bartholomew, Dr. R. H. Traquair, F.R.S., Prof. J. Walker, F.R.S., Prof. A. Robinson, Sir W. S. M'Cormick, Prof. Crum Brown, F.R.S., Prof. T. H. Bryce, Dr. Benjamin N. Peach, F.R.S., and Mr. W. A. Carter.

For several years past Dr. W. N. Shaw has organised for the months October to March a series of meetings at his office for the informal discussion of important contributions to meteorological literature, especially those by colonial or foreign meteorologists. When these meetings took place at the old Meteorological Office in Victoria Street their success was so great that the room available was scarcely sufficient to accommodate those who attended them. In the new quarters at South Kensington the space is nearly all that could be desired, and Dr. Shaw welcomes not only those who contribute observations to the office, but others interested in meteorology. The meetings take place on Mondays every fortnight, and the first of the series commenced last Monday. In the circular which announces the dates of the meetings a list of the suggested subjects for discussion is given, and these show the wide range which the discussions cover. The writer of this note has attended most of the meetings already held, and with others he knows that they serve a very useful purpose. The bringing together of those interested in meteorology and the friendly interchange of views is a sure way of accelerating the advance of the subject in question.

At the conclusion of the Harveian Oration, delivered by Dr. Theodore Williams at the Royal College of Physicians on October 18, the president of the college, Sir Thomas Barlow, presented the Baly and the Bisset Hawkins gold medals. The Baly medal was awarded to Prof. W. D. Halliburton, F.R.S. This medal was instituted in 1866 "in memoriam Gulielmi Baly, M.D.," and is awarded every alternate year to the person who is deemed to have most distinguished himself in the science of physiology, especially during the two years immediately preceding the award, and is not restricted to British subjects. The Bisset Hawkins medal was given to Dr. Clement Dukes. This medal was established in 1896 by Captain E. Wilmot Williams, at the suggestion of Dr. Theodore Williams, to perpetuate the memory of Dr. Bisset Hawkins. It is bestowed triennially on some duly qualified medical practitioner who is a British subject, and has during the preceding ten years done work deserving special recognition in advancing sanitary science or in promoting public health.

A Reuter message from Stockholm states that the Nobel prize for medicine has been awarded this year to Prof. Allvar Gullstrand, of the Upsala University, for his research work in connection with the dioptrics of the eye.

The fourth Norman Kerr lecture in connection with the Society for the Study of Inebriety will be delivered by Prof. G. Sims Woodhead on Tuesday, November 14, in the lecture theatre of the Pathological Department, Medical Schools, Cambridge, upon "The Action of Alcohol on Body Temperature and on the Heart."

At a recent meeting of the executive committee of the British Science Guild, a committee was appointed to consider the question of holding lectures and the reading of papers. Other matters considered were the reduction of postage on scientific literature, coordination of charitable effort, and pollution of rivers. In connection with the committee on the conservation of natural sources of energy, it was decided to print the report at the end of the year.

The members of the International Commission on Zoological Nomenclature have unanimously invited Prof. K. Kraeplin, Direktor des Naturhistorischen Museums, Steinthorwall Hamburg, Germany, to serve on the commission until the next International Congress, in the place of Prof. Maehrenthal, deceased; also Dr. P. Chalmers Mitchell, F.R.S., secretary of the Zoological Society of London, in the place of Dr. G. A. Boulenger, F.R.S., resigned.

A course of twelve Swiney lectures on geology, dealing with "The Natural History of Rocks," will be delivered by Dr. T. J. Jehu in the lecture theatre of the Victoria and Albert Museum, South Kensington, during November, on Mondays, Tuesdays, and Saturdays, beginning Saturday, November 4. Admission to the lectures is free.

As the result of a personal visit to Kew, the Rev. Hilderic Friend has been able to report to the director the discovery of a considerable number of new annelids in the Royal Gardens. These include, among others, *Achaeta bohemica*, Vejd., *Dero obtusa*, D'Udek., and others new to Kew; *Paranais naidina*, Bret., and others new to Britain; and *Limnodrilus aurantiacus*, Friend, *Enchytraeus exiguus*, Fr., and *Fridericia pulchra*, Fr., new to science. The descriptions of new species will appear in *The Naturalist* and elsewhere.

From Prof. A. G. Nathorst, of Stockholm, we learn that Prof. Paul Richter, of Quedlinburg, Germany, died on October 9, at fifty-seven years of age. Prof. Richter was well known among palæobotanists and geologists by his studies of the Cretaceous flora of Quedlinburg, of which he brought together extensive collections. He was the author of the following papers, among others:—"Die Gattung Credneria und einige seltnere Pflanzenreste" (1905), "Die Gattung Hausmannia Dunker" (1906), "Die Gattung Nathorstiana P. Richter und Cylindrites spongioides Goeppert" (1909), all of which are richly illustrated.

THE death is announced, at seventy-eight years of age, of M. Louis Grandeau, the distinguished French agricultural chemist, and author of the "Traité d'analyse des matières agricoles," perhaps the best known book of its time on agricultural analysis. M. Grandeau was one of the last surviving disciples of Boussingault, and maintained throughout the breadth of view and the lucid style of exposition that had characterised the master. He played a great part in the development of scientific agriculture in France, and held various high offices, such as the directorship of the Station agronomique de l'Est, a professorship at the Conservatoire nationale des Arts et Métiers, and was Inspecteur général des Stations agronomiques. He carried out numerous field experiments at L'École Mathieu de Dombasles, Nancy, and later at the Parc-aux-Princes, near Paris, and elsewhere, dealing with the effect of fertilisers on soils and on crops. He also made numerous investigations on the feeding of horses, especially of draft horses, his attention being attracted to this subject by his connection with the laboratory of the Compagnie générale des Voitures, Paris. There was no academic aloofness about M. Grandeau, and he recognised that the final test of his results must be their actual value to the practical man. Accordingly, he used the Press freely to disseminate his ideas; he was chief editor of the *Journal d'agriculture pratique*, and agricultural editor of the *Temps*. His main work was with technical problems. Of his more purely scientific work, perhaps the best known dealt with the black humic material that he extracted from soil, and regarded as an important agent in the nutrition of plants, a view, however, that has since undergone considerable modification.

THE first part of the plant protection scheme of the Selborne Society was to enlist the sympathy of the education authorities throughout the country, and the society has met with a hearty response to its suggestion that the authorities should distribute special leaflets to schoolmasters and schoolmistresses, and put up a card of advice to children in their schools. Many thousands of leaflets and cards have been asked for, and as the Selborne Society has authorised its plant protection section to apply any funds which it may receive to the furtherance of its own work, the society is now making an appeal to all those who desire to preserve the British flora to send subscriptions to the secretary at 42 Bloomsbury Square, London, W.C.

IN view of the reorganisation of the Aëronautical Society, a circular has been issued to members stating that persons desirous of joining the society as members under the old regulations (entrance fee 1*l.* 1*s.*, annual subscription 1*l.* 1*s.*) are still eligible if the application form is returned before November 1, 1911. A number of physicists, engineers, and others have already availed themselves of this privilege, including the Marquis of Tullibardine, the Hon. Maurice Egerton, Mr. Lionel de Rothschild, Profs. Archibald Barr, C. V. Boys, and H. F. Lunn, Captains A. H. Grubb and E. L. Gerrard, Lieuts. R. Gregory and C. R. Samson, Sir Charles D. Rose, Dr. W. Watson, and Messrs. Dugald Clerk, G. Holt Thomas, E. T. Willows, and Horace Short. In view of the uncertainty which probably exists as to the lines on which aëronautical problems may be developed in the future, it seems desirable that persons interested in aërial navigation, either on general or other grounds, who may wish to be associated with the future developments of the society should lose no time in putting themselves in communication with the secretaries, 53 Victoria Street, Westminster.

TAKING as his text the fact that the British Museum has recently established a series of free daily demonstrations in the exhibition galleries to parties of visitors, Lord Sudely, in a letter to *The Times* of October 21, headed "The Utility of Museums," strongly advocates the immediate extension of this system to other museums and kindred institutions throughout the country. The demonstrations, or peripatetic lectures, at the British Museum are declared to be admirable, although the attendance on the part of the public is still comparatively small. This, however, it is urged, might be increased by judicious advertising. Weekly demonstrations at the Imperial Institute, and lectures in some of the American museums (for which, except in the case of schools, small fees are charged), are declared to have attained a success far ahead of what was originally expected. Among London institutions, Lord Sudely specially selects the Victoria and Albert Museum and the Natural History Museum as being admirably suited for demonstrations of this nature, which should also be adopted at Kew. Should the officials at these establishments find it impossible to undertake these demonstrations in addition to their present duties, it is recommended that the respective staffs should be strengthened for this purpose. If lectures of this type were once established at all museums, the writer of the letter is of opinion that the attendance of the public would be largely augmented, while the knowledge and culture of the nation generally would be stimulated. As regards the Natural History Museum, it may be pointed out that popular explanatory labels are conspicuously displayed in most of the exhibition; but it may at once be acknowledged that a much larger amount of information could be conveyed (and, if the right persons were found, in a more interesting manner) by means of popular demonstrations.

IT would be interesting to know the condition of large dew-ponds, such, for instance, as that at Chanctonbury Ring, on the South Downs, at the end of the unusually dry summer of this year. Colonel W. Pitt states in the Journal of the Royal Society of Arts for October 20 that, curious to learn how dew-ponds in general have fared, he wrote to inquire of the Royal Engineers, under whose charge is that part of Salisbury Plain which is War Department property. The report received states that "all dew-ponds in the Plain have gone absolutely dry this summer without exception." The officer who supplied this information adds that the ponds are generally, but not always, placed where they will take surface drainage, and consequently they received, no doubt, a certain amount of what little rainfall there has been.

MR. J. R. HENDERSON, the successor of Mr. E. Thurston as superintendent of the Government Museum, Madras, reports considerable additions to the collections during the year 1910–11. On the archæological side the most important are eight gold-plated sheets of copper with figures of Siva and other Hindu gods, dating from the early sixteenth century. A collection of Pandyan gold coins from the south Canara district is one of the most interesting numismatic finds made in recent years in southern India. A large collection of birds, insects, and Mollusca made in the Shevaroy Hills by the superintendent forms a valuable accession. The marine aquarium, stocked with local sea animals and fishes, continues to flourish, the chief cause of mortality among the inmates being fights, in which victory is not always to the strong.

THE National University of La Plata has published in vol. xvii. of the *Revista del Museo de La Plata* a valuable monograph entitled "Los Tiempos Prehistóricos y Protohistóricos en la Provincia de Cordoba," prepared by Senhor Felix F. Outes, the secretary and director of the museum. This museum, founded by Dr. F. P. Moreno, has become, in its palæontological and anthropological departments, one of the most important in South America. It owes much to the collections of the late Dr. F. Ameghino, to which the present report is largely devoted. The writer reviews the collections from the earliest period, the most interesting series being the cave drawings and petroglyphs representing rude animal and other figures. The report—a scholarly production with full references to the literature of the subject—is an important contribution to our knowledge of the earlier civilisation of Argentina.

IN *Man* for October Prof. Flinders Petrie discusses a series of Roman portraits found at Hawara, on the eastern border of the Fayum, a site from which the most important existing specimens of this form of art have been obtained. The custom of decorating mummies with gilt stucco cases was much developed in Ptolemaic times. By the end of the first century A.D. it became the fashion to take the canvas portrait of the dead, which had hung in a frame on the house wall, and to place it over the face of the mummy as a substitute for a conventional stucco head. Wax was undoubtedly the medium for the colour, which was laid on either with a full brush or in a creamy state with short, sloping strokes. The personages depicted are of a mixed type, mainly European, but mingled in some cases with indigenous Egyptians, Syrians, and other Levantines attracted to the Fayum in the course of trade. Lastly, Roman jurisdiction had added an Italian upper stratum of officials, who had no objection to mixing with other local races; and we also find instances of a Spanish or Moresque-Spanish type in this curiously cosmopolitan population.

WITH the exception of one, by Dr. Annandale, on the batrachians and reptiles of Yun-nan, the papers in vol. vi., part iv., of Records of the Indian Museum are devoted to various groups of invertebrates, among which reference may be made to notes, by the same author, on fresh-water sponges from the Poona district of Bombay. One of these, *Corvospongilla burmanica bombayensis*, represents an Indian race of a species originally described from Burma.

THE appointment of Dr. F. A. Lucas to the directorship of the American Museum of Natural History has caused a vacancy in the office of chief curator of the Brooklyn Museum. According to the October issue of *The (Brooklyn) Museum News*, part of the work of excavating and laying the foundations of an extension of the Central Museum is in hand, while appropriations have been made for the erection of a new Children's Museum. A unique exhibit of animals and other organisms injurious to books and libraries was installed during the year. The insects include various larvæ passing under the general name of "book-worms," cockroaches, white ants, silver-fish, and the American spring-tail.

THE invertebrate marine fauna of the South Sandwich group (lying to the east of South Georgia) forms the subject of several short communications in series 3, vol. xiv., of the *Anales del Museo Nacional de Historia Natural de Buenos Aires*. In a general account of the history of the islands, which bears no author's name, although in the table of contents it seems to be attributed—apparently incorrectly—to Mr. Chevreux, it is recalled that the Sandwich group, which was discovered by Cook in 1755, consists of twelve islands, or rocks, situated in 58° S. lat. Most of the specimens were collected by Dr. F. Lahille, of the La Plata Museum, but others were obtained by Captain Larsen. The majority of the isopod crustaceans were examined by Miss Harriet Richardson, who describes two new species of Serolis, but a new Antarcturus is named in the article which bears no author's name. The amphipods comprise a new Œdiceroides and Eusirus, described by Mr. E. Chevreux; but the pynogonids, which were submitted to Mr. E. Bouvier, all pertained to previously known forms.

IN view of the attention now concentrated on the brown rat in connection with the spread of bubonic plague, and the damage inflicted by this rodent on agricultural produce, Mr. Newton Miller, of Clark University, has undertaken an investigation of the rate of its propagation, the results of which are published in the October number of *The American Naturalist* (vol. xlv., p. 623). From this it appears that these rats, which have a gestation period of from $23\frac{1}{2}$ to $25\frac{1}{2}$ days, breed in every month of the year, and may produce five or six litters annually, the number of young ranging from six to nineteen, and averaging between ten and eleven. Although full growth is not attained before the eighteenth month, sexual maturity is reached in both sexes at least as early as the end of the fourth month. In one particular instance seven litters were produced in as many months by a single female; and in cases when all the young perish at birth, it is presumed that there would be a dozen litters in the course of a year. In captivity brown rats devour nearly 50 per cent. of their young at birth, most, if not all, of these being eaten by the females. Full details are given in the article with regard to the growth and development of the young.

THE current issue (Bd. 43, Heft 3) of the *Morphologisches Jahrbuch* contains a description, by Dr. H. Bluntschli, of an ovarian dermoid cyst in which teeth of two dentitions are recognisable; and studies by G. P. Frets on variations in the vertebral column of fruit bats and squirrels, and by Dr. Kriegbaum on the anatomy of the pharynx of certain mammals, birds, and reptiles.

IN the *Zeitschrift für wissenschaftliche Zoologie* (Bd. 98, Heft 3) J. Sokolow gives an account of the eyes of Pantopoda ("sea spiders"), which he considers to be more primitive in structure than those of arachnids. Drs. Löhner and Micoletzky describe two new acœlous turbellaria, namely, a new genus, Monochœrus, and a new species of Convoluta (*C. pelagica*). The latter is light green in colour, owing to the presence in the parenchyma of clumps of symbiotic plant cells (zoochlorellæ). This worm, which is very voracious, feeding on pelagic copepods, was taken in numbers off the west coast of Istria.

THE source of Chinese medical rhubarb is discussed by Dr. C. C. Hosseus in an article—received as a separate pamphlet—appearing in *Archiv der Pharmazie* (vol. ccxlix.). The strongest evidence is put forward in a statement received from Mr. E. H. Wilson that *Rheum officinale* furnishes the commodity supplied from Tachien-lu, while the best quality, taken from a variety of *R. palmatum*, is exported from the Suntang region.

As in the Malay Archipelago, so in Siam, the family of Dipterocarpaceæ is predominant in the forests; but whereas species in the former region are numerous, only nine are recorded from Siam in the recent account provided by Mr. F. D. Ryan and Dr. A. F. G. Kerr in the Journal of the Siam Society (vol. viii., part i.). Of six species of Dipterocarpus, *D. tuberculatus* and *D. obtusifolius* are the most important, as they form in some localities almost pure, open jungle forests. *D. tuberculatus* is best developed on red clay; *D. obtusifolius* becomes dominant on sandy soil, while *Shorea siamensis* may also develop into forest on stony ground. Different forms, respectively tomentose and glabrous, were observed for several species; the tomentose form is associated with higher and drier situations. A peculiar feature is the storage of water by *D. obtusifolius*, so that if the stem be cut and turned upside down, a sufficiency is obtained to be serviceable to shooting parties.

OWING to the propensities of native growers and the traditions of the industry, the improvement and increase of cotton cultivation in India is a complicated problem; but, judging from the note compiled by Mr. B. Coventry, and published as Bulletin No. 26 of the Agricultural Research Institute, Pusa, appreciable success has already been attained with some measures, while others are proceeding favourably. The yield of Broach and other better-class native varieties has been improved by seed selection; coincidently stores have been established for distributing the pure improved seed. Promising results have been obtained by hybridisation at Surat and elsewhere. In Sind a good-class American cotton has been profitably raised, and Egyptian metafifi is being tried where canal irrigation is feasible. A signal failure is noted in the case of experiments with tree cottons, which have therefore been discontinued.

THE September number of *The American Journal of Science* contains an account, by Mr. O. A. Derby, of a big diamond recently obtained from the Bagagem district of Minas Geraes, where the famous "star of the south" was found. That stone weighed 255 carats; and the same locality also yielded the "Dresden diamond," with a weight when uncut of $119\frac{1}{2}$ carats; the new stone, "estrella de Minas," weighs 175 carats. All three diamonds are elliptical in shape, with curved faces. It is mentioned in the same note that the largest diamond known from Brazil was one found in 1906, the weight of which was estimated at 600 carats. Its owner, being doubtful whether it was really a diamond, caused it to be struck with a heavy hammer on an anvil, in the belief that if genuine it would be uninjured! Fragments weighing about 100 carats were saved, from which one diamond weighing 8 carats was cut.

THE valuable meteorological charts published by the U.S. Weather Bureau for the large oceans and the great American lakes for November have been received. In addition to the usual statistical and other useful information contained on the face of the charts, the reverse sides of those of the North Atlantic and North Pacific contain articles on the sea surface and air temperatures, currents, &c. It is shown, *inter alia*, that high barometric pressure usually prevails over the central portion of the North Atlantic, the crest lying between longitudes 25° and 40° W., having slightly increased since October. Low barometric pressure obtains north of 55°, between longitudes 20° and 50° W., having decreased since October. The increased steepness of the barometric gradient causes frequent storms over the Transatlantic routes.

A SUMMARY of the weather issued by the Meteorological Office shows that the rainfall for last week was again generally below the average, the only really appreciable excess being 0·48 inch in the south of Ireland. Contrary to recent experience, the duration of bright sunshine was below the average over the entire kingdom. The aggregate rainfall for the seven weeks of autumn as yet expired is below the average over the entire kingdom, except in the Channel Islands, where there is a slight excess, amounting to 0·09 inch. The deficiency in the west of Scotland is 3·59 inches, and in the north of Scotland 3·54 inches. The deficiency of rainfall since the commencement of the year is very great; in the north of Ireland it amounts to 8·76 inches, the west of Scotland 7·88 inches, the south-west of England 7·76 inches, and the Midland counties 7·70 inches. In the south-east of England the deficiency is 5·72 inches, where the excess of sunshine is 335 hours, which is the greatest excess in any part of the kingdom. The heavy rains of the present week will decrease somewhat the accumulated deficiency of rainfall.

ACCORDING to several communications which have been made to the *Physikalische Zeitschrift* recently, Drs. Elster and Geitel have succeeded in increasing the sensitiveness of the potassium photoelectric cell very materially by passing an electric discharge for a short time through the hydrogen in the tube. The potassium becomes covered with a greenish-blue film, which appears to give off negative electrons when illuminated much more readily than the metal itself. If the hydrogen remains in the tube the film disappears, and the sensitiveness of the cell falls. By replacing the hydrogen after the formation of the film by argon, the film becomes permanent and the sensitiveness constant. By covering the ordinary potassium kathode with a film of colloidal potassium a cell may be made sensitive to the infra-red rays. As an example of the use to which these sensitive cells may be put, the measurement of the decrease of the light from the moon during the eclipse of November 16, 1910, may be cited. With 232 volts on the cell full moonlight gave a current of 350×10^{-9} ampere, which sank to 220×10^{-9} as the moon entered the umbra, and to zero before totality was reached, owing to the passage of clouds.

THE Sociedad Matemática Española is to be congratulated on the success that is attending its efforts to remove a reproach from the annals of Spanish science. It was founded in April last, and has already published three numbers of its *Rivista*, a periodical which should play a notable part in the awakening and sustaining of mathematical interests throughout the peninsula. Each number opens with a biography and portrait, contains articles on pure and applied mathematics, reviews of current mathematical literature, articles on the history and methodology of the science, and a column for queries and answers. The society proposes to publish for the benefit of its members translations of foreign works on mathematics. This, when finances allow, is to be at less than cost price. On the same terms the society will supply to members translations of articles from foreign periodicals. A department has also been organised for the supply to members of references from the vast body of mathematical literature. The outlook is full of promise, especially when we remember that a much larger audience than Spain can at present produce awaits the appeal of the Sociedad in the intellectual centres south of the United States and north of the line joining Buenos Ayres and Valparaiso. The new society is a vigorous bantling. Time alone will show if it will rise to its opportunities. All information may be obtained from D. Jose Mingot, San Bernardo, 51, Madrid.

It is well known that the method of preparing nitrous oxide, which consists in heating ammonium nitrate, is not exempt from danger. A new and safer method of preparation, which gives a pure product, is described by A. Quarkaroli in the *Gazzetta Chimica Italiana* for September 19. It consists in heating 0·5 gram of nitre with 20–25 c.c. of formic acid, and collecting the gas which is evolved over a 20 per cent. solution of potash, which serves to absorb the carbon dioxide simultaneously formed. The heating must be done carefully, and it is best to apply a flame until the action just begins, and then remove it at once. When the action ceases another 0·5 gram of nitre is added to revive it, and this is continued until all the formic acid is used up. The action takes place quantitatively according to the equation

$$2KNO_3+6HCO_2H=N_2O+4CO_2+5H_2O+2HCOOK,$$

and this enables the decomposition to be applied to the estimation of nitrates. The action is carried out in a test-tube, and the gases collected over mercury in a graduated cylinder capable of taking 250 c.c.; the volume of mixed gases is first measured, and then the volume obtained after absorbing the carbon dioxide by introducing 2 c.c. of a concentrated solution of potash. The two measurements serve to control one another. The time occupied in an analysis by this method does not exceed five minutes, and as the results are practically as accurate as those obtained by the Schulze-Tiemann method, which takes an hour, the new method is to be preferred. In a second paper it is shown that the action involves initially the formation of nitrous anhydride, which then acts catalytically, and greatly accelerates the velocity of the change. By the addition of traces of substances such as chloric acid, hydrogen peroxide, or potassium permanganate, which destroy nitrous acid, the decomposition of the formic acid is greatly retarded; urea behaves in the same way, but is not quite so active.

A copy has been received of the "Collective Index of the Institute of Brewing," which forms an exhaustive book of reference to scientific work carried out in connection with the fermentation industries in all parts of the world. The original Laboratory Club first issued Transactions in 1887, so that the index covers the period 1887–1910. It is divided into an authors' index of 130 pages and a subject index of 415 pages, figures which suffice to indicate the enormous amount of work which has been done in connection with fermentation. Besides the publication of original papers and the discussion on them, the institute has included for some years appropriate abstracts of scientific papers in its volumes, and great praise is due to the editor and his colleagues for the efficient way in which this work has been performed. As a consequence, it is possible to keep more easily in touch with the scientific literature of fermentation than is the case in any other industry, and the collective index will make the journal of the society indispensable to future workers in this field. The matter is printed exceptionally clearly across the page, a method which, in our opinion, is far preferable to the double columns adopted by many other societies.

A paper on the endurance of metals was read by Messrs. E. M. Eden, W. N. Rose, and F. L. Cunningham before the Institution of Mechanical Engineers on Friday, October 20. The experiments, which were carried out at University College, London, took the form of determining the number of alternations of stress which a loaded rotating beam could withstand before rupture. The most remarkable point shown in these tests is the absence of all speed effect between 250 and 1300 alternations per minute. In the experiments of Reynolds and Smith a very large and perfectly definite speed effect was found for speeds between 1300 and 2000 alternations per minute. The entirely different results of the University College tests must be due to the different form of test and testing machine.

Some interesting figures are quoted from the report on breakdowns of various generating plants by Mr. Michael Longridge, chief engineer of the British Engine, Boiler and Electrical Insurance Company, in the leading article in *Engineering* for October 20. Two similar gas engines, built by the same maker, and bearing consecutive numbers, were at work 100 miles apart, and broke their crankshafts on the same day. The cause was bad design, the calculated stress being 21,000 lb. per square inch. Two cases of extraordinary endurance of cast iron are given, in both instances used for parts to which no one nowadays would venture to apply it. One of the cases was that of a cast-iron crank-shaft of an engine built in 1850. Between 1850 and 1873 the engine made 70,000,000 revolutions, and the stress on the neck at the beginning of the stroke was 3650 lb. per square inch; between 1873 and 1897 76,000,000 revolutions were made, the stress being 2270 lb. per square inch; between 1897 and 1910 41,000,000 revolutions were made with a stress of 2050 lb. per square inch. The other instance noted is that of a cast-iron gudgeon, which dated from before 1838. It has withstood, without fracture, at least 750 million applications of a stress equal to ± 1500 to 1700 lb. per square inch.

Messrs. Reynolds and Branson, Ltd., of Leeds, have issued an abridged catalogue of chemical apparatus and chemicals containing additions and corrections to the eleventh edition of their catalogue of chemical and physical apparatus.

The Emil Busch Optical Company, 35 Charles Street, Hatton Garden, London, E.C., has issued several well-illustrated pamphlets giving detailed particulars of the "bis-telar" objectives, of the Busch projection apparatus, and telephoto lenses.

Prof. Birkeland asks us to state that the times from U.S. Coast and Geodetic Survey stations given in his letter "On the Simultaneity of Certain Abruptly-beginning Magnetic Disturbances" in Nature of October 12 (p. 483) should have been in decimals of a minute and not in minutes and seconds; the correct times are thus:—Honolulu, 10h. 20·7m.; Porto Rico, 20·8m.; Cheltenham, 21·9m.

OUR ASTRONOMICAL COLUMN.

Mars.—In No. 4530 of the *Astronomische Nachrichten*, where M. Jarry Desloges's note concerning the brightness of Libya on October 12 is now published, there is also a message from Señor Comas Sola saying that on October 11 he observed a brilliant cloud on the Libya area.

M. Jarry Desloges also continues his preliminary account of the observations made at Massegros during the present opposition, and directs attention to numerous changes of appearance since 1909. A number of important "canals" are seen in the L. Mœris region, the lake itself presenting a variegated appearance. M. Cimmerium and M. Sirenum, seen under good conditions, appear as mosaics, while the L. Solis, although in a very pale region, is relatively dark and is surrounded by a complicated system of "canals"; it is constricted in the middle, and the eastern half is ever the darker. The "canals" around this lake appear abnormal, being very broad, diffuse, and pale. The south polar cap is still seen, but is very small, although at times very brilliant, and the north polar cap presents very sharp fluctuations of relative visibility, extent, and tone. The bluish tone seen in 1909 is still there, but seems to be more brilliant where the edges are better defined.

BELJAWSKY'S COMET, 1911g.—Dr. Kobold's ephemeris for comet 1911g is continued in No. 4530 of the *Astronomische Nachrichten*, from which we take the following abstract:—

Ephemeris 12h. M.T. Berlin.

1911	α (true) h. m.	δ (true)	log r	log Δ	mag.
Oct. 26	15 27·3	−9 12·7	9·7483	0·1309	4·3
,, 30	15 44·4	−13 13·0	9·8118	0·1649	4·8
Nov. 3	15 58·9	−16 36·8	9·8669	0·1961	5·2
,, 7	16 11·6	−19 32·0	9·9149	0·2266	5·6
,, 11	16 23·0	−22 3·2	9·9573	0·2507	5·9
,, 15	16 33·4	−24 15·3	9·9951	0·2744	6·2
,, 19	16 43·1	−26 11·9	0·0291	0·2960	6·5

The comet, then, is travelling down through Libra towards Scorpio, and its increasing south declination, its apparent proximity to the sun, and its decreasing brightness make it an almost impossible object except under the best conditions.

A number of earlier observations are recorded in the same journal, the general result being that about October 1–3 the comet was between the second and third magnitude, had a nucleus of magnitude 6·0, and a well-defined tail some 2° or 3° in length.

QUÉNISSET'S COMET, 1911*f*.—New elements and an ephemeris for comet 1911*f* are published by Dr. Ebell in No. 4530 of the *Astronomische Nachrichten*.

Ephemeris 12h. Berlin M.T.

1911	α (true) h. m.	δ (true) ° '	log r	log Δ	mag.
Oct. 24	15 42·2	+22 10·8	9·9378	0·1019	6·8
,, 28	15 43·8	+17 47·8	9·9230	0·1259	6·8
Nov. 1	15 45·0	+13 47·6	9·9109	0·1483	6·9
,, 5	15 45·8	+10 6·0	9·9020	0·1688	6·9
,, 9	15 46·4	+6 39·1	9·8969	0·1872	7·0
,, 13	15 46·8	+3 24·1	9·8960	0·2034	7·1

Perihelion passage takes place on November 12·39, and the comet is still observable, with increasing difficulty, in the evenings. The path lies through Serpens, and the comet will pass between β and γ Serpentis on October 29–30.

BROOKS'S COMET, 1911*c*.—Some photographs of Brooks's comet, taken by MM. Quénisset and Baldet at the Juvisy Observatory, are reproduced in the October number of *L'Astronomie*. One, on plate paper, taken with 2h. 3m. exposure on September 29, shows a large round head with two fine, slightly divergent streamers; between these, and at about 21′ from the nucleus, emerges the main tail, which presents but few of the undulations and condensations that characterised the tail of Morehouse's comet. A photograph taken with a short-focus camera on September 29 shows a tail 30° long going to the edge of the plate. The photographic intensity of the comet was then much greater than that of Daniel's comet, 1907*d*, but less than that of Morehouse's, 1908*c*.

THE CAPE OBSERVATORY.—Mr. Hough's report of the work done at the Cape Observatory during last year refers to many important pieces of astronomical research, from which we may but select one or two of the more striking facts. The travelling wire micrometer, in a modified form, was fitted to the transit circle, and gave excellent results; an instantaneous reversing gear has been fitted for use on stars near the pole. The heliometer was used on thirty-five nights for securing 166 observations of the position of Halley's comet. With the four-prism spectrograph attached to the Victoria telescope, 239 stellar spectra were secured, and with the one-prism spectrograph eleven photographs of the spectrum of Halley's comet were taken. The 6-inch equatorial was also used on the comet; and its mounting also carried other cameras, one, a Ross-Goertz (F=7·7) camera, having the large prism from the four-prism spectrograph mounted objectively; with this twenty photographs of the comet's spectrum were obtained, some showing also the tail. The astrographic reductions were submitted to the final control afforded by measures on overlapping plates. With the Dallmeyer photoheliograph 550 photographs of the sun were secured on 260 days between March 1 and the end of the year.

THE SPECTRUM OF P CYGNI.—The enigma presented by the mixed spectrum of P Cygni is somewhat further complicated by a preliminary note published by Mr. P. Merrill in No. 201 of the Lick Observatory Bulletins. It will be remembered that the spectrum is of the Orion type, with adjacent bright and dark lines, the latter being displaced toward the violet. Mr. Merrill now finds that the bright lines due to silicon are differentially displaced. Assuming that the wave-lengths of the bright lines of H, He, and N in the spectrum are those found for the same lines in laboratory and ordinary stellar spectra, the three bright silicon lines 4553, 4568, and 4575 are displaced 0·26 A.U. towards the red; the lines are also said to differ appreciably in appearance from the other lines in the spectrum.

MUSEUM CONFERENCE AT LIVERPOOL.

A CONFERENCE of members of the Museums Association and others interested in the work of museums was held at the Public Museum, Liverpool, on Wednesday, October 18. About sixty were present, including representatives from public museums at Manchester, Sheffield, Hull, Leicester, Stoke-on-Trent, Bolton, Warrington, and other towns.

After an address of welcome by Mr. F. J. Leslie, chairman of the libraries, museums, and arts committee, Dr. Clubb, director of museums, gave a brief description of the collections, and conducted the party on an inspection of the galleries. After tea the chair was taken by Mr. H. R. Rathbone, chairman of the museum subcommittee. Mr. E. Rimbault Dibdin directed attention to a clause in the Copyright Bill which has passed the House of Commons, the effect of which would be to take away the copyright in any work of art exhibited in a public gallery, and appealed to museum authorities to agitate for its rejection.

Dr. Clubb read a paper on the educational value of museums for schools, which was illustrated by the exhibition of some of the cabinets of natural history specimens which the museum circulated amongst the elementary schools of Liverpool, and by a number of drawings, wood carvings, and plasticine models made by pupils of one of the schools after a visit to the African gallery of the museum. Mr. P. Entwistle described the introductory series to the ceramic gallery in the Liverpool Museum, which exhibits the development of pottery from the earliest times, and includes a technological series explaining the process of manufacturing earthenware as now carried on. Mr. W. S. Laverock, in a paper on the botanical gallery of a public museum, said that he was forecasting an arrangement which did not as yet exist anywhere, which should include exhibits of English plants grouped according to their habit. This method would be more intelligible to the beginner than the usual systematic arrangement. Mr. J. W. Catmore described modern methods in taxidermy, which he illustrated by means of work in process and with examples of old and new specimens from the collections. The chairman suggested the desirability of adding pictorial backgrounds to some of the naturally mounted groups.

NEW BUILDINGS OF THE ROYAL ALBERT MEMORIAL UNIVERSITY COLLEGE.

FRIDAY last, October 20, was a red-letter day in the history of education in Devonshire, for the formal opening of the new University College buildings by the Lord-Lieutenant of the county was attended by such a gathering of influential people as to show that the County of Devon is now as much in earnest as the City of Exeter itself in the determination to maintain a fully equipped University College in its capital.

Dr. Alex. Hill, late master of Downing College, Cambridge, visitor of the college, delivered an address on the need for the highest branches of education and the importance of bringing such teaching within easy reach of all. Money spent in the establishment, endowment, and maintenance of such colleges, he said, would return to future generations an hundrdedfold. The Lord-Lieutenant, Earl

Fortescue, the Bishop of Exeter, Lord Clifford of Chudleigh, chairman of the Devon Education Committee, and the Sheriff of Exeter all followed in the same vein.

Hitherto, as was pointed out by the Mayor and by the principal, the college has been hampered and hindered in its growth by several causes. First among these was the inadequate accommodation of the old class-rooms and laboratories. This difficulty is no more, for the new buildings supply all that is essential for the needs of the present and for several years to come. The other difficulties have been acutely felt from time to time, especially when the commissioners from the Treasury have inspected the college. It had no permanent endowment fund, no long list of subscribers, and no considerable financial backing except from the city and citizens of Exeter itself.

At the meeting on Friday the governors were able to announce that they are making an attempt to raise an endowment fund of at least 30,000*l*., and the preliminary list already reached more than one-tenth of that sum. It seems certain that when the next inspection takes place the University College will be able to give a very different account of its position.

The buildings opened on October 20 represent the first instalment of a complete scheme for which the site has been secured, as funds do not at present admit of the erection of a great hall or of a wing to give modern accommodation for the fine art, applied art, technical and technological departments.

The front portion of the new wing contains chemical laboratories and lecture theatre, a common room for women students, six class-rooms and lecture-rooms for mathematics, classics, history, English, and modern languages, the biological laboratory and lecture-room, and rooms for the principal, professors, and staff. Behind this lies the day training college. There is no new provision for physics. This will be provided for in the York wing, opened in 1899 during the visit of the King and Queen when Duke and Duchess of York. The whole of this wing will now be devoted to physical science, except for one room allocated to geology.

New Buildings of the Royal Albert Memorial University College, Exeter.

AMERICAN ETHNOLOGY.

ABOUT the year 1895 Major J. W. Powell, director of the Bureau of American Ethnology, decided to prepare a linguistic map of that part of North America south of the Mexican boundary. This important work was, after the death of Major Powell, taken over by Drs. Cyrus Thomas and J. R. Swanton, who have now published the results in the 44th Bulletin of the Bureau of American Ethnology. Their report gives a detailed catalogue of the dialects in use throughout Mexico and Central America. Of particular interest is the evidence now provided, which corroborates the conclusion already arrived at that the linguistic elements of South America, at the time of the Spanish conquest, extended into the southern sections of Central America; and now for the first time the ethnical line dividing North and South America has been provisionally determined. This monograph is admitted not to be a final work, but an attempt to represent the present state of knowledge regarding a subject which may never be cleared entirely of obscurity.

It is a remarkable fact that the Cliff Palace in the Musa Verde National Park, Colorado, the largest, most picturesque, and most typical cliff-dwelling in the south-western States, so long escaped the knowledge of white settlers in the neighbouring Montezuma Valley. It is not mentioned in the early Spanish writings, and the first description of it was not published until about 1880. The classical account of these ruins is that by Baron Nordenskiöld in his "Cliff

Dwellers of the Musa Verde," translated from the Swedish original in 1893. This interesting monument, of which the most remarkable portion is a great round tower, has long suffered from the vandalism of casual treasure-seekers. It has now been taken in hand by the Government of the United States, which deputed Mr. Jesse W. Fewkes to effect a conservative restoration. The results of his operations are described in a valuable monograph, included in Bulletin 51 of the Bureau of American Ethnology. The buildings are prehistoric in the sense that there is no evidence of any culture derived from the white immigrants; and, though the relations of the Pueblo culture to that of the cliff-dwellers is still in some degree uncertain, the latter appears to be the earlier. Of special interest is the question of the disposal of the dead by cremation, the corpse being apparently dried before it was committed to the flames. The religion of this people, of which ceremonial dances formed an important part, cannot be clearly ascertained until the numerous cult objects obtained by excavation are more carefully examined.

GRANTS FOR AGRICULTURAL SCIENCE IN THE UNITED STATES.[1]

THE growth of the National Department of Agriculture during the past ten years has far exceeded that of all of its preceding history. This was pointed out by the Hon. Charles F. Scott, chairman of the House Committee on Agriculture, in submitting the new Agricultural Appropriation Bill last winter. As a full-fledged department with a Cabinet Minister at its head, the Department dates only from 1889. But if we go back to 1839, when 200*l*. was appropriated for "agricultural statistics," and include every dollar appropriated out of the Treasury of the United States for agricultural purposes down to and including the year 1900, the total sum is only 9,020,523*l*., while the aggregate of all the money appropriated from the end of 1900 to the end of the current fiscal year reaches a sum nearly double this, or 18,002,412*l*. For the fiscal year 1901 the appropriation for maintenance was 660,853*l*. This year the Department has at its disposal 3,094,127*l*. "Ten years ago the total number of persons employed in the Department was 3388: this year if all the rolls were called an army of 12,480 men and women would respond."

Under the Bill submitted by the committee referred to above, which after discussion and amendment received the signature of President Taft on March 4, provision is made for an even greater development during the ensuing year. The aggregate amount carried by the Act is 3,380,003*l*., which by far exceeds that granted in any previous measure, and is 177,590*l*. in excess of the estimates submitted by the Department.

There is an apparent increase over the Appropriation Act for 1911 of 682,476*l*., but of this 144,000*l*. is only nominal, since it merely replaces what has hitherto been provided automatically as a permanent appropriation to the State experiment stations under the Adams Act. It will be recalled that by the terms of that Act as subsequently construed in the Appropriation Act for 1907, definite appropriations were made only until July 1, 1911. The action taken by Congress now provides for the continuance of the Adams Fund on the same basis as the Hatch Fund, requiring the amounts to be appropriated annually in the Agricultural Bill. With due allowance for this item, however, there is still an actual enlargement of the appropriations of every bureau, and a net increase of fully 20 per cent. for the Department as a whole.

In general, the increased appropriations are for the purpose of extending and developing lines of work already under way, rather than the undertaking of new projects, and some of the principal increases are for what may be termed the administrative activities of the Department. One of the largest new items is an appropriation of 200,000*l*. for fighting and preventing forest fires in the national forests in cases of extraordinary emergency. This appropriation is in addition to the regular appropriation of 30,000*l*. for fire fighting under ordinary conditions, and supplements deficiency appropriations of more than 180,000*l*. incurred as a result of the disastrous fires of last summer.

The Federal meat inspection, which has been enforced by the Department from a permanent annual appropriation of 600,000*l*., receives an indirect increase of 31,000*l*. through the transfer of its clerical force to the statutory roll of the Bureau of Animal Industry. The Bureau of Chemistry receives 12,000*l*. additional for the enforcement of the Food and Drugs Act, and the Weather Bureau 15,098*l*. additional for its weather service. Provision is also made by an appropriation of 17,400*l*. for the enforcement of the Insecticide Act, which became effective on January 1, and for which a deficiency appropriation of 7000*l*. had been allowed for expenses to July 1.

A number of propositions involving general legislation were considered in connection with the Bill, but as finally enacted the law remains substantially a routine measure. The secretary was again authorised to continue investigations on the cost of food supplies at the farm and to the consumer, and a special appropriation of 1000*l*. was added for a study of chestnut-bark disease.

The Weather Bureau receives a total of 320,050*l*. Of this amount, 3000*l*. is for the restoration of the Weather Bureau station at Key West, Florida, wrecked by hurricanes in October, 1910. The allotment for maintenance of the bureau printing office was reduced to 3600*l*. by reason of the recent transfer of a portion of the equipment to the Government Printing Office. For investigation of climatology and evaporation 24,000*l*. was provided, as at present.

The appropriations to the Bureau of Animal Industry aggregate 330,150*l*. Aside from the increase due to the transfers from the Meat Inspection Act, previously referred to, the chief additions are those of 1424*l*. for the tick-eradication work, making that appropriation 50,000*l*.; an increase of 1400*l*. for the work of the Dairy Division, making its total 30,000*l*.; and of 1528*l*. for the Animal Husbandry Division, or 9496*l*. for that work. Under a new clause inserted in the Act, the Secretary of Agriculture is authorised to permit, under certain conditions, the admission of tick-infested cattle from Mexico into those portions of Texas below the quarantine line.

New appropriations were made of 13,000*l*. for the purchase of land for quarantine stations near Baltimore, Maryland, and Boston, Massachusetts; 2000*l*. for equipping the 475-acre experiment farm which has recently been acquired at Beltsville, Maryland; and 3300*l*. for constructing buildings at this farm and that at Bethesda, Maryland. It is expected to utilise the Beltsville farm for the experimental work of the Animal Husbandry and Dairy Divisions, and to reserve that at Bethesda for pathological investigations.

One of the largest increases in the Bill was accorded to the Bureau of Plant Industry, which will receive 60,696*l*. additional, making its total 412,337*l*. The lump-fund appropriation for general expenses is 288,307*l*., which is divided among thirty projects. Some of the largest of these are 70,000*l*. for the boll-weevil campaign (a net increase of 21,389*l*.); methods of crop production in the semi-arid or dry-land sections, and for the utilisation of lands reclaimed under the Reclamation Act, for which a net increase of 7654*l*. and a total of 28,612*l*. is granted: 28,584*l*. for the farm-management studies, of which 800*l*. is to be used in agricultural reconnaissance work in Alaska; studies of the production, handling, grading, and transportation of grains, for which 27,001*l*. is available, an increase of 4900*l*.; and the studies of fruit improvement and the methods of growing, packing, and marketing fruits, which will have 17,547*l*. The investigations of the cotton industry were extended to include the ginning and wrapping of cotton.

For the purchase and distribution of valuable seeds and plants the allotment made was 57,936*l*. This is an apparent decrease of 3982*l*., but it is accounted for in part by transfers of clerical employees to the statutory roll of the Bureau, and in part by the segregation as a distinct project of 4000*l*., which was formerly supported from this fund. The two items comprising this appropriation are the congressional seed distribution, which is continued on the usual basis, with 47,432*l*., and the allotment for the introduction of seeds and plants from foreign countries, which is increased to 10,504*l*.

[1] From the U.S. *Experiment Station Record*, vol. xxiv., No. 5, 1911. The dollars in the original have been converted into English currency.

The appropriations to the Forest Service reached a total of 1,100,620*l*., in addition to the various emergency appropriations to which reference has been made. This, as usual, represents the largest appropriation to any one bureau, and is also the largest increase over the previous year, the total for 1911 having been 1,001,620*l*. The policy of definite allotments to each of the 161 national forests for maintenance was continued. The Nebraska National Forest was authorised to furnish young trees free of charge to settlers in the surrounding region.

The sum of 30,000*l*. was granted for fighting forest fires and for other unforeseen emergencies, of which 14,000*l*. is immediately available. The allotment for permanent improvements on the national forests was increased from 55,000*l*. to 100,000*l*. Provision was made for the refunding to claimants of moneys erroneously collected in the administration of the national forests, and for the granting of easements under certain conditions for rights of way across the public lands, national forests, and reservations for the transmission of electrical power and for telephone and telegraph purposes.

Liberal provision for the development of investigational work was also made, 35,408*l*. being granted for investigations of methods for wood distillation and preservation and the economic use of forest products, including the testing of woods for paper-making, together with 3684*l*. for investigations of range conditions within national forests and range improvement, 50,238*l*. for silvicultural and dendrological experiments, and 6752*l*. for miscellaneous forest investigations and the preparation and dissemination of results.

The appropriation of the Bureau of Soils was increased to 52,412*l*. No appropriation was made for soil-erosion investigations, for which 1000*l*. has been allotted annually for many years. The soil-survey work received 29,000*l*., a net increase of 2608*l*., with a provision added limiting to 10 per cent. the expenditures in any State.

The Bureau was authorised to undertake a new line of work by the appropriation of 2500*l*. "for exploration and investigation within the United States to determine a possible source of supply of potash, nitrates, and other natural fertilisers," 500*l*. being made immediately available. It is expected that particular attention will be devoted to possible sources of potash in view of the present situation as regards the German potash supply. The work will also be supplemented by researches to be conducted by the Geological Survey, which received authority in the Sundry Civil Appropriation Act to expend 8000*l*. "for chemical and physical researches relating to the geology of the United States, including researches with a view of determining geological conditions favourable to the presence of potash salts." According to a recent announcement from the Survey, the expenditure of half this appropriation for the potash exploration is contemplated.

The Bureau of Entomology receives an aggregate of 120,384*l*. This is an increase of 13,948*l*., mainly for the extension of work to the alfalfa weevil and for enlarging the investigations on insects affecting rice and sugar-cane, for demonstration work against forest insects, and for additional studies in bee culture. The largest single allotment is for the continuation of the campaign against the gipsy-moth and brown-tail moth, for which the appropriation is 56,968*l*.

The large proportionate increase of 10,556*l*. was accorded the Bureau of Biological Survey, making its total 27,940*l*. All the various lines of work were continued on a more comprehensive basis, and new items were included of 500*l*. for the purchase, capture, and transportation of game for national reservations, and of 4000*l*. for the feeding, protecting, and removal of elk at Jackson's Hole, Wyoming, and vicinity. The latter appropriation is made immediately available, and remains available until expended.

The activities of the Office of Public Roads have been rapidly increasing in recent years, and to keep pace with the growing demands the appropriation was increased from 22,848*l*. to 32,144*l*. A new line of work authorised is the conducting of field experiments in road construction and maintenance, for which 2000*l*. is granted.

The total appropriation of the Office of Experiment Stations is 372,800*l*., of which 288,000*l*. is allotted to the State experiment stations under the Hatch and Adams Acts. Of the remainder, 11,300*l*. is for statutory salaries, and 7500*l*., a net increase of 1000*l*., is for general expenses. The allotment of 2000*l*. for the Agricultural Education Service was continued as at present.

The nutrition investigations received an increase of 1000*l*., making 3000*l*. available for this purpose. This increase will enable further extension of these investigations and the preparation of popular bulletins setting forth plans for the more economical and effective utilisation of agricultural products as human food, for which data a strong demand has been in evidence.

An estimate of 4000*l*., submitted for the preparation, publication, and dissemination of original technical reports of the scientific investigations of the experiment stations, by the Secretary of Agriculture in cooperation with the Association of American Agricultural Colleges and Experiment Stations, was favourably recommended by both the House and Senate Committees, but failed of passage.

The Alaska, Hawaii, and Porto Rico experiment stations were given 6000*l*. each, an increase of 400*l*. in each case, to equalise their funds with those received by the State stations from Federal funds, and the Guam station was continued at 3000*l*. The clause requiring the expenditure of 1000*l*. by the Porto Rico station for coffee experiments was omitted, thereby restoring the coffee work to the same basis on which it has been conducted for many years previous to the passage of the Act for 1911.

The irrigation and drainage investigations each received 20,000*l*., a net increase of 6564*l*. and 5196*l*. respectively. These increases will enable the extension of these lines of work, especially in the rendering of assistance to settlers in newly irrigated regions and in formulating plans for the reclamation of swamp lands. The provision requiring a special report of the aggregate expenses in the drainage investigations to date, and the areas in the several States and territories which have been investigated, was continued.

The work of the remaining bureaus was provided for along substantially the present lines. Including the increase previously noted for the enforcement of the Food and Drugs Act, the Bureau of Chemistry will receive 13,616*l*. more than at present, and a total of 192,756*l*. The Bureau of Statistics is given 46,324*l*.; the library, 8100*l*.; the office of the secretary, 55,290*l*.; the Division of Accounts, 19,504*l*.; the Division of Publications, 41,992*l*.; and the fund for contingent expenses, 22,000*l*. These all contain small increases, occasioned in general by the growth of the Department.

Eliminating the deficiency appropriations and that for the Forest Reservation Commission, these various appropriations, which are intimately connected with the work of the Department, would if added to the regular appropriations make a grand total of 4,514,003*l*. This is a large sum; but, as was pointed out by Chairman Scott in concluding the presentation of the Bill, "the money appropriated for the Department of Agriculture is an investment and not an expense. And that it has been a good investment the statistics showing the expansion of agriculture and the improvement in methods throughout our country bear eloquent witness. During these past ten years, while the Department of Agriculture has been expending 18,000,000*l*., the farmers of the United States have added to the wealth of the world the stupendous and incomprehensible sum of 16,000,000,000*l*. Without anything like a corresponding increase in the area of land under cultivation, the value of the farm products of our country has risen from slightly more than 800,000,000*l*. ten years ago to nearly 1,800,000,000*l*. in 1910.

"The conclusion is inevitable, therefore—and that conclusion could be made incontestable by innumerable other proofs if time permitted—that the farmers of America are applying better methods and getting better results from their labours than ever before. And in devising these better methods, in pointing the way for better results, the Department of Agriculture has been the undisputed leader, as it should be, and has thus beyond cavil or question derived from the money it has expended a percentage of profit to all the people which cannot be calculated."

THE PHYSIOLOGY OF SUBMARINE WORK.[1]

COMPRESSED air is used in all the great subaqueous works of to-day, in tunnelling, harbour works, shaft-sinking in wet soil, pier- and bridge-building, diving for pearl and sponges, salvage work, &c. The intercommunication of the great cities of the world depends on tunnels built with the aid of compressed air. All such works are limited to a certain depth by the pathological effects produced on the workers.

The Naked Diver.

The naked diver preceded the diver who uses compressed air. The body of the naked diver is pressed upon by the water, equally and in all its parts, by a pressure equal to one atmosphere (15 lb. per square inch) for every 33 feet (10·3 m.) of depth. He takes a deep breath or two, fills his lungs before, and holds his breath during, the dive. He places a foot in a stirrup attached to a heavy stone, and so is carried rapidly to the bottom. The air in his lungs, air passages, and middle ear must be compressed to half its volume at 33 feet (two atmospheres absolute), to one-third at 66 feet (three atmospheres absolute), to a quarter at 99 feet (four atmospheres absolute). The depths attained are usually not greater than 60 to 70 feet. The compression of the air in the lungs is rendered possible by the upward movement of the diaphragm and sinking in of the abdomen. Some of the air in the lungs must dissolve in the blood according to the law of partial pressures.

The amount of nitrogen dissolved from air at one atmosphere pressure and at body temperature is 0·85 per cent. This is the figure for the watery part of the body. The fat dissolves about 5 per cent., an important fact discovered by Vernon. At 66 feet (three atmospheres) the watery part can hold $0{\cdot}85 \times 3$ and the fat 5×3 per cent. Putting the fat against the solids of the body (bones, &c.), which do not dissolve gas, it may be assumed that the whole body dissolves about 1 per cent. of nitrogen per atmosphere. A man weighing 60 kgm., then, will dissolve when compressed from one to three atmospheres about 1200 c.c. of nitrogen, that is, if time were allowed for the blood to convey the nitrogen from the lungs to the tissues until saturation occurred. In the lungs there are about 4000 c.c. of air. Of course, far less than 1200 c.c. will be dissolved in the minute the diver is submerged. In addition to the solution of nitrogen, the blood will take up more oxygen, both in solution and chemically combined with the hæmoglobin; the diver working hard gathering pearl or sponge will use oxygen rapidly. It is clear, then, that the absolute volume of air must be reduced during the minute the diver stays submerged, but it is difficult to estimate by how much. To allow for the reduction of volume, both by compression and solution, in the body, it is clear that the diver must fill his lungs well, otherwise the diaphragm will be pushed up to such an extent that the action of his heart and the circulation of the blood become impeded. It is this, in part, which sets a limit to the depth to which the naked diver can go. The bleedings from mouth and nose which the unpractised naked diver suffers are due, no doubt, to both the congestion of the blood which results from holding the breath and to rarefaction of the air in the nose and middle ear during the ascent. Some time ago I put this question to Sir E. Ray Lankester: What happens in the case of the whale which sounds, perhaps, to a depth of 1000 feet? Does the whale allow the lungs to fill with water as the air becomes compressed to one-thirtieth of its volume? If not, what is the mechanism engaged which permits such compression? I fancy the whale allows water to enter, and blows this out again when it ascends to the surface. The naked diver can extend his stay under water by deep breathing before the plunge and filling the lungs with oxygen. The breathing is regulated by the concentration of acid (or the hydrogen ion) in the blood—carbonic acid is the natural end product of muscular metabolism; lactic acid is produced in the muscles when there is a deficiency of oxygen. Deep breathing before the dive will wash out much of the carbonic acid in the blood, owing to the increased ventilation of the lungs. The blood and muscles, too, will be better oxygenated, and thus less lactic acid will be produced during the submergence. If oxygen is breathed this will be still more the case, as Martin Flack and I have shown. After deep breathing air for two minutes we easily held our breath two or three minutes. After deep breathing oxygen five minutes one of our subjects held his breath more than eight minutes, and another just above nine minutes. Taking a deep breath and then holding it, J. M. pulled up a 60-lb. weight seventeen times in twenty-three seconds before he was compelled to take another breath. After deep breathing air for two minutes he held his breath while he pulled it up thirty times in fifty seconds, and after deep breathing oxygen for two minutes, seventy times in eighty-five seconds. Similarly, after a deep breath, R. A. R. held it while he ran 113 yards in twenty-nine seconds; 150 yards in $35\frac{3}{5}$ seconds after deep breathing air for two minutes; 256 yards in $62\frac{2}{5}$ seconds after deep breathing oxygen for two minutes. S. E. ran on one breath 470 yards in 110 seconds after deep breathing oxygen! At the end he ran blindly, having lost consciousness owing to the high concentration of CO_2 in his blood.

The high pressure of oxygen in the lungs enables one to hold one's breath until the pressure of CO_2 reaches 10 to 11 per cent., while if the pressure of oxygen is low a breath must be taken when that of the CO_2 reaches no more than half this amount. A balance is struck between the relative pressures of oxygen and carbonic acid. Mr. I. Feldman here has been breathing oxygen for some minutes; he will now put his face in a basin of water; you see he has now held his breath for three minutes without the least trouble.

It is clear, then, that the naked diver can stay longer and do more efficient work if he deeply breathed and filled his lungs with oxygen before each dive.

I will demonstrate my little apparatus by means of which oxygen can be generated from oxylithe (peroxide of sodium) and inhaled. Two blocks of oxylithe are put in the metal box—the generator—and a pint of water in the rubber bag. The mouthpiece of the bag is clipped, and the water allowed to enter the generator. Oxygen fills the bag, and a solution of caustic soda is formed. The man breathes in and out of the bag. This invention allows oxygen to be carried about, and has proved useful for mountain climbers who at high altitudes suffer from oxygen want.

Diving birds have double the normal volume of blood (Bohr), just as the llama and the human inhabitant of high altitudes have more red corpuscles and hæmoglobin. Observations on the blood of naked divers would probably show the same increase.

The Mechanical Effects of Pressure on the Body.

The body of the naked diver at a depth of, say, 66 feet is pressed upon equally on all sides by the water, and by a pressure of three atmospheres; for 33 feet of water = one atmosphere. The gas in his lungs (and intestines) is compressed into one-third of its volume, and that is the only effect of the pressure, for the pressure is transmitted equally and instantly by the fluids of the body to all parts, and as the fluids are practically incompressible the pressure has no mechanical effect.

The diver who uses gear, or the caisson worker, is surrounded with compressed air, and breathes freely in it. The body of either is pressed upon by the air, and the air pressure must always be just greater than that of the water to keep the latter out of the dress, bell, or caisson. I will demonstrate this on the model diver, diving bell, and caisson. Whether it be air or water that *uniformly* presses upon the body, the tissue fluids transmit the pressure equally; and thus, although it is computed that an extra atmosphere means an additional total pressure of 15,000 to 20,000 kilograms (40,000 lb.) on the body of a man, no mechanical effect is produced. Living matter is a jelly containing about 80 per cent. of water, and, like water, is practically incompressible. Since attention was first directed to compressed-air illness, the larger number of medical writers, ignorant of physical laws, have supposed that exposure to compressed air mechanically alters the distribution of the blood, forcing it inwards and causing a congestion, which is suddenly and dangerously altered on decompression.

[1] Evening discourse delivered before the British Association at Portsmouth on Friday, September 1, by Mr. Leonard Hill, F.R.S.

I have noted that the same false views are even now put forward in the daily Press to explain the symptoms, due to the rarefaction of the air, endured by aëroplanists. The sickness of high altitudes suffered by mountain climbers, balloonists, and aëroplanists has nothing to do with the mere mechanical effect of the lowering of barometric pressure. In an atmosphere enriched with oxygen U. Mosso has endured a lowering of barometric pressure until he could span the height of the column of mercury in the barometer with his hand. Oxygen want, due to the rarefaction of the air, is the prime cause of altitude sickness. At an altitude of 18,000 feet, where the barometric pressure is halved, a man, filling his lungs with air, takes in only half the *weight* of oxygen which he takes in at sea-level. His respiratory and circulatory organs can scarcely work hard enough for the body to get enough oxygen. The extra pulmonary ventilation washes the CO_2 out of the body, and produces a subnormal concentration of CO_2 in the blood and tissues. This is partly the cause of mountain-sickness. Individual variations in immunity to this sickness probably depend on variations in the chemical quality of the blood and power of the hæmoglobin to combine with oxygen.

That mere mechanical pressure, uniformly applied, is of no importance to living matter is shown by the existence of life in the greatest depths yet sounded, where the superincumbent pressure may equal two, three, and even five miles of water. By means of a small chamber and hydraulic pump and lantern I can project the shadow of the frog's heart beating in a suitable salt solution at a pressure of 2000 lb. (133 atmospheres), equivalent to a depth of nearly a mile of water. Regnard has compressed living aquatic animals, frogs' muscles, &c., to 500 and even 1000 atmospheres, and has found at the highest pressures the tissues become stiff and take up water, and life is destroyed. His experimental results and those of the deep-sea soundings (*Challenger* reports) are in contradiction. Regnard's experiments require repetition, with careful attention to the chemical composition of the water in which the living matter is compressed.

I refute the mechanical theories of compressed-air illness by this experiment: a frog's web is stretched over the glass window of the small pressure chamber, and is illuminated by the arc light, so that the circulation of the blood is projected on the screen. The circulation remains unchanged when the pressure is rapidly raised to twenty or even fifty atmospheres.

Manometric records of blood pressure taken from mammals enclosed in a pressure chamber, or from man, show no noteworthy change when the pressure is raised to three atmospheres. Similarly, I now show that a frog's heart or muscle contracts normally when suddenly submitted to a pressure of air equal to fifty atmospheres. After a time the contraction languishes; but that is not due to the pressure *per se*, but to poisoning by the high pressure (concentration) of oxygen. The pressure uniformly applied has no mechanical effect on the living protoplasm.

The Evolution of Diving Apparatus.

The use of compressed air for submarine work was a matter of slow development, owing, not to lack of invention, but to want of efficient air pumps and flexible tubes. The naked divers had a barrel, or bell-shaped vessel, standing on a tripod, lowered down to them full of air, to which they could return and breathe the air within every minute or two. They also chewed pieces of sponge dipped in oil, probably because swallowing inhibits the respiratory centre and checks the desire to breathe. One of the oldest inventions is that of a pipe conveying air from the surface to the mouth of the diver. Such a device cannot be used at any depth, because the body is pressed upon by the water plus the atmospheric pressure, while the lungs are exposed to the atmospheric pressure alone. This makes breathing difficult, and dangerously congests the lungs with blood, as I can demonstrate by this model. The cupping glass also demonstrates the congestive effect produced by lessening the atmospheric pressure at one part of the body only. Bernouilli (seventeenth century) formulated the correct theory that the diver must be supplied with air at the pressure of the water surrounding him. In the older inventions the air escaped from under the helmet, and only the head was dry. The air pressure in the modern diving dress (invented by Siebe), regulated by a valve in the helmet, keeps the water from entering at the wrist cuff, and the whole body is kept dry and warm and equally compressed. I demonstrate the modern diving dress which Messrs. Siebe, Gorman and Co. have lent me for this lecture. The pressure produced by the pump must keep up to that of the water as the diver descends, so long as he does not fall down. He can descend rapidly, *e.g.* 100 feet in two minutes; but it is dangerous to fall down, for if the pump does not keep up with the water pressure a cupping effect is produced, and the diver may suffer hæmorrhage from the lungs and mouth and nose.

By means of the escape valve the diver can adjust his specific gravity so that he is only slightly heavier than water, and can move easily along the bottom. He fills his dress more or less with air, just as the fish fills its swim bladder. If the dress becomes over-filled the diver is "blown up" to the surface; and in the old style of dress he may become helpless, arms and legs blown out stiff, unable to open his valve. You see how this happens in the case of the model diver. To prevent this accident the legs of the latest fashionable dress are laced up, as I now show you.

The Diving Bell and Caisson.

Anyone who pushed an inverted glass under water and saw it did not fill would conceive the idea of a diving bell. Sinclair (1665) fashioned a simple wooden bell to recover treasure from an Armada ship off Mull. At 33½ feet the air in such a bell is compressed to half its volume, and this, together with lack of ventilation, rendered such a bell of little use.

Halley, the astronomer, used a pipe and bellows for shallow work, while for deep work, when his bellows failed, he sank a cask full of air to a deeper level than the bell. From the cask to the bell passed a tube, and the water, entering the cask through a hole, displaced the air into the bell (model demonstrated). He descended to nine to ten fathoms with four others, and used up seven to eight barrels of air.

With the building of efficient air-pumps, Smeaton (1778) applied the bell to the important use of building the piles of bridges. Triger (1839) applied it to the sinking of coal shafts through quicksands, and the bell became thus evolved into the modern caisson—a steel chamber provided with a cutting edge below and an air-lock above for allowing the men to enter and leave without raising the bell. Finally, the caisson was applied to the purpose of horizontally tunnelling under rivers. To effect this a steel shield provided with cutting edge is driven forward by hydraulic jacks. Screens are placed in the shield to allow excavation of the soil in front of it. As fast as the shield is driven forward, segments of the iron tunnel are built into place. Water is kept out of the work by the use of compressed air. On entering, the men are "compressed" in the air-lock, *i.e.* the air pressure is raised to that in the tunnel, and on leaving the tunnel they are "decompressed," *i.e.* the air pressure is lowered in the lock down to the normal, so that the outer door of the lock may be opened.

A diver is "compressed" on descending into the water, as the pressure of his air-pump always keeps up to that of the water. On coming up he is "decompressed."

The Ventilation of the Diving Dress.

Divers in deep-sea water have in the past been unable to stay down long owing to a feeling of oppression, which they have ascribed to the pressure of the water. M. Greenwood and I have exposed ourselves in our compressed-air chamber to +92 lb. (seven atmospheres) and +75 lb. (six atmospheres) respectively, and found our breathing just as free and easy as at atmospheric pressure. Beyond the increasing nasal twang of the voice there are no symptoms produced, and there is no sense by which the pressure can be estimated. John Haldane has done great service in proving that the cause of the oppression is due to increased partial pressure of CO_2 in the helmet owing to deficient ventilation. The breathing is regulated by the pressure of CO_2 in the lungs, so that this is kept at 5 to 6 per cent. of an atmosphere. During work the amount of CO_2 given off is trebled or quadrupled, and during hard work it may be increased sixfold. The ventilation of the lung is increased *pari passu* so as to keep the percentage of CO_2 in the lung normal.

If the pressure of CO_2 in the inspired air is increased, the breathing is deepened so as to keep normal the CO_2 percentage in the lung. If the inspired air contain 3 per cent. CO_2, the volume breathed is about doubled, and moderate work in such air causes as much panting as hard work in pure air.

When the atmospheric pressure is altered it is not the percentage, but the absolute pressure of CO_2 which controls the breathing. Thus the percentage found in Greenwood's lungs was 5·4 at one atmosphere, 2·7 at two atmospheres, 0·9 at six atmospheres, and the partial pressure of CO_2—*i.e.* the percentage multiplied by the pressure in atmospheres—in each case was 5·4 per cent. of an atmosphere. This holds good also down to about two-thirds of an atmosphere in analyses taken at high altitudes. At lower atmospheric pressures than this oxygen want comes in, with the production of lactic acid in the tissues and blood as a disturbing factor. It is clear, then, that the effect of a given percentage of CO_2 in the diver's helmet varies with the depth. If air containing 5 per cent. CO_2 produces great panting at one atmosphere, air containing $5/7·4=0·68$ per cent. will produce the same degree of panting at 35 fathoms (7·4 atmospheres). It follows from this that whatever the pressure a diver is under, he requires the same volume of air measured at that pressure to ensure the ventilation of his helmet. At two atmospheres the ventilation must be doubled, at three atmospheres trebled, at six atmospheres increased sixfold. Under the old conditions of working, often with leaky pumps and tired men to pump, the ventilation has been actually less, not six times greater, as it ought to be, at a depth of 165 feet.

With a pressure of 2 per cent. of CO_2 in the inspired air the pulmonary ventilation is increased about 50 per cent., with 3 per cent. about 100 per cent., with 4 per cent. about 200 per cent., with 5 per cent, about 300 per cent., and with 6 per cent. about 500 per cent. If the diver is working hard the extra production of CO_2 will make him pant, and this, coupled with the effect of the excess in the helmet, which often reaches 3 to 4 per cent., makes breathing distressing and the feeling of oppression intense. Thus at a depth of 139 feet with a CO_2 pressure of 4·28 per cent. of an atmosphere, Lieut. Damant was unable to continue for more than eight minutes the exertion of lifting a weight of 56 lb. about 9 feet per minute. The Admiralty Committee found that the divers could continue work for long periods at depths of even 210 feet so long as the CO_2 pressure was kept below 3 per cent. of an atmosphere.

To keep the CO_2 down to this level a diver ought to have at least 1·5 cubic feet of air per minute when working, and he must have this volume of air pass through the helmet at whatever pressure he be at. Each cylinder of the regulation service pump ought to yield one-tenth cubic feet per revolution. Assuming an unavoidable leakage of the pumps of 10 per cent. at 100 feet and 24 per cent. at 200 feet, the Admiralty Committee ordered for 33 feet (depth) one cylinder, thirty revolutions per minute, and two men per spell, the work being estimated at 4440 foot-lb. per minute; while for 165 feet depth four cylinders, twenty-seven revolutions, and twelve men are required, the work being 34,000 foot-lb. per minute; for 198 feet (depth) six cylinders, twenty-three revolutions, eighteen men, the work being 43,000 foot-lb. per minute. Provision ought to be made to give a third more than this supply if the diver gets into difficulties.

At 210 feet thirty-six men were working very hard in alternate five-minute spells of rest and work, and were scarcely able to keep up the proper air supply. Long handles were supplied to allow three men on each side of the pump.

To avoid this excessive labour, R. H. Davis (of Siebe, Gorman and Co.) and I have added to the diving dress this metal box, containing trays of caustic soda. A mouthpiece is placed within the helmet, and a tube leads from this through the soda-box and back to the helmet. The diver when oppressed in the slightest degree can take hold of the mouthpiece with his lips and breathe through the caustic soda, and so lessen the concentration of CO_2. There is no risk of his suffering from want of oxygen so long as the pumps give him a moderate supply of air. This device ought to save a great deal of hard pumping work.

The Self-contained Diving Dress.

We have also contrived a self-contained diving dress fitted with cylinders containing compressed air enriched with oxygen (to 50 per cent.), and a caustic-soda chamber. The oxygen supply is delivered to the helmet by a reducing valve in constant supply (5 litres per minute), and the force of the oxygen stream is used, by means of an injector, to suck the air in the helmet through the caustic-soda chamber. No life-line or air-pipe is carried, only a light telephone cable, and this makes the dress suitable for exploration of flooded mines, tunnels, ships, &c., through which the heavy pipes and lines cannot be dragged. Air containing 50 per cent. oxygen is used in place of oxygen (Haldane), so that there is no risk of oxygen poisoning if used for an hour at depths of 70 to 80 feet, or even 100 feet, for half an hour.

Compressed-air Illness.

In all the great compressed-air works from first to last the men have suffered from illness and loss of life. There is no risk going into or staying in the caisson, as Pol and Watelle (1854) said, "On ne paie qu'en sortant." Out of sixty-four workers observed by them forty-seven remained well, fourteen had slight illnesses, sixteen more or less severe, two died. An absolute pressure of $4\frac{1}{4}$ atmospheres was reached. The men worked two shifts per diem of four hours each, and were decompressed in thirty minutes. At the St. Louis Bridge works, out of 352 workers there were 119 cases, fifty-six of paralysis, and fourteen deaths. The absolute pressure reached $4\frac{1}{3}$ atmospheres.

At the Nussdorf works 320 cases among 675 workers, and two deaths; the absolute pressure reached was $3\frac{1}{2}$ atmospheres.

In the East River tunnels (New York), under well-regulated conditions, the percentage of illness was 0·66, of death 0·0035 in 557,000 man-shifts, with a decompression rate of fifteen minutes from an absolute pressure of three atmospheres. Of the 320 cases at Nussdorf, v. Schrötter observed sixty-eight cases of ear trouble, 105 of pain in the muscles, sixty of pains in the joints, ten of girdle pains, seventeen of partial paralysis, twenty-six of paralysis of the lower half of the body, fourteen of vertigo and noises in the ear, two of sudden deafness, one of loss of speech, thirteen of asphyxial phenomena. Out of 3692 cases at the East River tunnels observed by Keays, 88·78 per cent. were pains in joints and muscles, "bends," 1·26 per cent. pains and prostration, 2·16 per cent. nervous symptoms, 5·33 per cent. vertigo, 1·62 per cent. dyspnœa and oppression, chokes, 0·46 per cent. loss of consciousness and collapse. There were twenty deaths. The trouble in the ear, which occurs during compression, is due to the inequality of air pressure on either side of the drum of the ear. It is relieved at once by opening the Eustachian tubes by swallowing, or by a forced expiration with the nose and mouth held shut. None of the other manifold symptoms come on while the men are under pressure. Mules were kept for a year in the Hudson Tunnel at three atmospheres absolute, and were healthy enough to kick and bite at all comers (E. W. Moir). The illness comes in after decompression, usually within a few minutes to half an hour, sometimes even later.

The Cause of the Illness.

The cause of the illness—so striking in its protean nature—was made clear by Paul Bert (1879), who showed by experiments on animals (1) that nitrogen gas is dissolved by the blood and tissue fluids in proportion to the pressure of the air (Dalton's law); (2) that the dissolved gas bubbles off and effervesces in the blood when an animal or man is decompressed too rapidly; the bubbles, by blocking up the capillaries and cutting off the blood supply here or there, produce the symptoms; (3) that during exposure to eight or nine atmospheres there is no ill-effect until the partial pressure of oxygen dissolved in the blood reaches such a point that it acts as a tissue poison; (4) that the illness which occurs on decompression is prevented by making the period of decompression sufficiently slow, by allowing time for the dissolved nitrogen to escape from the lungs. Looking through the works of Robert Boyle, I found that, after the invention of his air-pump, he "had a mind to observe whether when the air from time to time was drawn away, there would not appear some hidden swelling, greater or less, of the body of the animal by the spring and expansion of some air (or aërial matter) included in the thorax or the abdomen." He recorded that a viper's body and neck grew prodigiously tumid; that a bubble of air appeared in the aqueous humour of a viper's eye; that the heart of an eel grew very tumid and sent forth little bubbles; that blood boiled "over the pot" until the blood occupied only one-quarter of the volume of the whole, so great was the expansion of the bubbles given off from it. In the following surmise, concerning the death of animals submitted to rarefaction, Boyle forestalls Bert. "Another suspicion we should have entertained concerning the death of animals, namely, that upon the sudden removal of the wonted pressure of the ambient air, the warm blood of those animals was brought to an effervescence or ebullition, or at least so vehemently expanded as to disturb the circulation of the blood, and so disorder the whole economy of the body."

Hoppe-Seyler (1857) demonstrated bubbles in the blood-vessels of animals submitted to rarefaction. This was denied by Bert, but confirmed in the case of a rabbit by Greenwood and myself.

Out of thirty autopsies done on fatal cases of caisson illness, in nineteen gas-bubbles were visible in the blood-vessels; of the other cases most were old-standing lesions of the spinal cord.

The paralysis so often produced is due to a local death and degeneration of the spinal cord, produced by bubbles blocking the circulation there (v. Schrötter, Heller, and Mager).

Proofs that nitrogen gas dissolved in the body fluids and fat is the cause of the illness are the following. The blood collected from the artery of an animal while under pressure, and analysed with the gas-pump, shows that the amount of dissolved nitrogen varies with the pressure. Roughly, 1 per cent. per atmosphere is dissolved (Bert, Hill, and Macleod).

Exposed to one atmosphere at body temperature, blood dissolves just about 1 per cent. N, to two atmospheres 2 per cent., to three atmospheres 3 per cent., and so on. The tissue fluids take up the dissolved gas from the blood, and with time the whole body becomes saturated, according to Dalton's law. The saturation of the body fluids takes time, since the blood forms but 5 per cent. of the whole body weight, and it is the blood alone that comes in direct contact in the lungs with the increased atmospheric pressure. Probably about 5 kilograms of blood circulate through the lungs per minute, and this blood conveys the absorbed nitrogen to the 60 kilograms of tissues. The arterial blood saturated in the lungs yields the nitrogen to the tissues, and returns to be saturated again in the lungs. Those tissues which are plentifully supplied with blood will become saturated rapidly, while less vascular areas, and parts in a state of vasco-constriction, will saturate very slowly.

C. Ham and I exposed rats to ten to twenty atmospheres, killed them by instant decompression, and then, opening their bodies under water, collected and analysed the gas set free therein. We obtained in this gas CO_2 6·7 to 16 per cent., O_2 2·1 to 8·7 per cent., N 80 to 87 per cent., and a volume of N greater than that calculated according to solubility of N in tissue fluid. Some of the excess we found was due to air swallowed while under pressure, the rest to solution of N in fat.

M. Greenwood and I have tested upon ourselves the rate of saturation, using the urine as a test fluid. We were compressed in a large boiler, placed at our disposal by Messrs. Siebe, Gorman and Co. The chamber was fitted with electric light and telephone, and taps for slow decompression. The pressure was raised by means of a diving-pump driven by a gas engine. We drank a quart of water before entering, and collected samples of urine at varying pressures and times. The urine, collected in sealed bulbs, was evacuated by the blood gas-pump. We found the urine secreted in the next ten minutes after reaching any given pressure is saturated with N at that pressure.

To demonstrate the bubbling off of nitrogen on rapid decompression, I have spread the web of a frog's foot or wing of a bat over the glass window of a pressure chamber. The circulation of the blood is projected on a screen with aid of microscope and arc light. We can thus observe the circulation under twenty atmospheres of air, and watch the bubbles forming in the capillaries on rapid decompression. Recompression diminishes the size, and finally drives the bubbles again into solution.

When the larger mammals are exposed to high pressure, such as eight atmospheres, for an hour or so, and are then rapidly decompressed, they usually die in a few minutes. Small mammals, such as mice and rats, may escape, owing to the small bulk of body and rapid respiration and circulation. The young of rabbits, cats, &c., also escape more frequently than old animals. This is due rather to their smaller weight and more rapid circulation than to the youth of the body tissues. Paralysis in the limbs follows too rapid decompression, or the animals fall over and become unconscious. Noise of gas bubbles gurgling in the heart may be heard. Respiration becomes embarrassed, and the animals die. On dissection, the peritoneal cavity may be found distended with gas, or the stomach, and gas may be seen in the intestine. A part of this gas arises from the fermentative processes of digestion, and from air swallowed during compression. The veins of the portal system, the venæ cavæ, are seen to contain chains of bubbles; the heart is full of froth. Small hæmorrhages may be present in the lungs. The edges of the lobes of the lung are emphysematous, blown out by the rapid decompression. The fat often is full of small bubbles, so too are the connective tissues. Bubbles are seen in the joints, and may appear in the aqueous humour of the eye. On opening the skull, bubbles are seen in the veins of the brain. The bubbles are not restricted to the veins, but may also be seen in the arteries. The coronary vessels of the heart often show chains of bubbles. On microscopic examination the bubbles are seen in the capillaries; here and there they run together and form larger bubbles, sometimes rupturing the walls of the vessel and compressing the surrounding tissues. In the larger animals, decompressed from 100 lb. in four to seven seconds, we have found the cells of the liver, kidney, &c., vacuolated or even burst by bubbles. The gas set free in the heart can be collected and analysed; about 80 per cent. of it is found to be nitrogen (Bert, v. Schrötter, Hill and Macleod). Catsaras lowered dogs in a diving dress to depths of 43·7 m., and after about an hour rapidly drew them to the surface. He found bubbles set free in these dogs just as in those exposed in a pressure chamber.

In animals which escape without any severe symptoms, some gas bubbles may be found in the veins even six hours later. This shows how long it may take for nitrogen gas once set free as bubbles to escape from the lungs, and explains why caisson workers may suddenly be seized some half-hour or more after leaving the works. In such cases the bubbles may be swept from the abdominal veins—where they do no harm—into the heart, and impede the action of this organ, or they may penetrate the pulmonary circulation and enter the arterial system, and block up, perchance, the coronary arteries, or others in the brain or spinal cord.

The blood is a colloidal solution, and it takes time for the nitrogen to come out of solution and for the small bubbles to run together to form visible bubbles. The gas bubbles tend to collect in the veins, as the blood travels quickly through the arteries and slowly in the veins. It is only when the gas in the veins becomes sufficient in amount to produce foam in the heart, or when gas bubbles block up arteries of vital import, that grave symptoms arise. The place where bubbles in the arteries must always produce serious results is the central nervous system. In the liver, kidneys, muscles, fat, &c., bubbles may embolise small arteries and produce no grave effect, but in the spinal cord the interruption of the blood supply to any group of cells or tract of fibres is evidenced at once by pain and anæsthesia, spasm, and paralysis. In the medulla oblongata arrest of the circulation will stop respiration, and bubbles lodging there may produce immediate death. Lodging in the arteries of the great brain, bubbles may produce hemiplegia, aphasia, blindness, or mental disturbance.

Among men some are affected and others not. We can look for an explanation in the varying state of the blood, in fatness, in the varying vigour of the circulation and respiration and the effect of fatigue, in vaso-motor changes which alter the relative volume of circulating blood in viscera and muscles, and in the fermentative processes going on in the alimentary tract. The young man who is in perfect health, with powerful heart and deep respiration, can expel the dissolved nitrogen from his lungs far more rapidly than the old, the fat, the intemperate, or one who is over-fatigued by excessive labour. The records of caisson works seem to show that most men under twenty escape, while the percentage of cases increases with age, and is highest for men above forty; that long shifts increase the number of cases; that men who work the air-locks, passing material through, and undergoing frequent and short-lasting compression and decompression, are not affected. The longer the shift the more complete the saturation of the body; the higher the pressure the greater the risks and the graver the symptoms. The records show that practically no cases occur with a pressure below 2 to $2\frac{1}{2}$ atmospheres absolute, even though the decompression period be made only a minute or two.

At the Rotherhithe Tunnel the decompression period was three minutes, and the maximal pressure +22 lb. No cases of any gravity occurred. Nevertheless, we proved that the workers had excess of nitrogen in their bodies after decompression. We gave them a quart of beer to drink in the tunnel thirty minutes before decompression to provoke diuresis, and made them empty their bladders just before, and again ten minutes after, decompression. Their urine yielded more than the normal volume of N. The urine, passed immediately after their decompression, obviously effervesced.

Influence of Fatness.

As the fat holds five or six times as much nitrogen in solution as the blood, it saturates and desaturates slowly.

J. F. Twort and I have found 35·55 per cent. of nitrogen dissolved in olive oil which had been exposed to $7\frac{1}{3}$ atmospheres. The risk of exposure to compressed air varies with the fatness of the animal (Boycott and Damant). Greenwood and I have found fat pigs weighing 100 to 120 lb. are more susceptible than smaller pigs 50 to 60 lb. The bubbles once set free in the subcutaneous fat of pigs may stay there for days after decompression, as we have found to our cost, for it has seriously damaged the sale of the animals to the butcher, since the fat does not bleed white, but remains pink and mottled. All the results prove that fat men should be excluded from compressed-air work at pressures above two atmospheres absolute.

The varying percentage of fat in the blood, chyle, and liver must be an important factor in the evolution of bubbles in the blood. The less fat in the food eaten by caisson workers the better.

Ventilation and Illness.

Much has been made of the impurity of the air as a contributory cause of caisson sickness, in particular, of the percentage of CO_2. The ventilation of the tunnels built by the London County Council under the Thames have been carried out at enormous and needless expense in order to keep the CO_2 percentage down to a very low level. The work of the English physiologists is against this view. Divers generally work with 1, 2, or even 3 per cent. of an atmosphere CO_2 in their helmets. We have exposed ourselves to 3 to 4 per cent. of an atmosphere CO_2 without untoward results, beyond increased frequency of respiration, which prevents any increased concentration of CO_2 in the body.

Recently I have carried out many experiments on students sealed up in a small air-tight chamber, and found, as Haldane has, that it is the heat, moisture, and stillness of the air which cause discomfort and fatigue, and not the excess of CO_2 or deficiency of oxygen in the air breathed. The putting on of powerful electric fans, by whirling the air and cooling the body, gives very great relief, even when there is 4 to 5 per cent. of CO_2 in the chamber.

In open-air treatment the coolness and movement of the air are the essential qualities which promote health by stimulating the activity, the metabolism, and nervous well-being of the body.

Hot, moist, still air causes fatigue by taxing the cooling mechanism of the body; blood is sent to the skin to be cooled which ought to be going to muscle and brain. Fatigue increases the danger of decompression by making the circulation and respiration less efficient. The heat causes more blood to come to the skin and a more complete saturation with nitrogen there. The cold in the decompression chamber—due to expansion of the air—causes vaso-constriction and repels the blood from the skin, and so stops its desaturation. We have lost pigs by taking them from the warm caisson into the cold air.

Over-hot and moist—that is, under-ventilated—caissons have, therefore, a higher morbidity. To secure efficient work, the wet-bulb temperature must be kept below 75° F. (Haldane). The men should not pass from a warm caisson to a cold air-lock and a cold outside world. They should go through a warm lock to a warm room.

Hot, moist atmospheres are very disadvantageous to health and work. If the wet-bulb temperature is high in the caisson, the current of air should be increased or electric fans used to cool the workers. Electric fans have enormously increased the efficiency and health of Europeans in the tropics. An excess of CO_2 in the air-lock, or diver's helmet, during decompression is favourable, as it increases the pulmonary ventilation and the outbreathing of nitrogen. Haldane advises the air-pump to be slackened purposely. There is no harm in breathing 1 or even 2 per cent. of CO_2.

Methods of Decompression.

The safety of compressed-air workers depends on the relation of the period of decompression to that of compression.

The period of the saturation or desaturation of the body with nitrogen depends on the relation between the circulating volume of the blood and the volume (1) of the tissue fluid (2) of the body fat which dissolves the nitrogen—remember the fat dissolves five or six times as much as the tissue fluid. The more often the whole volume of the blood circulates round the body, the quicker will be the saturation or desaturation. The smaller the body, the more often does the volume of blood course round it. A mouse's heart beats six hundred or seven hundred times a minute against a man's seventy (F. Buchanan). The circulation and rate of respiratory exchange are twenty times faster in the mouse. In the case of a man, the smaller man, the leaner and harder the man (less fat and tissue fluid), the quicker will his body saturate and desaturate. The rate of the circulation and percentage of fat vary in different organs. There are parts quickly and parts slowly saturated or desaturated. The joints, tendons, subcutaneous fat, abdominal fat depôts, are relatively slow parts. The white matter of the brain and spinal cord has much fat in it, while the grey matter has little fat and a more active circulation. In the white matter of the spinal cord bubbles commonly form and lead to a stoppage of the circulation there, death of the tissue, and paralysis. Bubbles in the subcutaneous fat, or fat depôts of the belly, may be compared to stones scattered in the fields, and bubbles in the spinal cord to rocks thrown down on the main railway lines of London.

Muscular work increases the circulation and pulmonary ventilation five or six, even ten, times if the work is very hard. In warm, moist caissons the cutaneous vessels are dilated, and the circulation accelerated, and this makes the saturation of the peripheral parts quicker than in the case of the diver, who is surrounded with cool water. The diver also does not work so hard and so long as the caisson worker. Therefore the caisson worker suffers far more from "bends." The diver goes to much greater pressures for short times, and after a quick decompression may suffer from asphyxia, symptoms of paralysis—arising from bubbles in the heart and pulmonary vessels, or in the spinal cord. The caisson worker when decompressed stands quiet, and is subjected to the cooling effect of the expanding air, and this constricts his cutaneous vessels and prevents desaturation of the peripheral parts. The caisson worker ought to be decompressed in an air-lock which is comfortably warmed, and he ought to exercise himself hard in order to keep up the circulation and pulmonary ventilation, and so hasten desaturation.

Haldane thinks that the body of man is about half-saturated in one hour, and about saturated in four hours. Bornstein says six or seven hours are required for saturation of the fat. Greenwood and I found that the urine secreted by the kidney is about saturated after ten minutes' exposure to four atmospheres. About twenty minutes were occupied in reaching this pressure. On decompression of a saturated animal the viscosity of the colloidal blood prevents the formation of bubbles under a certain difference of gas pressure. It is found by experience that it is safe to decompress men in a minute or two from two atmospheres to one. Since the volume of a gas is halved at two atmospheres, made one-fourth at four atmospheres, one-eighth at eight atmospheres, and the volume of a bubble is doubled on lowering the pressure from eight to four, six to three, four to two, or two to one, Haldane concluded it was safe to come rapidly from four to two, six to three, or eight to four atmospheres. The supersaturated tissues then give nitrogen to the blood, and the blood to the lungs, and the nitrogen escapes without bubbling at the half-pressure stage, where a long pause is given. Successive stages may be given when required to secure the desaturation of the body, each stage by producing a safe degree of supersaturation accelerating the outgiving of the dissolved nitrogen. The stage method of decompression initiated by Haldane, and adopted by the Admiralty, has an advantage over the uniform in that it prevents the further, and perhaps dangerous, saturation of the slow parts. Supposing a diver had been for half an hour at six atmospheres pressure; if he were decompressed on the old plan, slowly and uniformly, his fat would become further saturated up to five atmospheres while he was being decompressed from six to five atmospheres. On the other hand, if he is decompressed rapidly from six to three, the further saturation of the fat at pressures above three atmospheres is altogether prevented. The stage method is of value to divers, who go down for short periods and do not work very hard, as it prevents the saturation of slow parts and hastens the period of decompression.

Caisson workers who do four to eight hours' shift are practically saturated; but they, too, are best decompressed by the stage method, because it accelerates the outgiving of the nitrogen by producing a safe degree of supersaturation of the blood. The safety is greatly enhanced if hard muscular work is done during the pauses. This can be effected by having a series of air-locks, and making the men walk, or better, climb, between each. In the East River tunnels this method was tried with good results—(1) +40 to +29 lb. in five minutes; (2) ten minutes walking in +29 lb.; (3) +29 to $+12\frac{1}{2}$ lb. in eight minutes; (4) ten minutes walking in $+12\frac{1}{2}$ lb.; (5) $+12\frac{1}{2}$ to +0 in fifteen minutes. Lengths of tunnel were arranged between locks for walking in. Total time, forty-eight minutes. The Admiralty table enforces ninety-seven minutes for this pressure.

As there were 1·60 per cent. cases of "bends" and no serious ones, the Admiralty time is demonstrated to be unnecessarily long. This is particularly so if *hard work* is done during decompression, for the same amount of nitrogen would be expelled in about one-fifth of the time as during rest.

Greenwood and I have tested the stage method on pigs, which are more like men in shape, diet, and habit than goats—the animals used in the investigations conducted for the Admiralty Committee. It appears from our results fairly safe to decompress even fat pigs from six atmospheres to $2\frac{1}{3}$ atmospheres in about ten minutes, and then after a pause of $1\frac{1}{2}$ hours from $2\frac{1}{3}$ to one atmosphere in twenty minutes. The pigs slept quietly in the warm caisson and never moved, and, being fat, were very unfavourable subjects. One death and no severe case of illness occurred among forty-seven pigs weighing 50 to 100 lb.: one severe and three slight cases among nineteen goats weighing 30 to 57 lb. A similar decompression of fat pigs from seven atmospheres, allowing 105 to 120 minutes interval at $2\frac{1}{3}$ atmospheres, gave unfavourable results, seven deaths and one severe case—among twenty-seven pigs weighing 81 to 115 lb. Only one pig out of all showed any symptoms after reaching the stage at $2\frac{1}{3}$ atmospheres. At these very high pressures there is great risk unless time enough is given, and plenty of exercise taken during the pause.

For pressures up to four atmospheres the method employed by Mr. Yapp at the East River Tunnel is evidently a very good one. For pressure two to three atmospheres it is an advantage to do work immediately after decompression, supposing work cannot be provided between two air-locks (Bornstein). At the Greenwich Tunnel, now being built, the men climb the shaft, 60 feet high, after decompression, and since I made the suggestion, and the engineer, Mr. E. H. Tabor, carried it out, the number of cases of "bends" has dropped from 1 in 94 to 1 in 240 man-shifts. For higher pressures it would not be safe to take exercise after; it ought to be taken during decompression and the pauses between the stage decompressions. The importance of this cannot be insisted on too much. Exercise during decompression is the simplest means of rendering compressed-air work safe and of keeping the period of decompression of a reasonable length.

The question of the length of shift desirable has been much discussed. Long shifts of eight hours are found to give more illness than shifts of, say, one to two hours. Every practical caisson engineer agrees to that. Divers are decompressed in a few minutes from high pressures (five to six atmospheres) with comparative immunity if they have been down for only a few minutes. Cases of illness occur when they exceed their stay, or after a succession of dives, each of which helps to saturate slow parts and increases the fatigue of the diver. The Admiralty table fixes the period spent at the bottom so as to prevent saturation of "slow" parts and shorten the period of decompression. The descent is hastened for the same reason. It is quite safe to descend to 200 feet in two minutes; slow descents only increase risk by increasing the saturation of the body. In the matter of the caisson workers at the East River Tunnel, two three-hour shifts per diem, with three hours' rest between, gave 1·07 per cent. cases, and one eight-hour shift 0·62 per cent. cases. The men are so far saturated in three hours of hard work that doubling the decompressions is worse than extending the shift to eight hours. As bubbles may persist for a long time in the tissues, and may act as starting points for the formation of other bubbles, it is wise to give long intervals of time between shifts; also in a short interval slow parts may not become desaturated. Haldane has suggested the men should return to a "purgatory" chamber, say at two atmospheres, and eat their dinner and rest there in the mid-period of an eight-hour shift, and again at the end of the shift, when, while waiting for decompression to one atmosphere, they could wash, change their clothes, and have some hot coffee to stimulate the circulation. In any large tunnel works such a chamber could be easily constructed out of a section of the tunnel. This would suffice for stage decompression, and would give excellent results if the men could be persuaded to take exercise in it, or be given oxygen to breathe before decompression to one atmosphere.

The quickest method of desaturating the body is to "wash" the nitrogen out by breathing oxygen for a few minutes before and during decompression. The only question is the safety of this proceeding, for high concentrations of oxygen act as a poison.

Oxygen Poisoning.

(1) I have found that all kinds of animals, worms, snails, flies, spiders, frogs, &c., are instantly convulsed and killed by exposure to fifty atmospheres oxygen. (2) The frog's heart beats, nerve conducts and muscle contracts for some time in fifty atmospheres oxygen, but there is evidence of progressive diminution in functional power; the muscles behave like a fatigued muscle. (3) Mice exposed to ten atmospheres oxygen are thrown into tetanic spasm, and on being decompressed continue to be convulsed by a touch. Bubbles of oxygen are to be then found in the central

nervous system compressing the nerve cells. As the bubbles are oxygen, the cells do not die, and the animals may recover, the oxygen being absorbed by the tissues and the circulation re-established. (4) +3 atmospheres oxygen convulsed animals in thirty to sixty minutes (Bert and Lorrain Smith), and the poisonous effect, depending as it does on the partial pressure of oxygen in the blood, comes on just as soon in larger animals as in small, *e.g.* cats, rats, and mice. (5) Fatal inflammation of the lung is produced by exposure to high partial pressures of oxygen, *e.g.* after twenty-five hours' continuous exposure to +7 atmospheres of air = 170 per cent. atmospheric oxygen (Lorrain Smith). This can be prevented by using nitrogen to dilute the air, and so lowering the partial pressure of oxygen. (6) It is quite safe to breathe one atmosphere oxygen, or five atmospheres air, for three to four hours. The men who wear the Fleuss apparatus for rescue work in mines have breathed it day after day for this period. I have spent much time with Mr. R. H. Davis in perfecting this apparatus on physiological lines, and so have studied particularly the effect of oxygen on man. In very hard work there may be a deficiency of the oxygen supply in the body, and then breathing oxygen helps the working power of the man.

If the body is getting enough oxygen the breathing of it has no effect on the metabolism. The man at rest cannot be fanned into a greater rate of activity by breathing oxygen. Poisonous pressures of oxygen lower the metabolism and diminish the carbonic acid output of animals. Martin Flack and I showed that the breathing of oxygen just before a race may help an athlete, because during his great effort he uses up oxygen quicker than his respiration and circulation can provide it. A shortage of oxygen leads to the production of acid products in the tissues and blood, which causes breathlessness and stiffness of the muscles.

Lactic acid appears in the urine after a short period of hard running (Ruffel). Feldman and I have found that breathing oxygen by means of the Fleuss dress during the run prevents the excretion or lessens the amount of lactic acid excreted. Thus the pressure of oxygen helps the caisson worker to do his work more easily. During decompression the pressure of oxygen is lowered, and this is of no advantage to him.

Bornstein at the Elbe Tunnel works has breathed oxygen (90 to 95 per cent.) for forty-eight minutes at a pressure of three atmospheres. Two other engineers breathed it for thirty minutes. Bornstein freed himself from "bends" by this means. These periods are the outside limits of safety. Bornstein began to have slight convulsive movements.

For every atmosphere the body dissolves nitrogen to about 1 per cent. of its mass—for a 60 kgm. man, say, 600 to 1000 c.c. per atmosphere. Von Schrötter calculates that oxygen plus exercise would turn out 1000 c.c. in five minutes, probably more.

Oxygen can be breathed economically by means of the Fleuss apparatus, which was used so effectively in the last great colliery disaster at Bolton. The apparatus can be put on and oxygen breathed for ten minutes before and during decompression. The breathing-bag must be washed out several times with a current of oxygen, from the emergency valve provided, to accelerate the output of nitrogen.

J. F. Twort and I have investigated the effect of breathing oxygen on the volume of nitrogen dissolved in the urine. Precautions were taken to collect the urine without contact with the atmosphere. About three pints of water were drunk thirty minutes before collection of urine, so that samples could be obtained every seven minutes or so. The samples were pumped out by means of the Gardner and Buckmaster gas-pump, in which there are no taps, and leakage of air is practically nil.

I cite the results of two experiments.

(1) Breathed air at three atmospheres. After fifteen minutes emptied bladder. Sample I. collected seven minutes later at three atmospheres. Decompressed to $1\frac{2}{3}$ atmospheres in three minutes. Sample II. collected six minutes later at $1\frac{2}{3}$ atmospheres. Decompressed to one atmosphere in three minutes. Sample III. collected three minutes later at one atmosphere.

	Nitrogen	Oxygen	Pressure atm.	Nitrogen calculated (0·85 per atm.)
Sample I. ..	3·054	0·152	3	2·55
,, II. ...	2·859	0·144	$1\frac{2}{3}$	1·416
,, III. .	1·609	0·081	1	0·85

(2) At three atmospheres for forty-four minutes. Emptied bladder and breathed oxygen for nine minutes, then took Sample I. Decompressed to $1\frac{2}{3}$ atmospheres in two minutes. Took Sample II. four minutes later. Decompressed to one atmosphere in $1\frac{1}{2}$ minutes. Took Sample III. five minutes later.

	Nitrogen	Oxygen	Pressure atm.	Nitrogen calculated
Sample I. ...	2·091	0·297	3	2·55
,, II. ...	0·8835	0·1985	$1\frac{2}{3}$	1·416
,, III. ...	0·5751	0·0941	1	0·85

The results show that the urine is supersaturated with nitrogen after decompression in the first case, and undersaturated after breathing oxygen in the second case.

The ideal method, then, for safe decompression from high pressure is (1) oxygen breathing for five minutes and rapid decompression to two atmospheres; (2) pause during which oxygen is breathed and exercise taken; (3) rapid decompression to one atmosphere while oxygen breathing and exercise are continued.

The period of decompression can be notably shortened by such means, how far further experiment will show. We want to know, in particular, how the fat of the spinal cord is desaturated under these conditions. The "quick" parts are evidently put right in a few minutes. Further experiments on fat pigs should give the required information.

Recompression.

Recompression is the one method of cure for the illness. Pol and Watelle (1854) recorded the benefit of this. Men with "bends" went back under pressure. A. Smith suggested the use of a recompression chamber at Brooklyn. E. W. Moir instituted it at the Hudson Tunnel. All caisson works are now provided with such. Men at the East River Tunnel works have truly been raised from the dead by its means.

In the frog's web experiment I have observed the bubbles shrink up on recompression. Experiments on animals show that recompression must be applied at once in dangerous cases, before vital parts are killed by the interference with the circulation. "Bends" may be relieved by compression long after they have come on.

Recompression relieved 90 per cent. of the cases at the East River Tunnel, and all but 0·5 per cent. were partly relieved by its means. Oxygen breathing can be employed with advantage in the medical lock. Decompression from the lock must be slow, for some of the bubbles, having run together to form larger ones, only shrink up on recompression, and do not quickly go into solution. These expand again on decompression. J. F. Twort and I have observed this happening, and measured the bubbles under the microscope.

For deep-diving work a recompression chamber should always be at hand. I have contrived a double-chambered diving bell, one chamber open to the sea, the other closed, save for a manhole communicating with the first. The divers after completing their work enter the inner chamber and close the manhole. The bell is raised on deck, and the men decompressed by the stage method. Such a contrivance prevents exposure to cold during, or risk of storm preventing, gradual decompression in the ordinary way by the diver climbing the shotted rope.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BRISTOL.—The annual Congregation for the presentation of degrees was held on Friday, October 20. After the deans had presented the graduands in the various faculties, the following honorary degrees were conferred:—*Doctor of Letters:* Prof. Alfred Marshall; *Doctor of Science:* Mr. Arthur Prince Chattock, Prof. Julius Wertheimer, and Sir William Ramsay. The recipients of the science degree were introduced by Prof. Francis, and described as follows:—

Mr. Chattock.—For twenty-one years professor of physics in University College, Bristol, and late Henry Overton Wills professor of physics in this University. A distinguished authority in those realms of physics which he made his own. A teacher who sacrificed himself to his students, and whose wide sympathies and varied knowledge were always at their disposal.

Prof. Wertheimer.—Officier de l'Académie, B.A. and B.Sc. of the University of London, principal of the Merchant Venturers' Technical College, dean of the faculty of engineering in this University. A man who by his energy and conspicuous talent for organisation has made the Merchant Venturers' Technical College one of the leading institutions in the kingdom, and has played no mean part in the formation of this University.

Sir William Ramsay.—K.C.B., Commander of the Crown of Italy, officier de la légion d'Honneur, Ritter of the order Pour le Mérite, D.Sc. of the Universities of Oxford, Cambridge, Dublin, Columbia, Liverpool, and Sheffield; LL.D. of the Universities of Glasgow and Birmingham; M.D. of the Universities of Heidelberg and Jena; Ph.D. of the Universities of Tübingen, Cracow, and Christiania; Nobel prizeman in chemistry (1904); F.R.S.; professor of chemistry in the University of London; and late professor of chemistry and principal of the University College, Bristol. Famous for all time for his discoveries of fundamental importance in physics and chemistry, and for his marvellous realisation of the transmutation of the elements.

PROF. MICHAEL E. SADLER has been appointed Vice-Chancellor of Leeds University, in succession to the late Sir Nathan Bodington.

IT is announced in *Science* that the class of 1886 has presented to Harvard University 20,000*l.*, the income of which is to be used for the benefit of the college. From Mr. W. J. Riley, of Boston, the University has received 5000*l.* for the establishment of scholarships in memory of his nephew.

THE dissolution of the City Polytechnic in 1907 rendered a new scheme for the management of the Northampton Polytechnic Institute, Clerkenwell, necessary, and this scheme has now been sealed by the Charity Commission. The principal matter of public interest arising out of it is that it gives the governors power to appoint a president of the polytechnic; in accordance with these powers H.R.H. the Duke of Connaught, K.G., has been offered, and has accepted, the new office.

THE first issue has appeared of a new educational periodical, published in Calcutta under the title of *The Collegian*. It is described as "an all India journal of university and technical education," and will appear fortnightly, with the object of keeping its readers in touch with the work of the five Indian universities and of higher education generally throughout India. Among a very varied table of contents we find an illustrated description of the College of Agriculture at Sabour, Bengal, by Mr. D. N. Mitra. The detailed information provided about the Indian universities will prove popular among the students in them.

IN response to the appeal to raise the sum of 15,000*l.* as a building fund for the Galton Laboratory for National Eugenics, the following sums, amounting to a total of 2260*l.*, have been given, promised, or promised conditionally on the buildings being commenced within two years:—Mr. W. E. Darwin, 500*l.*; Prof. Pearson, F.R.S., and Mrs. Pearson, 500*l.*; Prof. Arthur Schuster, F.R.S., 250*l.*; Mr. E. G. Wheler (first contribution), 250*l.*; the Earl of Rosebery, 100*l.*; Lord Iveagh, 100*l.*; Major Leonard Darwin, 100*l.*; Major E. H. Hills, F.R.S., 100*l.*; Institute of Actuaries, 52*l.* 10*s.*; Mr. C. B. Edgar, 50*l.*; Mr. W. H. Macaulay, 50*l.*; Dr. E. H. J. Schuster, 50*l.*; Mr. Alfred Tyson, 50*l.*; Mr. J. Archer, 25*l.*; Mr. H. R. Beeton, 21*l.*; the Master of Trinity, 10*l.* 10*s.*; Lord Avebury, 10*l.*; total, 2219*l.* An amount of 41*l.* 16*s.* has been received in smaller sums.

THE Calcutta correspondent of *The Times* states that the Government of India is understood to be prepared to sanction the scheme of a Mahommedan University provided that the funds actually collected are adequate and that certain changes are made in the draft charter. With regard to finance, the condition laid down is that an annual income of 33,000*l.* must be secured. So far, an income of 21,400*l.* has been obtained. In this sum are included the receipts of Aligarh College, which represent a capitalised value of 446,000*l.* The campaign led by his Highness the Aga Khan has resulted in promises to the amount of 240,000*l.*, which will undoubtedly be realised, though the sum in hand is as yet only 99,000*l.* To the estimated income of 21,400*l.* must be added an annual grant of 6600*l.* which has been promised by the Government of India, leaving an additional income of 5000*l.* to be raised by the Mahommedan community.

THE council of the Zoological Society arranged last year with the Education Committee of the London County Council for a series of demonstration lectures to school teachers. The society arranged the courses, provided the lecture-room and lantern, and allowed the teachers free admission to the Zoological Gardens, while the education authority made a grant towards the expenses. The course, which was repeated three times last session to three separate sets of 150 school teachers, consisted of three lectures, illustrated by lantern-slides, and a demonstration in the gardens. This year the number of demonstrations in the gardens is to be larger, and the Education Committee has increased its grant. The first lecture for the present session took place on October 21, and was attended by nearly 150 teachers, while four parties of twenty-five teachers were taken for a demonstration tour in the gardens by the lecturer, Mr. J. L. Bonhote. To suit the convenience of teachers, all the lectures and demonstrations are given on Saturday mornings. The syllabus has been made very simple, and it is devised to cover only such subjects as are likely to interest school children and to be understood by them.

THE current issue of *The Oxford and Cambridge Review* contains an article signed "Tu ne cede malis" on "The Education of Study." The conditions of life and work at Oxford and Cambridge are criticised very frankly. At Oxford, the writer says, it is urged "that collegiate life, with all its various activities, is the main thing; that such a life moulds character, and that academic study is a secondary affair." The complexion of the universities is reflected, says the writer, in the life of the nation. "An extraordinary obsession has attacked the minds of most classes of Englishmen. It is to the effect that book-learning of any kind—apart from the three *r*'s and the like—is of very little value." The author knows men "who maintain even violently that anything like academic study is ruinous to all practical efficiency." In another place we are told: "The chief mischief is that the great world has ceased to regard professional eminence as a substantial asset, unless it be accompanied and certified by a display only possible to a man of considerable pecuniary means." The writer's conclusion is "that an educational commission of the most extensive scope is absolutely necessary"; though "our educational system stands in need of nothing more than sensible reform, not of root and branch upheaval."

THE arrangements for the Congress of the Universities of the Empire, 1912, are making progress. The Home Universities Committee, consisting of the Vice-Chancellors or other representatives of the universities of the United Kingdom, is engaged in preparing the programme of subjects to be discussed at the congress, and has had before it communications on the matter received from some of the overseas universities. The preliminary Conference of Canadian Universities, held on June 6 in view of the congress, proved a very successful gathering. Seventeen of the nineteen Canadian universities accepted invitations to appoint representatives. Dr. R. D. Roberts, secretary of the congress, was present at the conference on behalf of the London Congress Committee; and we learn from the interesting and suggestive report which he submitted to the committee that the subjects which the Canadian universities regarded as amongst the most important for discussion at the congress are the increase of facilities in the universities of the United Kingdom for post-graduate and research work, and some plan for the interchange of university teachers. It appears that the majority of Canadian post-graduate students go to the American and German universities, and not to the universities of the United Kingdom. Reasons for this are set out in Dr. Roberts's report; and it may be confidently expected that the deliberations of the congress next year will lead to some combined action to remedy this state of things, for it is clearly of supreme importance, both from the university and the imperial points of view, that able students from the King's dominions overseas should be encouraged to pursue their post-graduate studies in the Mother Country.

A copy of the annual report, for the year ended May 31, 1911, of the Rhodesia Scientific Association, has reached us. It contains, among other interesting particulars of the work of the association, the address of the retiring president, Mr. F. P. Mennell, who took education in Rhodesia as his main subject. Dealing with scientific and technical training, the president pointed out that he had exceptional opportunities of coming into contact with the men who desire technical and scientific instruction, and proceeded to propose the following plan. In the first place, he said, a building would have to be hired or erected, which might be known as the Bulawayo Technical Institute. The expenditure of 2000*l*. would probably meet all requirements in the building line, provided, of course, that the convenience of the users was given first consideration and not the fancies of architects. In the next place it would be desirable to engage a man to act as organiser and principal, in addition to teaching one or more subjects. For other teachers it would be necessary to ask the cooperation of the museum, the Geological Survey, the Government mining engineer, and even local professional men. There might thus be secured, without great expense, the services of specialists, who would each conduct a particular course. The feature of the scheme would be the shortness of the courses. Each subject would be limited to a month, every morning and afternoon being devoted during that time to the same subject, until the course was finished. Practical, that is, experimental, work would necessarily be an essential feature of each course. As subjects Mr. Mennell suggested inorganic chemistry, physical geology, agricultural chemistry and geology, determinative mineralogy, theory of ore deposits, principles of sampling and opening up mines, metallurgy of gold. Possibly, in addition, it might be found practicable to teach gold assaying and simple methods of surveying. It need scarcely be said that most of these subjects could not be effectively taught in so short a period as a month. A great deal, however, could be done in that time. In the event of more extended courses being established, the president continued, Rhodesia would only be competing unavailingly with Johannesburg, whereas the people it is desired to attract are those who cannot afford either the time or the money to go there.

SOCIETIES AND ACADEMIES.

LONDON.

Institution of Mining and Metallurgy, October 19—Mr. H. Livingstone Sulman, president, in the chair.—H. Standish **Ball**: The economics of tube milling. The investigation, of which this paper is a report, was undertaken by the author at the McGill University, Montreal, for the purpose of determining the most efficient working conditions of the tube-mill on metal-bearing ores. An experimental tube-mill was constructed, with all necessary accessories, and a series of test runs was made under various conditions of feed, moisture, pebble load, and speed, the system adopted being that in each series of tests one of the above factors was varied whilst the others were maintained as constants. Taking the experimental mill as a standard, the result of the tests was to establish certain conditions for each of the four factors mentioned as those most conducive to efficiency; and the author believes that there is a possibility of estimating from the curves obtained from the different tests the probable results that would be derived from running the mill under different conditions. He deduces from this the rather startling theory that in any mill it would be possible by a similar series of tests to obtain the necessary information for running it to the best advantage. Among other results of his experiments he was able to ascertain the duration of time required by a mill to assume a uniform condition following a change of adjustment of its various component factors, and to test the efficiency of the mill during the transition periods. Having ascertained by tests the several conditions under which the mill worked at its best, a trial was made during which the critical factors were all complied with, and the resultant mechanical efficiency was found to show an increase of 14 per cent. above all previous tests, thus seeming to bear out the utility and value of experimental work in determining the proper conditions of working.—Eugene **Coste**: Fallacies in the theory of the organic origin of petroleum. The author sets out to show that the supporters of the organic theory founded their arguments on erroneous premises, and ignore the obvious facts presented by the petroleum occurrences and deposits, which point to a volcanic origin. In proof of his own theory he directs attention to the abundance of hydrocarbon emanations noted in connection with volcanic phenomena, as showing that the sources of carbon are not confined to the organic kingdom alone. The conclusion at which he arrives is that the constant recurrence of hydrocarbons in volcanic and igneous rocks, in volcanic emanations, in metallic and other veins, in meteorites, in comets and other stellar bodies, clearly demonstrates that petroleums are not organic, as if they were their distribution could not possibly resemble the actual occurrences which are met with. The petroleum deposits are not everywhere associated with rocks of a particular age, but are found in strata of all ages, and only along some of the tectonic disturbances; where there are no such disturbances the strata are barren. These occurrences are therefore, he claims, due to dynamic disturbances accompanied by magmatic emanations from the interior, which must be held to be of solfataric volcanic nature, and unlike anything else known to be to-day in the active process of formation in nature.

PARIS.

Academy of Sciences, October 9.—M. Lippmann in the chair.—L. **Mangin**: *Peridiniopsis asymetrica* and *Peridinium Paulseni*. These two species are currently known under the name of *Diplopsalis lenticula*. By the use of a boiling solution of 5 per cent. potash the nitrogen compounds are removed, and the structure can be more easily made out. The supplemental apical plate has either been missed by previous investigators or else its presence has been considered as an anomaly. This plate, however, is always present, and indicates a separate genus.—A. **Laveran**: Are trypanosomes latent in their vertebrate hosts? An account of some experiments undertaken with a view to verify facts put forward by Salvin, Moore and Breinl, Fantham, and Hindle. The conclusion is drawn that for the trypanosomes studied, especially *T. gambiense*, there is no non-flagellated stage of evolution in the vertebrate organism, and that the elements described under the name of latent bodies correspond to different stages of involution of the trypanosomes.—G. A. **Tikhoff**: The variable star of the Pleiades. Observations for the last sixteen years of the magnitude of this star have been plotted as a curve, magnitudes as ordinates, and the time as abscissæ. The period between a maximum and minimum is shown to be 565 days, the last maximum being on January 10, 1911.—P. **Chofardet**: Observations of the Quénisset comet (1911*f*) made at the Observatory of Besançon with the 33-cm. bent equatorial. Positions are given for September 26 and 29. The comet was estimated as of the eighth magnitude, with a round head 3′ in diameter. There is no well-defined nucleus, and the tail is absent.—Paul **Lévy**: A generalisation of the theorems of Picard, Landau, and Schottky.—A. **Blondel**: The reception of periodic trains of damped waves in radio-telegraphy.—F. **Croze**: The spectrum of the negative pole of oxygen. The group of bands shown in Sturbing's photograph cannot be represented by the ordinary formula or band spectra, and the number is too small to establish a regularity with certainty. The author has discovered a new less refrangible band, and shows that the differences are analogous to the nitrogen bands.—Félix **Robin**: Pitch in alloys and its variation with temperature. In steel tuning-forks chromium raises the pitch, whilst nickel lowers it. For a nickel steel containing 30 per cent. of nickel the pitch increases with rise of temperature up to 90° C. Four alloys are suggested as suitable for standard tuning-forks, the composition being such that the pitch is practically independent of the temperature.—Mlle. E. **Feytis**: The magnetic *rôle* of water in the constitution of some solid hydrates. The additive law cannot be considered as applicable with certainty when dealing with salt molecules containing strongly electropositive metals.—G. **Charpy** and S. **Bonnerot**: The cementation of iron by solid carbon. From their experiments, published in January, 1910, the authors concluded that solid carbon could not cause cementation in iron in a vacuum; since then, new experiments by M. Weyl have led to the opposite conclusion. The results of fresh experiments are now given, and it is concluded that the cementation of solid iron by carbon at about 950° C. is absolutely *nil* in the absence of gases capable of reacting on the carbon and metal.—Robert **Pers**: An equilibrium between chloropentaminecobaltic chloride and aquopentaminecobaltic chloride in aqueous solution.—Paul **Bary** and L. **Weydert**: The apparently reversible character of the vulcanisation reaction between indiarubber and sulphur. Reasons are put forward for the view that the vulcanisation of indiarubber by sulphur is accompanied by a process of depolymerisation.—Etienne **Boismenu**: The hypobromous amides. The reaction between hypobromous acid and amides has been found to take place according to the equation

$$R-CO-NH_2+BrOH=R-CO-NH-Br+H_2O$$

in the cases of the amides of propionic, benzoic, and formic acids. The bromo-acetanilide could not be isolated owing to its instability.—A. **Behal** and A. **Detœuf**: A new derivative of urea, monochlorurea. If chlorine is passed over urea at the ordinary temperature in the proportion of one atom of chlorine to one molecule of urea, a mass is obtained which gives reactions corresponding to a mixture of monochlorurea and urea hydrochloride in equal molecules, but these two substances could not be separated by organic solvents. By modifying the conditions of the experiment, the authors have been able to isolate pure monochlorurea and to study its reactions.—P. **Gaubert**: Helicoidal structures.—R. **Souèges**: The development of the embryo in *Mysorus minimus*. For demonstrating how the first cells in a dicotyledon are formed, *M. minimus* is a better example than *Capsella Bursa-pastoris* or any other Crucifer.—C. L. **Gatin**: Experimental reproduction of the effects of the tarring of roads on the neighbouring vegetation.—Raphaël **Dubois**: New researches on the physiological light in *Pholas dactylus*. The light is the result of an indirect oxidation of an albuminoid substance (luciferine) by a peroxydase (luciferase).—G. **Faroy**: Proof of the treponeme in tertiary syphilis of the kidney with amyloid degenerescence.—Foveau **de Courmelles**: The identification of charred bodies by the X-rays. Peculiarities of the bone structure could lead to the identification of bodies so burnt as to be otherwise unrecognisable.—Ch. **Gravier**: The polychætal annelids collected by the second French Antarctic Expedition (1908–1910).—Ph. **Négris**: The importance of the Eocene in eastern Greece and the discovery of the Trias.

DIARY OF SOCIETIES.

THURSDAY, October 26.

The Concrete Institute, at 8.—Fire-proofing: R. L. Humphrey.

FRIDAY, October 27.

Physical Society, at 5.—Further Observations on the After-glow of Electric Discharge and Kindred Phenomena: Hon. R. J. Strutt, F.R.S—Homogeneous Fluorescent X-radiation of a Second Series: Prof. C. G Barkla and J. Nicol.

SATURDAY, October 28.

Essex Field Club (at Essex Museum of Natural History, Stratford) at ·.—The Natural History of British Fresh-water Leeches, with Notes on their Occurrence in Essex: Henry Whitehead.—On the Remains of Vertebrate Animals found in recent excavations at Rayleigh Castle, Essex: Martin A. C. Hinton.—Report of Club's Delegate at Portsmouth Meeting of British Association: W. Whitaker, F.R.S., and D. J. Scourfield.

MONDAY, October 30.

Aristotelian Society, at 8.—The Relations of Universals and Particulars: Hon. Bertrand Russell, F.R.S.

WEDNESDAY, November 1.

Society of Public Analysts, at 8.—Notes on Shrewsbury and Knapp's Process for Estimating Cocoanut Oil: H. S. Shrewsbury and A. W. Knapp.—Note on a Counterfeit Gold Coin: H. S. Shrewsbury.—Note on the Examination of Finnish Turpentine: L. Myddelton Nash.—Note on the Approximate Estimation of Starch by Iodine: Lester Reed.—Note on the Gravimetric Estimation of Phosphorus in Milk: E. H. Miller.—Kobert's Reagent as a Test for Salicylic Acid: J. McCrae.—Precipitation of Nickel Compounds and Preparation of Spongy Nickel: W. H. Low.

Entomological Society, at 8.—The Effect of Temperature on Animal (especially Insect) Life: Dr. A. G. Butler.—Parthenogenesis in Worker Ants: W. C. Crawley.

THURSDAY, November 2.

Royal Society, at 4.30.—*Probable Papers*—Colour Blindness and the Trichromatic Theory of Colour Vision. Part III. Incomplete Colour Blindness: Sir W. de W. Abney, K.C.B., F.R.S.—Note on the Iridescent Colours of Birds and Insects: A. Mallock, F.R.S.—The Behaviour of the Infusorian Micronucleus in Regeneration: K. R. Lewin.—An Inquiry into the Influence of the Constituents of a Bacterial Emulsion on the Opsonic Index: A. F. Hayden and W. P. Morgan.—The Morphology of *Trypanosoma gambiense* (Dutton and Todd): Colonel Sir David Bruce, C.B., F.R.S.—Preliminary Report upon the Injection of Rabbits with Protein-free (tuberculo-) Antigen and Antigen-Serum Mixtures; Factors in the Interpretation of the Inhibitive and Fixation Serum Reactions in Pulmonary Tuberculosis: A. H. Caulfeild.
