RADIO-ACTIVE ELEMENTS AND THE PERIODIC TABLE.

The Chemistry of the Radio-Elements. Part ii. The Radio-Elements and the Periodic Law. By F. Soddy. Pp. v+46. (London: Longmans, Green and Co., 1914.) Price 2*s.* net.

MR. SODDY'S contention that there exist sets of elements, incapable of separation from each other by chemical means, has much experimental evidence to support it, taken from the behaviour of some of the radio-active elements. At first sight, the argument against such a statement would appear to be similar to one applicable to the "rare elements" of the earth series, lanthanum and its congeners, viz., that the methods of separation have not yet been found. But a little consideration must show this to be untenable. It is possible to apply electroscopic tests to the radio-active elements capable of estimating their amount with an accuracy of, say, 1 per cent. Suppose, then, that a certain process of separation is applied to a mixture of three elements, one of which is radio-active; and suppose that no diminution or increase is noticed in the relative amount of the radio-active element in either portion, it is legitimate to conclude that the radio-active element is inseparable from that element by the process used. By varying the process, if no separation is still effected, it appears a legitimate conclusion that separation by a chemical process is impossible. This, of course, does not exclude separation by a physical process, supposing the atomic weights of the "inseparable" elements to differ; for it is always possible to imagine the elements in a state of gas; and it is undeniable that a mixture of gases could be separated by diffusion into its constituents, provided the gases possess different densities.

In this volume Mr. Soddy gives a diagram showing the position of the elements of high atomic weight; on the assumption that when a radio-active element loses an atom of helium, weighing 4, it joins a group of inseparable elements. Thus, to take an example:—Radium F, of atomic weight 210, in losing an atom of helium, forms a variety of lead of atomic weight 206; similarly thorium C, of atomic weight 212, gives another element which passes as lead, inseparable from lead, of atomic weight 208; similarly radium C, of atomic weight 214, in losing an atom of helium, yields radium D, of atomic weight 210, inseparable from lead. But this is not all; in the β ray changes, the element shifts its position by one place in the opposite direction to that caused by the loss of an α particle, without perceptibly changing its atomic weight; thus thorium D, losing a β corpuscle, or electron, shifts to another group—the lead group—from the thallium group to which it actually belonged, without change of atomic weight. These processes are somewhat involved; but they appear to me to be a reasonable hypothesis, although further proof is desirable. This proof is evidently to be furnished by accurate determinations of the atomic weight of lead associated with thorium minerals on one hand and with radium minerals on the other. Supposing each variety of "lead" to be pure, the sample of "thorium lead" should have an atomic weight of about 208, while that of the "radium lead" should be about 206. Determinations with this object in view are now in progress. The word "isotopic" is suggested as a fitting name for two elements, both occupying the same place in the periodic table. In his account of the theory, due credit is given to Fleck, Russell, and Fajans, the last of whom stated independently an almost identical hypothesis.

The difficulty of two elements having an identical spectrum is considerable; it is suggested that inasmuch as the spectra are characteristic of the movement of the electrons in an element, rather than of its mass, two elements in which the electrons will have identical motions must have the same spectrum. Mr. Aston's researches on two "neons," which can be separated from each other by diffusion, but which show no difference in spectrum, are adduced as proof of this point of view. It will be remembered that it was owing to Sir J. J. Thomson's finding that ordinary neon contains a small proportion of an element of atomic weight 22, which led to Mr. Aston's research. Here, again, one can only wonder that two elements, neon I. and neon II., of different atomic weights, 20 and 22, which can be separated by diffusion, according to Mr. Aston, have identical vapour-pressures, for they cannot be separated by fractional distillation.

Mr. Soddy has invented a modification of the periodic table which represents his new arrangements; it is three-dimensional.

Much of the book under review is taken up with detailed discussion of the generalisation of which a brief account has been given. The concluding section on the "Nature of the Argon Gases," puts forward the view that these elements are inactive owing to their great affinity for their valency electrons. Whereas an atom of sodium, in combining with an atom of chlorine, loses an electron to the chlorine, itself becoming an ion, an atom of argon has no such tendency, being very firmly bound to its electron.

This work of Mr. Soddy's must be termed "provisional"; it brings before the reader the state of knowledge regarding the sequence of radio-active elements, but it does more; it elaborates a hypothesis capable of correlating these facts; a very ingenious theory which, however, its author would be the first to acknowledge is still in need of support. W. R.

TECHNICAL MYCOLOGY.

(1) *Einführung in die Mykologie der Gebrauchs- und Abwässer.* By Dr. A. Kossowicz. Pp. vii + 222. (Berlin: Gebrüder Borntraeger, 1913.) Price 6.60 marks.

(2) *Die Gärungsgewerbe und ihre naturwissenschaftlichen Grundlagen.* By Prof. W. Henneberg and Dr. G. Bode. Pp. v + 128. (Leipzig: Quelle und Meyer, 1913.) Price 1.25 marks.

(1) DR. KOSSOWICZ surveys the subjects of water and sewage purification from the bacteriological point of view. To a large extent the book summarises researches that have been carried out on these subjects, though, on account of their number, the summary of each research is necessarily very brief. Its chief value consists in the contained bibliography—every page teeming with references to the literature—and the student, engineer, or hygienist desiring a guide for his practice will be bewildered by the mass of detail. Diagrams and figures of filters and filter-beds, sterilising apparatus, sedimentation tanks and plant for the biological treatment of sewage have been freely introduced, and form a useful feature.

The earlier chapters deal with the bacterial content of waters and the factors which modify it, the occurrence of pathogenic microbes in water, and the self-purification of water, and in subsequent chapters the subjects of sand-filters, chemical and other methods for the purification and sterilisation of water, sewage farms, the biological treatment of sewage, and the purification of trade effluents are considered.

(2) This little book gives a brief and simple, though at the same time excellent, survey of fermentations and the fermentation industries. The yeasts, bacteria, and moulds concerned in fermentations—alcoholic, souring of milk, acetic and butyric acids, etc.—are first described, with an account of their structure, development, and occurrence. The chemical composition of the substances fermented, the nature of the chemical changes involved, enzymes and enzyme action are next considered, and finally a description is given of the industrial processes involved in the production of beer, wine, and spirits, pressed (German) yeast, bread and vinegar, soured milk and "sauerkraut," cocoa and coffee. The text is illustrated with a number of figures of the micro-organisms involved and of the industrial plants employed in the fermentation industries.

R. T. HEWLETT.

HUMAN MATHEMATICS.

(1) *A First Book of Practical Mathematics.* By T. S. Usherwood and C. J. A. Trimble. Pp. iv + 182. (London: Macmillan and Co., Ltd., 1913.) Price 1s. 6d.

(2) *Practical Geometry and Graphics for Advanced Students.* By Prof. Joseph Harrison and G. A. Baxandall. Enlarged Edition. Pp. xiv + 677. (London: Macmillan and Co., Ltd., 1913.) Price 6s.

(3) *Practical Mathematics.* By Norman W. M'Lachlan. Pp. viii + 184. (London: Longmans, Green and Co., 1913.) Price 2s. 6d. net.

(4) *Exercices d'Arithmétique.* Enonces et Solutions. By J. Fitz-Patrick. Avec une Preface

de J. Tannery. Troisième Edition. Pp. vi+707. (Paris: A. Hermann et Fils, 1914.) Price 12 frs.

(1) IN the old days a boy had to reason in geometry "acording to the rules of the game." Many a boy felt that he must put aside common sense for fear that it might contradict the "rules," and that he must "play the game according to the rules." Hence came grotesque howlers, and the boy felt it unreasonable that grotesque results should be ridiculed, for they arose from strict adherence to rules. While in the present happy days we have altered that as regards geometry, the old method persists in algebra; the subject is treated in a purely abstract manner, it has no relation to anything in everyday life; the student can only commit to memory the rules of the game, and do his best to play the game. In this case the results also are generally abstract, so that appeal to common-sense would be impossible even if the boy allowed the validity of the appeal.

Now, however, a brighter dawn is breaking for the ill-treated boy. Usherwood and Trimble connect the algebraic work with the concrete throughout. The boy no longer has to play a game with rules he does not understand. Each algebraic process arises out of concrete instances, which are themselves easy of comprehension, and give a common-sense meaning to the process. The book is thus in the van of the movement to humanise algebra as geometry has been humanised, and in another generation no headmaster will mourn the blighting influence which $x+y$ had upon him.

The authors approve of the use of contracted methods, as do most of the best teachers at the present moment. We venture, however, to question whether these authors and teachers do well in this matter. It is customary to work to a significant figure more than will be required in the result; this generally gives the result to the required approximation, but not always. Are we to chance the accuracy, or are we to complicate the process further by an estimate of the trustworthiness of the result? Moreover, the estimation of the number of figures to be retained, even in the normal case, is a matter of no little skill; we have frequently known professors and schoolmasters of good standing to be at fault.

There appears to be no educational principle at stake, and the question is simply whether contracted methods conduce to speed and accuracy or not. Does the shortness of the contracted calculation compensate for the time spent in deciding how far to contract, and for the chance of error by excessive contraction? For the expert calculator, like the teacher of arithmetic or the observatory computer, it compensates without doubt. For ourselves, and we imagine for most people (adults and children), contracted methods in their strict form do not compensate. For us the best way is to calculate stolidly through, and at the end throw away the unnecessary figures, or if the numbers get very heavy, to contract to a modified extent, keeping, perhaps, two or three more figures than a strict contractionist would allow.

(2) Why do the universities so carefully exclude Mongian geometry from their "pure" mathematical courses? To many a pure mathematician the happening upon such a book as Harrison and Baxandall's is like the acquisition of a new sense. His ideas of solid geometry are those of Euclid's Eleventh Book, in which he is instructed to "draw a plane through three given points," or to carry out in three dimensions some construction that has been discussed in the plane, and which he had imagined was meant to be carried out on a sheet of paper with ruler and compasses. On arriving at the Eleventh Book he discovers that when Euclid says "draw a plane through three given points," he only means that three points determine a plane; on the Book I. construction carried out in three dimensions he has to put such interpretation as he can.

In course of time he happens upon a book on Practical Solid Geometry and regions unknown to Euclid and the universities. With what joy he finds that it is possible to represent points in space upon a sheet of paper, and actually possible to draw a plane through them. He wishes he was young again so that he might follow up all the wonderful consequences, actually carrying out all the constructions and not merely talking about "how it is done," as was his custom at the university. And Harrison and Baxandall would be a first-rate book to use if he could be young again. It contains the most alluring problems, wonderful in variety. There are no watertight compartments, but every branch of mathematics that can help is allowed to do so. The language, moreover, is excellent, a statement that cannot always be made of English mathematical writing.

Part III. of Messrs. Harrison and Baxandall's book is Graphics, an admirable subject, neglected in pure mathematics in the same unaccountable way as Mongian geometry. The story runs that Prof. P. G. Tait held that the analytical method was always superior to the graphical, and applied it to ascertain the stresses in the Forth Bridge. Although a man of unrivalled intellectual power he failed that time. Those days are gone, the schools are learning the value of Graphic Statics, and perhaps in time the universities may follow.

(3) Mr. M'Lachlan's book is mainly a collection of exercises in geometry, arithmetic, algebra, and trigonometry. They are all good, natural questions, straight from the workshop and other human sources. For the engineering student (for whom they are designed) they are ideal, while other students also will find much of value. The text is inferior in value, as if the writing of it had been a perfunctory task; but there is not much text, and the exercises alone are well worth the half-crown at which the price is fixed.

(4) M. Fitzpatrick's book of exercises in algebra might have been written for the express purpose of enabling English mathematicians to thank God that they are not as other men. There are 1300 questions, drawn mainly from French examination papers. The book contains all the old artificial questions which England is in process of discarding, and among the whole thirteen hundred we have been unable to find one natural problem taken straight from human life. In one particular, however, it is for the English mathematician to drop the *rôle* of Pharisee and take up that of Publican. We have nothing but praise for the clearness and exactness of the language of M. Fitz-Patrick's book, while in the first and third of the English books now under review we find carelessness of language that often produces ambiguities, and sometimes amounts to misstatement. In language we have much to learn from France. D. B. M.

OUR BOOKSHELF.

The Child: Its Care, Diet, and Common Ills. By Dr. E. Mather Sill. Pp. viii+207. (New York: Henry Holt and Co.) Price 1 dollar net.

In the modern nursery the mother requires information on many questions which used to be disregarded or left entirely to the discretion of the doctor. She now realises that in her kingdom of the nursery, preventive medicine depends to a large extent upon her care and foresight. If she provides her children with the conditions they require for healthy development, they tend to remain well and happy, and the services of the physician will be required seldom.

Dr. Sill has had a large experience of children's medicine, and, in this small volume, he has contrived to present, in simple language, much valuable information on the clothing, feeding, general hygiene, and minor ailments of children. It is an unpretentious book, admirably adapted to its purpose as a handbook for young mothers. It is well printed, and is supplied with attractive illustrations and an index.

Some useful tables are included, and a few recipes for invalid dishes, together with clear directions for the preparation of simple domestic remedies, such as the various kinds of medicated baths. The common slight ailments of childhood are described, and a list is given of the poisons most liable to invade the nursery, together with their domestic remedies.

In every treatise on infant care, the instructions for the modification of cow's milk for bottle-fed babies are apt to be involved and lengthy, and perhaps in the little volume under review the author has not been entirely successful in avoiding this fault.

The book closes with advice to parents to tell their children some elementary physiological facts about the phenomenon of reproduction and the care that they should take of their bodies. This wise advice is strengthened by suggestions as to the best way of explaining these matters to children.

Dr. Sill's book is one to recommend cordially, as it is certain to be appreciated by those for whom it is intended.

An Account of the Morisonian Herbarium in the possession of the University of Oxford. By Prof. S. H. Vines, F.R.S., and G. Claridge Druce. Pp. lxviii+350+plates. (Oxford: Clarendon Press, 1914.) Price 15*s.* net.

All who take an interest in the history of botany, and especially the history of botany in Britain, will be glad to see the second work on the Oxford Collections, which has just been issued under the joint authorship of Prof. Vines and Mr. Druce. These names are a guarantee both of accuracy and of erudition, nor will the reader fail to discover on every page of the interesting and valuable introduction a breadth of acquaintance with the old literature, as well as with sources of information by no means readily accessible. The position of the Bobarts, father and son, in relation to the carrying out of Morison's great work, is made very clear, and, incidentally, the earlier history of the Oxford Botanic Garden is well told in the letters and remarks of those who were interested in its inception and early progress.

The bulk of the work is occupied by the "Plantarum Historiæ universalis Oxoniensis, pars secunda et pars tertia." The second part of the "Historia" was issued by Morison, while the younger Bobart was entrusted with the completion of the third part. In the present work, in which the plants are enumerated, the modern reader will find the critical notes incorporated by the authors of great service in identifying the older names and descriptions. The book is a scholarly one, and well worthy of the reputation of its authors.

A Gypsy Bibliography. By Dr. G. F. Black. Pp vii+226. (London: Bernard Quaritch, 1914.) Price 15*s.* (Gypsy Lore Society, Monograph No. 1.)

For the first time, Dr. G. F. Black, of the New York Public Library, has undertaken the difficult task of compiling a comprehensive bibliography of gypsy literature. A preliminary edition of this bibliography was issued for revision by European and American scholars in 1909, and the information thus obtained has been used in the present compilation, which includes 4577 entries, accompanied by a good subject index. No attempt has been made to sift the chaff from the wheat, and many books and articles now included have obviously no claim to be regarded as scientific authorities. In a new edition it would be well to define by special type those publications which are really of value. The leading writers on gypsy lore have been fully dealt with—Borrow with 103 entries, Wlislocki, 182, and Bataillard, 41; while the work of English authorities like MacRitchie, Sampson, Thompson, and Winstedt, is adequately recorded.

The bibliography is prepared on scientific principles, and footnotes to the more important articles supply useful information. It is disappointing to note that the Oriental material has been less carefully examined than that of the West. For example, in the case of India, much second-rate material is recorded, while the records of recent ethnographical surveys, and locally published books and pamphlets have often been neglected. It may be hoped that in a new edition the libraries of the India Office, Royal Asiatic Society, the Imperial Library at Calcutta, and other local sources will be more carefully examined.

A Textbook of Domestic Science for High Schools. By Matilda G. Campbell. Pp. vii + 219. (New York: The Macmillan Company, 1913.) Price 4s. net.

HAD this book been published a few years ago in this country it would probably have been described in its title as a book of "domestic economy." It is concerned chiefly with cookery, which is regarded frankly as an art, and taught as usual by recipes. The treatment is not scientific in the proper sense, and the few chemical formulæ and statements of fact about chemistry introduced will serve only to confuse the student. Under a different title, and with some omissions, we should have here a good book on practical cookery.

The Religious Revolution of To-day. By Prof. J. T. Shotwell. Pp. ix + 162. (Boston and New York: Houghton Mifflin Co., 1913.) Price 1.10 dollars net.

PROF. SHOTWELL here publishes the William Brewster Clark Memorial lectures he delivered last year at Amherst College. These lectures are in memory of Dr. W. B. Clark, who graduated from Amherst in 1876, and their object, a foreword to the volume states, is to assist "in throwing light in a genuinely scientific spirit upon the relation of the research, discovery, and thought of the day to individual attitude and social policy." The titles of the lectures are: "Contrasts," "Devolution or Evolution?" "The Problem and the Data," and "The New Régime."

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Active Nitrogen.

A FURTHER paper by Tiede and Domcke has appeared (*Berichte*, February 7, 1914) in which it is stated that bomb nitrogen passed over copper moderately heated (to about 400° C.) is incapable of giving the glow characteristic of active nitrogen. This is held to confirm the previous statement by the same authors relative to nitrogen prepared by heating a metallic azide. In each case the result is attributed to the successful elimination of any trace of oxygen.

We have carefully repeated this new experiment, taking every precaution. All parts of the apparatus were sealed together by fusion. Its lightness was thoroughly tested, both before and after the experiment, and occluded gases were carefully got rid of. The column of copper employed consisted of rolls of the finest gauze (ninety threads to the inch), carefully reduced from the oxidised condition. Its length was 50 cm., and its diameter 17 mm. The temperature was slowly taken up from 15° C. to 480° C., without any distinct change in the intensity of the glow at any stage. The experiment has been repeated on several occasions before colleagues. A subsequent examination of the copper showed that oxidation had not proceeded for more than 8 cm. We emphatically dissent therefore from Tiede and Domcke's conclusion, in this case, as in the previous one.

The rest of their paper is an attempt to show that some of the characteristic effects can be got with oxygen only, in the entire absence of nitrogen. We must content ourselves here with saying that we do not agree with their observations, but that these would not tell against the existence of active nitrogen, even if they were correct. The conclusive fact is the capacity of the gas to react with, *e.g.* hydrocarbons, to form hydrocyanic acid. This they have not attempted to dispute.

We are glad to see that Koenig and Elöd (*Berichte*, February 21, 1914) are in agreement with us that azide-nitrogen gives the glow perfectly well.

H. B. BAKER.
R. J. STRUTT.

Imperial College of Science, March 3.

Remarkable Upper-Air Records at Batavia.

Two sounding-balloons liberated at Batavia during the present rainy season have met with exceedingly low temperatures, when entering the stratosphere at the usual height of about 17,000 metres (10·6 miles).

On December 4, 1913, −90·9° C. (−131·6° F.) was registered, and on November 5 −91·9° C. (−133·4° F.). Though in this last case the clockwork had stopped, the register may be accepted without reservation. I believe this air temperature of −91·9° C. to be the lowest on record.

On December 4 the balloon (weight 2·2 kg.) reached a height of 26,040 metres (16·2 miles), and the registering, both in the ascent and in the descent, is to be depended upon, as will be proved below. What is most remarkable in the temperature record is that from 17,000 metres upward an increase from −91·9° C.

to $-57{\cdot}1^\circ$ C. is shown, the latter agreeing with the value which is usually found in Europe. In former balloon ascents made at Batavia, temperature records have been obtained only twice for heights above 20 km. In one of those cases (August 6, 1913), an increase similar to that of December 4 was recorded, viz., $-82{\cdot}6^\circ$ C., at 17 km., and $-63{\cdot}7^\circ$ at 22 km.; in the other case, however (October 2, 1912), the temperature showed a much smaller increase (-80° C. to -75° C.), the balloon reaching 23 km.

Regarding the trustworthiness of the records, the scale-values of the thermo- and barograph may be entirely depended upon, the instruments having been subjected to thorough verification before the respective ascents.

The only seemingly prejudicial circumstance is that, though the balloon was liberated before sunrise, the sun rose above the horizon as the balloon entered the stratosphere, so that the insolation may have caused an apparent rise of temperature, notwithstanding the sun was low in the sky. Comparison of the temperature records for ascent and descent, however, prove that this has not been the case. The balloon descended at a quicker rate than it ascended; accordingly ventilation was more efficient in the downward movement, and consequently any heating effect of the sun-rays smaller. Thus we should expect higher temperatures during the ascent, even if we take into account that the sun had risen higher in the meantime. On the contrary, however, on December 4 the temperatures during ascent were lower than, and on August 6 nearly equal to, those recorded during descent. The higher temperatures in the descent on December 4 are easily explained as an effect of sluggishness of the thermograph, especially as the sign of the difference between ascent and descent changes with the temperature gradient, when going from the troposphere to the stratosphere, quite in accordance with any effect of sluggishness. The values of temperature and ventilation are given here for heights from 15 km. upwards :—

Height in km.	Temperature Ascent	Temperature Descent	Average	Temperature higher in ascent	Ventilation (m.p. sec.) Ascent	Ventilation (m.p. sec.) Descent
	°C.	°C.	°C.	°		
15	−76·4	−79·6	−78·0	3·2	0·5	1·6
15·5	−79·0	−84·0	−81·5	5·0		
16	−83·1	−89·1	−86·1	6·0	0·4	1·6
16·5	−87·1	−90·9	−89·0	3·8		
17	−89·5	−89·7	−89·6	0·2	0·3	0·9
17·5	−88·8	−85·8	−87·3	−3·0		
18	−87·4	−83·2	−85·3	−4·2	0·4	0·5
19	−81·3	−74·9	−78·1	−6·4	0·2	0·6
20	−74·5	−68·9	−71·7	−5·6	0·2	0·6
21	−69·7	−66·7	−68·2	−3·0	0·2	0·7
22	−67·8	−64·2	−66·0	−3·6	0·2	0·7
23	−64·0	−62·0	−63·0	−2·0	0·2	0·7
24	−60·0	−60·0	−60·0	0·0	0·2	0·7
25	−59·4	−59·4	−59·4	0·0	0·2	0·2
26	−57·2	−57·2	−57·2	0·0	0·2	0·2

As to the temperature gradients, it may be remarked that in the stratosphere they show a succession of low and very high ($>1{\cdot}0$) values.

I believe the remarkable behaviour of temperature in the tropical stratosphere, revealed by these upper-air soundings, will furnish a key to the explanation of the two salient features of the stratosphere, viz., the lowering of the temperature at its base and its rise in height, when proceeding from the poles to the equator.

W. VAN BEMMELEN.

Batavia, January 23.

The Vertical Temperature Distribution in the Atmosphere.

In the observations described by Dr. van Bemmelen in the foregoing letter, the vertical temperature distribution in the tropics is so typically represented that it seems worth while to consider a little more closely the essential difference between the curve obtained from them and curves obtained in temperate latitudes, and to discuss its probable cause. This difference, as Dr. van Bemmelen has pointed out already, chiefly relates to the greater height of the stratosphere and the large and rapid increase of temperature in it.

As to the vertical temperature distribution in higher latitudes, theory has already been able to give account of its principal properties. These theories (Humphreys, Gold, Emden[1]), however, deal only with those latitudes and not with the particular features of the tropical atmosphere. I will briefly formulate the results of these researches so far as they will be used in the further discussion.

(1) When convective temperature equilibrium is supposed to exist and the decrease of water vapour with height is taken into account, Gold finds that above the isobaric surface of a quarter atmosphere, radiation has a heating effect, below a cooling influence. In Europe this surface has a height of 9500 metres. With a slightly different conception as to the distribution of water vapour Emden calculates nearly the same height for the limit between heating and cooling effect, viz., 8950 metres.

(2) According to Emden, his equations used for the lower regions do not hold good in the upper part of the troposphere in consequence of the very small quantity of water vapour. Taking this small amount of vapour into account, he derives a minimum radiation temperature of -59° C. Supposing the condition in (1) to be gradually changing into those mentioned in (2), his theory fully agrees with the facts observed over the tropics.

(3) The equations of Emden show at greater elevations a gradual increase of temperature in the stratosphere, in agreement with the results of observation.

The very low temperatures, observed in the upper part of the tropical troposphere, which are about 30° C. below those observed at the same height in temperate regions, must be ascribed to another effect. Besides the radiation and the resulting vertical convection currents, which explain the principal features of the gradients in higher latitudes, in the low-pressure belt of the tropics the rising air currents of the general atmospheric circulation cooperate. They disturb the temperature distribution as determined by radiation, and shift the troposphere to greater heights.

Dr. van Bemmelen, who found at Batavia the upper limit of the anti-trade winds at about the same level as the base of the stratosphere, thereby proved that the convection currents reach as high as the upper limit of the troposphere.

Also from a theoretical point of view, it is evident that the vertical convection currents do not reach higher than the limit of strato- and tropo-sphere, as this would be inconsistent with the stability of the temperature gradients of the stratosphere; on the other hand, it is improbable that their height remains much below this limit, for without convection the high radiation temperatures would rapidly take possession of their dominion.

At higher levels the conditions in the stratosphere will rapidly approach those of the temperate latitudes at the same height. Therefore the marked increase of temperature, as shown by the observations is exactly what might be expected.

[1] R. Emden: Uber Strahlungsgleichgewicht und atmosphärische Strahlung. Ein Beitrag zur Theorie der oberen Inversion. Sitz. Ber. d. math.-phys. Klasse d. K. B. Akad. d. Wiss. zu München, 1913, Heft 1.

The upheaval of the stratosphere in the tropics may be demonstrated in a very instructive way by comparison of its height with the height of the cirrus clouds. In my opinion, as indicated below, the base of the cirrus fairly well represents the height of the hypothetical dividing surface between the cooling and heating effect of radiation for moist air (as mentioned in (1)). This surface is one of nearly uniform temperature, as shown by the temperatures of the cirrus level:—

Bossekop (70° N.L.),	height of cirrus 8·3 km.,	temp.	−45° C.
Potsdam (52° N.L.),	,, 9·2	,,	−46° C.
Batavia (6° S.L.),	,, 11·4	,,	−48° C.

Parallel to this surface runs the base of the stratosphere, the analogous dividing surface for atmospheric air (that is, for rather dry air as mentioned in (2)), with a nearly constant temperature of −55° C. The deviation from this parallel intercourse, which appears in the tropics and subtropics, in consequence of a shifting which only affects the upper surface, gives a direct measurement of the disturbing influence of the vertical convection currents belonging to the general circulation.

In the *Meteorologische Zeitschrift* of 1913 (Heft 10, p. 493) I have already discussed the question of the cirrus level as a dividing surface for radiation effects. In this paper, which may be referred to here, attention was directed to the fact that there exists an essential difference between the cloud formation in the cirrus level and above it, as compared with the lower regions, a phenomenon very evident in the quiet tropical atmosphere. The upper part of the high cumulus clouds (their height may be estimated at about 13 or 14 km.) does not, as the lower part, dissolve rapidly, but assuming a flattened form and cirrostratus-like appearance, it remains drifting along for a considerable time. This difference I attributed to a cloud-dissipating (cooling) effect of radiation in the lower, and a cloud-forming (heating) effect in the upper levels.

As a fixed amount of water radiates and absorbs more strongly in the condensed form than in the gaseous state, in the regions where radiation has a cooling effect, as in the lower strata of the atmosphere, the cooling will be relatively strong in the clouds as compared with the surrounding air. But a heating effect will be experienced in the clouds in higher levels, where radiation is heating them more intensely than the surrounding air. When left to themselves, after convection has finished, they will descend and dissolve in the first case, but, on the contrary, will be upheld or rise, and consequently prolong their existence or develop in the second case.

At that time I had not read Emden's paper. By attributing the relatively low radiation temperatures of the air at these heights to ozone, I tried to explain the circumstance of the different radiation effect observed either with regard to the cirrus clouds or to the air in which they are floating.

Perhaps such an influence cooperates, but Emden's results mentioned above may also explain the matter. It is very probable that his statement (1) may be applied to clouds on account of their large amount of water in condensed and gaseous form. In this case the limit above which radiation has a heating effect (8950 metres) is indeed situated just below the cirrus level, which at Potsdam has a height of 9200 metres. As to radiation, the conditions in the surrounding air at this height approach those mentioned in (2), and the radiation effect will still remain a cooling one. Thus the lower limit of the cirrus clouds may be regarded as the level where, for air of abundant water contents, the influence of radiation changes its sign.

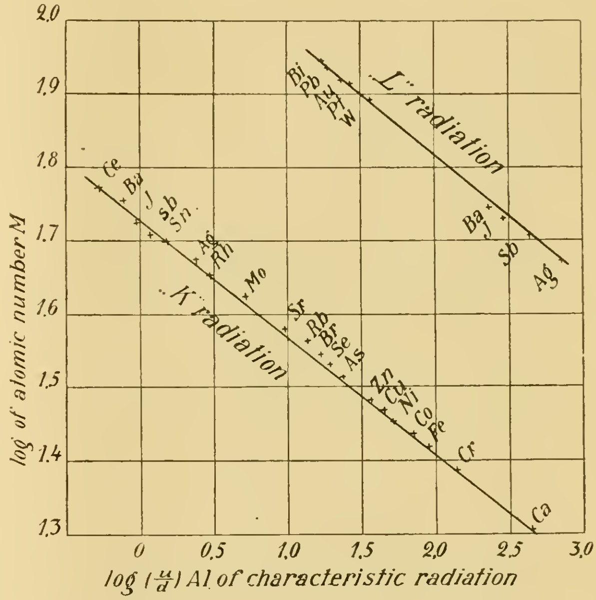
Batavia, January 23. C. BRAAK.

Atomic Models and Regions of Intra-atomic Electrons.

THAT, as concluded by Prof. Nicholson (NATURE, February 5, p. 630) the atoms of lithium, beryllium, and boron cannot consist of 3, 4, 5 electrons rotating round a nucleus of 3e, 4e, 5e, respectively, with equal angular momenta in one circular orbit, may be concluded also from the periodic system, as instead of 1, 0, 1, 2, 3 electrons of valency, we should then expect a regular increase from 0 to 5, or no valency at all. No atomic model, so far as I know, has succeeded in making this difference plausible; but it is not essential to the hypothesis, that, independently of any atomic model:—(i) Three distinct regions of intra-atomic electrons exist, the number of which (say P, Q, R) may be calculated for each atom from the periodic system; and (ii) on these numbers most, if not all, of the non-periodic properties of the elements depend, so that (NATURE, December 25, 1913, p. 476):—

(i) M = P + Q = (1) the charge on the nucleus on Rutherford's theory; (2) the number of electrons surrounding that nucleus; (3) the atomic number of an element in Mendeléeff's series.

P = (1) the number of peripheric electrons (those of



valency included); (2) $8r+p$ (p being the maximum valency and r the number of rows preceding that of the element: rare-earth period not counted).

Q = (1) the inner electrons, giving probably the characteristic radiation; (2) the number of aperiodic elements (H, He, Co, Ni, &c., and rare-earth elements).

R = (1) the free nuclear electrons of which part can be ejected as β rays (Bohr, *Phil. Mag.*, vol. xxvi., p. 501, 1913); (2) A/2 − M, if the positive part of the nucleus consists of α particles for by far the greatest part; (3) kP^2, as $A/2 - M = kP^2$ for all elements (NATURE, December 25, p. 476); and that:—

(ii) On M, or some function of it, depend (1) the large-angle scattering of α particles (NATURE, November 27, p. 372) (on M^2); (2) wave-number of the characteristic radiation for elements from nickel to zinc (on $(M-1)^2$) (Moseley, *Phil Mag.*, vol. xxvi., p. 1024, 1913); (3) the absorption of the characteristic radiation for all elements (see figure); (4) the minimum velocity of β rays required to produce it (on M or M − 1); (5) for hydrogen M only gives a possible value for the charge, and normal values for absorption, etc., while A/2 does not.

And (iii) on P, or some power of it depend (see table) (1) the percentage of the incident β radiation reflected for UrX, RaE, Act D); (2) the absorption of kathode, or β rays (see Lenard, *Ann. d. Phys.*, vol. lvi., p. 275, 1895, and Crowther, *Phil Mag.*, vol. xii., p. 379, 1906); (3) the number of nuclear electrons and β particles ejected (see Soddy, *Jahrb. Radioakt. und Elektronik*, 1913, vol. x., p. 193); (4) quanta of energy the β particle looses on Rutherford's theory (*Phil Mag.*, vol. xxvi., p. 717, 1913) in traversing the non-nuclear electrons of the atom it came from; (5) probably the decrease of velocity of α particles traversing matter (Bohr, *Phil. Mag.*, vol. xxv., p. 27, 1913). The table gives the number of electrons, causing this decrease, in approximate values.

	P	$\frac{\mu}{D}$	$\frac{10\mu}{NP^2}$	Perc. Refl. β rad.			Perc. Refl. β rad./$P^{\frac{1}{2}}$			N, Bohr
				UrX	RaE	AcD	UrX	RaE	AcD

An Early Slide Rule.

DE MORGAN, in article "Slide Rule" in the *Penny Cyclopaedia*, points out that though Gunter first used a logarithmic scale, the real inventor of the logarithmic slide was Oughtred. "In the year 1630 he showed it to his pupil, William Forster, who obtained his consent to translate and publish his own description of the instrument, and rules for using it. This was done under the following title, 'The Circles of Proportion and the Horizontal Instrument,' London, 1632; followed in 1633, by an 'Addition, etc.,' with an appendix having title, 'The Declaration of the two Rulers for Calculation.'" After referring to a republication of this work in 1660, he goes on:—"The next writer whom we can find is Seth Partridge, in a 'Description, etc., of the Double Scale of Proportion,' London, 1685. He studiously conceals Oughtred's name; the rulers of the latter were separate, and made to keep together in sliding by the hand; perhaps Partridge considered the invention his own, in right of one ruler sliding between two others kept together by bits of brass."

Prof. F. Cajori, in his book, "A History of the Logarithmic Slide Rule," 1909, the result of an exhaustive inquiry into the literature of the subject, quotes De Morgan, and continues (p. 17), "To Partridge we owe, then, the invention of the slide." In an addendum (p. vi.), and in NATURE, February 24, 1910, p. 489, he refers to a copy of Partridge's book in his own possession, published in 1662, in which it is stated that the book was written in 1657.

Dr. Alexander Russell, in NATURE, January 30, 1910, p. 307 states:—"A few years before 1671, Seth Partridge rediscovered the sliding principle, perfected it, and gave an almost complete specification for the slide rule which is used to-day by engineers. . . . Personally, I consider that Seth Partridge is the real inventor of the modern 10-in. slide rule."

My object in writing is to direct attention to the fact that there is in the Science Museum at South Kensington a slide rule which is inscribed, "Made by Robert Bissaker for T. W., 1654." This proves that the slide was invented and *in use* three years before Partridge wrote his pamphlet, and eight years before the earliest known date of its publication.

This very early example of the instrument is of boxwood, well made, and bound together with brass at the two ends. It is of the square type, a little more than 2 ft. in length, and bears the logarithmic lines first described by Edmund Gunter. Of these, the *num.*, *sin.*, and *tan* lines are arranged in pairs, identical and contiguous, one line in each pair being on the fixed part, and the other on the slide. As Seth Partridge describes no feature which is not embodied in this example of the instrument, it would appear that less credit is due to him for invention in connection with the slide rule than has hitherto been given.

In this year of the Napier tercentenary celebration it is interesting to know that a slide rule is still in existence which was made only forty years after the invention of logarithms.

DAVID BAXANDALL.

The Permeability of Echinoderm Eggs to Electrolytes.

IN 1910 J. F. McClendon showed that the electrical conductivity of echinoderm eggs is considerably increased after fertilisation, and inferred from this fact that the act of fertilisation causes an increase in the permeability of the egg-surface to electrolytes. In his recent book ("Artificial Parthenogenesis and Fertilisation") Prof. Loeb suggests that the increase in conductivity is not due to an increase in permeability, but would be produced "if in consequence of membrane-formation the degree of electrolytic dissociation of the surface film of the egg should be increased" (p. 122).

I have recently found that the electrical conductivity of unfertilised and fertilised eggs is very greatly affected by the presence of very low concentrations of simple trivalent positive ions; a concentration of 0·0002M $Ce^{\cdots}$ decreases the conductivity of the unfertilised eggs of *Sphaerechinus granularis* by as much as 40 per cent. Such solutions likewise affect the conductivity of the fertilised eggs, but to a less degree. Whereas it is almost inconceivable that these phenomena are due to a decrease in the electrolytic contents of the surface-film of the egg, I have found considerable evidence in support of the suggestion that the electrical conductivity of these eggs is determined, at least partially, by the charge on the egg-surface. As Perrin, Girard, and Mines have shown, this factor also determines the degree of permeability of membranes to electrolytes. In short, McClendon's original contention, that the increase in electrical conductivity of eggs after fertilisation is due to an increased permeability of the egg-surface, is very much more satisfactory than Prof. Loeb's suggestion.

THE BEGINNING OF ART.[1]

THE subject of prehistoric art has never failed to engage the public interest. It not only exhibits to us the beginning of all that is now embraced under the comprehensive term of Art, but it furnishes us with a more clear and precise insight into the mind of prehistoric man than can be given by any other branch of archæology. The authenticity of the records again has never, and can never, be seriously questioned by the most sceptical or the least learned in these matters.

For a long time the examples of prehistoric art were limited to carvings or gravures, the medium being bone, horn, or tooth, but since 1887, and particularly since 1901, attention has been more directly focussed upon the incised figures found on rocks, usually on the walls of caves, and not infrequently coloured with ochre. The caves so decorated are chiefly found in the Dordogne district of France, and along the Cantabrian coast of Spain.

Although the honour of first appreciating the significance of these paintings belongs to the late M. Piette, it is to the enthusiasm, ability, and labours of Abbé Breuil that we are chiefly indebted for most of our knowledge regarding them. A good example of the peculiar ability of Abbé Breuil, amounting indeed to what might be justifiably regarded as genius, for seeing things which are hidden from less acute observers, is given on pp. 146–8 of the volume on "La Caverne de Font-de-Gaume." In May, 1906, Abbé Breuil on casually looking through Abbé Parat's collection of "pierres utilisées," found on one of them what he conceived to be the head and fore part of a rhinoceros. A further more minute examination led him to the opinion that there were two silhouettes of a rhinoceros almost superimposed upon each other. M. Breuil showed the specimen to M. Salamon Reinach, who, however, was only able to decipher the two outlines when they were traced for him with a pencil. M. Boule was next shown the specimen, but expressed himself as sceptical on the matter. A few days afterwards a galvano-plastic impression was obtained at the Musée de Saint Germain, which removed all question of doubt as to the accuracy of the Abbé's opinion, as M. Boule readily acknowledged.

In the present publication Abbé Breuil has had the advantage of the cooperation of MM. Capitan et Peyrony for the French caves, and of MM. Rio et Obermaier et Père Lorenzo Sierra for the Spanish caves. Mention is also certainly due to M. Lasalle, for the very valuable and highly efficient services which he has rendered under very great difficulties in photographing the "paintings." Last but not least, we are indebted to S. A. S. le Prince de Monaco, who has shown his appreciation of the value of these records in the most practical way by undertaking their publication, increasing materially thereby the great debt which all archæologists already owe him.

Those who have seen the previous publications under the same auspices will be prepared for something as near perfection as anything can well be, nor will they be disappointed, for these books in matter and form, in text and illustration, leave nothing to be desired.

The caves in which these wall paintings are found occur in Cretaceous Limestone, and are both very extensive and tortuous. The "pictures" begin only after a certain distance has been traversed from the entrance, but this is to be explained, as the authors point out, on the ground that those at or near the entrance have become blurred and effaced by atmospheric agencies.

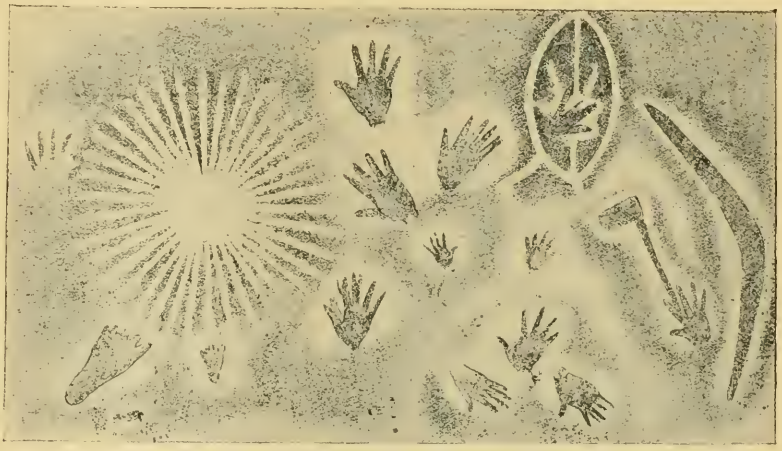

FIG. 1.—Hands, feet and weapons printed in colour on a rock in Australia (after Worsnop). From "Les Cavernes de la Région Cantabrique."

A large number of pieces of flint adapted for the purposes of drawing, and pieces of ochre suitable for colouring the figures, have been recovered from the caves, and the presumption that they were the actual instruments and material used is very strong. The date of the "paintings" may be assigned to the Aurignacian, Solutrean, and Magdalenian periods, possibly even to the end of the Mousterian. The pictures themselves are nearly all concerned with the portrayal of the larger members of the fauna existent at the period, the mammoth, rhinoceros, bison, bear, horse, deer, goat, wolf, &c. The interest attached to them is manifold. There is their intrinsic interest as works of art produced at a very remote period, there is the interest arising out of the change which takes place in the technique, and permits of our identification of no fewer than five distinct periods. Then there is the zoological interest, for the animals are so carefully drawn,

[1] "La Caverne de Font-de-Gaume aux Eyzies (Dordogne)." Par le Docteur L. Capitan, l'Abbé Henri Breuil et D. Peyrony. Pp. viii+271+lxv plates.
"Les Cavernes de la Région Cantabrique (Espagne)." Par H. Alcalde del Rio, l'Abbé Henri Breuil et le R. Père Lorenzo Sierra. Pp. viii+265+100 plates.
"La Pasiega a Puente-Viesgo (Santander)." Par l'Abbé Henri Breuil le Docteur H. Obermaier et H. Alcalde del Rio. Pp. 64+xxix plates. (Monaco: Imprimerie Artistique Vve A. Chene, 1910–13.)

with such attention to detail, that they afford very strong evidence as to the appearance of these species now in many cases extinct. Lastly, there is the interest attached to the chronological order of the paintings as it may be determined by an examination of those examples far from rare in which one figure is superimposed on another. The evidence from this source is not, however, so complete that we can tell the order in which certain animals have become extinct. We find by a curious caprice that the mammoth, for instance, in "La Caverne de Font-de-Gaume" appears only in "paintings" belonging to the first and fifth periods.

There is naturally a special interest in those frescoes in which Man himself is the subject. Unfortunately there is no clear and full representation of Man. The figure in the cave Hornos de la Peña is almost certainly not that of a man. There is, however, a very spirited delineation of a human arm in "La Pasiega," while the number of times in which the human hand is depicted is remarkable. Representations of the left hand preponderate greatly over those of the right hand, a fact which is explained no doubt rightly by assuming that man had already ceased to be ambidextrous. It is a very curious coincidence that among the native Australians the custom of drawing or painting the hand on the wall of a cave is not infrequently practised. The accompanying figures show how closely related such examples may be. In Australia the boomerang is often found associated, while in Spain instruments of a similar shape are also sometimes introduced. Naturally there are many other markings the meaning of which it is difficult to determine, "tectiform," "scutiform," "claviform" figures. It is tempting to think that some of the former are meant to represent huts, it is at any rate difficult to know what else they could be while their resemblance to the homes of primitive people in all parts of the world is striking.

The value of these important books, the great labour they have entailed, the vast knowledge they have exacted, will be readily granted when it is further noted that they include a "description raisonée" of all the animals depicted, a description based on an examination of all the art specimens extant representing the animals, whether gravure, carving, or "painting." There is again a very careful and scientific comparison made between these old examples and those of the modern African Bushman.

The books constitute, with the archæological books already published from the Monaco press, a series of classics which mark an epoch in the history of our knowledge of archæology. They enable us to view the past as through a telescope.

WILLIAM WRIGHT.

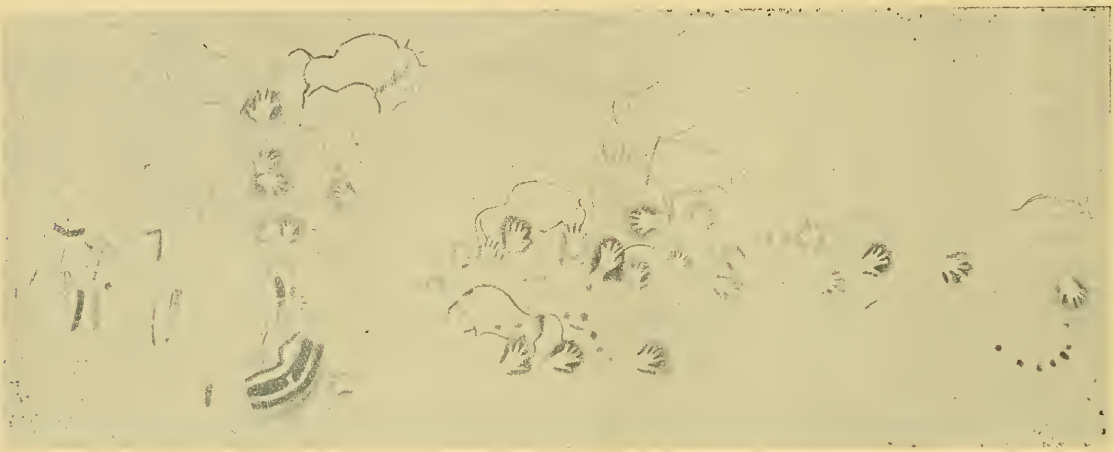

FIG. 2.—Fresco of hands, animals and weapons (?) on the wall of the cavern at Castillo. From "Les Cavernes de la Région Cantabrique."

THE HOPE REPORTS.[1]

IF anyone would undertake the task of writing the history of zoological science during the past fifty years, an interesting chapter could be written on the attitude of the leading authorities towards the work of the pure systematist.

Fewer than fifty years ago every zoologist who ventured to express his opinions on the philosophical questions that gathered round the science was a recognised authority on the systematic zoology of some one group of animals. Haeckel had studied the Radiolaria and Medusæ; Darwin wrote a monograph on the Cirripedia; Huxley contributed to our knowledge of the systematic zoology of the Siphonophora. But the time came when, for a period, the study of a special group was discouraged, and the student, passing from his course of general study, started on his investigations on embryology or morphology, without taking the trouble to become acquainted with the difficulties of systematic work, or to train himself in the observation of minute differences of structure upon which the arrangement of animals into specific groups must, in so many cases, be based.

[1] The Hope Reports. Edited by Prof. E. B. Poulton, F.R.S. Vol. viii, Appendix, 1890–1910, Including Five Sub-families of the Blattidæ. By R. Shelford. Vol. viii., 1910–13. With a Separate Appendix. Vol ix., 1911–13. The Natural History and Description of African Insects, especially the Acræine Butterflies. (Oxford, 1913.)

The value of such work was well expressed in the letter written by Huxley to Francis Darwin ("Life of Darwin," vol. i., p. 347), which begins with the sentence :—"In my opinion your sagacious father never did a wiser thing than when he devoted himself to the years of patient toil which the Cirripede book cost him."

The three volumes of the Hope reports that have recently been issued may be regarded as an indication of the revival of systematic zoology after a period of comparative neglect, and a sign that some of our best thinkers are beginning to realise that "the great danger which besets all men of large speculative faculty is the temptation to deal with the accepted statements of fact in natural science as if they were not only correct, but exhaustive."

The entomologists who are associated with Prof. Poulton in the Hope Department at Oxford are engaged in the study of large and important speculative questions, but, as these volumes show, their work is based upon the careful detailed study and descriptive statement which pure systematic work demands. They have the great advantage which the rapid growth of the collections in the Hope department affords of basing their conclusions upon the study of a very large number of specimens that have been sent to the museum from various parts of the world by the band of skilled collectors and keen observers that Prof. Poulton has interested in his work; and whether we agree with the conclusions or not, we must feel confident that the work has been done with a thoroughness and wealth of illustration that has probably been unequalled in the history of speculative zoology.

Our interest naturally centres, in the first instance, on the progress that has been made during the period, of which these volumes form the record, in the study of mimicry and protective resemblance. It has been urged so frequently as an objection to the theories of Batesian and Müllerian mimicry that the insects that are supposed to exhibit them are not subject to the attacks of birds or other vertebrates gifted with eyes that can see or be deceived by colour patterns; and that the palatability of their flesh cannot in any way be an advantage to them in their struggle for existence; that the experiments in this connection of Mr. Pocock on the palatability of British insects, and the observations of Mr. Swynnerton on butterflies attacked by birds in Rhodesia are of special interest. The negative evidence of observers who say they have never seen a particular species of insect attacked by birds is really of very little value compared with the positive evidence that is accumulating, and the onus of proof is now shifted from those who support the theory of mimicry to its opponents.

But a still more interesting discussion for the general reader upon which these volumes throw much new light is on the question of the origin of the mimetic forms. Have, for example, the four mimetic females of the well-known African butterfly *Papilio dardanus* arisen by sudden mutations, or by the natural selection of small variations from a common type? It will be difficult for Prof. Poulton to persuade the mutationists that they are wrong, that in this particular instance the many transitional forms between the dominant mimetic forms that the Hope collections include do indicate that it is by the selection of slight variations in the right direction that the similarity between the mimics and their models has been reached, but the gradually accumulating series of facts bearing upon this discussion which these volumes contain are of extraordinary value in giving those who have not yet declared themselves on one side or the other a rich harvest for their consideration.

It is in a discussion such as this that the trained eye and detailed knowledge of the systematic entomologist is of supreme value, and the weighty article by Mr. R. C. L. Perkins on the colour groups of Hawaiian wasps, and the paper by Colonel Manders on his temperature experiments on Danais and Hypolimnas in Colombo, will be read with much interest.

It is quite impossible in a short notice to do justice to the many articles of interest that the volumes contain, but special attention may be directed to the interesting address by Dr. Dixey, as president of the Entomological Society, on the effect of external influences on the germ plasm in insects, and the evidence it affords bearing on the theories of evolution, and to the essay by Mr. Guy Marshall on the limitations of the Müllerian hypothesis. To the morphologist, Prof. Poulton's memoir on the structure of the lepidopterous pupa, and Mr. Eltringham's account of the male genital armature of the species of the genus Acraea, and to the systematist Mr. Shelford's elaborate and beautifully illustrated memoirs on the Orthoptera, Mr. Eltringham's important contributions to our knowledge of the African species of the genus Acraea, Colonel Bingham's memoir on the Aculeate Hymenoptera and other shorter papers will prove to be of interest.

Prof. Poulton and his colleagues may be heartily congratulated on the extensive and important contribution to knowledge they have made during the period that is covered by these three handsome volumes.

S. J. H.

DR. MAWSON'S ANTARCTIC EXPEDITION.

DR. MAWSON has returned from the Antarctic to Australia, and readers of his message to the *Times*, recounting his wonderful escape after a month's march alone, when he had witnessed the death of two companions, will congratulate him on the courage and endurance which saved him from an end like theirs. The three were on a march of exploration south-eastward from the main base in Adélie Land, in November-January, 1912–13, when Lieutenant Ninnis fell with a loaded sledge into a crevasse. Dr. Mertz and Dr. Mawson, in the face of starvation owing to this disaster, returned to within one hundred miles of the base, when Mertz succumbed, and Mawson was only saved by the discovery of a *cache* of food left by a search party, after he had made a long and dreadful solitary journey.

Dr. Mawson's principal object was to explore that section of Antarctica which lies due south of Australia (Fig. 1). To the east of his own field of operations lies the region opened up by the work of Scott and Shackleton; to the west of the base established by his colleague, Mr. Frank Wild, a thousand miles distant in a direct line from his own, the German *Gauss* expedition was at work in 1902–03, and gave the name of Kaiser Wilhelm II. Land to its sphere of action. The intervening area was very little known; landings had not been previously made in either of the districts covered by Dr. Mawson and Mr. Wild, and the coast-line was only known—and that, as the present expedition has proved, by no means certainly—at a few points reported by expeditions made more than seventy years ago, by Balleny, by Dumont D'Urville, and by Wilkes.

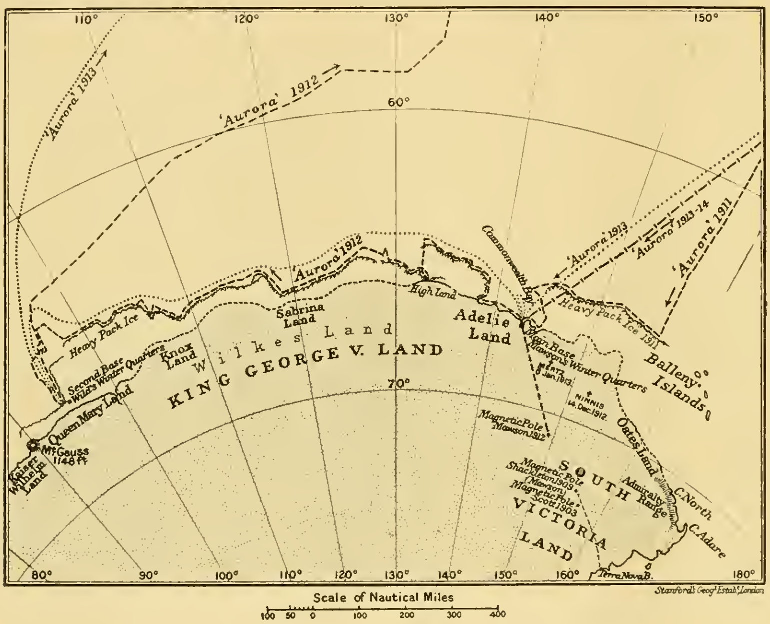

FIG. 1.—Field of operations of the Mawson Antarctic expedition.

The data are, of course, insufficient to attempt as yet any detailed estimate of the scientific value of the work of Dr. Mawson's expedition. But it must be substantial. We know something of it already from the reports of Mr. Wild and Captain J. K. Davis (who commanded the ship of the expedition), which they made on returning from the Antarctic last March.

The wireless telegraphic station established on Macquarie Island has already proved its worth, and may form the first step in a system of weather-forecasting, important not only to shipping in Australian waters, but to agriculturists and others in Australia. We hear of the discovery of minerals, including coal and copper. Exploratory journeys over the sea-ice and the continental plateau are stated to have covered 2400 miles from the main base and 800 miles from the western base. From the ship valuable results have been obtained by deep-sea dredging and other means, and the antarctic continental shelf has been traced through 55 degrees of longitude. It must also be remembered that the work of the general scientific programme has been continued at the main base through two complete years, though through one only at the western base.

NOTES.

THE following fifteen candidates have been selected by the council of the Royal Society to be recommended for election into the society:—Dr. E. J. Allen, Mr. R. Assheton, Mr. G. T. Bennett, Prof. R. H. Biffen, Dr. A. E. Boycott, Mr Clive Cuthbertson, Dr. H. H. Dale, Prof. A. S. Eddington, Prof. E. J. Garwood, Mr. T. H. Havelock, Dr. T. M. Lowry, Prof. D. Noël Paton, Mr. S. Ruhemann, Dr. S. W. J. Smith, and Dr. T. E. Stanton.

MR. J. DEWRANCE has presented the sum of 2000*l*. to the donation fund of the Royal Society. The income arising from this fund is used mainly for the promotion of experimental researches.

A YEAR ago announcement was made of a gift of 15,000*l*. to the Middlesex Hospital for the purpose of building an institute of pathology, a department greatly needed in order to raise the hospital to the standard required by modern scientific medicine. At the annual court of governors of the hospital on February 26, Prince Alexander of Teck announced that the donor was Sir John Bland-Sutton.

IN our issue of February 12 (p. 667) particulars were given of the conference of persons interested in the physical aspects of the study of the air, the earth, and the sea, to be held in Edinburgh next September. Sir John Murray is to be the president of the conference. We have since received information that arrangements are in progress for a Meteorological Congress to be held in Venice in the same month, and that meteorologists of all countries are to be invited to it. The president of the executive committee of this proposed congress is Prof. S. Urbani, director of the Patriarcal Meteorological Observatory, Venice.

THE London School of Tropical Medicine has sent an expedition to China to study the mode of dissemination of human diseases caused by trematode parasites, especially bilharziosis, and the relation of such diseases to those occurring in domestic animals. Investigations into ankylostomiasis will also be carried on. The members of the expedition are Dr. R. T. Leiper, helminthologist of the Tropical School, Surgeon E. L. Atkinson, R.N., and Mr. Cherry-Garrard. The two last-named were members of Scott's Antarctic Expedition, and the name of Surgeon Atkinson is familiar to the public as the leader of the search party which recovered the bodies of Capt. Scott and his companions. Surgeon Atkinson also made a large and important collection of Antarctic parasites, and since his return from the expedition he has been occupied in working out the helminths in collaboration with Dr. Leiper. Drawings of the helminths collected were exhibited by Dr. Leiper and Surgeon Atkinson at a recent scientific meeting of the Zoological Society. The collection of Antarctic Protozoan parasites still remains to be worked out.

THE recent review of the position of Army aviation in a statement to Parliament by the Secretary of State for War is interesting as showing the progress of aviation in England, and also the need for further improvement before aeroplanes can be regarded as having reached a satisfactory degree of development. Six years from the date of the first successful flights in Europe, it can be said that in the year just ended there were only six flying days on which flights by officers and men of the Royal Flying Corps did not take place. This is a significant indication of the rapidity of development of the science of aviation which is made still more noticeable by the statement that during this time journeys amounting to more than 100,000 miles were made without any loss of life. It appears that aeroplanes are being taken out in stronger and stronger winds, and a record of nearly seventy miles an hour stands to the credit of one of the officers of the Royal Flying Corps. In spite of such striking performances, it is clear that there is still much to be learnt. Colonel Seely pointed out the necessity for keeping 200 machines in being, so that 100 of them may be ready for use at a given time. In other words, at least half the life of a modern aeroplane is spent in the repair shop. This fact makes it necessary to attempt to raise the factor of safety of aeroplanes, and an inspection department has been organised by the War Office to deal with this aspect of the problems relating to aviation.

THE committee of the Lister Memorial Fund has commissioned Sir Thomas Brock, R.A., to execute a medallion portrait of the late Lord Lister, to be placed in Westminster Abbey. This will form part of the international memorial to commemorate the priceless services of Lord Lister to the cause of science and the alleviation of human suffering. Further subscriptions are required to enable the committee to carry out adequately the proposed scheme for the establishment of an International Lister Memorial Fund for the advancement of surgery. Among the subscriptions recently received are the following:—American Surgical Association, 135*l.*; received through Dr. W. W. Keen, of Philadelphia, 35*l.* (second donation); Committee of Surgeons in Holland, 125*l.*; faculty of medicine, University of Copenhagen, 109*l.*; members of the medical profession in Victoria (Australia), 91*l.*; Medical and Surgical Societies in Japan, 31*l.*; Union of Swedish Hospital Surgeons, 20*l.*; Newcastle-on-Tyne committee and members of the Clinical Society, 113*l.*; City of Belfast committee, 54*l.* Donations may be sent to the honorary treasurers of the fund (Lord Rothschild and Sir Watson Cheyne) at the Royal Society, Burlington House, W.

PROF. ERNST HAECKEL's eightieth birthday (February 16) has just been celebrated with natural enthusiasm at Jena. The heartiness of the congratulations from far and near must have delighted the veteran, who has had the great reward of seeing the successful development of the evolutionist doctrine of which he was an early champion. There were some noteworthy addresses summing up various aspects of his work, one of the weightiest being that delivered by Prof. Maurer, director of the Anatomical Institute, and published by Mr. Gustav Fischer, Jena. He refers to Haeckel's education and the influences of Leydig, Kölliker, and Virchow (then inclined to be an evolutionist), and still more of Johannes Müller, the "Origin of Species," and Gegenbaur. It was in the early days of his friendship with Gegenbaur that Haeckel wrote his monumental "Generelle Morphologie," in many ways the greatest of his works. We have become familiar with much of its teaching, *e.g.* that the individual development is essentially related to the racial evolution, or that classification is an attempt to discern a genealogical tree, and we are thus apt to forget what forceful new ideas these once were. Prof. Maurer directs attention to Haeckel's strong historical sense, so well expressed in the early chapters of "The Natural History of Creation," to the permanent influence that his radiolarian work (he described some 4000 new species) had throughout his life, to the extraordinary success of his educative expository writings, to his exceptional talent as an artist, to his unwavering consistency and courage, often expressed in polemical writing which gave little hint of the charm of his personality, and to the strenuousness with which he has realised the ever serious purpose of his life. Since an unfortunate accident a few years ago, Haeckel has not been able to go about, but it is delightful to hear that he is still youthful in spirit, able to follow the progress of science, and even to share in it. We would join in the congratulations which have been recently offered to him.

MR. W. CAMERON FORBES is about to start for Central and South America, for the purpose of collecting specimens of birds for the museum of Harvard University.

THE death is announced, in his seventy-sixth year, of Dr. L. Schöney, late professor of pathology and clinical microscopy in the New York Eclectic Medical College. He had made numerous contributions on botany and histology to scientific journals.

DR. R. K. DUNCAN, director of the Mellon Institute of Industrial Research, and professor of industrial chemistry at the University of Pittsburg, has died at the age of forty-five. He was a Canadian by birth, and was educated at the University of Toronto. After teaching science for several years in various American secondary schools, he was appointed in 1901 to the chair of chemistry in the Washington and Jefferson College. In 1906 he became professor of industrial chemistry at the University of Kansas, where he initiated a new scheme of industrial fellowships which has since grown to large proportions. His Pittsburg appointment dated from 1910. He discovered new processes for manufacturing glass and phosphorus.

He edited the "New Science Series," and was the author of "The New Knowledge," "The Chemistry of Commerce," and "Some Chemical Problems of To-day." Dr. Duncan was popularly known through his articles on radio-activity in *McClure's Magazine*, and on industrial chemistry in *Harper's*, for which he made special inquiries abroad.

Among the victims of the *Titanic* disaster in April, 1912, was Mr. H. Forbes Julian, whose work as a mining engineer, and for metallurgical science, was referred to appreciatively at the time in these columns (vol lxxxix, p. 325). On February 24 a memorial tablet erected by a committee which included the names of many distinguished men of science was unveiled to Mr. Julian in St. Mary Magdalene Church, Torquay, by the Ven. Archdeacon of Totnes, in the presence of a large congregation. The inscription on the tablet is as follows:—"Ad Majorem Dei Gloriam. This tablet is erected by a wide circle of friends in affectionate remembrance of Henry Forbes Julian, member of the Institution of Mining and Metallurgy, born Ascension Day, 9th May, 1861; married in this church 30th October, 1902; passed away 15th April, 1912. During the whole of his working life he laboured at the solution of metallurgical problems in three Continents, and both by his writings and practical skill exercised an influence which will long endure. He was amongst those who gave their lives for others in the disaster which befell the R.M.S. *Titanic*. This heroism and self-denial called forth admiration from the Throne to the cottage. 'Greater love hath no man than this, that a man lay down his life for his friends.'"

The duration of bright sunshine at Greenwich in February was 106 hours, which is exactly double the average of the past thirty years, and is the brightest February on record; the highest previous record for February was ninety-nine hours in 1899. In February this year at Greenwich there were twelve days with more than five hours' sunshine, whilst in July last year there were only seven days with more than five hours' sunshine. The total hours of bright sunshine in February are ten hours more than in the whole of July last year. At Kew the duration of bright sunshine in February was eighty-one hours, at South Kensington sixty-nine hours, and in the City, at Bunhill Row, 44 hours, the latter being ten times more than in January. The following gives the duration of bright sunshine at a few stations in England, chosen promiscuously from the reports of the Meteorological Office. For the several stations the duration was:—Dover, 119 hours; Hastings, 111 hours; Yarmouth, 108 hours; Margate, 106 hours (the same as at Greenwich); Brighton, 103 hours; Torquay, about 80 hours; Bath, 70 hours; Liverpool, 66 hours; and Buxton, 55 hours. The excess of sunshine in and round London is far more striking than in other parts of England.

The inaugural meeting of the Institution of Petroleum Technologists was held at the Royal Society of Arts on Tuesday, February 3. Sir Boverton Redwood, the president of the institution, who occupied the chair, said, in the course of his opening remarks, that the aims of the institution are to enable technologists engaged in the petroleum or shale oil industry to meet, correspond, and accumulate trustworthy information regarding the production or winning of petroleum and oil-shale, the conversion of the raw materials into manufactured products, and the characters and uses of these products, together with their transport and storage; and, in the second place, to promote the better education of persons desirous of becoming professional consulting petroleum technologists, engineers, geologists, or chemists, and to elevate the professional status of those employed in the industry by setting up a high standard of scientific and practical proficiency, and by insisting upon the observance of strict rules in regard to professional conduct.

At the thirty-sixth annual general meeting of the Institute of Chemistry, held on Monday, March 2, the president, Prof. Raphael Meldola, who was in the chair, referred, in the course of his address, to the endeavours of the institute to secure fuller recognition for the profession of chemistry. The council of the institute, in a memorandum submitted to the Royal Commission on the Civil Service, stated that the chemical staff in the department of the Chief Inspector at Woolwich Arsenal should be controlled by a chemist of the highest efficiency. The real expert whose knowledge and experience are of most value to the community is the highly trained man who has specialised in some particular field. Surely such a man is the most competent to control the work of any public department which is concerned with his own subject. Why, therefore, should there be this tendency to subordinate expert scientific service to non-expert control? While the medical service takes army "rank," the chemist, whose services are of equal importance, not only takes no "rank" at all, but is made responsible to superiors having no special knowledge of his subject. This state of affairs, rendering as it does the public service of chemists an unattractive career to the best talent in the profession, is fraught with danger to the future well-being of the country, and is a shortsighted policy which, in time of trouble, may well lead to disaster. Prof. Meldola then dealt at considerable length with the report of the conference of professors of chemistry, held under the auspices of the institute in October last, which was attended by professors from practically all the principal educational centres of the country, the institute thus providing an arena for the free discussion of the broad question of the education of professional chemists. Sir William Ramsay, in proposing a vote of thanks to the president for his address, endorsed the views which had been expressed with reference to placing men having no technical knowledge in the control of experts, and remarked on the absurdity of requiring them to sign reports only fully understood by the specialist.

Miss M. A. Murray discusses, in the February issue of *Man*, the evidence for the custom of killing the king in ancient Egypt, in connection with the Osiris cult, as explained by Dr. J. G. Frazer in "The Golden Bough." She interprets the name of Isis as Isé, "the throne-woman," and Osiris, or Usiri, "the occupier of the throne, the king." She notes that Arab legends of the ancient kings of Egypt mention the disappearance of two monarchs, and thus seem to preserve the tradition of the divine spirit leaving the world. The art evidence begins only from Roman times, and the ceremonial record is less conclusive, being connected with the obscure Sed festival, of which she offers a new explanation. It seems to be connected with a fertility cult. But the Egyptian evidence, though when the details are taken together, it is suggestive, is far from being so clear as the practice of king-killing among the Shilluks of Fashoda, which was fortunately recorded in time for its use by Dr. Frazer in the new edition of his great work.

THE January number of *Eugénique*, which is the monthly journal of the Société française d'Eugénique, is largely occupied by Dr. Saleeby's lecture on the progress of eugenics, which was delivered before the society on January 7. In the discussion which followed it, M. March, the head of the French Government Statistical Department, made some interesting observations on the relations between biometry and Mendelism. He pointed out that Mendel's laws themselves are statistical laws based on the theory of probabilities, while biometry is simply the application of statistical methods to biological problems. With regard to the controversy concerning the effect of alcoholism on the offspring, M. March condemns those as unscientific who criticise the results obtained by the Galton Laboratory, on the ground that they render weaker the struggle against alcoholism, and says further:—"Temperance societies know well the eternal objection made by peasants, 'Look at my neighbour; he is eighty years of age, in splendid health, and has always drunk.' On this point, as on all others, numerous observations, well conducted and well analysed, are the best means of reaching the truth."

FROM an article in the *Journal of Heredity*, vol. v., No. 2, we learn that, as the result of experiments conducted by Mr. Alexander Graham Bell in Nova Scotia, high feeding of ewes just before the autumn pairing season results in the production of a much higher percentage of female lambs than ordinary, the proportion of this sex in his flock being 72 per cent., whereas in those of neighbouring farmers there was a percentage of 88½ males.

THE first number of a new monthly journal devoted to microscopy has been issued. It is entitled *The Journal of Microscopy and Natural History Mirror*, and is edited by Mr. Edwards, the secretary of the Postal Microscopical Club, Reading. Its object is to foster the study of natural history with microscope and camera, and to help and instruct the amateur microscopist. The present number contains short articles on photomicrography, pond-life, mounting, and so on.

BULLETIN No. 36 of the Agricultural Research Institute, Pusa, India, contains a note by Major Holmes, on the McFadyean staining reaction for anthrax bacilli. This consists in staining under-fixed films with methylene-blue, by which procedure the bacilli are stained blue, and appear to be surrounded with a pale purple capsule. Major Holmes confirms the diagnostic value of this reaction, and makes the interesting observation that cattle in India rarely die of anthrax, even if inoculated with it.

IN *The American Naturalist* for February, Prof. W. E. Castle directs attention to the interest—from the point of view of Mendelian colour-inheritance—of two new colour-phases of the brown rat, respectively known to breeders as the pink-eyed yellow, fawn, or cream, and the black-eyed yellow, fawn, or cream. The former seems to have first appeared about 1910 or 1911, while the originator of the second strain, as we learn from an appendix to the paper, was brought to Liverpool by a ship in 1912. Their special interest lies in the fact that yellow phases—due to the suppression of black and brown pigment—has hitherto been unknown in this species.

A REMARKABLE instance of the needless multiplication of technical names in zoology has recently occurred in the case of Grévy's zebra. Some years ago Mr. R. I. Pocock pointed out that this species was so markedly distinct from other Equidæ as to be worthy of subgeneric separation, although he did not suggest a new subgeneric title. In 1912, Dr. Max Hilzheimer (*Abh. Senckenberg Ges.*, vol. xxi., p. 85), proposed for this species the subgeneric name, Megacephalon, which is preoccupied (1846) by a well-known genus of birds. In the same year Mr. N. Heller (Smithsonian Misc. Collect., vol. lx., No. 8, p. 1), apparently without knowledge of Dr. Hilzheimer's work, proposed the name Dolichohippus, in a generic sense. Unaware of this, Dr. A. Griffini, in an article on zebras and quaggas, orginally published in vol. iv. of *Natura* (Padua), but of which separately paged reprints have just reached this country, suggests the name, Ludolphozecora (from "Zecora," the designation by which Ludolphus alluded to the species), to replace the preoccupied Megacephalon.

A COPY has been received from Washington of the report of the secretary of the Smithsonian Institution for the year ending June 30, 1913. We learn from it that a plan has been formulated and some progress has been made in certain lines of field work for a geological survey of Panama, under the joint auspices of the Isthmian Canal Commission, the United States Geological Survey, and the Smithsonian Institution, and a grant has been made from the institution's funds toward the expenses of such investigation. The general plan of the survey comprises a systematic study of the physiography, stratigraphy, and structural geology, geological history and correlation, mineral resources (including coal, oil, and other fields), petrography and palæontology of the canal zone, and of as much of the adjacent areas of the isthmian region as is feasible. The biological survey of the canal zone, organised by the institution in 1910, was brought to a close during the year so far as field work was concerned, and some of the results have been referred to in these columns.

IT has long been recognised that a necessity exists for the improvement of the important medicinal plants.

One of the first steps necessary to inaugurate such work is to determine the variation of the active constituents in individual plants and the extent to which such variation is influenced, if at all, by the various factors affecting the growth and cultivation of the plant. Investigations in this direction have been carried out with belladonna recently, and are reported by Mr. A. F. Sievers to the new *Journal of Agricultural Research* (vol. i., No. 2). The variation in the alkaloidal content of the leaves throughout the season was determined, but no relation appeared to exist between the physical appearance of the plant and the amount of alkaloid present. It was found advisable, however, to aim for a greater yield of young leaves of rather lower content than to delay picking until higher content and lower aggregate yield is only obtainable. The plants experimented with show, among themselves, a very great variation in alkaloidal content, separation into two groups being possible, the content of the one being twice that of the other. By selection and cultural means the total production of alkaloids ought to be capable of great increase.

A REPORT by Dr. J. V. Eyre on the possibility of reviving the flax industry in Great Britain has been published as a supplement to the Journal of the Board of Agriculture. A brief historical review of the subject is given, followed by a discussion of the effect of soil, manure, climate, and cultivation, on the crop. Harvesting, retting, and subsequent treatment are described in detail, and the whole forms a valuable guide to the condition of the industry in this country. The crop has many advantages to recommend its more general adoption, especially by the small holder, provided that efforts are directed to the preparation of high grades of fibre. There certainly is reason for believing that the judicious revival of the industry, managed according to improved methods, would be productive of benefit to British agriculture, and would induce people to find regular employment in rural districts by creating a demand for skilled labour.

THE indexes to the Physics and Electrical Engineering volumes of *Science Abstracts* for 1912 have reached us. The former volume extends to 750 pages, with more than 2000 abstracts, and the latter to 670 pages, with nearly 1300 abstracts. The greater average length of the electrical engineering abstracts appears due to descriptions of installations and appliances. The initials of the abstractor at the foot of each abstract and a reference to the list of abstractors at the beginning of each volume, show that in nearly all cases the abstract has been written by one who has a special knowledge of the subject, and so long as this characteristic of Science Abstracts is maintained, so long will it continue to enjoy the confidence of those who make use of it. The indexing appears adequate, the name-index in the physics volume covering thirty and the subject-index fifty-six pages.

WE have received from the Reichsanstalt a number of memoirs dealing with the work done there, which have appeared in recent numbers of the *Annalen der Physik*, the *Zeitschrift für Instrumentenkunde*, and other periodicals. One by Dr. F. Henning deals with new determinations of the boiling points of oxygen and carbonic acid, and the freezing points of mercury and other liquids. The temperatures were measured by five platinum resistance thermometers, which had been previously compared with the constant volume hydrogen thermometer. The static method was used for the boiling points. The results are:—Normal boiling points: Oxygen, -182.97°, carbonic acid, -78.53; freezing points: mercury, -38.89, ethyl ether, -123.6; melting points, carbon bisulphide, -112.0, chloroform, -63.7, chlorobenzene, -45.5° C. Others by Drs. W. Jaeger and H. von Steinwehr deal with comparisons of various copies of the ohm amongst each other and with the mercury standard, and with current measurements with the silver voltameter. They show that the German ohm agrees with the English to within a few hundred thousandths, and that the electromotive force of a Weston cell is 1.01829 volt at 20° C.

THE White Star liner *Britannic* was launched from Messrs. Harland and Wolff's yard at Belfast on February 26. The following particulars of this vessel are taken from illustrated articles in *Engineering* and the *Engineer* for February 27. The principal dimensions are:—Length over all, about 900 ft.; breadth, extreme, about 94 ft.; depth moulded, 64 ft. 3 in.; total height from keel to navigating bridge, 104 ft. 6 in.; gross tonnage, about 50,000 tons; propelling machinery—reciprocating engines of 32,000 i.h.p. exhausting into a Parsons low-pressure turbine of 18,000 shaft-horse-power; sea speed, 21 knots. Accommodation is provided for 2,579 passengers and 950 crew, a total of 3,529 persons. The vessel is probably the strongest passenger ship structurally constructed up to the present time, and is so amply divided by longitudinal and transverse bulkheads that her destruction by any dangers of the sea is incredible. The double system of construction is carried up the sides of the vessel to a considerable distance above the load water line, and the walls are literally honeycombed with compartments. None of these compartments will be opened on the inner side during a voyage. There are sixteen transverse bulkheads, five of which extend to a height of more than 40 ft. above the deepest load line, and all the others are carried to a height of more than 21 ft. above the water line. The bulkheads are of very heavy construction. The lifeboat arrangements will meet fully the requirements of the recent International Convention.

MESSRS. FLATTERS AND GARNETT, LTD., have issued a supplementary catalogue of the lantern slides added to their stock during 1913. Among these additions are a large number of photographs of British wild flowers and a series of slides illustrating the commercial geography of the north of England, arranged by Dr. A. Wilmore.

AMONG recent additions made by Messrs. Jack to their "People's Books" are "Applications of Electricity for Non-Technical Readers," by Mr. A. Ogilvie, and "Wild Flowers," by Mr. M. Skene. The first book explains in simple language, which takes no previous knowledge of the science for granted, the elementary facts upon which the chief everyday applications of electricity are based. The volume on wild flowers contains two hundred black and white illustrations of common flowers, and descriptions of these and others arranged in chapters according to their colours. Thus we have chapters on white, yellow, red, blue, flowers, and so on. The price of each volume in the series is 6*d.* net.

OUR ASTRONOMICAL COLUMN.

STARS WITH VARIABLE RADIAL VELOCITIES.—In the *Astrophysical Journal* for January (vol. xxxix., No. 1, p. 39) Mr. Oliver J. Lee contributes numerous measures of variable radial velocities of stars determined in the course of measuring Bruce spectrograms. Of the twenty-eight stars to which reference is made, eighteen have been previously announced as spectroscopic binaries, but the remaining ten are new. The following table is abstracted from the information given in the paper, and indicates the star in question, position, magnitude, and class :—

Star	R.A. h. m.	Dec. ° ′	Mag.	Class
89 *f* Piscium	1 13	+ 3 5	5·3	A_2
73 ξ^2 Ceti	2 23	+ 8 1	4·3	A
125 Tauri	5 34	+25 50	5·0	B_3
40 Aurigæ	6 0	+38 30	5·3	A

SUN-SPOTS: THEIR INTERNAL MOTION AND SHORT-PERIOD VARIATIONS.—The fifth volume of the *Publikationen der Sternwarte des Eidg. Polytechnikums zu Zurich* contains two contributions, the first by William Brunner, on the investigation of the internal motions in sun-spots, and the second by Elsa Frenkel, on short-period variations in the frequency of sun-spots. The former is a detailed research, carried out in a systematic manner, on the internal motions, chiefly divergent. The chief result leads the author to associate this divergent motion with the origin and development phases of spot groups. The data employed were those of the period between January 1, 1887, and January 1, 1905, and were the result of observations made with the refractor of the Zurich Observatory. Numerous plates accompany the text. The second paper involves the discussion of the Zurich observations made during the period 1876–1911. Readers must refer to the original publication for the detailed account of the research, but the chief conclusions may be stated briefly as follows. The author finds a probable period of 200 days, but this is not apparent during the last three eleven-year periods, when the spot activity went below a certain limit. The length is not constant, but varies about a mean value of 150 to 200 days. The ordinate of the periodigram is about 100 times smaller than the eleven-year period, and the amplitude about ten times smaller than that of the eleven-year period. Another period of 68·5 days was indicated, but this will be investigated again at a later date. Attention is directed to the lengths of these two periods, namely 200 and 68·5 days, and the sidereal times of revolution of the two inner planets, namely Mercury, 87·9 days, and Venus, 224·7 days. The text is accompanied by a large number of plates showing the observed and smoothed curves of the daily relative numbers.

DETERMINATIONS OF GRAVITY IN EGYPT AND THE SUDAN.—Survey Department Paper No. 18 (Cairo) contains details of the determination of "g" at eight stations in Egypt and the Sudan, carried out by Mr. P. A. Curry, in connection with the geodetic survey. Almost the whole of the observations and the whole of the computational work have been done by Mr. Curry himself. The stations range from Helwân to Khartoum, nearly 15° of latitude, and the height above sea-level varies from 42 to 383 metres, but the topographical correction has been *nil* for each of the stations. The Stuckrath pendulum apparatus employed was borrowed from the South Kensington Museum, where it had been deposited after the return of Captain Scott's first Antarctic Expedition. This instrument provides essentially for the determination of the time of oscillation of each of a number of invariable pendulums swinging in separate cells of a vacuum chamber. Besides the correction due to the rate of the chronometer, *four* instrumental corrections need to be determined, namely, for temperature, pressure, amplitude of vibration, and flexure of pillar. Kew was taken as the base and Helwân was made the primary Egyptian station. 981·201 cm./sec.^{2} (based on the Potsdam system) was adopted as the value of "g" at Kew, and from a discussion of *ninety-eight* separate determinations 979·295 cm./sec.^{2} was obtained as the final value of this constant at Helwân, the probable error being ±0·0027. The values obtained for each of the stations have been reduced to sea-level and compared with the theoretical value for the latitude of the station given by Helmert's formula (1901). Remarkably close agreement obtains, ranging only between +0·009 and −0·013, whence it is concluded that there is nothing very abnormal about the values of gravity at these eight stations.

THE COBAR COPPER FIELD.

COBAR, on the western plains of New South Wales, 464 miles by railway from Sydney, is one of the most important, though not most profitable, of the copper fields in Australia; it yielded 6500 tons of copper in 1911, and has produced more than 90,000 tons since its discovery in 1869. The development of the field was hampered by its remote position and its semi-arid climate, for with a rainfall of only 15 in. it is surrounded in dry seasons by a wide, waterless tract. In its early days, however, the export of ore was once stopped by floods, which inundated the plains beside the Darling River for a width of fifty miles. Another trouble was an invasion in 1890 by millions of rabbits, which destroyed the vegetation by devouring the shrubs and ring-barking the trees.

The rocks of the mining field belong to three main divisions.[1] The oldest is the Cobar Series, which comprises semi-metamorphic sediments of perhaps pre-Silurian age; its most important member consists of thick beds of chert, which Mr. Andrews regards as a recrystallised organic precipitate. The account of these beds suggests their resemblance to the Heathcotian Series of Victoria, which are of Cambrian age. The middle division, the Mallee Tank beds, includes fossiliferous limestones, and its age is certainly Silurian. The upper division is Devonian, and includes a varied series of quartzites, shales, and claystones. The rocks of all three divisions have been disturbed by intense compression due to earth movements at the beginning and at the end of the Devonian period. The pressure was so powerful that the minimum dip observed in the Silurian rocks is 30°, and the Devonian

[1] E. C. Andrews: Report on the Cobar Copper and Gold-field. Part i. (Department of Mines, New South Wales, Mineral Resources, No. 17). 1913, xi. Pp. 207+xlv plates+19 maps in separate portfolio.

rocks have been overthrust and the pebbles in the conglomerates sheared and shattered. One striking feature of this mining field is the rarity of igneous rocks; they are represented only by two small pipes of orthoclase-porphyry, which appear to have no connection with the ores. The mineral deposits are attributed by Mr. Andrews to the post-Devonian earth movements. Certain features suggested that they might be bedded ores; but, as so often happened with ores so regarded, more detailed study has shown that they are of secondary origin. They have been formed in connection with great fault movements and by the replacement of slate by sulphides. This conclusion is definitely established by Mr. Andrews's excellent monograph, which includes a detailed account of the geology, history, and mines of this field.

The chief copper-bearing mineral is chalcopyrite, and it is associated with pyrrhotite, ordinary iron pyrites, and a silicate of iron, which is identified by Mr. Card as ekmannite. The ores have undergone great secondary concentration, which Mr. Andrews attributes, with great probability, to the arid climate and prolonged stability of the field. Ever since the post-Devonian disturbances the country does not appear to have been affected by any earth movements except some minor oscillations; and the level has only been lowered by denudation about 200 ft., according to Mr. Andrews's estimate, during all later geological times. The chemical analyses are of especial value owing to the determination of an unusually large number of constituents. The description of the field is illustrated by a series of plates, some of which are coloured, showing the intimate structure of the ores and the relation of their constituent minerals; and the memoir is accompanied by a portfolio of maps and mine plans. All the separate mines are described in detail. The discussion of the ores shows wide acquaintance with the recent literature on the subject, and the author's conclusions command respect owing to the obvious care and accuracy with which the work has been conducted. The author's view that magnetite is formed only under conditions of great heat is perhaps too general, and the remark that the Murray River enters the sea near Adelaide might mislead a reader who is not used to judging proximity by Australian standards of distance. J. W. G.

PUBLIC HEALTH.

WE have received the report, for 1912–13, of the Medical Officer of the Local Government Board. There is no greater authority than Dr. Newsholme on all matters of public health, and every page of his report should be read by all who care for our national health and efficiency. Among many other subjects of interest, he directs attention to the practical problems of "typhoid carriers," the present rather threatening facts of cerebro-spinal fever and poliomyelitis, and the contrast of the steady decline of scarlet fever, diphtheria, and typhoid, with the obduracy of measles. Of smallpox, 121 cases were notified during 1912 in England and Wales, but only nine died. It may be worth noting that, in one household, three small children died, whose parents had declined vaccination for them.

Tuberculosis, naturally, occupies a great part of Dr. Newsholme's report. For, beside the grant of some 60,000*l*. annually for research, the year 1912–13, as Dr. Newsholme says, "will always stand out as a landmark in the history of the administrative control of tuberculosis. During this year the Board made all forms of tuberculosis compulsorily notifiable; the provisions of the National Insurance Act, 1911, as to sanatorium benefit, came into operation; the capital grant under the Finance Act, 1911, of $1\frac{1}{2}$ millions sterling for the provision of institutions for the treatment of tuberculosis in the United Kingdom, became available; and the important offer was made by the Treasury to defray one-half of the annual cost of schemes for the treatment of tuberculosis, proposed by local authorities and approved by the Local Government Board, which are available for the entire population, after deducting any contribution received from the local insurance committee or from other sources." Other points of interest, in Dr. Newsholme's report, touch the work of the Medical Department of the Board; the work of the International Health Office, the International Sanitary Conference in Paris, 1912, and other services rendered to the public by the Medical Department.

After Dr. Newsholme's report, come Dr. Bruce Low's admirable and authoritative monographs on plague, cholera, and yellow fever, giving a full account of the incidence on the world, during 1911 and 1912, of these three scourges. Then comes a great number of shorter reports. Altogether, this volume is of singular value to all who are concerned—and who is not?—with the health and safeguarding of our country.

FORTHCOMING BOOKS OF SCIENCE.

AGRICULTURE.

A. and C. Black.—The World's Cotton Crops, Prof. J. A. Todd, illustrated. *Crosby Lockwood and Son.*—Agriculture: Extensive and Intensive, Prof. J. Wrightson, in conjunction with J. C. Newsham.

ANTHROPOLOGY AND ARCHÆOLOGY.

John Bale, Sons and Danielsson, Ltd.—Hausa Folk-Tales, Major A. J. N. Tremearne. *Chatto and Windus.*—A History of Babylonia and Assyria from Prehistoric Times to the Persian Conquest, L. W. King, illustrated, vol. ii., A History of Babylon from the Foundation of the Monarchy to the Persian Conquest, vol. iii., A History of Assyria from the Earliest Period to the Fall of Nineveh. *Constable and Co., Ltd.*—Amulets, Prof. W. M. Flinders Petrie, F.R.S., illustrated; Kinship and Social Organisation, Dr. W. H. R. Rivers, F.R.S. *Macmillan and Co., Ltd.*—Knossian Atlas, edited by Sir A. J. Evans, F.R.S., vol. i., The Wall Paintings, including coloured lithographic plates i.-xiii., from drawings by E. Gilliéron, with short descriptive sketch by the editor (to which are appended Lumière illustrations), and Notes on the Technique of the Frescoes by N. Heaton; The Nine Minoan Periods, a Summary Sketch of the Characteristic Stages of Cretan Civilization, from the Close of the Neolithic to the Beginning of the Iron Age, Sir A. J. Evans, F.R.S., illustrated; The Eastern Libyans, O. Bates, illustrated; Marriage Ceremonies in Morocco, Prof. E. Westermarck; The Native Tribes of the Northern Territory of Australia, Prof. W. B. Spencer, C.M.G., F.R.S., illustrated. *The Medici Society, Ltd.*—Mexican Archæology: An Introduction to the Archæology of the Mexican and Mayan Civilizations of Pre-Spanish America, Thomas A. Joyce, illustrated. *Methuen and Co., Ltd.*—The Nomads of the Balkans, A. J. B. Wace and M. S. Thompson, illustrated. *Oxford University Press.*—Contributions to Anthropology: vol. i., Coos Texts, J. Frachtenberg, vol. ii., The Ethnology of the Salish Tribes, J. A. Teit. *G. P. Putnam's Sons.*—The Folk-Ballads of Southern Europe, S. Jewett. *Williams and Norgate.*—The Antiquity of Man, Prof. A. Keith, F.R.S.

BIOLOGY.

F. Alcan (Paris).—Transformisme et Créationisme, Prof. J. L. de Lanessan. *D. Appleton and Co.*—Plant Breeding, J. M. Coulter. *A. and C. Black.*—Wild Life in the Woods and Streams, C. A. Palmer, illustrated; Common British Beetles, Rev. C. A. Hall, illustrated (Peeps at Nature Series). *Cambridge University Press.*—The Cambridge British Flora, Dr. C. E. Moss, assisted by specialists in certain genera, illustrated, vol. ii., The Earlier Dicotyledonous Families; The Philosophy of Biology, J. Johnstone; Bird Studies, W. P. Westell (Cambridge Nature Study Series); Pond Problems, E. E. Unwin (Cambridge Nature Study Series); The Annals of the Bolus Herbarium, vol. i., part 1, edited by Dr. H. H. W. Pearson. *Cassell and Co., Ltd.*—The Progress of Eugenics, Dr. C. W. Saleeby; Rock Gardening for Amateurs, H. H. Thomas, illustrated; Wild Flowers as They Grow, H. E. Corke and G. C. Nuttall, illustrated, Series vi. and vii.; Dogs and All About Them, R. Leighton, illustrated. *J. and A. Churchill.*—The Horticultural Record, R. Cory, illustrated. *J. M. Dent and Sons, Ltd.*—A History of Botany, Prof. J. R. Green, F.R.S. *Duckworth and Co.*—Glossary of Botanical Terms, Jackson, new edition. *W. Engelmann (Leipzig).*—Die Vegetation der Erde, edited by Profs. A. Engler and O. Drude, Band ix., A. Engler, Die Pflanzenwelt Afrikas insbesondere seiner tropischen Gebiete, Band iii., Charakterpflanzen Afrikas II., Archichlamydeen, Dikotyledoneen, Angiospermen, Heft. 1. *G. Fischer (Jena).*—Die Entstehung der Pflanzengallen, Prof. W. Magnus, illustrated; Tafeln zum Vergleiche der Entstehung der Wirbeltierembryonen, Prof. A. Greil. *W. Heinemann.*—Animal Life in Africa, Major Stevenson-Hamilton, four parts, illustrated, part i., Carnivora. *H. Holt and Co. (New York).*—Essentials of College Botany, Profs. C. E. Bessey and E. A. Bessey, eighth edition, entirely revised and rewritten of Bessey's Essentials of Botany; Students' Handbook of Botany, F. L. Sargent; General Zoology, Prof. E. G. Conklin; Economic Zoology and Entomology, Prof. V. L. Kellogg and R. W. Doane. *Hutchinson and Co.*—Insect Artisans and their Work, E. Step, illustrated. *C. H. Kelly.*—Sea-Side Wonders, and How to Identify Them, S. N. Sedgwick, illustrated. *Longmans and Co.*—Flowering Plants of the Riviera, H. S. Thompson, with an introduction on Riviera Vegetation, by A. G. Tansley, illustrated. *Macmillan and Co., Ltd.*—The History and Theory of Vitalism, Prof. H. Driesch, authorised translation by C. K. Ogden, revised throughout and in part rewritten by the author for the English edition; The Problem of Individuality, lectures delivered before the University of London, Prof. H. Driesch; A Treatise on Embryology, edited by W. Heape, F.R.S., vol. i., Invertebrata, Prof. E. W. MacBride, F.R.S., illustrated; Physiological Plant Anatomy, Prof. G. Haberlandt, translated by J. M. F. Drummond, illustrated; Cocoa, Dr. C. J. J. van Hall, illustrated. *Methuen and Co., Ltd.*—Diversions of a Naturalist, Sir E. Ray Lankester, K.C.B., F.R.S., illustrated; Some Minute Animal Parasites, Dr. H. B. Fantham and Dr. A. Porter, illustrated; Spade-Craft, H. A. Day. *John Murray.*—Trees and Shrubs Hardy in the British Isles, W. J. Bean, 2 vols., illustrated; Concerning Animals and other Matters, E. H. Aitken, with a memoir of the author, illustrated; The Genus Rosa, Ellen Willmott, illustrated, concluding part. *Quelle and Meyer (Leipzig).*—Fauna von Deutschland, edited by Dr. P. Brohmer, illustrated; Lehrbuch der allgem. Botanik, by R. Heuer, illustrated; Leitfaden für biolog. Schülerübungen, by Dr. R. Rein, illustrated; Biologische Beobachtungs-aufgaben, by Dr. L. Spilger, illustrated; Garten und Landwirtschaft, Prof. E. Hahn, Die Süsswasserflora, by Prof. H. Glück, illustrated. *Williams and Norgate.*—All About Leaves, the late F. G. Heath.

CHEMISTRY.

D. Appleton and Co.—Chapters from the History of Chemistry in U.S.A., E. F. Smith. *J. and A. Churchill.*—The Synthetic Use of the Metals in Organic Chemistry, A. J. Hale. *G. Fischer (Jena).*—Grundzüge der chemisch-physikalischen Theorie des Lebens, Dr. H. Lundegardh. *Longmans and Co.*—An Introduction to the Study of Organic Chemistry, H. T. Clarke. *Macmillan and Co., Ltd.*—A First Book of Chemistry, W. A. Whitton. *Methuen and Co., Ltd.*—A Third-Year Course of Organic Chemistry, Dr. T. P. Hilditch. *John Murray.*—A First Book of Chemistry, W. D. Rogers. *University Tutorial Press, Ltd.*—Chemical Calculations, H. W. Bausor.

ENGINEERING.

Cassell and Co., Ltd.—Railway Wonders of the World, F. A. Talbot, vol. ii., illustrated. *Constable and Co., Ltd.*—Gas Turbines, N. Davey, illustrated; Single-phase Electric Railways, E. Austin. *Longmans and Co.*—Some Considerations Regarding Cast Iron and Steel Pipes, J. Sharp, with diagrams. *G. Routledge and Sons, Ltd.*—Railways of the World, E. Protheroe, illustrated. *Seeley, Service and Co., Ltd.*—Submarine Engineering of To-day, C. W. Domville-Fife. *University Tutorial Press, Ltd.*—Electrical Engineering, W. T. Maccall. *Whittaker and Co.*—Modern Illuminants and Illuminating Engineering, L. Gaster and J. S. Dow; Electrical Measuring Instruments, W. H. F. Murdoch and U. A. Oschwald; Gas Supply: The Principles and Practice of the Applications of Gas to the Purposes of Lighting, Heating, Cooking, and the Generation of Motive Power, W. H. Y. Webber; Practical Electric Light Fitting, S. C. Batstone; Alternating Current Work, W. P. Maycock; Telegraphy: A Detailed Exposition of the Telegraph System of the British Post Office, T. E. Herbert; Polyphase Currents: A Practical Treatise on Polyphase Working for Electrical Engineers, S. Still; Practical Ironfounding, J. G. Horner.

GEOGRAPHY AND TRAVEL.

E. Arnold.—Kulu and Lahoul: An Account of my Latest Climbing Journeys in the Himalaya, Lieut.-Col. the Hon. C. G. Bruce, illustrated. *G. W. Bacon and Co., Ltd.*—The Map and its Story; Correspondence College Atlas, new edition; Contour Wall Map of Scotland, 12 in. globe; A New Series of Physical Wall Atlases, part i., Asia. *A. and C. Black.*—The Cradle of Mankind: Life in Eastern Kurdistan, Dr. W. A. Wigram and E. T. A. Wigram, illustrated; An Intermediate Text-Book of Commercial Geography, A. L. Curr, illustrated; Junior Physical Geography, H. C. Barnard, illustrated; Geographical Pictures, edited by S. M. Nicholls, series ii., Elevation and Depression of the Land; Junior Regional Geography of Asia, J. B. Reynolds, illustrated; Pictures of Famous Travel, H. C. Barnard, illustrated; School Geography of the World, Prof. L. W. Lyde, illustrated, new edition. *W. and R. Chambers, Ltd.*—Concise Gazetteer of the World, new edition. *Constable and Co., Ltd.*—The North-Western Tributaries of the Amazons, being Notes of a Year Spent Among Cannibal Tribes, Capt. T. Whiffen, illustrated. *H. Holt and Co. (New York).*—Industrial and Commercial Geography for High Schools, Prof. J. R. Smith. *Hutchinson and Co.*—Indo-China and its Primitive People, Capt. H. Baudesson, illustrated. *Macmillan and Co., Ltd.*—Travels in Turkey, Sir Mark Sykes, Bart., M.P., illustrated; The Wilds of Maoriland, J. M. Bell, illustrated; Impressions of Canada, F.

Parbury, illustrated. *Methuen and Co., Ltd.*—Modern Mexico, R. J. MacHugh, illustrated; Brazil and the Brazilians, G. J. Bruce, illustrated; The Upper Reaches of the Amazon, J. F. Woodroffe, illustrated; A Guide to South America; A Woman in the Antipodes, M. Hall, illustrated.

GEOLOGY.

Cambridge University Press.—Coal-Mining, T. C. Cantrill (Cambridge Manuals). *H. Holt and Co.* (*New York*).—Geology: Briefer Course, Profs. T. C. Chamberlin and R. D. Salisbury. *Macmillan and Co., Ltd.*—The Quaternary Ice Age, W. B. Wright, illustrated. *T. Murby and Co.*—Minerals and the Microscope, H. G. Smith, illustrated. *Quelle and Meyer* (*Leipzig*).—Geologische Wandkarte Deutschlands, Prof. J. Walther.

MATHEMATICAL AND PHYSICAL SCIENCE.

F. Alcan (*Paris*).—Le Hasard, Prof. E. Borel; Henri Poincaré: L'œuvre scientifique—L'œuvre philosophique, Profs. V. Volterra, J. Hadamard, Langevin, and P. Boutroux. *A. and C. Black.*—A First Book of Experimental Science for Girls: The House: Hydrostatics and Heat, Mrs. Jessie White. *Cambridge University Press.*—The Sun, Prof. R. A. Sampson (Cambridge Manuals); Photo-Electricity, Dr. A. Ll. Hughes (Cambridge Physical Series). *J. and A. Churchill.*—Molecular Physics, J. A. Crowther, illustrated. *W. Engelmann* (*Leipzig*).—Kristallberechnung und Kristallzeichnung, Dr. B. Gossner, illustrated; Elemente der Theorie der Kristallstruktur, Dr. S. Kreutz, illustrated. *G. Fischer* (*Jena*).—Photographisches Wörterverzeichnis in fünf Sprachen: Ido, Deutsch, Englisch, Französisch und Italienisch, Prof. L. v. Pfaundler. *Longmans and Co.*—Flying: Some Practical Experiences, G. Hamel and C. C. Turner, J. E. Adler will contribute a chapter on the Physiological and Medical Aspects of Aviation, and the Hon. G. Marconi on Wireless Telegraphy, and there will be other special contributions, illustrated; Flight without Formulæ: Simples Discussions on the Mechanics of the Aeroplane, Commander Duchene, translated from the French by J. H. Ledeboer, illustrated; The Teaching of Algebra (including the Elements of Trigonometry), Dr. T. P. Nunn; The Groundwork of Arithmetic, M. Punnett; Exercises in Arithmetic, M. Punnett, Books I., II., III.; The Teaching of Geometry, G. E. St. L. Carson; Slide-Rule Notes, Col. H. C. Dunlop and C. S. Jackson; Projective Geometry, G. B. Mathews, F.R.S.; Examples in Differential and Integral Calculus, C. S. Jackson and S. de J. Lenfesty; Non-Euclidian Geometry, Dr. H. S. Carslaw. *Macmillan and Ct., Ltd.*—The Theory of Relativity, Dr. L. Silberstein. *Methuen and Co., Ltd.*—The Complete Photographer, R. C. Bayley, illustrated, new edition; Practical Applied Physics, H. Stanley; Preliminary Practical Science, H. Stanley. *G. P. Putnam's Sons.*—The Call of the Stars, Dr. J. R. Kippax, illustrated; Sun Lore, W. T. Olcott, illustrated. *G. Routledge and Sons, Ltd.*—Photography in Colours, Dr. G. L. Johnson, illustrated, new edition *The S.P.C.K.*—A Voyage Through Space, Prof. H. H. Turner, F.R.S.

MEDICAL SCIENCE.

John Bale, Sons, and Danielsson, Ltd.—Renal Diagnosis in Medicine and Surgery, Dr. V. Blum, translated by W. B. Christopherson; Acute General Miliary Tuberculosis, Prof. G. Cornet, translated by Dr. F. S. Tinker; Tropical Medicine and Hygiene, Dr. C. W. Daniels, with a chapter on Snakes by A. Alcock, part ii., Diseases Due to the Metazoa, new edition; Defensive Ferments of the Animal Organism, Prof. E. Abderhalden, translated by Dr. J. O. Gavronsky, third edition; Lehrbuch der Localanæsthesie, Hirschel, translated; Die Pathologie und Therapie der plötzlich das Leben gefährdeten Krankheitszustände, Lenzmann, translated; Lehrbuch der Tracheo-Bronchoskopie, Mann, translated; Defective Children, edited by Dr. Kelynack. *Cambridge University Press.*—The Respiratory Function of the Blood, J. Barcroft; Isolation Hospitals, Dr. H. F. Parsons (Cambridge Public Health Series). *W. Engelmann* (*Leipzig*).—Die Diagnostik mittels Röntgenstrahlen in der inneren Medizen und den Grenzgebieten, Prof. E. Grunmach, illustrated; Monographien: Anatomische und entwicklungsgeschichtliche, edited by Prof. W. Roux, 3 Heft, Remarques sur le mécanisme du modelage des embryons humains, Courbes embryotectoniques, Dr. E. Bujard, illustrated. *A. and C. Black.*—Radiography, X-Ray Therapeutics, and Radium Therapy, Dr. R. Knox, illustrated; Tuberculosis of Bones and Joints in Children, Dr. J. Fraser, illustrated; Black's Medical Dictionary, edited by Dr. J. D. Comrie, illustrated. *Cassell and Co., Ltd.*—Hygiene and Sanitation Manual, Lieut.-Col. S. G. Moores, illustrated; A System of Surgery, edited by Drs. C. C. Choyce and J. M. Beattie, illustrated, vol. iii. (British Red Cross Society Manuals). *J. and A. Churchill.*—A Manual of Dental Anatomy: Human and Comparative, C. S. Tomes, F.R.S., new edition, edited by Dr. H. W. Marett Tims and A. Hopewell-Smith, illustrated. *Constable and Co., Ltd.*—A Way of Life, Sir W. Osler, Bart., F.R.S. *G. Fischer* (*Jena*).—Diätetische Behandlung innerer Krankheiten, Dr. J. Grober. *W. Heinemann.*—Ophthalmoscopic Diagnosis, Dr. C. Adam, translated by Dr. M. L. Foster, illustrated; Local Anæsthesia, Dr. A. Schlesinger, translated by F. S. Arnold, illustrated; Affections of the Orbit and Accessory Cavities, Dr. C. R. Holmes, illustrated; Examination and Refraction of the Eye and Eye-strain, Dr. W. L. Pyle, illustrated; Medical Ophthalmology, Dr. A. Knapp, illustrated; Ophthalmic Surgery, Dr. J. Meller, illustrated. *H. Holt and Co.* (*New York*).—The Nervous System, R. P. Angier. *T. C. and E. C. Jack.*—The Modern Family Doctor. *H. K. Lewis.*—Industrial Lead Poisoning, Sir T. Oliver; Æquanimitas, Sir W. Osler, Bart., F.R.S., new edition; Anæsthetics, Dr. D. Buxton, new edition; The Ileo-Cæcal Valve, Dr. A. H. Rutherford; The Value of Tuberculin in the Treatment of Pulmonary Tuberculosis, the Medical Staff of the King Edward VII. Sanitorium, Midhurst; Health: A Course of Lectures based on the Syllabus of the London County Council, Dr. M. M. Burgess, illustrated. *Longmans and Co.*—Spectrum Analysis Applied to Biology and Medicine, Dr. C. A. Macmunn. *Macmillan and Co., Ltd.*—Diseases of the Arteries and Angina Pectoris, Sir T. Clifford Allbutt, K.C.B., F.R.S., two vols. *John Murray.*—Therapeutics of the Circulation, Sir T. Lauder Brunton, Bart., F.R.S., illustrated, new edition. *Oxford University Press.*—Plague and Pestilence in Literature and Art, R. Crawfurd, illustrated; Case Studies of Mentally and Morally Abnormal Types, W. Healy; The Evolution of Modern Medicine, Sir W. Osler, Bart., F.R.S. *G. P. Putnam's Sons.*—A Text-Book of Anatomy and Physiology for Nurses, A. E. Pope, illustrated.

METALLURGY.

J. and A. Churchill.—Modern Steel Analysis, J. A. Pickard.

TECHNOLOGY.

A. and C. Black.—Photographs for the Papers: How to Take and Place Them, J. Everard, illustrated. *Cassell and Co., Ltd.*—The Amateur Mechanic, edited by B. E. Jones, illustrated; Dynamos and Electric-Motor Building, edited by B. E. Jones, illustrated; The Commercial Motor Handbook, G. W. Watson, illustrated. *Constable and Co., Ltd.*—Mechanical Technology, Prof. Charnock; The Stability and Equilibrium of Floating Bodies, B. C. Laws. *W. Heinemann.*—The Conquest of Oil, F. A. Talbot, illustrated. *Crosby Lockwood and Son.*—The Modern Boot Repairer, D. Lawrence-Lord, illustrated; Workshop Practice Handbook, E. Pull; Electric Wiremen's Work, J. H. Havelock, illustrated; Hand Sketching for Mining Students, G. A. Lodge, illustrated. *Longmans and Co.*—Mechanics for Builders, E. L. Bates and F. Charlesworth, part ii., illustrated; Masonry, G. R. Barham; British Factory Administration and Accounts, E. T. Elbourne, with contributions on Industrial Works Design by A. Home-Morton, and Financial Accounts by J. Maughfling. *Methuen and Co., Ltd.*—Gearing: A Practical Treatise, A. E. Ingham, illustrated; A Text-Book of Elementary Building Construction, A. R. Sage and W. E. Fretwell. *G. Routledge and Sons, Ltd.*—Broadway Text-Books of Technology, edited by G. U. Yule and C. Hamilton:—Safety-Lamps and the Detection of Fire-Damp in Mines, G. Forster; Electrical Engineering, F. Shaw; The Science of Building and Building Materials, E. Holden; Applied Mechanics, C. E. Handy; Mechanics for Textile Students, D. Hardman; Drawing for Electrical Engineers, G. W. Worrall; Carpentry, J. E. Marshall; Machine Construction and Drawing, Book II., A. E. Ingham; Geometry for Builders, F. E. Drury; Building Construction, A. Dean; Mathematics, A. E. Young. *Scott, Greenwood and Son.*—The Art of Lithography, H. J. Rhodes; The Analysis of Woven Fabrics, A. F. Barker and E. Midgley. *University Tutorial Press, Ltd.*—Manual Training, A. H. Jenkins.

MISCELLLANEOUS.

F. Alcan (Paris).—L'éducation de l'Effort: Psychologie, Physiologie, Prof. G. Demeny. *A. and C. Black.*—Salmon-Flies: How to Tie Them, Choose Them, and Use Them, Dr. T. E. Pryce-Tannatt, illustrated; The Construction of Mortality and Sickness ables, W. P. Elderton and R. C. Fippard. *Cambridge University Press.*—Know Your Own Mind, W. Glover. *Cassell and Co., Ltd.*—Wonders of Land and Sea, Edited by G. Williams, illustrated, vol. i. *Constable and Co., Ltd.*—Philosophies Ancient and Modern, W. James and H. V. Knox. *W. Engelmann (Leipzig).*—Arbeiten zur Entwicklungspsychologie, edited by Prof. F. Krueger, Band i., Heft 1, Ueber Entwicklungspsychologie, Prof. F. Krueger, Band i., Heft 2, Ueber die Vorstellungen der Tiere, Dr. H. Volkelt; Gibt es denkende Tiere? Dr. S. von Máday. *Hutchinson and Co.*—Aviation, Lieut. M. Calderara, illustrated. *Longmans and Co.*—Education and Psychology, M. West. *Macmillan and Co., Ltd.*—The History of Greek Philosophy, Prof. J. Burnet, vol. i.; From Thales to Plato; An Introduction to Logic from the Standpoint of Education, L. J. Russell. *T. Murby and Co.*—The Mind at Work: A Textbook of Applied Psychology, edited by G. Rhodes. *G. P. Putnam's Sons.*—Glimpses of the Cosmos: A Mental Autobiography, Dr. L. F. Ward, 12 vols., vol. i., Adolescence to Manhood, Period 1858–1871, Age 16–30, vol. ii., Scientific Career Inaugurated, vol. iii., Dynamic Sociology.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—An exhibition of 50*l.* a year tenable for two years is offered each year by the governing body of Emmanuel College to a research student commencing residence at Cambridge as a member of Emmanuel College in October. Applications should be sent to the master of Emmanuel not later than September 24.

It is proposed to confer the following honorary degrees on June 9, on the occasion of the opening of the new physiological laboratory:—Doctor of Law: Prince Arthur of Connaught, Viscount Esher, Baron Moulton of Bank, and Col. S. M. Benson; Doctor of Science: Sir William Osler, Bart., Sir David Ferrier, Sir Edward A. Schäfer, and Prof. E. H. Starling.

Dr. Norman Moore has been appointed to the office of reader on Sir Robert Rede's foundation for the present year.

Mr. J. M. Wordie has been appointed demonstrator of petrology.

SHEFFIELD.—Mr. L. Southerns has been appointed assistant lecturer and demonstrator in physics, in succession to Dr. R. T. Beatty, resigned; and Mr. A. Pringle Jameson has been appointed assistant lecturer and demonstrator in zoology, in succession to Mr. T. J. Evans, resigned.

MR. J. ADAMS, assistant in botany in the Royal College of Science, Dublin, has recently been appointed to a position under the Canadian Government.

LORD CHELMSFORD will present prizes and certificates to students of evening classes and day college at the South-Western Polytechnic Institute, Chelsea, on March 27. Laboratories and workshops will be open to public inspection about 9.15 p.m. Tickets of admission may be obtained on application at the institute.

BY the will of the late Alderman H. Harrison, Blackburn, legacies amounting to 82,600*l.* are bequeathed to public objects, among which are the following:—1000*l.* each to the Imperial Cancer Research Fund, the Cancer Investigation Department of the Middlesex Hospital, and the Cancer Hospital for cancer investigation; 5000*l.* to Manchester University for general purposes, and 1000*l.* for the Chinese chair; 2000*l.* to Blackburn Grammar School for playing-fields, and 1000*l.* for university scholarships.

IN the House of Commons on February 25 Sir P. Magnus asked the Prime Minister whether the Government intended to introduce this session a Bill for the reorganisation of the University of London, and, if so, whether that Bill would be presented as a separate measure or as part of the measure for the development of a national system of education. In reply, Mr. Asquith said:—"Pending the report of the Departmental Committee on the University of London, I am not in a position to announce the intentions of the Government. It will probably be convenient and desirable to deal with this question in a separate measure."

A SERIES of conferences on the educational value of the kinematograph was held in connection with the recent International Exhibition in Glasgow. The inaugural address at the opening of the exhibition by Sir John Ure Primrose was largely devoted to the educational possibilities of the kinematograph. The educational conferences were begun on February 19, under the presidency of the Lord Provost of Glasgow by an address from Prof. J. W. Gregory on the kinematograph as an educational medium, in which he described its value in many fields of educational work, and notably in geography and technology. In later sessions of the conference Mr. J. Cuthbertson, of the Glasgow High School, opened a discussion on the kinematograph as an aid to literary studies, Mr. G. Eyre-Todd on its use in the teaching of history and geography, Mr. D. B. Duncanson, of the Glasgow Provincial Training College, on its scientific and industrial applications, and Dr. John Smith, chairman of the Govan School Board, on its value in nature-study. At the close of the conference a resolution directing the attention of the Scottish Board of Education to the educational value of the kinematograph was adopted unanimously.

In a pamphlet entitled "Some Roads Towards Peace," a report to the trustees of the Carnegie Endowment for International Peace, Mr. Charles W. Eliot gives an open-minded and businesslike account of his sojourn in China and Japan in 1912. The keynote of the report is education, modern scientific education, such as Japan has developed and China would fain see established. According to his report, the well-known and often repeated taunt that the Japanese tradesmen are untrustworthy in commercial dealings is now quite out of date; and this is plainly due to the enlightened educational policy of the leaders of Japan during the last generation. His picture of the evils attending the introduction and development of factories is not pleasing; but it is certainly no worse than in Western lands. The influence for good of the missionary, and especially the medical missionary, is strongly emphasised. Among some of the immediate outcomes of Mr. Eliot's official visit to the far Orient may be mentioned three memorials which appear among the six appendices to the pamphlet. One is an appeal from prominent Chinamen to the trustees of the Carnegie Endowment for a free public library in Peking; the second is an appeal to the same trustees for an international hospital for Tokyo, signed by leading Japanese and European and American residents; and the third is a memorial on the subject of the education of the children of foreign residents in the Far East—the great need of a well-endowed school to take the place of the present inadequate Tokyo Grammar School. There is little doubt that by supporting such educational and medical needs the trustees of the Carnegie Endowment would do effective service in the cause of international peace.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, February 26.—Sir William Crookes, O.M., president, in the chair.—Lord **Rayleigh**: The diffraction of light by spheres of small relative index.—Prof. H. E. **Armstrong** and Prof. F. P. **Worley**: Studies of the processes operative in solutions. XXXI.—Sulphonic acids and sulphuric acid as hydrolytic agents: a discussion of the constitution of sulphuric and other polybasic acids and of the nature of acids. XXXII.—The influence of sulphonates on the hydrolytic activity of sulphonic acids: a contribution to the discussion on the influence of neutral salts.—Prof. H. E. **Armstrong**, R. T. **Colgate**, and E. H. **Rodd**: Morphological studies of benzene derivatives. V.—The correlation of crystalline form with molecular structure: a verification of the Barlow-Pope conception of "valency-volume."—Prof. E. **Wilson**: The magnetic properties of iron when shielded from the earth's magnetism. When iron is subjected to a considerable magnetising force, a species of polarisation is produced which has the effect of reducing the permeability and increasing the dissipation of energy due to magnetic hysteresis for given values of the magnetic induction. The residual effects can be removed by careful demagnetisation or annealing. It was thought by analogy that the earth's magnetic force would also have a polarising influence upon exposed iron, and this is the subject of the present paper. An effort has been made to remove the residual effects of the earth's magnetism by placing the specimen, which is of ring form, in a magnetic shield, and carefully demagnetising it. The magnetic properties of the material were then examined in the usual manner with a ballistic galvanometer, and a comparison made with those obtained from the exposed or unshielded specimen. It has been found that the permeability of *freshly* demagnetised and shielded iron, corresponding to a given value of the magnetic induction, is considerably larger than in the case of the unshielded specimen.—Dr. J. N. **Pring**: The occurrence of ozone in the upper atmosphere. In the Alps, at an altitude of 2100 metres, the mean concentration of ozone is about 2·5 parts by volume in one million of air, and at an altitude of 3600 metres, about five parts in one million of air. In this country the *mean* quantity found between ground-level and an altitude of 20 kilometres was about two parts by volume in one million. No trace of either hydrogen peroxide or nitrogen peroxide could be detected in these cases. Measurements made in the laboratory on the action of ultra-violet light on air showed that a definite equilibrium amount of ozone is obtained, and that this value increases with fall in temperature, but decreases rapidly with fall in pressure. The formation of hydrogen peroxide or nitrogen peroxide by ultra-violet light radiation could not be detected.—W. A. D. **Rudge**: A meteoric iron from Winburg, Orange Free State. In this paper some account is given of the structure, and mechanical and magnetic properties, of the Winburg meteorite, which is stated to have fallen in 1881. It appears to be composed of large crystals of ferrite with veins and crystals of an iron nickel alloy. The total amount of nickel is not more than 3 per cent.—W. A. D. **Rudge**: The electrification produced during the raising of a cloud of dust. During the raising of a cloud of dust a considerable amount of electrification occurs. Insulated conductors held in a stream of dust become charged to a potential of some hundreds of volts. The dust particles seem to be charged by friction amongst themselves, some with positive, others with negative, electricity.—Prof. W. M. **Thornton**: The electrical ignition of gaseous mixtures. This is an experimental examination of the mechanism of ignition of gaseous mixtures by electric sparks. It is found that there are two distinct types of curve connecting percentage of gas in air and the least current which, when broken, causes ignition by the break-spark. In one, characteristic of continuous currents, the current required is proportional to the percentage of gas present; in the other, of the alternating-current type, it is a quadratic function of the percentage, having a minimum, at the mixture giving combustion, midway between CO and CO_2. Ignition by continuous-current break-sparks is largely ionic or electronic, but by alternating currents is more nearly a simple thermal process. The gases examined were hydrogen, carbon disulphide, benzene, alcohol, and the paraffin series up to pentane.

Linnean Society, February 5.—Prof. E. B. Poulton, president, in the chair.—J. **Davidson**: The mouth-parts and mechanism of suction in *Schizoneura lanigera*, Hausm. The object of this paper is to give a detailed description of the anatomy and relations of the mouth-parts of aphids, with special reference to the working of these structures during the processes of feeding.—Dr. L. **Cockayne**: The vegetation of White Island, New Zealand.—W. E. **Collinge**: The range of variation of the oral appendages in some terrestrial Isopods. After carefully examining and considering the variations described, the conclusion is reached that the oral appendages are subject to a considerable amount of variation, and for purposes of specific distinction are not of the value generally supposed, and certainly not so constant as to the form of the head, the mesosomatic segments, the antennæ, the telson, uropoda, and thoracic appendages; they may, however, serve to characterise the larger divisions of the group.

February 19.—Prof E. B. Poulton, president, in the chair.—Dr. J. P. **Lotsy**: The origin of species by crossing. In all questions of evolution facts are gathered from individuals, because species as well as varieties are abstractions, not realities. Nobody is able to show a species or a variety; all he can do is to show one or more individuals which he believes to belong to the species or variety under discussion. Of *individuals* we know two kinds: homozygotes and heterozygotes. The first are stable, the latter segregate, earlier or later, into new homozygotes. The offspring of a homozygote is identical with its parent with the exception of mere temporary, non-transmittable modifications. If this be true, selection in the progeny of a definite homozygote can have no effect. That it *has* no effect has been proved by Johannsen. A homozygote consequently is absolutely stable and produces offspring which is genetically identical to it. Different kinds of homozygotes may be called genotypes, because they differ in genetical constitution, and we can then say that the world is populated—with the exception of heterozygotes—by a large number of sharply defined absolutely stable genotypes. Under such conditions evolution may well seem impossible; fortunately, the behaviour of the heterozygotes shows us that it is very well possible. A careful study of the descendants of a heterozygote shows us that it segregates in the next or later generations in a number of individuals, part of which are heterozygous, but part of which are homozygous, and that these homozygotes belong to different genotypes. It was submitted that the real units of the living kingdom are genotypes; that such genotypes can, under proper precautions, be kept pure for an indefinite time; and that there is no certain evidence that they can be changed in any other way than by crossing. What then is *the reason of the apparent variability of a species in the Linnean sense?* In the first place the fact that a Linnean species is a *collection* of independent stable Jordanian species. The author expressed his firm conviction, as explained before, that no transmittable variation exists, and that all apparent variability is due to an original cross. Finally, the author proceeded to the origin of species before sexual reproduction took place.

Physical Society, February 13.—Prof. C. H. Lees, vice-president, in the chair.—R. Ll. **Jones**: The moving coil ballistic galvanometer.—A. **Campbell**: Vibration galvanometers of low effective resistance. The mathematical theory of the motion of the moving coil of a vibration galvanometer is first given (partly following Wenner), and simple relations are shown to hold between the two resonance frequencies, the free frequency, and the amplitude time constant. It is also shown how all the constants of the equation of motion can be deduced from observations of the direct- and alternating-current sensitivities, the alternating voltage sensitivity and the "dead" resistance. A complete table of the observed and deduced constants is given for a series of very small coils, the number of turns in these varying from one to forty.—Dr. H. J. S. **Sand**: Vacuum-tight lead seals for leading-in wires in vitreous silica and other glasses. The author has found that lead which has been allowed to solidify in contact with glass will, if free from oxide, form a vacuum-tight joint with the latter. Owing to the very great firmness with which the metal adheres, and owing to its great plasticity, these joints can stand temperature changes without damage.

Zoological Society, February 17.—Prof. E. A. Minchin, vice-president, in the chair.—Dr. R. T. **Leiper** and Surgeon E. L. **Atkinson**: The Helminthes collected by the British Antarctic Expedition (*Terra Nova*), 1910–13. The collection contained nine forms previously recorded from the Antarctic zone, three previously recorded only from the Arctic regions, and one other previously recorded elsewhere and now found in the Antarctic zone, and fifteen new species and four new genera. Of the forms obtained in tropical and temperate zones during the voyage, three had been recorded previously and five were new species.—C. G. **Seligmann** and S. G. **Shattock**: The seasonal assumption of the "eclipse" plumage in the mallard (*Anas boscas*) and the function of the testicle. Though the seasonal change of plumage did not correspond with the spermatogenic function of the testicle, its connection with the production of an internal secretion could only be settled by castration followed absolutely without regeneration; this could be ensured only by reopening the abdomen under an anæsthetic and removing any reproduced tissue found.—Dr. F. **Wood-Jones**: Some phases in the reproductive history of the female mole (*Talpa europea*).—H. C. **Chadwick**: Notes on an imperfectly developed specimen of the sea-urchin (*Echinus esculentus*).—C. F. U. **Meek**: The possible connection between spindle-length and cell-volume. In *Forficula auricularia*, *Helix pomatia*, and man the ratio between the lengths of the mitotic spindle in the two spermatocyte metaphases seemed to be identical or almost identical with the ratio between the radii of two spheres, of which the volume of one is equal to twice that of the other; and, since the volume of the primary spermatocyte cell in the metaphase is presumably equal to twice that of the secondary spermatocyte, connection was suggested between the spindle-length and cell-volume at this stage.—F. F. **Laidlaw**: A further contribution to the study of the dragon-fly fauna of Borneo. The paper dealt with the Gomphinæ and Chlorogomphinæ, of which a number of new species and subspecies was described.

Royal Anthropological Institute, February 17.—Prof. A. Keith, president, in the chair.—S. Hazzledine **Warren**: The experimental investigation of flint fracture and problems of early man. The paper describes experiments conducted for the purpose of investigating the chipping properties of flint, when operated upon by forces of measured strength. In the case of mechanical concussions the chief method employed was by the impact of bodies of known weight falling under the acceleration of gravity from a measured height. Some striking illustrations of the lines of least resistance in flint were thus obtained. As an instance of this, free chipping was obtained by blows of an energy of 0·8 foot-pounds, delivered at a velocity of 15 ft. a second, in one direction upon a flint. But, at the same time, blows of an energy of 22 foot-pounds, delivered at a velocity of 18·8 ft. a second, upon the opposite side of the same flint, had no effect except to continue chipping in the original direction by the back-pressure of the support on which the flint was placed for experiment. The lines of least resistance depend very largely upon the original shape of the piece of flint used for the experiment. It is argued that these properties must also have their influence in the chipping of flints by natural agencies, and may well induce a deceptive appearance of purposeful blows having been delivered in one direction only. A series of experiments showing the effects of differential movement under loads of from 14 to 250 lb. are also described. The similarity of these mechanical effects to the "eoliths" of Kentish type is pointed out.

Royal Meteorological Society, February 18.—Mr. C. J. P. Cave, president, in the chair.—Dr. W. N. **Shaw**: The interpretation of the results of soundings with pilot balloons. The author dealt with the calculation of the distribution of pressure and temperature from the observed horizontal wind velocity at different heights and gave examples of the application of this method to certain types of atmospheric structure represented in Mr. Cave's book. When we find irregular fluctuations in the wind velocity we must look for corresponding irregularities in temperature and pressure differences at the several levels. These irregularities are obvious characteristics of the observations of wind velocity, pressure difference, and temperature difference.—G. M. **Dobson**: Pilot balloon ascents at the Central Flying School, Upavon, during the year 1913. These balloon ascents are made with the object of obtaining information which will be of use for pilots in flying. The results given in this paper are based upon ninety-seven ascents. It is found that the direction of the wind veers from, and its velocity increases with, increasing height above the ground, until the gradient direction and velocity are reached. The gradient velocity is usually reached at a height of 300 metres, though the gradient direction is not found until a height of about 800 metres. At higher altitudes the velocity tends to increase, and the direction continues to veer, slightly beyond the gradient velocity and direction.

CAMBRIDGE.

Philosophical Society, February 9.—Prof. Seward, vice-president, in the chair.—A. S. **Marsh**: The history of the occurrence of Azolla in the British Isles and in Europe generally. *Azolla filiculoides* has recently been found in Jesus Ditch, Cambridge. This species, which is now common in the Norfolk Broads, has been several times wrongly described as *A. caroliniana*, an earlier introduction, from which it is distinguished by its larger size, different habit, and the microscopic characters of the reproductive organs.—R. C. **McLean**: Amitosis in the parenchyma of water plants. The author described the occurrence of the direct or amitotic form of nuclear division in the cortical parenchyma of certain water plants. The nuclei show peculiar sigmoid forms and remain associated in pairs in the cells. The phenomenon is most frequent in actively growing regions, so cannot be due to senility. —Agnes **Arber**: Root development in *Stratiotes aloides*, L., with special reference to the occurrence of amitosis in an embryonic tissue. An account is given of certain features of the general development and the cytology of the adventitious roots of *Stratiotes aloides*. The various points dealt with include the nature of the root-cap, the origin of the lacunæ of the middle cortex, &c. The greater part of the paper, however, is concerned with an account of amitosis in the root-cap, cortex, and stele of the immature root.

DUBLIN.

Royal Irish Academy, February 23.—Rev. Dr. Mahaffy, president, in the chair.—M. W. J. **Fry**: Extension of number by the introduction of the symbols $+$, $-$, and i. Recognising that quantities of the same kind are divisible into two groups, usually styled positive and negative quantities, to distinguish the author called a unit to measure quantities of one group α, and a unit to measure quantities of the other group β. Two quantities, such as 12α and 9β combine to give 3α, and so on. Denoting ordinary numbers by a, b, c, he defined $+a$ written in front of any quantity $b\alpha$ or $b\beta$, to mean that the quantity is to be multiplied by a and the unit not altered, and by $-b$ that the quantity is to be multiplied by b and the unit altered to the other unit, so that $+ba\alpha = ba\alpha$, $-ba\alpha = ba\beta$, $-ba\beta = ba\alpha$, $+ba\beta = ba\beta$. The rule of signs in this generalised multiplication is then obvious, and as $b\beta = -b\alpha$, the symbol β may be dispensed with, and any quantity may be expressed in the form $x\alpha$, where x is an ordinary number with the sign $+$ or $-$ prefixed to it, and forms a generalised number, or real number. From these definitions he developed the algebra of real numbers, which is incomplete in the well-known ways. To generalise number further so that all operations may be performed, he began with a group of four fundamental units α, α', β, β', arranged in cyclical order instead of two. Of these four an opposite pair, α, β, are a pair of units considered before, and the other pair are any other similarly related pair whatsoever. Defining ia written in front of any quantity $b\alpha$ or $b\alpha'$, or $b\beta$ or $b\beta'$ to mean that the quantity is to be multiplied by a and the unit altered to the next in cyclical order, it follows that $2^2 = -1$, $2^3 = -2$, $2^1 = 1$, and that any quantity $a\alpha + b\beta + c\alpha' + d\beta'$ can be written in the form $(x + iy)\alpha$. Thus the further generalised quantity is $(x + iy)\alpha$, and further generalised number $x + iy$. From these definitions he developed the algebra of complex numbers.

PARIS.

Academy of Sciences, February 23.—M. P. Appell in the chair.—E. **Guyou**: The homogeneity of equations and the simplification of problems when certain quantities become small.—Paul **Sabatier** and M. **Murat**: Contributions to the study of benzhydrol: the preparation of benzhydrol and tetraphenylethane. In the preparation of benzhydrol by the Grignard synthesis from benzaldehyde or ethyl formate and phenylmagnesium bromide the yield of benzhydrol is poor, symmetrical tetraphenylethane appearing as the main product of the reaction. This has now been traced to the conditions of hydrolysis of the organo-magnesium compound. During the fractional distillation of the ether solution of the reaction products decomposition of the benzhydrol takes place, and this has been shown to be due to the catalytic action of small proportions of impurities in the liquid, since a similar change does not occur when pure solutions of benzhydrol are distilled. The conditions for obtaining a good yield of the benzhydrol are given.—A. **Véronnet**: The cooling of the earth: its evolution and duration. The formula established is similar to that of Fourier, but the proof is simpler. The time is 2·46 times that given by the Fourier hypothesis, but it remains of the order of millions of years.—M. **Fessenkoff**: The capture of comets by Jupiter.—J. **Guillaume**: Observations of the sun made at the Observatory of Lyons during the fourth quarter of 1913. Tables are given showing the number of spots, their distribution in latitude, and the distribution of the faculæ in latitude.—J. **Darmois**: The method of Laplace.—G. **Pick**: The evaluation of distances in functional space. Ph. **Franck**: The approximate evaluation of the smallest characteristic value of some integral equations.—G. **Kowalewski**: Intrinsic geometry and the first fundamental proposition of Sophus Lie.—Alfred **Rosenblatt**: Certain integrals of a system of two ordinary differential equations of the first order satisfying initial singular conditions.—Louis **Benoist** and Hippolyte **Copaux**: Some new proofs of the laws of transparency of matter for the X-rays in the special case of complex mineral salts. The substances examined included potassium ferrocyanide, cobaltic chloropentammine and potassium silicomolybdate. There was a good agreement between the found values and those calculated on the assumption that the transparency to the X-rays is an atomic property.—B. **Szilard**: The measurements of electrical potentials at a distance without wires. A disc coated with 0·1 milligram of radium bromide is insulated and connected with a static electrometer. When the disc is placed facing a charged conductor it acquires a potential varying with the distance, and this potential as read off on the electrometer can be used to measure the potential of the charged conductor. For the instrument described, the disc being at a distance of one metre from the charged plate, the voltage shown by the electrometer was about one-twentieth of that of the plate. Various practical applications of the method are indicated.—S. **Ratner**: A new form of electric breeze.—Jean **Bielecki** and Victor **Henri**: The influence of the ethylene linkage and the carbonyl and carboxyl groups on the absorption of ultra-violet light. Ten substances were studied and the results summarised on three diagrams.—Eugène **Wourtzel**: The decomposition of gaseous ammonia under the influence of the radium emanation and the influence of temperature on the chemical effects produced by the radiations of radio-active bodies. Ammonia is decomposed solely into hydrogen and nitrogen by the radium emanation. The quantity of gas formed per unit of emanation destroyed increases with the pressure. Rise of temperature favours the destruction of the ammonia. The number of cubic centimetres of ammonia destroyed per unit of radiation is nearly doubled at 108° C., and more than tripled at 220° C.—F. **Leprince-Ringuet**: Experiments on the absorption of gases by coal. Three kinds of coal were treated with a gaseous mixture approximating to the fire-damp of a coal mine, and the absorption studied at varying pressures. The results afford no explanation of the sudden disengagement of marsh gas in fiery mines.—F. **Ducelliez** and A. **Raynaud**: The bromination of manganese in ethereal medium. Finely divided manganese and bromine, if dry, do not react at the ordinary temperature: in presence of ether the compound,

$$MnBr_2.(C_2H_5)_2O,$$

is readily formed, and this when heated loses ether and yields the anhydrous manganese bromide. When the bromine is in large excess another bromide is formed having the composition $MnBr_3(C_4H_{10}O)_3$.—Maurice **Billy**: Improvement in the preparation of some pure metals. A description of the preparation of pure titanium free from iron, by the interaction of titanium tetrachloride and sodium hydride. The use of sodium hydride as a reducing agent possesses the advantage that the reduction takes place at about 400° C., and consequently the whole apparatus can be constructed of ordinary soda glass.—J. B. **Senderens** and Jean **Aboulenc**: The esterification of glycerol by acetic acid in the presence of catalysers. As catalytic agents potassium bisulphate, anhydrous aluminium sulphate, and 1 per cent. sulphuric acid were used, the latter being found to give the best yields.—E. **Gourdon**: The mineralogical constitution of the southern Shetlands (Deception Island).—Miramond de **Laroquette**: Variations of food ration and the weight of the body under the action of solar radiation at various seasons of the year.—G. **Marinesco** and J. **Minea**: Culture of the spinal ganglia in heterogeneous media. Spinal ganglia from the dog and cat were cultivated in the plasma of the rabbit, and the mode of growth studied.—A. **Moutier**: Arterial hypertension.—Jean **Gautrelet** and Henri **Neuville**: The blood of the mammoth.

DIARY OF SOCIETIES.

THURSDAY, MARCH 5

ROYAL SOCIETY, at 4.30.—The Action of Light on Chlorophyll: H. Wager.—Formaldehyde as an Oxidation Product of Chlorophyll Extracts: C. H. Warner.—The Controlling Influence of Carbon Dioxide in the Maturation, Dormancy, and Germination of Seeds: F. Kidd.—The Functional Correlation between the Ovaries, Uterus and Mammary Glands in the Rabbit, with Observations on the Œstrous Cycle: J. Hammond and F. H. A. Marshall.—The Chromaffine System of Annelids and the Relation of this System to the Contractile Vascular System in the Leech, *Hirudo medicinalis*: Dr. J. F. Gaskell.

ROYAL INSTITUTION, at 3.—Heat and Cold: Prof. C. F. Jenkin.

CHILD STUDY SOCIETY, at 7.30.—The Sense of Humour in Children: Miss C. C. Graveson.

LINNEAN SOCIETY, at 8.—Results of Crossing *Euschistus variolarius* and *E. servus* with Reference to the Inheritance of an Exclusively Male Character: The Misses K. Foot and E. C. Strobell.—Short Cuts by Birds to Nectaries: C. F. M. Swynnerton.—Buprestidæ: Ch. Kerremans.—Platypodidæ and Ipidæ from the Seychelles: Lieut.-Col. Winn Sampson.—Scatopsidæ and Simuliidæ: Dr. G. Enderlein.—Heteroneuridæ—Milichiidæ: C. G. Lamb.

FRIDAY, MARCH 6.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Maihak Indicator and Bottchers Power Counter: F. E. Rainey.

GEOLOGISTS' ASSOCIATION, at 8.—A Study of Ballstone and the Associated Beds in the Wenlock Limestone of Shropshire: Miss M. C. Crossfield and Miss M. S. Johnston.

SATURDAY, MARCH 7.

ROYAL INSTITUTION, at 3.—Recent Discoveries in Physical Science: Sir J. J. Thomson.

MONDAY, MARCH 9.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—The Nigeria-Kamerun Boundary Commission of 1912–13: Capt. W. V. Nugent.

TUESDAY, MARCH 10.

ROYAL INSTITUTION, at 3.—Modern Ships. II. Ocean Travel: Sir John H. Biles.

ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—The Magical Siege of Troy: A. Upward.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Further Discussion*: Rail-steels for Electric Railways: W. Willox.—Rail-corrugation and its Causes: S. P. W. D'Alte Sellon.

WEDNESDAY, MARCH 11.

ROYAL SOCIETY OF ARTS, at 8.—Bacterial Treatment of Peat, and its Application as a Fertiliser: Prof. W. B. Bottomley.

GEOLOGICAL SOCIETY, at 8.—An Apparently Palæolithic Drawing on a Bone from Sherborne (Dorset): Dr. A. Smith Woodward.

THURSDAY, MARCH 12.

ROYAL SOCIETY, at 4.30.—*Probable Papers*: Note on a Functional Equation Employed by Sir George Stokes: Sir James Stirling.—The Mercury Green Line $\lambda = 5461$ as Resolved by Glass and Quartz Lummer Plates and on its Zeeman Components: Prof. J. C. McLellan and A. R. McLeod.—The Electrical Condition of a Gold Surface During the Absorption of Gases and their Catalytic Combustion: H. Hartley.—The Diffusion of Electrons through a Slit: J. H. Mackie.—The Rate of Solution of Hydrogen by Palladium: Dr. A. Holt.

ROYAL INSTITUTION, at 3.—Heat and Cold: Prof. C. F. Jenkin.

CONCRETE INSTITUTE, at 7.30.—Forms for Concrete Work: A. Graham.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Design of Rolling Stock for Electric Railways: H. E. O'Brien.

FRIDAY, MARCH 13.

ROYAL INSTITUTION, at 9.—An Indian State: Sir Walter R. Lawrence, Bart.

MALACOLOGICAL SOCIETY, at 8.—Diagnosis of Four New Land Shells from German New Guinea: C. R. Boettger.—Characters of Three New Species of Ennea from Southern Nigeria: H. B. Preston.—A Synopsis of the Family of Veneridæ. II.: A. J. Jukes-Browne.

ROYAL ASTRONOMICAL SOCIETY, at 5.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Lightning Conductors and their Tests: F. H. Taylor.

ALCHEMICAL SOCIETY, at 8.15.—Roger Bacon: R. Rowbottom.

PHYSICAL SOCIETY, at 8.—Time Measurements of Magnetic Disturbances and their Interpretation: Dr. C. Chree.—The Ratio of the Specific Heats of Air, Hydrogen, Carbon Dioxide and Nitrous Oxide: H. N. Mercer.—The Asymmetric Distribution of the Secondary Electronic Radiation produced by X-Radiation: A. J. Philpot.

SATURDAY, MARCH 14.

ROYAL INSTITUTION, at 3.—Recent Discoveries in Physical Science: Sir J. J. Thomson.

CHEMISTRY FOR ADVANCED STUDENTS.

(1) *A Treatise on Chemistry.* By H. E. Roscoe, F.R.S., and C. Schorlemmer, F.R.S. Vol., ii., The Metals. New edition completely revised by the Rt. Hon. Sir Henry Roscoe and others. Pp. xvi+1470. (London: Macmillan and Co., Ltd., 1913.) Price 30*s.* net.

(2) *A Dictionary of Applied Chemistry.* By Sir Edward Thorpe, C.B., F.R.S. Assisted by Eminent Contributors. Revised and enlarged edition. In five volumes. Vol. v., Pp. viii+830. (London: Longmans, Green and Co., 1913.) Price 45*s.* net.

JUST as the leaves of our deciduous plants fade away in autumn, and in winter perish, so do our science books have their autumn and their winter. They cannot live long under a *régime* which changes with the fleeting years. The publisher's spring-time brings forth an array of fresh books, but none are more welcome than some of the older and familiar forms revitalised and newly adapted to the change of environment. The reviewer has therefore a pleasing task in introducing the new editions of the above-named books to readers of NATURE, and this the more because each book is a familiar friend to chemists the world over.

(1) The new edition of "Roscoe and Schorlemmer"—as it is colloquially called—merits a hearty welcome. This book stands on the most convenient shelf in the libraries of thousands of chemists, and its well-thumbed pages bear eloquent testimony to its utility and value. This has continued, edition after edition, since 1878, when vol. i. was published. The first edition was thus born before many of us, in this generation, took up the test-tube and the wash-bottle; and we have grown up using "Roscoe and Schorlemmer" as a kind of alkoran. The book, in consequence, must have exercised a deep influence on the present generation, and it is a book of which British chemists have been proud.

It is interesting to see how the concepts of physical chemistry gradually permeate, modify, and illume even so conservative a subject as the "Systematic Description of the Metals and their Derivatives." True enough, there are no very marked changes in the descriptive matter ranging from pages 224 to 1406, yet the first 223 pages are largely occupied by physical chemistry, and the last 42 pages have a clear succinct account of the present state of our knowledge of that fascinating subject, "The Radioactive Elements." In the chapter on specific heats, a page or two might perhaps have been spared for Einstein's work on the atomic heats of solids to show how theory has at last given a reasoned explanation of the "constancy" of the number 6. The chapters on crystallography and on spectrum analysis are specially good. The new edition has all the strong points of former editions, and it can therefore be confidently recommended to advanced students as the best text-book extant on descriptive inorganic chemistry.

(2) The fifth volume of "Thorpe's Applied" completes the work. The concluding volume maintains the high standard of those which precede, and the observations on the fourth volume in NATURE, August 14, 1913, are of equal weight here. This volume covers subjects ranging from "Sodium to Z." The longer articles deal with sodium, soils, solutions and solubility, specific gravity, spectrum analysis, starch, sugar, sulphide dyes, sulphur and sulphuric acid, synthetic drugs or medical products, tannins, tartaric acid, tea, terpenes, thermometers, thermostats, thorium, tin, titanium, tobacco, toluene and toluidines, toxins and antitoxins, triphenylmethane colouring matters, tungsten, ultramarine, uranium, urea, uric acid, urine, vanadium, varnish, vat dyes, vegetable alkaloids, water, waxes, whisky, wine, destructive distillation of wood, wool, zinc, zirconium, etc. This list is quite inadequate, and gives but a feeble idea of the immense range of the subjects discussed in this volume. I am informed that the whole set of volumes contains some six thousand articles—short or long. The work is therefore *ganz deutsch* in its thoroughness.

As a rough imperfect test, in order to find how the fifth volume happens to fit the subjects in which I personally am interested, I wrote a list containing twenty items, and then consulted the "dictionary." I did not succeed in finding any mention of a thermostat for high temperatures (say 500°–1100°) for electrically heated muffles; or of μ- and λ-sulphur and their effect on the melting-point of the so-called "pure" sulphur. In the remaining eighteen cases the dictionary emerged triumphant. This result is very good, and illustrates the high probability that the work will not be found wanting when occasion demands. The dictionary, as a whole, reflects great credit on the wisdom and acumen of the editor, on the skilful and accurate condensations by the contributors, and on the enterprise and good taste of the publishers.

J. W. MELLOR.

DYNAMICS: OLD AND NEW.

(1) *Leçons sur la Dynamique des Systèmes matériels.* By Prof. E. Delassus. Pp. xii+421. (Paris: A. Hermann et Fils, 1913.) Price 14 francs.

(2) *The Theory of Relativity.* By Prof. R. D. Carmichael. Pp. 74. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1913.) Price 4*s.* 6*d.* net.

(1) THIS volume is the result of an experiment made by the author to improve on the usual methods of introducing students to the study of dynamics. The first respect in which this has been essayed is in presenting the subject from the beginning in a general form, instead of beginning with those problems which are geometrically most simple. Thus the volume has rather the appearance of a treatise on what is usually known as analytical dynamics. But the object which the author has in view is not so much the development of the advanced analytical theory, which becomes largely a study of differential equations, as a unification of method which shall obviate the feeding of the student on a multiplicity of isolated problems in which the dynamical properties are essentially of the same type.

Special attention is paid to the class of systems the equations of motion of which can be integrated by quadratures. An elaborate study is made of two special questions in respect of which the author considers wrong notions to be prevalent. The first of these is the assumption usually made in respect of a unilateral constraint, such as that which occurs when a body rolls or slides on another body, that the constraint will cease to be conformed to at the moment when the force required to maintain it vanishes and changes sign; examples are given in which the assumption that this is true where there is more than one point of contact between two bodies leads to wrong conclusions.

The other point which is called in question is the assumption, which the author considers to be often tacitly made, that if the constraint imposed on a system is realised by means of auxiliary bodies of negligible mass, these auxiliary bodies have no influence on the motion of the system. An example given is that of a heavy particle constrained to move in a horizontal plane by attachment to an axis bearing two weightless wheels which roll and slide respectively on a fixed horizontal plane. It is clear that if the wheels and axis have ever so little inertia and are set in motion with a rotation about the vertical, the particle cannot describe a straight line, but the example points to such an obvious objection to the assumption referred to that it is difficult to believe that as a general rule it has really been commonly asserted.

(2) After reading this careful course on classical dynamics, it is an abrupt transition to the first book published in English on the principle of relativity, and to read of a revision of the fundamental concepts, not only of space and time, but also of mass. Prof. Carmichael sets out to give a popular account of the way in which these magnitudes are regarded by the exponents of this most up-to-date of generalisations, without going into the details of its origin in electrical theory.

The project is well carried through, but it seems doubtful whether even yet the public mind is prepared to face the shock of the postulate (p. 20): "The velocity of light in free space, measured on an unaccelerated system of reference S, is independent of the velocity of S." But less objection seems to be taken to one of the consequences of the assumption of the complete relativity of all physical phenomena, namely, the dependence of the mass of a body upon its velocity, in spite of its reducing the status of Newtonian mechanics to that of an approximate theory.

The reason for this is probably that experiment seems to have demonstrated without doubt that the mass of the electron must be admitted to be variable, and we can find no reason for denying the possibility of the mass of any body varying within the limits of error admitted by astronomical theory.

The real obstacle to the acceptance of the theory of relativity is the carrying over of a conception of space and time, which is based on, or rather part of, Newton's dynamical theory into regions where that theory is certainly no longer tenable in its entirety. Prof. Carmichael's book deals entirely with these fundamental matters and will help to make more familiar a more logical and less metaphysical view of space and time in their physical bearing.

NEW ZEALAND: THEN AND NOW.

(1) *Camp Fire Yarns of the Lost Legion.* By Col. G. Hamilton-Browne. Pp. xiii+301. (London: T. Werner Laurie, n.d.) Price 12*s.* 6*d.* net.

(2) *Social Welfare in New Zealand.* By Hugh H. Lusk. Pp. viii+287. (London: William Heinemann, 1913.) Price 6*s.* net.

THESE two books present a most vivid picture of the progress which has occurred in New Zealand during the last fifty years. The first is essentially personal, the account of strange and curious adventures of individuals; the second is largely impersonal, the account of the development of a system of State Socialism. Both works tell the story of the reaction between outsiders from overseas and the environment which they found awaiting them in these distant islands.

(1) The gallant colonel, typically a frontiersman, presents a picture of the Maori wars, and demonstrates the dangers of the trackless bush. The Maori regarded war as essentially the work for men; their curious outlook caused them to regard the shot which landed in their "pah" during a bombardment and failed to explode as the enemy's method of supplying them with powder with which to continue fighting. Mr. Lusk, formerly a member of the New Zealand Parliament, states that Maoris nowadays receive old-age pensions on the same terms as the white men.

The camp-fire yarns are racy, redolent of the soldier's vocabulary, and make excellent reading; the parliamentarian account (2) of organised attention to the well-being of the community as a whole community, and not as a congeries of classes of society, is calm, dispassionate, careful, and on this account eminently readable.

Steadily, step by step, the State interfered with manifestations of private enterprise, prevented the permanent establishment of a landed gentry, or of a body of yeomen tenant farmers; established systems of communication by rail, by telegraph, and by telephone, which have contributed greatly to a feeling of national unity; freed the country from outside influences as regards fluctuations in coal prices; secured loans of capital for all the people at advantageous rates, so preventing the exploitation of the farmers because they were necessitous; and, by controlling the development of the country, secured a high average of prosperity to all members of the State, without causing the growth of either a wealthy or a poverty-stricken caste.

Mr. Lusk is of opinion that New Zealanders grew, without definite intention, or without definite leadership, to regard the welfare of all as paramount, and he is further of the opinion that New Zealand sets an object-lesson to the whole world in its regard for all members of the body politic; he pays more attention to the principle which underlies these progressive movements than to the fact that New Zealand is a special case. Regarded as a contribution to the knowledge of the world, New Zealand's progress is a striking illustration of the unique reaction to its own local environment, which occurs in a more or less isolated community. More than a thousand miles from its nearest neighbour, with a small population of a million souls, with a large area of cultivable land, in the happy position of having one market only, and that a certain one for its surplus of food-stuffs and raw material, almost outside the stress and strain of international competition, New Zealand has developed along lines which were only possible in such comparative isolation. But it is hazardous to generalise from so specific an example; while, on one hand, it is possible to note the fact of New Zealand's prosperity, it is incorrect, on the other, to infer from New Zealand's experience principles of State activity which shall be regarded as of general application.

It does not necessarily follow that what is good for one million people on the edge of the modern business world and mainly occupied and dependent upon the cultivation of the soil is equally good both in method and in result for more than forty millions of people, with an industrial population in ratio to that employed on the land of roughly four to one, situated at the hub of world commerce and the centre of concentration of a world-wide competition.

B. C. W.

OUR BOOKSHELF.

Camping in Crete: With Notes upon the Animal and Plant Life of the Island. By Aubyn Trevor-Battye. Including a Description of Certain Caves and their Ancient Deposits. By Dorothea M. A. Bate. Pp. xxi+308+plates. (London: Witherby and Co., 1913.) Price 10*s*. 6*d*. net.

THIS pleasant record of camping experiences in Crete falls into two parts. In the body of his book Mr. Trevor-Battye, who declines to discuss questions of politics and excavations, describes a series of tours through the island. With Canea as his headquarters, he made trips by steamer along parts of the coast, journeyed so far as Sitia on the east, traversed the island to Sphakia, and again to Retimo, with a long and arduous march from Sphakia, *viâ* Mt. Ida, to Candia. The main object of these excursions was the collection of zoological and botanical specimens, many of which have been valuable additions to the South Kensington Museum. He succeeded in bringing home two ibex kids to the Zoological Society, one of which, the male, died from an accident, but the female is now at Regent's Park, and has given birth to twins. He gives a delightful account of these charming animals.

He finds that a narrow waist, which appears in the Minoan frescoes, is quite characteristic of the islanders. He gives useful accounts of the geology, describing the curious high-level plains of Homalo and Nidha, Mt. Ida, and Kurnás, the only lake in the island. He was kindly received by the Turkish officials, the monks, and the villagers. But it is only the most enthusiastic traveller who will risk the privations and difficulties of journeys over breakneck passes.

The appendix is one of much scientific interest. Miss D. M. A. Bate, one of the best authorities on the island, describes the caves, many containing animal remains, and gives a list of the mammals. The birds are catalogued by Mr. Trevor-Battye, who also deals with geology, harbours, agriculture, industries, and ethnology. The book is well illustrated, and is supplied with a good index. This account of the island forms a supplement to the standard authorities—Pashley in 1834 and Spratt in 1865, both of which, with due acknowledgment, are frequently quoted.

The State Provision of Sanatoriums. By Dr. S. V. Pearson. Pp. viii+80+iv plans. (London: Cambridge University Press, 1913.) Price 3*s.* net.

THIS book deals in a practical manner with a subject of considerable interest and importance at the present time. In the earlier chapters the author discusses what is meant by sanatorium treatment, the reasons why the State should provide this, and what other countries are doing in this direction. "Sanatorium" is defined as "an institution in the country for the treatment of resident patients suffering from any form of tuberculosis," and such institutions as farm colonies are excluded. Valuable suggestions are given on the financing, construction (with diagrams), and management of sanatoriums, and the advantages of sanatorium over domiciliary treatment are emphasised.

The author is a strong advocate for the provision of sanatoriums by the State, largely to the exclusion of other forms of treatment. We do not find, however, any estimate given of the number of beds that would be required for the necessary sanatorium treatment of tuberculosis in this country. The State is the trustee of the funds entrusted to it by the taxpayers, and it is the duty of the State to expend those funds to the best advantage of the *community* as a whole. Whether the erection of a number of substantial and costly buildings (the author estimates the cost as at least 170*l.* a bed) all over the country, with their medical and nursing staffs, is really the most efficient and economical way of dealing with the tuberculosis question is a debatable point, and one on which we probably have not sufficient data at present to guide us. It behoves us, therefore, to move warily, and not to launch out into the erection of numbers of sanatoriums, a large proportion of which might hereafter have to be scrapped, and in the meanwhile to improve our domiciliary and dispensary treatment with the adjunct of a certain number of farm colonies and sanatoriums. It must be recognised that tuberculosis is now decreasing, and it is not always remembered that this decline commenced before the institution of any administrative measures against the disease!

Stanford's Geological Atlas of Great Britain and Ireland, with Plates of Characteristic Fossils. By Horace B. Woodward. Third edition. Pp. xii+214. 50 plates. (London: Edward Stanford, Ltd., 1914.) Price 12*s.* 6*d.* net.

THE first edition of this invaluable atlas was reviewed in the issue of NATURE for February 2, 1905 (vol. lxxi., p. 315), and readers may be referred to that notice for particulars of the general characteristics of the volume. The late Mr. Woodward amplified the present edition by an account of the geological features of the Channel Islands and by further descriptions of facts observable along railways in England and Wales. Small corrections have been made, and the maps have been revised.

Bill's School and Mine: a Collection of Essays on Education. By W. S. Franklin. Pp. vii+98. (South Bethlehem, Pennsylvania: Franklin, Macnutt and Charles, 1913.) Price 50 cents, cloth.

MR. FRANKLIN is known on both sides of the Atlantic as the author of useful scientific textbooks, and it is not surprising to find him insisting in his very readable essays upon the value and importance of a training in scientific method in a complete system of education. He quotes Nietzsche as saying: "The time will come when men will think of nothing but education"; it may be hoped that the time will soon be reached when in this country, in addition to thinking about it, people come to believe in it enough to pay sufficient for it to secure competent educators for the next generation.

Heaton's Annual. Tenth Year, 1914. Edited by E. Heaton and J. B. Robinson. (Pp. 590. (Toronto: Heaton's Agency. London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.) Price, British edition, 5*s.*

ATTENTION has been directed on previous occasions to former issues of this useful work of reference, which is described in its sub-title as the "Commercial Handbook of Canada and Boards of Trade Register." The first half of the volume brings together facts about Canada which business men are wanting to refer to continually, and the second contains, among other useful material, up-to-date descriptions of all Canadian towns of any importance.

A Handbook of Wireless Telegraphy: Its Theory and Practice. For the Use of Electrical Engineers, Students, and Operators. By Dr. J. Erskine-Murray. Fifth edition. Revised and enlarged. Pp. xvi+442. (London: Crosby Lockwood and Son, 1914.) Price 10*s.* 6*d.* net.

THE general characters of this valuable handbook were described in the review of the third edition which appeared in the issue of NATURE for August 24, 1911 (vol. lxxxvii., p. 239). The most important additions to the present edition are those concerned with the uniform alternating current and shock excitation systems. Recent measurements of transmitted power have been added also.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Alexander Agassiz and the Funafuti Boring.

PROF. POULTON has directed attention (NATURE, February 26, p. 712) to the fact that "very little has been said" concerning the evidence on coral-reef formation obtained by the boring at Funafuti, and he also refers to the views upon the subject held by the late Prof. Alexander Agassiz.

It will be remembered that the very successful borings at Funafuti were carried out by Profs. Sollas and Edgeworth David, and their assistants, under the auspices of the Royal Society, with valuable aid from the Admiralty and the Government of New South Wales. The place for the experiment was selected by a committee of the Royal Society, on which every shade of theoretical opinion was represented, this committee having the invaluable assistance of the late Admiral Wharton, who recommended Funafuti as perhaps the most typical atoll that could be found on the globe.

The very complete set of cores, with all the other materials obtained during these borings, were, by the permission of the Board of Education, received in the geological laboratories of the Royal College of Science at South Kensington, where they were studied by the members of the staff, with the invaluable assistance of Dr. G. J. Hinde, much aid being also given by the officials of the British Museum (Natural History) and of the Geological Survey.

Those who were responsible for the preparation of the report on the undertaking, published by the Royal Society in 1904, felt it to be outside their duty to advocate any particular theory of the origin of coral-reefs; their aim was simply to place on record the evidence obtained; and it may be added that this evidence is always open to examination and criticism from the circumstance that the halves of all the cores are now deposited in the British Museum, with the sections and other specimens, while duplicate halves of the cores have been sent to Sydney University.

During the eight years that the work of studying the materials from Funafuti was in progress, I received many visits from my friend, Prof. Alexander Agassiz, and gladly profited by his advice and suggestions. He showed his confidence in the manner in which the work was being carried on by entrusting to me the materials he collected from the upraised coral-reefs of the Pacific, with the request to have them examined side by side with the Funafuti cores, the result being published at his own expense.

I should not be justified in trying to reproduce the views of Agassiz as communicated to me in our frequent friendly discussions—everyone who knew him will accept my statement that they were always candidly and fairly expressed. But, fortunately, in the work published since his death, his position in the controversy is very clearly indicated. His own researches had demonstrated that, over very considerable areas in the Pacific, elevation, often to the extent of 1000 ft. or more, had taken place. Agassiz maintained that the masses of coral-limestone in the upraised islands—which were much altered, like the limestones in the lower part of the Funafuti boring—were Tertiary rocks, and that the lower cores of Funafuti were of the same age. His views are very clearly illustrated in a diagram reproduced in the "Letters and Recollections," p. 343, together with their relation to the views of others, as understood by himself.

I may add that the most careful study of the Funafuti limestones did not supply any evidence of such a change in the fauna as would justify their being assigned to any of the Tertiary periods. But even if such evidence had been found, the geologist would have been justified in arguing that this would only prove that subsidence had taken place with extreme slowness, or had been subjected to long interruptions. On the other hand, the fact, which Agassiz so fully demonstrated, that certain areas in the Pacific have undergone elevation in recent times, would suggest to every geologist, taking into account what we know of "the warping of the earth's crust," that other areas must simultaneously have been undergoing subsidence, and this was the view maintained by Darwin.

We are entitled then to say that a boring, initiated and carried out under the direction of representatives of all the rival theories on coral-reef formation, was attended with brilliant success. In an island selected as a very typical atoll, the main boring was carried down more than 900 ft. below the lowest depth at which, as all naturalists agree, reef-forming corals can flourish. The materials from top to bottom yielded only those organisms that thrive near the surface of the ocean, often in the position of growth. In opposition to the view that the boring may have penetrated only a talus on the side of the reef, it must be pointed out that two additional borings were made *in the very centre of the lagoon*, which revealed, down to the depth of 100 ft. below their limit of growth, the same reef-forming corals. Finally, in this very typical atoll, all idea of solution going on at the bottom of the lagoon was negatived by the luxuriant masses of the delicate calcareous alga, Halimeda, which, with the thinnest shelled Foraminifera, everywhere abounded in a perfectly uncorroded state.

With Prof. Poulton, then, we may fairly say that while the theory of subsidence is not of "universal application"—and Darwin in all his later writings candidly admitted that such was the case—yet the "validity" of this theory of subsidence is fully established in the case of the only atoll in which the test by boring has been carried out. JOHN W. JUDD.

Kew, February 28.

An X-Ray Absorption Band.

FOR some time past I have been trying to make accurate comparisons of the intensities of the various orders of X-ray spectra reflected by crystals. The purpose of the inquiry is to make experimental tests of the theoretical discussions by Debye and Sommerfeld in relation to the influence of molecular motions upon reflecting power. Of some of their predictions I have found it easy to obtain confirmation which is at least roughly quantitative. For instance, the intensities of the higher order spectra are much more affected by rise of temperature than the lower, and the amount of the change is of the right order of magnitude; also rock salt and sylvine show greater changes than fluorspar.

In one case, however, the results have been puzzling. The relative intensities of the spectra of the diamond at ordinary temperatures are quantities of much importance. Now the diamond which I use is a thin flake which intercepts only a fraction of the incident primary ray, a fraction which diminishes as the diamond is set at a greater angle to the primary beam in order to obtain the higher order reflections. It would appear, therefore, to be necessary to make allowance for this waste of reflection opportunities, a correction which would not be necessary in the case of the other crystals, which are thick enough to intercept all the primary rays. Yet the intensity ratios are, to all appearances, nearly correct before the allowance is made, and become quite wrong afterwards. The diamond behaves as if, like the other crystals, it were quite thick.

I have therefore renewed a search for an effect which I have more than once failed to find, a special absorption of rays which are undergoing reflection. Since the earlier attempts the apparatus has gained in sensitiveness and accuracy, and I now find that the effect is easily visible. That is to say, when the pencil of rays strikes the diamond at the proper angle for reflection there is a diminution in the amount transmitted.

In the experiment as arranged at present a pencil of X-rays from a rhodium bulb passes through a slit one-tenth of a millimetre wide, and falls upon the diamond, which is mounted on the revolving table of the spectrometer. The rays that pass through the diamond fall afterwards upon a crystal of rock salt so placed as to reflect a pencil into the ionisation chamber. When the diamond is turned, a minute of arc at a time, through the angle (about 9°) at which the diamond itself reflects the principal rhodium ray, the intensity of the ray reflected by the rock salt drops in the ratio 100 to 70. No doubt this ratio could be increased by more accurate arrangement.

The principal rhodium ray is really a doublet, the two constituents of which are separated by an angle of four minutes under these arrangements. The doublet is resolved not only in the pencil reflected by the diamond, but also in the absorption band occurring in the reflection from the rock salt.

The effect is no doubt analogous to the selective absorption shown by crystals of chlorate of potash (R. W. Wood, *Phil. Mag.*, July, 1906).

The University, Leeds.

Experiments Bearing upon the Origin of Spectra.

IT has been known for some years that a stream of luminous vapour can be distilled away from the mercury arc *in vacuo*, the vapour still remaining luminous when it has passed far beyond the limits of the electric field. It is known also that this luminosity is quenched when the stream passes near a negatively electrified metal surface.

I have from time to time attempted to extend these results to other less volatile metals, and have now succeeded in a large number of cases.

A preliminary account of some of the more significant observations will be given, without dwelling on experimental details.

In the case of sodium under favourable conditions, a very curious behaviour is observed. Where the distilled luminous vapour leaves the lamp, and where, of course, it is most brilliant, the light is yellow, and is dominated by the D lines. Further on, it becomes green, and the lines of the two subordinate series outshine the D lines. Finally, further still, the D lines again predominate. It would seem that if we represent the intensity of each series as dependent on time by a curve, the curve for the principal series will cut that for the subordinate series at two points. It is not, however, easy to find a law of decay which seems physically probable, and will satisfy this condition.

Another interesting effect is seen when the luminous stream is made to pass through a negatively electrified wire net. As in the case of mercury, the glow is partially extinguished. But, if the glow is watched through a spectroscope while the negative potential is applied to the gauze, it is seen that the lines of the subordinate series are far more affected than the D lines.

We may regard the distilled glow as due either to persistent vibration of the luminous centres originally excited in the arc, or to some subsequent interaction occurring in the gas, such as molecular association, or the neutralisation of ions. Whichever view is taken (and neither view is free from difficulty, as I shall show in a more complete publication) we must attribute the action of the electrified gauze to its power of attracting and neutralising positively charged ions. On either view the experiment cited shows that *the systems which gave rise to the subordinate series are not the same as those which give rise to the principal series.*

In the case of potassium, the development of the subordinate series in the distilled glow is very striking, and the existence of a series relation between the lines is visible at a glance, since the series are not confused by extraneous lines. The photography of this spectrum will be undertaken, and it is hoped will lead to an improvement in existing knowledge of the series and their convergence point.

Lastly, I will refer to the behaviour of the glow from magnesium vapour. Initially, the colour is green, dominated by the triplet *b*, and the green band of the "magnesium hydride" spectrum, upon which as a background *b* lies. As the vapour moves on these die out, but the blue flame line at $\lambda 4571$ survives much longer. The vapour was passed through a wire gauze screen. On electrifying this to -40 volts, all the features of the spectrum which have been mentioned were seen to diminish in intensity, but the effect on the blue line and on the bands of magnesium hydride was much stronger than the effect on *b*. The extinction of the band spectrum of magnesium hydride is specially significant.

Unidirectional Currents within a Carbon Filament Lamp.

THE following experiments are good illustrations of the thermionic current, or Edison effect, in a carbon filament lamp, and require only such apparatus as is usually found in a laboratory.

The type of lamp used is that having two large loops in the filament, with the middle of the loop fixed by a short wire fused in glass at the top of the lamp. If the terminals are earthed and a charged body, either positive or negative, is brought near the lamp, then the two leaves diverge like two leaves of a simple electroscope. The loops may touch the glass bulb, and, if so, they spring back discharged.

But if the lamp is lighted and a pointed rod, connected to a Wimshurst, gives a powerful positive discharge, the loops are not displaced, even if the point is close to the bulb. On the other hand, with a negative discharge, even a foot or two away, the two loops of the filament rapidly and repeatedly strike the glass and spring back. Apparently this action will go on for a long period, if the point of discharge is continued.

The action may be explained from the fact that the lamp acts like a valve, and that the current can pass in one direction only, between the hot filament and the interior of the bulb. There can only be a thermionic current of electrons from the filament to the sides, and when there is an equilibrium distribution the carbon is at a relatively high positive potential compared with the inner wall. If this equilibrium is disturbed, it is adjusted by a thermionic current only, in one direction, or by movement of the loops only, in the other direction.

Thus if the negatively charged plate of an electrophorus is brought towards the lamp, the loops will diverge and strike the sides. Or if the displacement is only partial, the loops will swing back to their original place of rest directly the charged plate is removed to a distance. If, however, the metal disc of the electrophorus, positively charged, is brought towards the still lighted lamp, there is no movement of the loops. Equilibrium of potential is attained by emission of electrons from the filament. But as the disc with its positive charge is being moved away the loops diverge and may strike the glass.

What is most remarkable is this, that if the displacement of the loops is only partial, and not up to the glass, then when the disc is removed, the loops retain their displaced position and very slowly creep back to their original place of rest. It is this last phenomenon which clearly indicates the great difficulty of negative electricity returning to the glowing filament, or of positive ions leaving it.

The Beta rays from a few milligrams of radium near the lamp produce in it an ionisation current which accelerates the creep into a rapid motion, to the natural position of the filament.

These experiments with the electrophorus can all be carried out through a dry wooden drawing-board more than half an inch thick. When projected by a lens on a screen the motions of the filament afford interesting lecture-room illustrations of the thermionic current.

The valve action inside high vacuum lamps was explained by Fleming (Proc. Roy. Soc., 1890, vol. xlvii., p. 122). An account of his work is given in his well-known book on "Electric Wave Telegraphy" (second edition, p. 478).

So far as I know, the experiments described in this letter, with an electric force, produced outside the lamp, have not been previously published.

A. S. EVE.

McGill University, Montreal, January 29.

The Densities of the Planets.

THE prominence you give to M. F. Ollive's note in *Comptes rendus*, tome 157, No. 26, induces me to point out that M. Ollive's so-called empirical formula is really a simple statement about the densities of the planets. The formula is $r^3 = kRR'v'^2$, where r is the mean radius of any planet, R its mean distance from the Sun, R′ the mean distance of any satellite from its primary, and v' the mean orbital velocity of the satellite. v'^2R' for any satellite can be replaced by γM, where γ is the gravitation constant, and M is the mass of its primary, since we can ignore the mass of the planet as compared with its primary. We get then $r^3 = k'RM$, where k' is a new constant. But $M = \frac{4}{3}\pi\rho r^3$ where ρ is the mean density of a planet. Thus we get $R\rho =$ constant. This is what M. Ollive's formula amounts to. In other words, his formula does not derive any generality by the introduction of the satellites. The fact that his results for the various satellites of any given primary agree *inter se* is merely Kepler's third law.

The value of M. Ollive's "empirical" formula is thus to be measured by the extent to which the formula $\rho R =$ constant is true of the planets of the solar system. As it happens, this is at all approximately correct only for Earth, Mars, Jupiter, and Saturn. The densities as generally accepted are, taking the planets from Mercury outwards, 0·85, 0·89, 1·00, 0·71, 0·24, 0·13, 0·22, 0·20. The density of the earth is taken as the standard. M. Ollive's formula gives 2·58, 1·39, 1·00, 0·66, 0·19, 0·10, 0·05, 0·03. It is evident that M. Ollive's "empirical" formula is quite wrong for all but the four planets mentioned, and even for these the agreement is by no means encouraging.

It may be urged that the densities are not observed directly, but are inferred from the masses and the radii of the planets, so that a small inaccuracy in the observed radius of any planet may well account for a considerable error in the inferred density. But I very much doubt whether astronomers will be ready to admit possible errors of 50 per cent. in the radius of Uranus and 100 per cent. for Neptune. They will certainly decline to concede an error of 50 per cent. in the radius of Mercury and of 12 per cent. in the radius of Venus.

SELIG BRODETSKY.

University of Bristol, March 3.

An Optical Representation of Non-Euclidean Geometry.

LET us suppose Euclidean space to be filled with a medium of variable refractive index. Then to an observer in that medium the curved path of a ray of light will present all the appearances of a straight line, and, further, if the observer estimates the distance between two points by the time light takes to pass between them, this path will appear to be the shortest distance between the two points.

Suppose now that one or more such observers conduct an Ordnance Survey of the region occupied by the medium, using theodolites to measure angles, and imagine them to be equipped with instruments capable of measuring the time interval occupied by optical signals in transmission from one station to another, this interval being used as a measure of the distances between the stations. It is clear that these observers will obtain what to them must be a convincing proof that the sum of the three angles of a triangle cannot possibly be always equal to two right angles. And it would not be easy for an individual whose methods of observation of the geometrical properties of such a region were limited to those here assumed to believe that the space in which he lived could contain a Euclidean geometry.

G. H. BRYAN.

NATURE RESERVES.

IT is only too true that man is slowly but surely destroying the beautiful wild animals and plants of the world, and is substituting for them queer domesticated races which suit his convenience and his greed, or else is blasting whole territories with the dirt and deadly refuse of his industries, and converting well-watered forest lands into lifeless deserts by the ravages of his axe. It is not too late to rescue here and there larger and smaller areas from this awful and ceaselessly spreading devastation. In remote lands there are large tracts which may be taken in charge by the local government and rescued from destruction, and to some extent this has been done. Even in our over-crowded European states there are still lovely bits of forest, marsh-land, and down which man has not yet irretrievably befouled, and from which he has not yet driven by assault nor removed by slaughter the beautiful living things which nature has guided and nurtured in their seclusion. There is yet time! Some of these little scattered fragments of our great mother's handiwork can still be preserved even in England, Wales, Scotland, and Ireland, so that future Britons may not utterly curse us, but enjoy, with gratitude to those who saved them, the precious living relics of the world as it was before man destroyed it.

There must be many who have in these days learnt to know the difference between "the country" and the "wilderness," and have discovered the rare and over-powering charm of the latter. The "country," with its manured fields, its well-trimmed hedges, and artificial barriers, its parks planted with foreign trees and shrubs, its roadways stinking of tar and petrol, and its streams converted into chemical drains or else into over-stocked fish-stews, is only rendered less repulsive than the town by the survival here and there of a pond or a copse or a bit of ancient moor-land (happily too swampy for golfers) where nature is still allowed to pursue her own way without the arrogant interference of that prodigiously shameless barbarian, the "civilised" man.

Who does not know the charm of the real wilderness—far from the madding crowd—still accessible, even in southern England, to those in the secret? It is perhaps most directly to be found on a sea-shore bounded by sand dunes and marsh lands, or overhung by rocky cliffs on the untamed summits of which strange plants and legendary birds still linger. It is the real and effective absence of the marplot man which gives its vast beauty and fascination to that world protected by the great sea which is exposed as the tides withdraw from the rocks and pools. Here the passionate lover of nature seeks the unparalleled joy of contact with her, unsullied by human trail. And he finds it, too, in the desolate marshes, the remote sand-wastes of our coasts and estuaries, as well as in the still-surviving moorlands of the north. Plants of many kinds, the insects which depend on them, and timid birds—all of which perish in the presence of civilised man—are still to be seen in these precious and adorable sanctuaries. Even an old-time pond, undisturbed by man's improvements, is for the naturalist who can use the microscope a real "nature-reserve" full of the mystery and beauty of isolation.

It is proposed to secure by purchase or gift the right to preserve from destruction in this country as much and as many as possible of the invaluable surviving haunts of nature. A society has been formed for the promotion of nature reserves. It is in cooperation with societies and individuals having a like purpose in other European countries and in other continents, and has already sent representatives to an international conference recently held at Berne, which was attended by delegates from eighteen countries, and was the means of effecting an important exchange of views as to purposes and methods. The Speaker of the House of Commons is the president of the Society, Mr. Ogilvie Grant and the Hon. F. R. Henley are its secretaries. Its official address is "The Natural History Museum, Cromwell Road," and on its council we find such influential public men as Sir Edward Grey, and Mr. L. V. Harcourt, the two Secretaries of State, and many of our leading naturalists such as Profs. Bayley Balfour, J. B. Farmer, Edward Poulton, Sir David Prain, Sir Francis Darwin, and the Hon. Charles Rothschild.

The main objects of the Society for the Promotion of Nature Reserves, more explicitly stated, are "to collect and collate information as to areas of land in the United Kingdom which retain their primitive conditions; to obtain these areas, and to hand them over to the National Trust, and thus to preserve for posterity as a national possession some part, at least, of our native land, its fauna, flora, and geological features." It is hoped that naturalists and lovers of wild life in every district will keep a watchful eye on primitive and unspoilt tracts, and bring them to the notice of the society by writing to the secretary at Cromwell Road. Often such areas, if sought in good time, may be purchased at a low rate per acre; often local interest and public spirit as well as individual generosity, will facilitate the acquirement of the purchase-money, whilst "the National Trust" has proved itself a capable guardian, and will accept the trusteeship of such "reserves" with the necessary conditions imposed by the Society as to the absolute preservation of their natural conditions. No doubt there may be some care needed in arranging for the occasional admission of visitors to these reserved lands so as to avoid the access to them of too large a concourse, or of persons who are merely bent on holiday frolics—no less than of those who, actuated by the cupidity of the collector, would root out and destroy, under the false pretence of being naturalists and nature-lovers, all the rarer living things, as they have done in so many unprotected spots.

Already a beginning has been made in England. A part of Wicken Fen in Cambridgeshire has been acquired for the nation; also the shingle and salt-marshes of Blakeney in Norfolk. Near Oxford, too, there is a "Ruskin Reserve."

In foreign countries the government has long been active in the way of establishing "reserves," especially where, as in the United States, there are large tracts of uninhabited country. In Germany there is a department of State to control and assist in the preservation of nature, having a very large annual budget. There are already 100 reserves in that country. The yew and the holly are protected in the Government forests, and none may be cut: whilst the service tree is also protected. In this country we have no department of forestry, no knowledge or practice of forestry, and we shall very soon have no forests. The incapacity and want of authority in this subject which has been allowed to grow up in the British official world is lamentable, and was characteristically exhibited in the proceedings of the recent commission on Coast Erosion.

In Germany military exercising grounds and rifle ranges are made into nature reserves so far as is possible and consistent with their military use. The same thing might be, and should be, done in this country. There is no Government department in this country which can either advise or control in such matters. Commons, when taken over by public authority for preservation, should not be utterly drained of water and converted into

London parks, as has been the case at Hampstead, where the small bog above the Leg of Mutton Pond, in which grew the Sun-Dew (Drosera) and the Bog-bean (I used to visit them there!) might well have been left as a bog for the delighted contemplation of London naturalists. There was plenty of dry ground on Hampstead Heath without destroying the bog. There is danger of all such open spaces being converted into a common-place garden or a football field or a golf course unless the new society can extend its protection to them.

The purpose of this article is to invite all lovers of the wilderness, all worshippers of uncontaminated nature, to enter into communication with the Society for the Promotion of Nature Reserves, and see how far they can help in promoting its most worthy national objects.

E. RAY LANKESTER.

P.S.—The following series of inquiries issued by the Society for the Promotion of Nature Reserves will enable the reader to appreciate its purposes and mode of going to work.

Answers will be treated as strictly confidential, and will be at the disposal of the executive committee only. Name of Place. District and county where area is situated. Name and address of society or person giving information. (A) Is the suggested area worthy of permanent preservation as:—(1) A piece of typical primeval country? (2) A breeding-place of one or more scarce creatures? (3) A locality for one or more scarce plants? (4) Showing some section or feature of special geological interest? (B) Is the place recommended primarily for birds, insects, or plants? (1) To whom does it belong? (2) Would the owner be willing to sell, or could the area be leased? (3) Could you get local financial aid should it be considered desirable to acquire the area? (4) Is the place or site locally popular as a pleasure resort? This form should be filled up and returned to the secretary, Society for Promotion of Nature Reserves, c/o Natural History Museum, Cromwell Road, London, S.W.

GOVERNMENT LABORATORY REPORT.[1]

FROM the report of the Government Chemist,[1] issued a short time ago, it appears that the work of the Department increased considerably during the year 1912–13. The total number of samples examined was 209,502, as compared with 195,170 in the previous year.

It is noted that many questions of a consultative and advisory nature, apart from those connected with the examination of samples, are referred to the laboratory by various Government departments. Above 600 such references were dealt with during the year. They included such diverse matters as the causes of the deficiency in the non-fatty solids of milk; the relation between the citric acid solubility and the availability of the phosphates in slags; the selection of suitable denaturants for growing tobacco; stamps for National Health Insurance; and the supply of lime juice to the mercantile marine.

In connection with the attempts to cultivate tobacco and sugar in this country, it is interesting to note that 224 samples of home-grown leaf tobacco were examined, and also specimens of beet-juice, sugar, and molasses from the recently erected beet sugar factory at North Cantley.

Imported dairy produce was generally satisfactory as regards freedom from adulteration. Thus fresh (pasteurised) milk was not below the statutory regulations for quality, and contained no preservatives or artificial colouring substances. Imported butter, of which 1223 specimens were analysed, occasionally contained a small excess of water, but gave no evidence of the presence of fat other than butter fat.

In connection with the supervision of dangerous trades, a large number of lead glazes, dust, and other articles were analysed. From works where lead poisoning had occurred, fifty-eight specimens of lead glaze were taken; in most of these nearly the whole of the lead was in a soluble form, and therefore readily dissolved by the acids of the gastric juice. The principal chemist notes also that important investigations were conducted during the year for the Home Office Committees appointed to consider questions concerning (1) celluloid, and (2) the use of lead compounds in the painting of buildings and coaches.

A large part of the report is devoted to an account of the work done by the laboratory in exercising chemical control over the production and sale of dutiable articles. The account is accompanied by brief outlines of the reasons for this control, and shows how it is exercised. For example, it is explained that the duty on beer brewed in this country is charged on the wort or unfermented saccharine liquid from which the beer is brewed; that the basis of the charge is a statement made by the brewer as to the quantity of materials used and unfermented wort produced, and that the accuracy of this statement can be checked at any time subsequently by analysing the fermented wort. That there is some need for such control is shown by the fact that out of 11,641 samples examined, 1628 were found to have been "declared" at less than their true value. In this and numerous similar ways the laboratory has become an indispensable ancillary of the fiscal departments.

The report shows steady progress of the laboratory, and records a useful year's work.

[1] The Report of the Government Chemist upon the work of the Government Laboratory for the year ended March 31, 1913. (Cd. 7001). Price 3*d*.

NOTES.

THE meeting of the Royal Society on March 19 will be a meeting for discussion, the subject being "The Constitution of the Atom." The discussion will be opened by Sir Ernest Rutherford.

MR. LAURENCE BINYON, assistant-keeper in the British Museum in charge of the sub-department of Oriental Prints and Drawings; Dr. R. M. Burrows, principal of King's College, London; and Mr. A. G. Lyster, president of the Institution of Civil Engineers, have been elected members of the Athenæum Club under the provisions of the rule which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public services."

The death is announced of Mr. John Gott, widely known among telegraph engineers and electricians by his pioneer work in electrical testing and practical telegraphy.

The death is reported, in his forty-seventh year, of Dr. A. H. Pierce, professor of psychology since 1900 at Smith College, Massachusetts. He was editor of the Psychological Bulletin, and author of "Studies in Space Perception."

Dr. W. W. Bailey, professor of botany at Brown University, Rhode Island, from 1881 to 1906, has died at the age of seventy-one. His publications included "Botanical Collector's Handbook," "Among Rhode Island Wild Flowers," "Botanical Note-book," "New England Wild Flowers," and "Botanizing," as well as a volume of poems.

It is announced that the Government will ask the House of Commons to sanction a grant of 13,000*l*. for special investigation into the movements of ice in the North Atlantic. The grant is provided for in the Estimates for Mercantile Marine Services for 1914–15, and represents an increase of 11,000*l*. on the sum voted for this purpose last year.

In the Civil Service Estimates for the year 1914–15, issued a few days ago, it is announced under the head of "Grants in Aid of Scientific Investigation," that the sum of 5000*l*. is to be voted this year towards the expenses of the British Transantarctic Expedition, which Sir Ernest Shackleton is to conduct across the south polar continent. Another 5000*l*. is to be voted next year. This grant of 10,000*l*. forms part of the sum of 50,000*l*., which was already guaranteed before the public announcement of the expedition.

A new magnetic observatory is being established in Swider, near Warsaw, in connection with the magnetic researches now being carried on in Poland by Dr. St. Kalinowski. The observatory will be provided with registering instruments (Adolf Schmidt's system), and for the absolute determinations a large Sartorius magnetic theodolite and an earth inductor will be used. Dr. Kalinowski hopes that the new observatory will be in active operation in the present year.

In accordance with the resolution adopted by the eighteenth International Congress of Americanists, held in London in 1912, the Smithsonian Institution have made arrangements for holding the nineteenth congress in Washington on October 5–10. The organising committee, of which the chairman is Prof. W. H. Holmes, head of the department of anthropology, United States National Museum, has already drawn up a provisional programme. This includes an archæological excursion to the aboriginal quarries and workshops at Piney Branch. A feature of the congress will be an exhibition of rare Americana and other objects and a special exhibition in the museum of the daughters of the American Revolution.

On Tuesday, March 24, Mr. A. H. Smith, keeper of Greek and Roman antiquities in the British Museum, will begin a course of two lectures at the Royal Institution on landscape and natural objects in classical art, and on Thursday, March 26, Dr. C. W. Saleeby will deliver the first of two lectures on the progress of eugenics: (1) "The First Decade, 1904–14," (2) "Eugenics of To-day: its Counterfeits, Powers, and Problems." The Friday evening discourse on March 27 will be delivered by Prof. J. A. Fleming on improvements in long-distance telephony, and on April 3 by Sir J. J. Thomson on further researches on positive rays.

Prof. E. Naville, in the *Times* of March 6, describes a remarkable discovery in the course of excavation at Abydos. Strabo, in his account of what he calls the "Fountain of Abydos," speaks of a labyrinth with covered ways roofed with enormous slabs resting on pillars. Two gigantic colonnades have now been discovered not far from Seti's temple, leading into a great hall, now empty, as it has been a quarry for centuries. The texts, however, which survive on the walls, copies of the Book of the Underworld, show that this was the famous tomb of Osiris. Like the pyramids in the case of the monarchs of Egypt, this splendid building was a fitting tomb for a god. What has become of his body, whether only his head was preserved, whether the remains were enclosed in a sarcophagus—we shall probably never know.

The Army Estimates for 1914–15 provide a million pounds sterling for the air service, of which nearly 200,000*l*. is for buildings. Colonel Seely's memorandum on the Estimates points out that good progress has been made during the past year with the development of the Military Wing of the Royal Flying Corps. By the end of this month the number of officer fliers will have grown to about two hundred. During the past year an Inspection Department for Aviation has been formed and is finding much scope for its activities in inspecting new supplies of all kinds, and also in overhauling periodically the aeroplanes, engines, and so on of the flying squadrons. A special section of the Army Ordnance Department is also about to be formed to deal with the storage and supply of the highly technical and complicated *matériel* used in this branch of the service. As a general indication of the progress made in the past year, it may be said that, as compared with 100 aeroplanes in existence on March 20, 1913, there were on February 25 last 161 on hand, and between those dates 87 had been struck off as unserviceable and replaced.

Some of the recent work at Rothamsted in connection with the partial sterilisation of soils has found application in the Lea Valley district just north of London, where a great market garden and glasshouse industry flourishes. So much interest has been aroused among the growers that they have banded themselves together to form an Experiment Station where the various problems arising out of the industry can be investigated in a scientific manner, and where advice may be obtained as to plant diseases, pests, and so on. The growers have raised a large sum of money among themselves for the erection and maintenance of the station, and, in addition, a substantial Government grant has been made, and the county councils have also contributed; the financial success of the scheme therefore seems assured. The problems to be investigated are of great technical importance and high scientific interest. A strong committee of management has been formed, one-half being practical growers, and the other half men of science nominated by the committee of the Rothamsted Experimental Station. The scientific side of the work will, therefore, be amply represented, and there is every prospect that a sound programme of work will be drawn up.

Mr. G. Marconi delivered a lecture in Rome on March 3 before the King and Queen of Italy, members of the Italian Government, both Houses of Parliament, and the Diplomatic Corps. He described the progress which had been made in wireless telegraphy, and the difficulties which had been overcome since his previous lecture in Rome in 1903. His voyage to South America on board the *Principessa Mefalda* had illustrated that communication in a north and south direction was easier than communication in an east and west direction. Mr. Marconi described his new system for generating continuous waves, and its use in wireless telephony. He then described the apparatus for producing waves, divided into regular groups, and dealt with the improvements effected in receivers, giving a practical demonstration of the reception of messages in the lecture hall from Poldhu, in Cornwall, and Tripoli. Mr. Marconi finally described the practical applications of radio-telegraphy to all types of vessels, including submarines, as well as its uses in war and peace. He concluded with an acknowledgment of the help which he had received from the King and Queen of Italy.

An appeal on behalf of the Alfred Russel Wallace Memorial Fund, signed by the executive officers, Prof. R. Meldola, Prof. E. B. Poulton, and Mr. James Marchant, was published in the issue of Nature for December 11 last (vol. xcii., p. 425). If a sufficient sum can be raised, the following memorials are proposed:—(1) A memorial medallion for Westminster Abbey, to which the Dean and Chapter have given their consent; (2) a portrait; (3) a copy of the portrait for presentation to the nation; and (4) a statue to be offered to the trustees of the British Museum for erection in the Natural History Museum. It is estimated that the complete scheme can be carried out for 1100*l.* The subscriptions received or promised amount to 200*l.* The medallion for Westminster Abbey will, it is estimated, necessitate the expenditure of at least 300*l.*, and the executive committee is anxious to complete this part of the work as soon as possible. The second part of the scheme, the portrait, will be proceeded with as soon as an additional sum of 350*l.* is subscribed. The most convenient course for intending subscribers to adopt is to send cheques made payable to the "Alfred Russel Wallace Memorial Fund," to the manager, Union of London and Smith's Bank, Holborn Circus, London, E.C. It is earnestly to be hoped that a sufficient response to the appeal will be speedily forthcoming to enable the executive officers to complete what will be worthy memorials of a great naturalist.

The report of the council of the Physical Society (adopted at the annual general meeting on February 13) states that owing to the improved financial position it is felt that the society's field of activity should be increased; careful consideration has, therefore, been given, during the past year, to the possibility of introducing new features, such as the issue, from time to time, of reports upon certain subjects of general interest. The first subject selected for the purpose is radiation. Mr. J. H. Jeans, F.R.S., has expressed his willingness to write the report upon this subject, and to have it complete during the summer. An occasional or annual lecture by some eminent physicist will also be arranged. This series of lectures, the first of which will be found summarised elsewhere in this issue, will be known as the Guthrie Lectures, in memory of the late Prof. F. Guthrie, through whose efforts the society was founded. A committee has been appointed by the council to consider questions in regard to nomenclature and symbols and allied matters, and consists of Prof. H. L. Callendar, Mr. A. Campbell, Dr. C. Chree, Dr. W. Eccles, Prof. G. Carey Foster, Sir George Greenhill, Dr. A. Russell, Prof. the Hon. R. J. Strutt, Prof. S. P. Thompson, and Prof. W. Watson, with Dr. Eccles as secretary and convener. At present the committee is discussing electric and magnetic quantities; but reports on mathematical and mechanical nomenclature and symbols, so far as these concern physicists, and on heat are also projected.

A summary of the weather for the past winter in the several districts of the United Kingdom, as shown by the results for the thirteen weeks ended February 28, has been issued by the Meteorological Office. The mean temperature for the whole period was above the average over the whole of the British Isles, the excess being greatest in the English districts. The highest temperature in any district was 61° in the midland counties, and the lowest reading 5° in the east of Scotland. In the north-east of England the lowest winter temperature fell to 9°, and in all other districts it fell below 20°, except in the English Channel district, where the lowest reading was 25°. The summary shows the rainfall to be less than the average except in the north of Scotland and the north of Ireland; the greatest deficiency was 2·15 in. in the midland counties, where the total rainfall was only 67 per cent. of the average. In the north-east of England the rainfall was 70 per cent. of the average, in the east of England 75 per cent., and in the south-west of England 86 per cent. of the average. The greatest aggregate measurement for the winter was 19·16 in. in the north of Scotland, and the least measurement 3·83 in. in the north-east of England. There was a deficiency in the number of rainy days in all the English districts. The duration of bright sunshine was deficient over the entire kingdom, except in the south-east of England, where, however, the excess was very slight.

In the Annals of the South African Museum, vol. xiii., part i., Mr. L. Péringuey, the director, gives an interesting list of inscriptions left by early European navigators to the East in South Africa. The earliest inscribed stone is that of Diego Cão, A.D. 1484. This was found in German territory in 1893. By orders of the German Emperor, the original has been removed to Germany; one replica has been erected on the spot where the original stood, and a second has been promised by the German authorities to the South African Museum. The first English record is that of Antony Hippon, mate or master of the *Hector*, dated in 1605. The next is that of the *Thomas* in 1618. The paper throws new and interesting light on the early history of European discoveries in the East, and the evidence now provided will be useful for comparison with the early records in the India Office.

The University Museum of Philadelphia has started an interesting experiment for the study of some Indian tribes. Mr. L. Shotridge, a full-blood Tlinget, from the Chilkat river in south-eastern Alaska, has been appointed an assistant on the museum staff. He has made for the museum a model of a section of his native village, and in this article, in the issue of the journal of the museum for September, 1913, he gives a detailed account, with plans, of the methods of house-construction. Those of chiefs are sometimes elaborately decorated, and are looked on with respect, because in them are kept the old relics—ceremonial costumes, helmets, batons, carved and painted screens and posts—which have come down from the family ancestor. The house drawings are interesting as showing the methods of native architecture and carpentry.

No. 6 of the fourth volume of the Journal of the College of Agriculture of Tokyo is devoted to an account by Mr. Tsunekata Miyaké of the Japanese insects of the neuropterous group Mecoptera, a group of which Japan is already known to possess more than forty species, while Europe and America collectively do not own more than twenty. It was at one time supposed that these insects, as typified by Panorpa, were of value to agriculturists on account of their destroying other insects, but their importance in this respect appears to have been overrated.

The receipt of a copy of the February issue affords a welcome opportunity of bearing testimony to the high standard of excellence attained, both from the zoological and the artistic point of view, of Mr. Douglas English's illustrated monthly journal, *Wild Life*, which has now entered its third volume. Among the contents of the present issue an article by Mr. C. J. King on the grey seal in the Scilly Isles, illustrated by photographs showing the wonderful difference between the coat of the new-born young and half-grown individuals, is one of the most interesting. Attention may also be directed to the photograph by Mr. Seth Smith of the male pigmy hippopotamus recently presented to the Zoological Society by the Duke of Bedford, which, although taken when the animal was too much in the shade, serves to show the small head, slender limbs, and widely separated toes distinctive of the species. The society now possesses a pair of these rare animals.

The Transactions of the Royal Scottish Arboricultural Society, vol. xxviii., part 1 (January, 1914), contain the concluding part of Mr. A. D. Hopkinson's account of the State forests of Saxony, which are perhaps the best managed in Europe, being worked upon a strictly commercial basis. These forests, with an area of 426,105 acres, yielded in 1910 a gross return of 790,753*l.*, from which, if the working expenses, 327,869*l.*, are deducted, there remains a net annual revenue of 462,885*l.*, or 1*l.* 1*s.* 9*d.* an acre. The expenses comprise cost of administration, maintenance of roads and buildings, cost of felling and planting, etc., and include also such items as 1044*l.* for research work, and 8035*l.* for insurance of workmen. The main species in cultivation is spruce, which is felled at an age of eighty years. Of special interest to plant ecologists is Mr. G. P. Gordon's article on the different associations constituting the beautiful natural forest of the Zernez district in the Engadine, which has lately been made a nature reserve by the Swiss Government. Continental forestry is further dealt with in the official account of the visit of the society to Switzerland in July, 1913, and by numerous notes on the forests of France and southern Germany. The main article on home forestry deals in a practical way with the successful planting of a considerable tract of high-lying peat at Corrour, in Inverness-shire. The method adopted is a Belgian one, which was introduced by Sir John Stirling-Maxwell in 1908.

There seems to be some probability of more unfavourable ice conditions in the North Atlantic this year than existed during 1913. Although bergs were sighted throughout the whole of that year, they were comparatively few in number, and of small dimensions on the Transatlantic routes. The meteorological charts of that ocean for the present month published by the Meteorological Office and by the Deutsche Seewarte contain useful notes upon the subject. Bergs were seen at Belleisle early in January last, and also several about 46° N., between 46° and 49° W. On January 30, in 48·2° N. and 48·7° W., the steamer *Czar* had to alter her course considerably to get clear of field ice, and some ships bound for Canada have had, owing to unfavourable ice conditions, to take to the more southerly route before the usual time agreed upon. There was much ice on the west coast of Iceland in the early part of January, and several trawlers are reported to have received damage.

A bibliography of the Antarctic, from the earliest works to 1913, by J. Denucé, forms a bulky appendix to the thin report of the International Polar Commission held at Rome in April, 1913 (Bruxelles: Hayez, 1913). The first outcome of the ambitious projects of this scheme was the "Liste des Expéditions Polaires depuis 1800," compiled in 1908 by the same author, and republished in a revised form in 1911. The present bibliography is excellently arranged under various subjects, and in cases where the entries are numerous, a regional subdivision has been adopted. The entries under each heading are in chronological order, and classified with an index number on the decimal system. The division of the Antarctic into four equal quadrants is a mistake, as it results in the partition of the Ross Sea, but any scheme of division must have its drawbacks, especially as the isolated known areas become linked by further exploration. M. Denucé has founded his work on the polar library which the commission is trying to form in Brussels, but he has gone far beyond the scope of that collection, and has spread his net wide enough to include various important reviews of Antarctic works, many newspaper articles, and notes in geographical publications, some of which inevitably would be lost sight of but for a careful compilation of this kind. On the other hand, there is room for revision and additions. We have noted a few omissions, and some slight errors in references, besides the premature inclusion of some papers announced, but not yet published. However, M. Denucé's work is a welcome supplement to Dr. H. R. Mill's bibliography in the "Antarctic Manual" of 1901.

THE symbol $|x|$ as applied to real quantities denotes the numerical value of x irrespective of algebraic sign. In a recent paper (Moscow: I. N. Kouchnéreff and Co., 1913), Dr. D. Riabouchinsky, director of the aerodynamic institute of Koutchino, treats this quantity as a function of the variable x, and shows how this method leads to interesting formulæ involving the solution of equations, differentiation, and integration. A number of elegant geometrical applications are also given, such as equations of broken lines, and equations of limited portions of planes, such as a square area.

THE first number of the *Washington University Studies* contains an interesting paper by Mr. Benjamin M. Duggar on Lycopersicin, the red pigment of the tomato, and the effects of conditions on its development. This red pigment is partially or completely suppressed when green fruits are ripened at a temperature of 30° C. or above, the inhibition of reddening being proportional to the temperature above this point. The factors for reddening are not destroyed by high temperatures, and a return of the fruit to normal conditions causes rapid pigmentation. The presence of oxygen is necessary to bring about reddening, and fruits maintained in an oxygen-free atmosphere fail to redden at the normal ripening temperature. The colouring matter of the red peppers and of the arils of Momordica exhibit the absorption bands of Lycopersicin.

THE *Photographic Journal* for February contains a condensed account prepared by Mr. F. F. Renwick of Dr. H. Ewest's thesis on quantitative spectrophotography. After giving a short account of most of the methods used previously, the author gives a description of his own apparatus, and the tests he has made in order to see that it is capable of giving trustworthy results. The light from a Nernst lamp is condensed on the slit of a direct-vision spectroscope, and the spectrum is produced on the photographic plate to be tested. Immediately in front of the plate is a neutral Goldberg absorbing wedge which covers the whole plate, and is raised with the plate at a uniform rate. The curve separating the opaque from the transparent portion of the negative then allows the character of the plate to be determined, and the relations between the time of exposure, the intensity of the light, and the density of the negative in all parts of the spectrum to be investigated. The method seems convenient and trustworthy, and should lead to an extension of our knowledge in this field.

AN important paper on the nature of enzyme action by Mr. Hendrik S. Barendrecht appears in the *Biochemical Journal* (vol. vii., part 6). In this paper, which bears the title, "Enzyme Action, Facts and Theory," it is pointed out that the researches of the past few years on the kinetics of enzyme action have brought more confusion than clearness into this field. An attempt is made by Mr. Barendrecht to clear up some of the contradictory statements regarding the kinetics of some of the most simple enzyme actions. As a working hypothesis it is assumed that enzyme action spreads like a radiation from an enzyme particle as centre; this conception is developed mathematically for the cases of more or less concentrated solution of the substrate, and the effect is considered of the products of the action exercising an absorption on the active radiations, and hence on the velocity of the change. In this way velocity equations are derived, which explain certain cases which have appeared to be abnormal. In particular the special cases of the action of invertase on cane sugar, of lactase on milk sugar, and of maltase on maltose are considered, with especial reference to the effect of the resulting sugars on the velocity constants.

IN the course of an interesting and suggestive paper on the calculations and details for steel-frame buildings, read at the Concrete Institute on February 26, Mr. W. Cyril Cocking urged that all constructional engineers and draughtsmen should support the London Building Acts 1909 Amendment. It may be thought by some that certain amendments to the Act would be desirable, but no concessions can be expected unless all concerned with its working combine to make the best of it as at present framed. Time has shown already that the Act has been the means of improving considerably the general design of steelwork. The 1909 amendment is an Engineer's Act essentially, and the reinforced concrete regulations will be more so, and it seems within the possibilities of the near future that, provided the engineer takes advantage of his opportunities, he might assume the more important position—the architect then confining his attention solely to the architectural treatment. Whole-hearted cooperation between engineer and architect will tend to provide London with buildings in which the architecture is more fully developed, and combined with sound construction in such a manner that the demands of economy and scientific utility are satisfied fully.

A GENERAL discussion on every aspect of the passivity of metals was held at the meeting of the Faraday Society on November 12 last, and was reported in the issue of NATURE for November 20, 1913 (vol. xcii., p. 356). The eight papers read on that occasion, together with the discussion upon them, have now been reprinted from the Transactions of the Faraday Society in book form, and can be obtained at the price of 7*s*. 6*d*.

The following books relating to science are announced, in addition to those referred to in our issue of March 5:—In *Anthropology*—The Ban of the Bori: an Account of Demons and Demon-Dancing in West and North Africa, Major A. J. N. Tremearne, illustrated (Heath, Cranton, and Ouseley); in *Biology*—The Wonder of Life, Prof. J. A. Thomson, illustrated (A. Melrose, Ltd.); In Nature's Ways, M. Woodward, illustrated (C. A. Pearson, Ltd.); British Flowering Plants, illustrated by Mrs. H. Perrin, with descriptive notes and an introduction by Prof. Boulger, 4 vols. (B. Quaritch); in *Chemistry*—Chemical Lecture Diagrams, Dr. G. Martin; The Wonderland of Modern Chemistry, Dr. G. Martin, illustrated (Sampson Low and Co., Ltd.); Elements of Physical Chemistry, J. L. R. Morgan, new edition (New York: J. Wiley and Sons, Inc.); in *Engineering*—Modern Practice in Tunnelling, D. W. Brunton and J. A. Davis; Subaqueous Foundations, C. E. Fowler; Influence Lines for the Determination of Maximum Moments in Beams and Trusses, M. A. Howe (New York: J. Wiley and Sons, Inc.); in *Geography and Travel*—Sport and Science on the Sino-Mongolian Frontier, A. de C. Sowerby (A. Melrose, Ltd.); Hunting and Hunted in the Belgian Congo, R. D. Cooper, illustrated; South Polar Times, reproduced in facsimile, new volume (Smith, Elder and Co.); in *Geology*—A.B.C. of the Useful Minerals, A. McLeod; Engineering Geology, H. Ries and T. L. Watson (New York: J. Wiley and Sons, Inc.); in *Mathematical and Physical Science*—Science and Method, H. Poincaré, translated by F. Maitland (T. Nelson and Sons); The Stars Night by Night, J. H. Elgie, illustrated (C. A. Pearson, Ltd.); Meteorological Treatise, F. H. Bigelow; Theory of Numbers, R. D. Carmichael; Elementary Theory of Equations, L. E. Dickson; Invariants, L. E. Dickson (New York: J. Wiley and Sons, Inc.); in *Medical Science*—Industrial Gas Poisoning, Prof. Glaister and Dr. D. D. Logan (E. and S. Livingstone).

OUR ASTRONOMICAL COLUMN.

Comet 1913*f* (Delavan).—In this column for February 12 we gave the ephemeris of comet 1913*f*, discovered by Delavan, which was computed by Dr. G. van Biesbroeck. This ephemeris is now continued here for the rest of the month so far as it is published:—

oh. M.T. Berlin.

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
March 13	2 47 21	+5 53·6	10·7
17	49 27	6 38·5	10·7
21	51 44	7 23·7	10·7
25	2 54 12	+8 9·2	10·6

The magnitudes are based on the assumption that the comet was of magnitude 11·0 on December 17. The current number of the Lick Observatory Bulletin (No. 250) contains another computation of the parabolic elements of this comet undertaken by Messrs. S. Einarsson and S. B. Nicholson, and an ephemeris based on those elements by Miss Julia I. Mackay and Mr. C. D. Shane, of the same institution. The elements are very closely similar to those calculated by Dr. Biesbroeck, and the ephemeris differs only slightly. According to the last-mentioned computers, it is stated that assuming the brightness of the comet to have been 1·00 on December 29 of last year the comet may become visible to the naked eye.

On the other hand, M. R. Goudey contributes to the *Astronomische Nachrichten* (No. 4717) elliptic elements of the above comet based on observations extending between December 18, 1913, and January 15 of the present year. The position he gives in his ephemeris for March 21 is almost identical with that stated in the foregoing table.

A Large Reflector for Canada.—It is very satisfactory to be able to record that Canada will soon be equipped with a fine large reflecting telescope, contracts having been given for its construction. When it is mentioned that Messrs. J. A. Brashear and Co. will be responsible for the optical parts, and Messrs. Warner and Swasey Co. for the mounting, the well-known capabilities of these firms should certainly secure a fine instrument. Prof. J. S. Plaskett is to be congratulated on the successful issue of his endeavour to secure an instrument of large aperture for Canada, and his account of the proposed form of mounting, programme of work, etc., contributed to the current number of the Journal of the Royal Astronomical Society of Canada will be read with interest. The telescope will have a parabolic mirror of 72 in. clear aperture, with a central hole of 10 in., the focal length being 30 ft.; it is to be mounted similarly to the Melbourne reflector. It will be primarily used for spectrographic observations of stellar radial velocities, but it is planned to have the telescope available for the direct photography of nebulæ, clusters, etc. One of the principal considerations in the design is to enable work "to be done in the most efficient and convenient way possible with the simplest possible mechanical design." The communication in question describes in detail the simplifications with which it is intended the instrument shall be equipped.

The Smithsonian Astrophysical Observatory.—The report of the Astrophysical Observatory for 1913, under the direction of the Smithsonian Institution, contains a good account of progress made; in fact, the director, Mr. Abbot, refers to the work of the observatory as "uncommonly successful." We notice that for the solar work at Mount Wilson there has just been erected a Tower telescope, 40 ft. high, for use with the spectrobolometer, for the study of the distribution of radiation over the sun's disc. The report states many results of the year's work. Thus the mean value of the solar constant of radiation at the earth's mean distance from the sun, from about 700 observations made at high and low stations between 1902 and 1912 is 1·932 calories per square centimetre per minute. The fluctuation of the "solar constant" values is attributed to the variability of the sun, and in addition to the periodicity due to sun-spots, there is another "irregular, non-periodic variation, sometimes running its course in a week or ten days, at other times in longer periods and varying over irregular fluctuations of from 2 to 10 per cent. of the total radiation in magnitude." Further, a combination of the effects of sun-spots and volcanic haze is put forward as explaining the principal outstanding irregularities in the temperature of the earth for the last thirty years. Finally, in the Californian expedition, in which sounding balloons were employed, the solar radiation values at very high altitudes indicate that the direct pyrohelion metric observations gave results of the same order of magnitude as the solar constant work of 1902–12 by high and low sun observations on homogeneous rays, according to Langley's methods.

THE IMPORTATION OF BIRDS' PLUMAGE.

TO the *Fortnightly Review* for March Miss L. Gardiner contributes, under the title, "The Fight for the Birds," a timely article apropos of Mr. Hobhouse's Plumage Bill now down for second reading. She gives a history of the rise and progress of the contest against the slaughter and extermination of so many of the most useful and ornate birds of the world for the plumassier trade, which has never been more in evidence than in the past season or two, during which women have "so gaily worn the brand of Cain in the street." Miss Gardiner quotes statistics from brokers' catalogues, mainly of 1911, 1912, 1913, which show that, besides others, 132,000 "ospreys" were killed, 8700 birds of paradise, 22,000 crowned pigeons, 24,000 humming-birds, 23,000 terns, 162,000 kingfishers, 1200 emeus, and 4500 condors. It is significant that, as the author remarks, "reports on the quantities now sold are no longer published in the *Public Ledger* since the House of Lords inquiry."

The outcry against this wholesale slaughter is not confined to the lovers of nature and the humanitarians as such, but is loud from the agriculturists of the Himalayas, of Madras, and other parts of India, of Georgia, Florida, and Carolina, and of Egypt, whose crops are devastated by reason of the scarcity of the birds that heretofore destroyed the insect pests now ruining them. Strong official support has been given by the Zoological Society to Mr. Hobhouse's Bill, and also by the British Ornithologists' Union, although the trade journals claim both societies, as well as quote the names of numerous distinguished scientific men, many of whose names were authorised under the impression that they were supporting the principle of the Bill—as in favour, not of the Bill, but as supporters of the Committee for the Economic Preservation of Birds. Unfortunately, the Zoological Society has been made to appear to the general public to support the Economic Committee—to which it is absolutely hostile—through the secretary of the society having accepted, in his private capacity, the chairmanship of the committee. The corresponding Economic Committee in Paris, as recorded recently in NATURE (January 29, p. 617), was entirely defeated on its very strenuous attempts to check the growing force of opinion in France in favour of the protection of birds, fostered by the Acclimatisation Society.

Miss Gardiner's article should be widely studied by all who desire to know the rights and wrongs of the plumage traffic. In a letter "On the Need for Protection of Rare Birds," in the *Times* for March 3, the Hon. Charles Rothschild says he is impelled to write "as there is a danger of the [Plumage (Prohibition)] Bill being defeated through the efforts of those opposed to the measure, who have formed themselves into . . . the Committee for the Economic Preservation of Birds." His observations fully corroborate what Miss Gardiner has stated about the objects of this committee in the *Fortnightly Review*. "One thing is certain," as Mr. Rothschild remarks, "that many of the most beautiful birds have never been in greater need of protection than at the present time. In the *Times* of March 6 Mr. C. F. Downham, replying to Mr. Rothschild, trails once more the red-herring of the "dead" egret feathers across the question. It has been abundantly proved that the plumes offered as "dead" were wrongly so described to quieten public opinion; and if, indeed, any "dead" feathers now come to the market, they are brought with the same object, and for the reason that the supply from slaughtered birds has decreased below the demand, not "because the area of protection is increasing," but because the heronries themselves have been so depopulated. It is amusing to read Mr. Downham's statement that "the nuptial plumes of the egret are borne by the birds long after the nesting time, and that the birds carry their feathers for seven or eight months of the year."

In the March issue of *Pearson's Magazine* Mr. Hesketh-Pritchard describes the almost incredible cruelties perpetrated by the professional plume-hunters, the sworn testimony of one of whom he quotes, which is directly contradictory of the plume-traders' reiterated declarations that the "egrets" are moulted feathers. The *Spectator* of March 7 has also a powerful article on the need for the Plumage Bill, from which the following sentences are extracted:—". . . the activities of the [economic] committee appear at present to be centred hardly so much on the protection of birds which are being harassed, as upon definite opposition to the Bill which prohibits the importation of their plumage. . . . The plumage of all birds is at its brightest in the breeding season, and it is at this season, therefore, that the bird is killed. No 'economic preservation' will alter that fact. The plain issue, in short, is . . . whether traffic in feathers which admittedly involves cruelty and which leads inevitably towards the extinction of species shall be permitted at all. So far as Great Britain is concerned, we hope that a Plumage Act will be the answer."

A public meeting will be held at Caxton Hall, on Thursday, March 19, at 5.30, under the patronage of the Royal Society for the Protection of Birds, the Zoological Society, the Avicultural Society, the British Ornithologists' Union, the Society for the Promotion of Nature Reserves, the Society for the Preservation of the Wild Fauna of the Empire, and other bodies, in support of the Plumage Bill. When the Bill is passed it will be illegal to import the feathers or skins except for scientific purposes, for which purpose a licence will be obtainable from the Board of Trade. It is confidently believed that such legislation will have far-reaching effects towards the preservation of rare and beautiful wild birds. The trade in ostrich feathers is specially exempted from the provisions of the Bill. Tickets (free) for the meeting may be obtained through the secretaries of the patron societies, or from the hon sec., Plumage Meeting, 34 Denison House, Westminster.

THE VITAMINES OF FOOD.[1]

FLEURENT, in his "Le pain de Froment," shows that the grain of wheat consists, by weight, of the protective coat (15·6 per cent.), the embryo or germ of millers (1·4 per cent.), and the white flour (83 per cent.). The coat includes, in addition to the pericarp and testa, the aleurone layer of the endosperm, the remainder of which forms white flour. The bran of the miller, as removed by the metallic roller, includes the aleurone layer, which is not only a starchless layer, rich in fats, but contains the newly discovered bodies to which C. Funk has given the name of vitamines, and of which the first detailed authoritative account has appeared this year ("Die Vitamine," von Casimir Funk, J. F. Bergman, Wiesbaden, 1914).

A discussion of their chemical nature would be out of place now, and must be left to organic chemists. It may be mentioned, however, that they do not contain phosphorus, they are not fatty bodies, and are distinct from lipoids. They are nitrogenous and of highly complex structure (*e.g.* the formula of one is $C_{26}H_{20}O_9N_4$); they are indispensable for

[1] Summary of a lecture entitled a "Grain of Wheat," delivered in the National Museum, Dublin, on February 24, by Prof. T. Johnson.

life, and no diet is complete without them. If the brain, "one of the three legs of the tripod of life," is starved by a vitamineless diet troubles of all kinds—called by Funk *deficiency diseases*—arise, and these may end in death. The muscles dwindle away, the nerves degenerate, and heart and bone troubles result. Their absence is a predisposing cause of tuberculosis. Vitamines are found in plants, and especially in their seeds. So far as is known at present, animals are incapable of making them. Animals, however, obtain them by feeding on plants. Thus vitamines occur normally in meat, fresh milk, and yolk of egg. They are soluble in water, and insoluble, mostly, in ether. They are thermolabile, and are destroyed by exposure for 10–20 minutes to a temperature of 120°–130° C., as well as by extreme dryness. Thus cattle may, following on a long drought, suffer from a vitamineless fodder.

Funk regards vitamines as the mother-substance of ferments and hormones, and of vital importance to the thyroid and other ductless glands. It is thus evident that the diet standards of the text-books must be revised in the light of their discovery, which throws a flood of light on the milk and other food problems. White flours and corn flours are deficient foods because the vitamines have been removed in the milling process.

Wherever any cereal, robbed of its aleurone or vitamine layer, forms the chief food of a people, there a deficiency disease appears. Rice is eaten by more people than any other grain, in the tropical regions of both hemispheres. The marked increase of beri-beri caused by eating *polished* rice, claiming thousands of victims yearly in Japan, etc., coincides with the replacement of the primitive whole-grain stone-milling by the modern steel roller. The United States Government has already made the polishing of rice in the Philippines illegal. Indian corn (*Zea mais*) is largely eaten in north Italy, the Balkan provinces, the southern part of the United States, Brazil, etc. In all these countries pellagra, which affects the skin, digestive organs, and mental powers, is prevalent. The disease could be stamped out by adding to the diet potatoes, one of the cheapest and most practical sources of vitamines. Though the tax of 32*s*. 6*d*. a ton on potatoes has been removed, the U.S. Government has at the same time closed its ports to European potatoes, as a precaution against the introduction of potato diseases, such as Spongospora, though pellagra is on the increase, and American potatoes are becoming dearer.

Rickets, scurvy, osteomalazia, etc., are also deficiency diseases caused by the use, as the main articles of diet, of such vitamineless foods as sterilised milk, condensed milk, cornflours, starch, and sugar. The mixed diet of most people protects them from deficiency diseases.

Vitaminous foods are fresh milk and (though less rich in them) pasteurised milk, whole grains, potatoes, carrots, and other fresh vegetables, lime and other fruit juices, beans, peas, lentils, and the like, meat, beef-tea, barley-water, yeast, and apparently cod liver oil The discovery of vitamines leaves the vexed question of the relative values of white bread, standard bread, etc., where it was, as the heat of the oven, far above that of the autoclave in milk sterilisation, probably destroys the vitamines of the wholemeal bread.

Phaseolus mungo. L. (*P. radiatus*, L.), added to polished rice effectively supplies the removed vitamines, prevents beri-beri, and has long been regarded by the Chinese as a delicacy in the form of vermicelli. A yeast extract is already available for a similar purpose in this climate.

ATMOSPHERIC REFRACTION AND GEODETIC MEASUREMENTS.[1]

AMONGST the many perplexing problems with which geographical surveyors have to deal those which concern the determination of altitude are not the least. For purposes of practical ability, such as the levelling of roads or the laying out of contours and gradients where differential altitude is comparatively small and progressive, existing methods are quite sufficiently scientific and accurate. It is in the determination of the relative altitudes of large geographical features, where angular measurements become necessary, that there arises a series of complications due to variations in the amount and effect of refraction, or in that of the plumb-line deflection, which have been by no means exhaustively investigated, and which introduce errors of an appreciable quantity. These errors are seldom of large practical importance, so that an investigation into their origin and the scientific methods of their dispersion is more or less matter of academic interest to that limited public which concerns itself with mountain altitudes and is generally content to accept the reading of a cheap aneroid as sufficient proof of the correctness of a value determined by triangulation.

By the scientific geodesist, however, Mr. Hunter's investigations will be warmly appreciated. The book before us is No. 14 of the Professional Papers of the Survey of India, and it contains a careful analysis of the chief sources of error which beset the ordinary estimates of the amount and effect of terrestrial refraction. The error due to refraction is usually disposed of by the assumption that the angle of refraction bears a constant ratio to the angle contained by the ray of observation at the centre of the earth. When reciprocal observations can be taken (*i.e.* from A to B, and from B to A) this ratio can be determined, and it is then recorded as the "coefficient of refraction," and is applied to other observations which, not being reciprocal, require to be corrected for the effect of refraction. This method Mr. Hunter calls a "makeshift," and it is with the object of putting the consideration of "angular measurements affected by terrestrial refraction on a more accurate and scientific basis," that he has deduced formulæ from his investigation which, in the concrete form of tabulated corrections, may assist in dispersing the errors arising from variations in the density, temperature, and atmospheric pressure of the air between the station of observation and the point observed. The only assumption which he makes is the natural one that "layers of equal density in the air are concentric with the (circular) section of the earth in the azimuth of the ray," an assumption which includes that of thermal equilibrium. The formulæ derived in chap. i. show that refraction depends very largely on the rate at which temperature changes with the height, and with the change of this rate, as well as on the differential height to which the ray extends. Mr. Hunter confirms the accepted rule that refraction is least in the middle hours of the day, but he further regards its variations as seasonal, *i.e.* it is least in the springtime of the year.

But when all is said and done, it is the errors arising from the deflection of the plumb-line (not always ascertainable at the point of observation), and the possible variation in the actual height of the point observed (common enough in the case of snow-capped peaks), which chiefly affect the accuracy of angular determinations of altitude, and it is probably to these rather than to the unequal conditions affecting the

[1] "Formulæ for Atmospheric Refraction and their Application to Terrestrial Refraction and Geodesy." By J. de Graaff Hunter.

intermediate stratum of air that we must ascribe (*exempli gratia*) the doubt whether Kinchinjunga or K_2 is to hold the honourable position of second in altitude to Everest amongst the world's highest peaks. T. H. H.

REPORTS OF MUSEUMS.

THE report of the Bristol Museum for the year ending September 30, 1913, records praiseworthy activity, especially in the department of vertebrate zoology. Three plates show how attractively some of the more important specimens are displayed. A tiger shot by the King in Nepal, and presented by his Majesty, has been set up by Messrs. Rowland Ward, in a crouching attitude among bamboo stems, while the background, painted by Mr. Stanley Lloyd, shows the shooting-party approaching on elephants in the distance. Three springboks are placed near the margin of a veldt, on which other animals are browsing; this background was painted by Mr. G. E. Butler. The picturesque group in which pheasants are feeding (harmlessly) in the stubble, is backed by a view of Ashton Park, with the Clifton Suspension Bridge in the distance, composed by Mr. A. Wilde Parsons. This utilisation of really competent artists is an example to be followed. The geological department has not shared in the general progress, and considering the recent work of Vaughan and others in the west of England, this fact is rightly deplored by the committee.

With the aid of local naturalists, the small staff of the Hancock Museum at Newcastle-upon-Tyne has during the past two years accomplished some excellent work. From a 45-ft. Rorqual (*Balaenoptera borealis*) cast ashore near Amble, the complete skeleton, including ear-bones, hyoids, and rudimentary hip-bones, was obtained. The larger bones have been satisfactorily prepared in a sand-pit; but the smaller bones which were macerated as usual in water made so little progress that they have now been transferred to sand. A promising beginning was made with classes from the elementary schools, each of which went through a definite course of six lessons, given by the teachers, who were first rehearsed in the lesson by the curator, Mr. E. L. Gill. Unfortunately this regular system could not be followed in the second year, owing to the overcrowded curriculum of the schools, and the visits are now of small educational value. Perhaps the committee recently appointed by the British Association may devise some scheme that will overcome this difficulty.

The report of the Manchester Museum for the year 1912–13 bears witness to plenty of hard work, but contains nothing of outstanding interest. It is, however, worth reading in order that one may admire the healthy spirit of cooperation as regards museum matters that breathes in Manchester. Representatives of the University, of the City Council, and of subscribers among the outer public, constitute the committe of management. The City Council has increased its grant from 400*l.* to 800*l.* per annum. Professors of the University supervise and aid the museum staff. In the transference of the Egyptian antiquities to the new building, which, with its cases, was provided by Mr. Jesse Haworth, valuable help was given by a number of ladies and gentlemen. Several ladies have maintained a supply of fresh flowers, and at least four other names are mentioned in connection with solid pieces of work of more expert character. To a museum combining so many forces there naturally flow considerable donations, both in money and in kind.

RADIATION OF GAS MOLECULES EXCITED BY LIGHT.

THE first Guthrie lecture of the Physical Society was delivered on February 27, at the Imperial College of Science, South Kensington, by Prof. R. W. Wood, of Johns Hopkins University, Baltimore. The lecture has been established in memory of Prof. F. Guthrie, who was professor of physics in the Royal College of Science, and was founder of the society, the first meeting having been held in his lecture theatre at the college in 1874. Before Prof. Wood's lecture, Prof. G. Carey Foster gave a short biography of Guthrie, who was born in 1833 and died in 1886, and Sir Oliver Lodge recalled some personal reminiscences of him. Prof. Wood's lecture is summarised in the subjoined abstract, published by the Physical Society.

The emission and absorption of light by molecules and the allied phenomenon of dispersion have led us to the conception of something within the atom which is capable of responding to light waves in much the same way as a tuning-fork responds to sound waves of the same frequency as its own, and many mathematical treatments have been built up which explain more or less perfectly many of the phenomena in question. These still leave us very much in the dark as to what is going on. Helmholtz explained absorption by introducing a frictional term into his equations of motion for the atom, and though this led at once to an expression which represented anomalous dispersion, it left us ignorant of how the energy absorbed by the molecules was transformed to heat, or how the mean velocity of the molecules was increased by the excitation of vibrations within them. Planck avoided this difficulty by considering that the energy abstracted from the beam of light is re-emitted, though at the time the only experimental evidence was to be found in selective reflection, which occurs only in liquids and solids.

What becomes of the absorbed energy in the case of a gas? This was what he had been asking himself for many years. While he did not require a working model of the atom, he could not, however, be satisfied by an equation in which absorption was represented by a frictional term or selective reflection predicted by the occurrence of an imaginary quantity.

The problem of the constitution of the atom is one which must be approached from many sides, as it is improbable that any single mode of attack will reveal the secret. The spectroscope alone has proved itself powerless, one great difficulty being that in all known methods of exciting spectra one got "the whole or nothing."

Flames, arcs, sparks, and vacuum-tube discharges set a host of vibrations simultaneously in operation within the atom, and resulted in a complex of lines which were difficult to interpret.

His line of attack had been to maintain the molecules in as calm and tranquil a state as possible, by keeping them cool, and then to excite them to radiation by the application of an alternating electromagnetic field of a definite frequency—usually called monochromatic light. That this method has in some degree simplified matters was proved by the fact that sodium vapour could be made to emit only one of the D lines instead of the usual two.

The conditions necessary to stimulate radiation in this way varied considerably with the nature of the element studied. He would begin, however, with the simplest case, that of a vapour which exhibits a single absorption line and emits radiations similar in every respect to the exciting radiations when stimulated by light of frequency equal to that of the absorption line. This condition was perfectly fulfilled by the vapour of mercury, which has an absorption line at $\lambda=2536$ in the ultra-violet.

If a beam of monochromatic light of this wave-length was focussed at the centre of an exhausted quartz bulb containing a drop of mercury at atmospheric temperature, it was found that the light was powerfully scattered by the vapour, photographs of the bulb made with a quartz lens showing the cone of rays much as if the bulb were filled with smoke. The scattered light is invariably much more homogeneous than the incident beam, in which the "line" has a finite width, whereas the scattered light corresponds only with the centre of this line. The rest gets through the vapour unaffected. With the light thus scattered—the *resonance radiation*—a photograph was made of a quartz bulb containing a minute drop of mercury at room temperature. The bulb appeared as if filled with ink owing to the opacity of the vapour for the rays.

These phenomena, visible only to the camera, can be visually reproduced in the case of sodium vapour excited by the light from a sodium flame. If the density of the vapour is increased by warming it, the distance which the light can penetrate into the bulb is diminished and eventually the resonance radiation is all emitted from a region so close to the surface that it appears as a bright yellow patch on the inner surface of the glass.

If this patch is now used as a lamp, and focussed by a concave mirror on the surface of the same globe (or another in which the vapour is of sufficient density to give the patch effect) so as to fall partly on a surface whitened by deposited magnesia and partly on the enclosed vapour, the brightness of the two contiguous patches thus formed is practically equal.

This proves that, under those conditions, at comparatively low densities, *true absorption does not exist*, the light abstracted from the incident beam being re-emitted as light of the same wave-length but in all directions.

The factor of true absorption makes itself manifest as soon as we admit air or some other foreign gas. Even if the pressure is only a millimetre or two the effect is very marked.

Another point which can be brought out by this method of attack is whether or not the mechanisms the vibration frequencies of which correspond to the various lines in a spectrum are independent of each other or are interconnected.

An ingenious method was described whereby a beam of considerable intensity, consisting, however, of only D_1 or D_2 light, could be obtained, and if the sodium vapour excited by either of these was examined spectroscopically the emitted light contained only that one of the lines which was used to excite it. This shows that the D_1 and D_2 mechanisms are quite independent. In other cases, however, vapours excited by light of any one line of their spectrum gave out a resonance spectrum of that line and one or more others showing that some groups of mechanisms were interdependent and could not be excited separately.

Stimulation by Waves of Very Short Wave-Length.—Experiments were then described in which air, nitrogen, etc., had been caused to emit ultra-violet light when exposed to the action of radiation of wave-length less than the Schumann rays, the smallest waves hitherto known. Schumann rays were completely absorbed by quartz, but would pass through a considerable thickness of fluorite, but the rays to which he referred could be reduced in intensity by 98 per cent. by a plate of fluorite 1 mm. thick.

Nitrogen was more actively stimulated than air by these rays, as oxygen seemed to have a destructive effect on the phenomena. Thus iodine vapour, if mixed with nitrogen, emitted a green light under the action of the rays, while remaining dark if mixed with oxygen.

He urged the necessity of an exact mathematical treatment of the phenomenon of a molecule of vapour re-emitting radiation which it has abstracted from an incident beam, true absorption being absent.

At the conclusion of the lecture a number of interesting experiments illustrative of the subject of the lecture were shown. These included the resonance radiation of sodium stimulated by D light, of iodine vapour stimulated by the light from a quartz-mercury lamp, and of the author's method of extinguishing one of the D lines from the light from a sodium flame.

STRUCTURAL ANALOGIES BETWEEN IGNEOUS ROCKS AND METALS.

It was in Sheffield that the late Dr. H. C. Sorby lived and worked. It was to the Sheffield Literary and Philosophical Society that, in 1864, Sorby presented the first account of his microscopical examination of the structures of commercial steel. In Sheffield the worth of Sorby's work is now being recognised, and during the presidency of Mr. Arthur Balfour the Sheffield Society of Engineers and Metallurgists, an active and growing society closely associated with the industries of the city, has founded the "Sorby Lecture," to "mark its progress," and to perpetuate the memory of its late honorary member.

The first Sorby Lecture, on February 28, was the occasion for a large gathering of Sheffield's leading manufacturers and citizens at the Cutlers' Hall. The lecture was delivered by Prof. W. G. Fearnsides, the occupant of the Sorby chair of geology at Sheffield University, "On Some Structural Analogies between Igneous Rocks and Metals."

In the first part of the lecture Prof. Fearnsides traced the progressive development of the research by which Sorby, already trained to a knowledge of optics and of chemistry, learned from Williamson the art of making transparent sections of hard objects, and applied it (1849) to the study of rocks. Limestones were the first rocks to claim his attention (1851), then slates (1856), and then igneous rocks (1857), and from these, through meteorites (1862), he was led to study irons (1863–4). The difficulties which Sorby encountered and his patient toil, continued in defiance of indifference and ridicule, were discussed, and it was conjectured that the apathy with which his results were received was due to his own inability to appreciate the difficulties which his refined technique and the vector variations of the optical properties of minerals presented to other people.

The recognition of the value of Sorby's petrographic methods grew gradually through the sixties and seventies of last century, but it was not until after his announcement to the Iron and Steel Institute in 1886, that in the previous year a new microscope had enabled him to see the true composite nature of the "pearly constituent" of steel, that his pioneer work on metals attracted any attention.

It was by a fortunate but unforeseen coincidence that the first Sorby Lecture was delivered within a few days of the fiftieth anniversary of the day on which Sorby read the first of all papers dealing with the micro-structure of commercial metals, and the subject for the lecture was chosen accordingly.

The second part of the lecture dealt with the modern view that igneous rocks and metals are alike products derived by progressive partition of components during the crystallisation of mixed solutions. Being thus homologous in the manner of their origin, it was maintained that a mineralogical nomenclature which is properly applicable to the constituents of igneous rocks is similarly applicable to the constituents of steel; and though a phase rule (temperature-concentration) diagram affords a ready means for the discussion of the behaviour of phases during their partition into other pairs of phases, a metallographic description of their structure modelled on the nomenclature usual in petrography is more manageable when the number of constituents is large.

Special analogies between igneous rocks and metals were suggested. Segregation of the phosphorus and the sulphur in steel ingots was paralleled with "differentiation-*in-situ*" as it occurs in igneous rocks. The time taken in cooling through the temperature range of active crystal growth was shown to control the texture both of igneous rocks and of metals. Viscosity as another factor controlling crystal growth was considered, and the absence of any structures in metals analogous to those developed in viscous rock magmas and in devitrifying glass—*e.g.* "spherulitic structure"—was attributed to essential differences in this respect. "Skeletal crystals," so common in metals, are characteristic of over-rapid growth and as a passing stage in the development of polyhedra are not unknown in rocks.

"Eutectic structures" in metals are like the "graphic" and "pegmatitic" structures of rocks, and their obliteration with slower cooling, both from rocks and metals, was noted.

"Cores" in "mixed crystals" of metals are analogous to "zonary banding" in non-homogeneous isomorphous minerals, and the successive crystallisation of distinct phases above and below a change-point has its parallel in the "corona structure" of some norites.

Partition of solid solutions always at the margins or along the cleavage of pre-existing crystal grains, a process so important in the heat treatment of commercial steels, finds its analogue in the orderly separation of the "schiller constituents" within the minerals of plutonic rocks. "Perthitic structure" in slow-cooled felspars seems to require a similar explanation.

From analogies such as these it was argued that the experience of the geologist may be useful to the metallurgist, and that the knowledge of the structure of metals, which for commercial purposes are manufactured under controlled conditions of temperature and of stress, may provide a key of great adaptability with which, in conjunction with his map, his hammer, and his microscope, the geologist may decipher and interpret the autobiographical secrets of the record contained in the rocks

INDUSTRIAL RESEARCH IN AMERICA.[1]

GERMANY has long been recognised as pre-eminently the country of organised research. The spirit of research is there immanent throughout the entire social structure. This is not the time or place, however, nor is it necessary before this audience, to refer in any detail to the long record of splendid achievement made by German research during the last fifty years. It is inscribed in luminous letters around the rock upon which Germany now stands secure among the nations of the world.

The virility and range of German research were never greater than they are to-day. Never before have the superb energy and calculated audacity of German technical directors and German financiers transformed so quickly and so surely the triumphs of the laboratory into industrial conquests. Never has the future held richer promise of orderly and sustained progress, and yet the pre-eminence of Germany in industrial research is by no means indefinitely assured. A new competitor is even now girding up his loins and training for the race, and that competitor is, strangely enough, the United States—that prodigal among nations, still justly stigmatised as the most wasteful, careless, and improvident of them all.

To one at all familiar with the disdain of scientific teaching which has characterised our industry, and which still persists in many quarters, this statement is so contrary to the current estimate that its general acceptance cannot be expected. It will have served its purpose if it leads to a consideration of the facts which prove the thesis.

The country of Franklin, Morse, and Rumford, of McCormick, Howe, and Whitney, of Edison, Thomson, Westinghouse, and Bell, and of Wilbur and Orville Wright, is obviously a country not wholly hostile to industrial research or unable to apply it to good purpose. It is, however, not surprising that with vast areas of virgin soil of which a share might be had for the asking, with interminable stretches of stately forest, with coal and oil and gas, the ores of metals, and countless other gifts of nature scattered broadcast by her lavish hand, our people entered upon this rich inheritance with the spirit of the spendthrift, and gave little heed to refinements in methods of production and less to minimising waste. That day and generation are gone. To-day their children, partly through better recognition of potential values, but mainly by the pressure of a greatly increased population and the stress of competition between themselves and in the markets of the world, are rapidly acquiring the knowledge that efficiency of production is a sounder basis for prosperity than mere volume of product, however great.

The long-continued and highly organised research which resulted in the development of American agricultural machinery has led to the general introduction of machines which reduce the labour cost of seven crops 681,000,000 dollars, as measured by the methods of only fifty years ago.

You need not to be reminded that the ubiquitous telephone is wholly a product of American research. Munchausen's story of the frozen conversation which afterward thawed out is a clumsy fable. Think of the Niagaras of speech pouring silently through the New York telephone exchanges where they are sorted out, given a new direction, and delivered audibly perhaps a thousand miles away. New York has 450,000 instruments—twice the number of those in London. Los Angeles has a telephone to every four inhabitants. Why should one care to project one's astral body when he can call up from the club in fifteen seconds? Our whole social structure has been reorganised. We have been brought together in a single parlour for conversation and to conduct affairs, because the American Telephone and Telegraph Company spends annually for research, the results of which are all about us, a sum greater than the total income of many universities.

The name of Edison is a household word in every language. The Edison method is a synonym for specialised, intense research, which knows no rest until everything has been tried. Because of that method and the unique genius which directs its application, Italian operas are heard amid Alaskan snows and in the depths of African forests; every phase of life and movement of interest throughout the world is caught, registered, transported, and reproduced, that we may have lion hunts in our drawing-rooms and the coronation in a five-cent theatre. From his laboratory have come the incandescent lamp, multiple

[1] From the presidential address delivered before the American Chemical Society at Rochester, New York, September 9, 1913, by Arthur D. Little.

telegraphy, new methods of treating ores, and a thousand other diverse inventions, the development of a single one of which has sometimes involved millions.

Such development as that of the automobile industry in America has been based upon and vitalised by an immeasurable amount of research, the range and influence of which extend through many other industries. It has accelerated the application of heat treatment more than any other agency. One tyre manufacturer spends 100,000 dollars a year upon his laboratory. The research department organised by my associates for one automobile company comprised within its staff experts in automobile design, mathematics, metallography, and heat treatments, lubrication, gaseous fuels, steel and alloys, paints and painting practice, in addition to the chemists and physicists and assistants for routine or special work.

The beautiful city the hospitality of which has so greatly added to the pleasure and success of the present meeting of our society is the home of two highly scientific industries of which any community may well be proud. The Bausch and Lomb Optical Company, through its close affiliation with the world-famed Zeiss works at Jena, renders immediately available in this country the latest results of German optical research. The Eastman Kodak Company is perhaps more generally and widely known than even the Zeiss works, and in capital, organisation, value of product, and profit of operation will bear comparison with the great German companies whose business is applied science. Like them, it spends money with a lavish hand for the promotion of technical research and for the fundamental investigation of the scientific bases on which its industry rests. As you have happily been made aware, this work is carried on in the superb new research laboratories of the company with an equipment which is probably unrivalled anywhere for its special purposes. The laboratory exemplifies a notable feature of American industrial research laboratories in that it makes provision for developing new processes, first on the laboratory scale and then on the miniature factory scale.

To no chapter in the history of industrial research can Americans turn with greater pride than to the one which contains the epic of the electrochemical development at Niagara Falls. It starts with the wonderful story of aluminium. Discovered in Germany in 1828 by Wöhler, it cost 90 dollars a pound in 1855. In 1886 it had fallen to 12 dollars. The American Castner process brought the price in 1889 to 4 dollars. Even at this figure, it was obviously still a metal of luxury with few industrial applications. Simultaneously Hall in America and Heroult in Europe discovered that cryolite, a double fluoride of sodium and aluminium, fused readily at a moderate temperature, and, when so fused, dissolved alumina as boiling water dissolves sugar or salt, and to the extent of more than 25 per cent. By electrolysing the fused solution, aluminium is obtained.

On August 26, 1895, the Niagara works of the Pittsburgh Reduction Company started at Niagara Falls the manufacture of aluminium under the Hall patents. In 1911 the market price of the metal was 22 cents, and the total annual production 40,000,000 lb.

A chance remark by Dr. George F. Kunz in 1880 on the industrial value of abrasives turned the thoughts of Acheson to the problem of their artificial production, and led to the discovery in 1891 of carborundum and its subsequent manufacture on a small scale at Monongahela City, Pennsylvania. In 1894 Acheson laid before his directors a scheme for moving to Niagara Falls—to quote his own words :—

"To build a plant for 1000 horse-power, in view of the fact that we were selling only one-half of the output from a 134 horse-power plant, was a trifle too much for my conservative directors, and they one and all resigned. Fortunately, I was in control of the destiny of the Carborundum Company. I organised a new board, proceeded with my plans, and in the year 1904, the thirteenth from the date of the discovery, had a plant equipped with a 5000 electrical horse-power, and produced more than 7,000,000 lb. of those specks I had picked off the end of the electric light carbon in the spring of 1891."

The commercial development of carborundum had not proceeded far before Acheson brought out his process for the electric furnace production of artificial graphite and another great Niagara industry was founded. In quick succession came the Willson process for calcium carbide and the industrial applications of acetylene, phosphorus, ferro-alloys made in the electric furnace, metallic sodium, chlorine, and caustic soda, first by the Castner process, later by the extraordinarily efficient Townsend cell, electrolytic chlorates and alundum.

Perhaps even more significant than any of these great industrial successes was the Lovejoy and Bradley plant for the fixation of atmospheric nitrogen, which was perforce abandoned. It is well to recall, in view of that reputed failure, that the present-day processes for fixing nitrogen have made little, if any, improvement in yields of fixed nitrogen in a kilowatt hour over those obtained in this pioneer Niagara plant.

In the year 1800 a young assistant of Lavoisier, E. I. du Pont by name, emigrated to the United States, with others of his family, and settled on the banks of the Brandywine, near Wilmington, Delaware. He engaged in the manufacture of gunpowder. To-day the du Pont Company employs about 250 trained chemists. Its chemical department comprises three divisions : the field division for the study of problems which must be investigated outside the laboratory, and which maintains upon its staff experts for each manufacturing activity, together with a force of chemists at each plant for routine laboratory work; second, the experimental station, which comprises a group of laboratories for research work on the problems arising in connection with the manufacture of black and smokeless powder, and the investigation of problems or new processes originating outside the company; third, the Eastern Laboratory which confines itself to research concerned with high explosives. Its equipment is housed in seventy-six buildings, the majority being of considerable size, spread over fifty acres. Since no industrial research laboratory can be called successful which does not in due time pay its way, it is pleasant to record that the Eastern Laboratory is estimated to yield a profit to its company of 1,000,000 dollars a year. In addition to the generous salaries paid for the high-class service demanded by the company, conspicuous success in research is rewarded by bonus payments of stock.

The Gayley invention of the dry air blast in the manufacture of iron involves a saving to the American people of from 15,000,000 dollars to 29,000,000 dollars annually. A modern furnace consumes about 40,000 cubic feet of air a minute. Each grain of moisture in a cubic foot represents one gallon of water an hour for each 1000 cubic feet entering a minute. In the Pittsburgh district the moisture varies from 1·83 grains in February to 5·94 grains in June, and the water an hour entering a furnace varies accordingly from 73 to 237 gallons. In a month a furnace using natural air received 164,500 gallons of water, whereas with the dry blast it received only 25,524 gallons. A conservative statement, according to Prof. Chandler, is that the invention results in a 10 per cent. increase in output and a 10 per cent. saving in fuel.

Especially notable and picturesque among the triumphs of American industrial research is that by means of which Frasch gave to the United States potential control of the sulphur industry of the world. There is in Calcasieu Parish, Louisiana, a great deposit of sulphur 1000 ft. below the surface under a layer of quicksand 500 ft. in thickness. An Austrian company, a French company, and numerous American companies had tried in many ingenious ways to work this deposit, but had invariably failed. Misfortune and disaster to all connected with it had been the record of the deposit to the time when Frasch approached its problem in 1890. He conceived the idea of melting the sulphur in place by superheated water forced down a boring, and pumping the sulphur up through an inner tube. In his first trial he made use of twenty 150-h.p. boilers grouped around the well, and the titanic experiment was successful. The pumps are now discarded, and the sulphur brought to the surface by compressed air. A single well produces about 450 tons a day, and their combined capacity exceeds the sulphur consumption of the world.

An equally notable solution of a technical problem which had long baffled other investigators is the Frasch process for refining the crude, sulphur-bearing Canadian and Ohio oils. The essence of the invention consists in distilling the different products of the fractional distillation of the crude oil with metallic oxides, especially oxide of copper, by which the sulphur is completely removed, while the oils distill over as odourless and sweet as from the best Pennsylvania oil. The copper sulphide is roasted to regenerate the copper. The invention had immense pecuniary value. It sent the production of the Ohio fields to 90,000 barrels a day, and the price of crude Ohio oil from 14 cents a barrel to one dollar.

Turning from these examples of individual achievement so strongly characteristic of the genius of our people in one aspect, let us again consider for a moment that other and even more significant phase of our industrial research, namely, that which involves the coordinated and long-continued effort of many chemists along related lines.

Chemistry in America is essentially republican and pragmatic. Most of us believe that the doctrine science for science's sake is as meaningless and mischievous as that of art for art's sake or literature for literature's sake. These things were made for man, not for themselves, nor was man made for them. Most of us are beginning to realise that the major problems of applied chemistry are incomparably harder of solution than the problems of pure chemistry, and the attack, moreover, must often be carried to conclusion at close quarters under the stress and strain induced by time and money factors. In these circumstances it should not excite surprise that a constantly rising proportion of our best research is carried on in the laboratories of our great industrial corporations, and nowhere more effectively than in the research laboratory of the General Electric Company, under the guidance of your past president, Dr. Whitney.

Any attempt to present adequately the enormous volume of research work, much of which is of the highest grade, constantly in progress in the many scientific bureaus and special laboratories of the general government, or even to indicate its actual extent and range, is utterly beyond the limits of my attainments or of your patience. The generous policy of the Government toward research is unique in this, that the results are immediately made available to the whole people.

The United States is still essentially an agricultural country, and agriculture is, in its ultimate terms, applied photochemistry. The value of our farm property is already more than 42,000,000,000 dollars, and each sunrise sees an added increment of millions. Even small advances in agricultural practice bring enormous monetary returns.

Chief, therefore, among the government departments, in the volume of industrial research is the Department of Agriculture, which includes within its organisation ten great scientific bureaus, each inspired by an intense pragmatism and aggressively prosecuting research in its allotted field.

The research work of the Department of Agriculture is greatly augmented and given local application through the agency of sixty-four State agricultural experiment stations, established for the scientific investigation of problems relating to agriculture. These stations are supported in part by federal grants, as from the Hatch and Adams funds, and for the rest by State appropriations. Their present income exceeds 3,000,000 dollars. All are well equipped; one of them, California, includes within its plant a superb estate of 5400 acres, with buildings worth 1,000,000 dollars.

It may be said without fear of contradiction that through the combined efforts of the Department of Agriculture, the experiment stations, the agricultural colleges, and our manufacturers of agricultural machinery, there is devoted to American agriculture a far greater amount of scientific research and effort than is at the service of any other business in the world.

In the United States Patent Office Dr. Hall has developed a remarkably comprehensive index to chemical literature, which now contains 1,250,000 cards, and is open to every worker. The Bureau of Fisheries devotes 40,000 dollars to a single study, and the Geological Survey 100,000 dollars to the investigation of the mineral resources of Alaska.

The Bureau of Mines of the Department of the Interior was established to conduct on behalf of the public welfare fundamental inquiries and investigations into the mining, metallurgical, and mineral industries. Its appropriation for the current fiscal year is 662,000 dollars, of which 347,000 dollars is to be devoted to technical research pertinent to the mining industry.

Perhaps no better evidence could be adduced of the present range and volume of industrial research in America than the necessity, imposed upon the author of such a general survey as I am attempting, of condensing within a paragraph his reference to the Bureau of Standards of the Department of Commerce. Its purpose is the investigation and testing of standards and measuring instruments, and the determination of physical constants and the properties of materials. To these objects it devotes about 700,000 dollars a year to such good effect that in equipment and in the high quality and output of its work it has in ten years taken rank with the foremost scientific institutions in the world for the promotion of industrial research and the development and standardisation of the instruments, materials, and methods therein employed. Its influence upon American research and industry is already profound and rapidly extending.

I cannot better conclude this cursory and fragmentary reference to governmental work in applied science than with the words of the distinguished director of the Bureau of Standards:—

"If there is one thing above all others for which the activities of our Government during the past two or three decades will be marked, it is its original work along scientific lines, and I venture to state that this work is just in its infancy."

The present vitality and rate of progress in American industrial research is strikingly illustrated by its very recent development in special industries. It has been said that our best research is carried on in those laboratories which have one client, and that one themselves.

Twenty-five years ago the number of industrial concerns employing even a single chemist was very small, and even he was usually engaged almost wholly upon routine work. Many concerns engaged in business of a distinctly chemical nature had no chemist at all, and such a thing as industrial research in any proper sense scarcely came within the field of vision of our manufacturers. Many of them have not yet emerged from the penumbra of that eclipse, and our industrial foremen as a class are still within the deeper shadow. Meantime, however, research has firmly established itself among the foundation-stones of our industrial system, and the question is no longer what will become of the chemists. It is now what will become of the manufacturers without them.

In the United States to-day the microscope is in daily use in the examination of metals and alloys in more than 200 laboratories of large industrial concerns. An indeterminate but very great amount of segregated research is constantly carried forward in small laboratories, which are either an element in some industrial organisation or under individual control. An excellent example of the quality of work to be credited to the former is found in the development of cellulose acetate by Mork in the laboratory of the Chemical Products Company, while a classic instance of what may be accomplished by an aggressive individualism plus genius in research is familiar to most of you through the myriad and protean applications of Bakelite. The rapidity of the reduction to practice of Baekeland's research results is the more amazing when one considers that the distances to be travelled between the laboratory and the plant are often, in case of new processes and products, of almost astronomical dimensions.

Reference has already been made to the highly organised, munificently equipped, and splendidly manned laboratories of the Du Pont Company, the General Electric Company, and the Eastman Kodak Company. There are in the country at least fifty other notable laboratories engaged in industrial research in special industries. The expenditure of several of them is more than 300,000 dollars each a year. The United States Steel Corporation has not hesitated to spend that amount upon a single research, and the expenses of a dozen or more laboratories probably exceed 100,000 dollars annually. One of the finest iron research laboratories in the world is that of the American Rolling Mills Company.

The steel industry in its many ramifications promotes an immense amount of research, ranging from the most refined studies in metallography to experimentation upon the gigantic scale required for the development of the Gayley dry blast, the Whiting process for slag cement, or the South Chicago electric furnace. This furnace has probably operated upon a greater variety of products than any other electric furnace in the world. Regarding the steel for rails produced therein, it is gratifying to note that after two and one-half years or more no reports of breakage have been received from the 5600 tons of standard rails made from its output.

Industrial research is applied idealism. It expects rebuffs, it learns from every stumble, and turns the stumbling-block into a stepping-stone. It knows that it must pay its way. It contends that theory springs from practice. It trusts the scientific imagination, knowing it to be simply logic in flight. It believes with F. P. Fish, that "during the next generation—the next two generations—there is going to be a development in chemistry which will far surpass in its importance and value to the human race that of electricity in the last few years—a development which is going to revolutionise methods of manufacture, and more than that, is going to revolutionise methods of agriculture"; and it believes with Sir William Ramsay that "the country which is in advance in chemistry will also be foremost in wealth and general prosperity."

Modern progress can no longer depend upon accidental discoveries. Each advance in industrial science must be studied, organised, and fought like a military campaign. Or, to change the figure, in the early days of our science, chemists patrolled the shores of the great ocean of the unknown, and, seizing upon such fragments of truth as drifted in within their reach, turned them to the enrichment of the intellectual and material life of the community. Later they ventured timidly to launch the frail and often leaky canoe of hypothesis, and returned with richer treasures. To-day, confident and resourceful, as the result of many argosies, and having learned to read the stars, organised, equipped, they set sail boldly on a charted sea in staunch ships with tiering canvas bound for new El Dorados.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The City Council has renewed the annual grant to the University. An amendment by a Socialist member opposing the renewal, on the ground that the elementary education of the city and the technical school were being starved, was defeated by seventy votes to twenty-nine.

Dr. J. E. H. Sawyer has been appointed assistant to the chair of medicine.

Mr. H. A. Scarborough has been recommended to the Commissioners of the Exhibition of 1851 for a research scholarship.

Prof. Bostock Hill is to represent the University at the congress of the Royal Sanitary Institute in July next.

CAMBRIDGE.—The work submitted by Mr. T. W. Price, of Clare College, entitled "Osmotic Pressure of Alcoholic Solutions," has been approved by the Degree Committee of the Special Board for Physics and Chemistry as a record of original research.

OXFORD.—Under the existing constitution of the University, certain seats in the Hebdomadal Council are limited to the heads of colleges and professors respectively. A statute providing for the abolition of "orders" and for throwing the whole of the seats open to members of Convocation of five years' standing, which had been passed by small majorities in Congregation, was submitted in its final stage to Convocation on March 10. The proposed statute was supported by Prof. Geldart, and opposed by the rector of Exeter, and the warden of Wadham. It was rejected on a division by 97 to 83.

The preamble of a statute providing for the establishment of an additional professorship of chemistry, to be called "Dr. Lee's Professorship," passed Congregation without a division.

THE presentation of the portrait of Sir William Ramsay, K.C.B., to University College, London, and of the replica to Lady Ramsay, will be made on Wednesday next, March 18, at 4.30, in the Botanical Theatre.

THE appeal made by Girton College for 8000*l*. by January 1, 1914, to meet conditional promises of 12,000*l*. from an anonymous benefactor and 4000*l*. from Rosalind Lady Carlisle, has been completely successful, and the purpose of the appeal, which was the extinction of a mortgage debt of 24,000*l*., has now been achieved. The donation, we learn from the

Times, included 1000*l.* from the Drapers' Company and 500*l.* from the Clothworkers' Company.

THE presidency of Johns Hopkins University, Baltimore, which has been vacant since the resignation of Dr. Ira Remsen in 1912, has been filled by the appointment of Dr. Frank J. Goodnow, recently professor of administrative law at Columbia University, New York. In choosing an expert in this subject to succeed a chemist, Johns Hopkins has precisely followed the example of Harvard a few years ago, when Prof. A. Lawrence Lowell took the place of Dr. C. W. Eliot.

THE Local Lectures Summer Meeting will be held this year at the University of Cambridge on July 31–August 24. The new University examination halls and lecture-rooms will be used. The inaugural lecture will be delivered at 8 p.m. on July 31 by Sir J. J. Thomson. The lectures will be grouped round the general subject, "Some Aspects of Modern Life," and among the courses announced we notice one by Dr. L. Doncaster on heredity in animals and man. Forms of entry and further information about the meetings will be supplied by the Rev. Dr. Cranage, Syndicate Buildings, Cambridge.

LAST year Messrs. Harrods, Ltd., established a scheme of scholarships providing the holders with a year's training at their stores in commercial English, handwriting, arithmetic, French or Spanish, shorthand, typewriting, business routine, and salesmanship, with free meals. The scholarships are awarded on the nomination of shareholders; the nominees must be between the ages of fifteen and eighteen years, have had a fair education, and be able to pass a medical examination. They will secure a commercial education in which practice and theory will be combined; for the mornings are given to class instruction, and the afternoons to work in the departments, the holder of a scholarship being attached to a different department each month. This arrangement has worked admirably during the past year. Fifty scholarships will be available in September next, and the test examination for the nominees will be held in June or July. Messrs. Harrods' enterprise in establishing this system of training young people in the principles and practice of business-building is to be commended, and we believe it will achieve notable success.

AN article in the *Westminster Gazette* of March 3, by the Berlin correspondent of our contemporary, reveals a growing demand in Germany for more universities. It is alleged that existing universities are overcrowded owing chiefly to the invasion of foreign and of women students, and the more general need of university education for officials. The number of such institutions is smaller than it was a century ago. Cologne, Trier, Duisburg, Helmstedt, Wittenberg, Frankfurt-on-Oder, Mainz, Erfurt, Altdorf, and Ingolstadt have all been university towns. Since the empire was founded the number of students has increased fourfold. In 1880 there were 30,000 students; in 1905, 42,000; and last year more than 60,000. There are 5300 foreign and 3500 women students, and about 4000 non-student auditors. The agitation for new universities came to a head last year when Hamburg, Frankfurt-on-Main, Dresden, Posen, Cologne, and some smaller towns proposed to establish universities. The impulse in some cases was the desire of existing special and technical high schools to expand into universities with full university status, but with a reduced number of faculties. The advocates of new universities complain that the universities have recognised with ill-will the increasing specialisation of science; and that specialisation is now hopelessly ahead of them. Some reformers want not only specialisation within universities, but specialisation of the institutions themselves. Each university, while keeping its faculties and its general culture system, should aim at a predominant position in a particular branch of science; and should be specially well supplied with professorial chairs, seminaries, libraries, and collections bearing on its speciality.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 5.—Sir William Crookes, president, in the chair.—Harold **Wager**: The action of light on chlorophyll. When chlorophyll is decomposed by light, at least two distinct substances are formed, one of which is an aldehyde or mixture of aldehydes, and the other an active oxidising agent, capable of bringing about the liberation of iodine from potassium iodide. The decomposition of chlorophyll appears to be due directly to the action of light and is not an after effect of the photo-synthesis of carbon dioxide and water. It takes place only in the presence of oxygen, and it appears to be a case of photo-oxidation, for oxygen is used up so completely in the process that chlorophyll can be used instead of pyrogallol and caustic potash to determine the amount of oxygen in a given amount of air. In the absence of oxygen no bleaching takes place. Carbon dioxide is not necessary to the photo-decomposition of chlorophyll and is not used up in the process, even when present in considerable quantities.—C. H. **Warner**: Formaldehyde as an oxidation product of chlorophyll extracts.—Franklin **Kidd**: The controlling influence of carbon dioxide in the maturation, dormancy, and germination of seeds. Experiments are described showing that germination of seeds can be completely inhibited by carbon dioxide in the atmosphere (20–30 per cent., varying with the temperatures used). This inhibition is not accompanied by injury. The seeds germinate at once after removal from inhibitory CO_2 pressures. Experiments in the field showed that this action of CO_2 may actually occur in nature. If a quantity of green plant material is buried deep in the ground, seeds planted in the soil over this decaying material are inhibited in their germination by the CO_2 produced beneath them. This is of agricultural significance, and the fact that in the case of mustard seeds suspension of vitality continues, even after the external CO_2 has been removed, suggests an explanation of the common occurrence of dormant seeds of this plant in fields, and possibly of other natural cases of delayed germination.—J. **Hammond** and F. H. A. **Marshall**: The functional correlation between the ovaries, uterus, and mammary glands in the rabbit; with observations on the œstrous cycle.—Dr. J. F. **Gaskell**: The chromaffine system of annelids and the relation of this system to the contractile vascular system in the leech, *Hirudo medicinalis.* The possession of a chromaffine system, consisting of cells which take a yellow stain with chrome salts, is a common property of almost all members of the vertebrate kingdom. The presence of this reaction is coincident with the secretion of the pressor substance, adrenalin, and is probably dependent upon it. Even in the lowest vertebrate, Petromyzon, the system is well developed, being diffusely though segmentally arranged throughout the body. Chromaffine cells have also been observed in certain annelids by Sommet and Poll, reaching their highest development in the Hirudinea; the reaction is given by six nerve cells in each segmental ganglion. The conclusion is drawn that the contractile vascular system of vertebrates and its regulators, the chromaffine system and the sympathetic system, originally arose together in the annelid group.

Institution of Mining and Metallurgy, February 19.—Mr. Bedford McNeill, president, in the chair.—H. W. **Hutchin**: The assay of tin ores. The work recorded in this paper is the result of a prolonged use and study by the author of the well-known Beringer assay of tin ores, and the essential modification introduced consists in the use of lime as a diluent in place of zinc oxide, thus forming calcium stannate, which is more readily soluble in warm hydrochloric acid than is zinc stannate. Temperature influences the speed of the reaction, and the author's detailed experiments showed that the lime modification method was appreciably quicker than the zinc oxide method at "tin furnace" temperatures. Experiments made with diluents other than those already mentioned, as, for instance, barium carbonate and magnesia, showed the general superiority of lime, except in cases where only a small proportion of siliceous mineral is present, in which event zinc oxide shows a superiority to lime. The tests made were varied by differentiating between "tin furnace" and Bunsen burner temperatures, and the author's final opinion is in favour of a large Techlu burner used in conjunction with an asbestos boss, as giving the best conditions for ignition.—E. A. **Wraight** and P. Litherland **Teed**: The assay of tin ores and concentrates: the Pearce Low method. The authors have carried out an exhaustive series of tests with regard to the accuracy of this particular method of assaying tin, the results of which are embodied in their joint paper. As a result they arrived at the following conclusions. The degree of fineness of the ore must be at least 100 mesh, otherwise a representative sample cannot be obtained; nickel crucibles are superior to iron ones, and for tailings fusion in an iron crucible should be avoided; the amount of hydrochloric acid should be about 125 c.c.; the bulk of the solution before reduction should be about 400 c.c.; the temperature of the tin solution at titration should not be more than 70° F.; the strength of the standard solution should not generally be more than 11 grams of iodine and 20 grams of potassium iodide per litre, or less than one-third of that strength; before titration the calcite should have entirely dissolved; titanium, tungsten, and bismuth must be removed, and copper and iron should in special circumstances also be removed before titration; and nickel should always be used for reduction. With the observance of these precautions, the authors are of the opinion that the error should not exceed 2 lb. of black tin a ton with rich ores, and less with poor ores.—W. P. **Dreaper**: Formation of mineral deposits: precipitation and stratification in the absence of gels. This paper is a record of experiments made to determine whether the presence of gels is necessary to induce stratification, and for this purpose precipitation was conducted in capillary tubes, thereby avoiding certain disturbing influences. Under these conditions the author has been able to obtain stratification effects in the absence of secondary gels added to one of the reacting solutions. The substances experimented with comprised lead chloride, lead ferrocyanide, lead sulphate, barium sulphate, barium carbonate, and lead sulphide, and the results seem to show that stratification may be independent of the presence of gels.—T. R. **Archbold**: A device for filling ore sacks. This is a description of a simple device introduced in an out-of-the-way district for filling sacks with ore. A drum is divided into six compartments, and used in conjunction with a hopper, in such a manner that the revolutions of the drum serve to fill the compartments with a fixed amount of ore and deliver it into the sacks, six sacks being dealt with in each complete revolution.—E. O. **Marks**: A mining model. A description of a model constructed of iron, copper, and brass wire to show the direction and the extent of the workings of a mine. For convenience the block of ground is divided into unit sections of 1000 ft. cube, reduced in the model to a scale of 100 ft. to the inch, and the skeleton cubes representing these units are successively fitted with brass and copper wires showing the direction and length of shafts, levels, crosscuts, etc. The advantage of a model of this type, apart from its graphic character, lies in the ease of extension as the mine undergoes development.

Zoological Society, March 3.—Prof. E. W. MacBride, vice-president, in the chair.—C. Tate **Regan**: Freshwater fishes from Dutch New Guinea collected by the British Ornithologists' Union and Wollaston Expeditions. *Symbranchus bengalensis* was obtained for the first time in New Guinea. The collections included examples of two species of Melanotæniine Atherinids.—H. Wallis **Kew**: The nests of Pseudoscorpiones: with historical notes on the spinning-organs and observations on the building and spinning of the nests. The paper described the nests in which these animals enclose themselves for moulting, for brood purposes, and in some cases for hibernation. They are closed cells of spun tissue, with or without a covering of earthy or vegetable matters. The tissue is of innumerable threads crossed and coalesced irregularly, without interspaces, and almost like silk-paper. With regard to the spinning-apparatus, confusion has existed; but the author's observations on living animals place it beyond doubt that the cephalothoracic glands are the organs concerned. Contrary to previous statements, the "combs" of the cheliceræ have nothing to do with the silk. The manner in which the nests are built and spun was described in detail.—H. R. **Hogg**: A collection of spiders. The collection was made by Mr. P. D. Montague, supplemented by a few specimens sent by Mr. T. H. Haynes from the Montebello Islands off Onslow, on the north-west coast of Australia. These islands, from geological evidence, were part of the old coast-lines, though now about ninety miles away. Although the larger specimens are mostly widely spread and possibly more or less recent importations, the smaller are nearly all new species, showing evidence of a much longer separation from their congeneric relations on the mainland. Out of seventeen species ten are new, as well as a new genus and two new varieties.—D. M. S. **Watson**: The skull of a Pariasaurian reptile and the relationships of that type. The skull of Pariasaurus is completely described, with the exception of the bony labyrinth of the ear. It is compared with all the members of the order Cotylosauria, which are well enough known to make a comparison of any value, and shown to differ in the very important characters of the brain-case from all of them, representing an entirely distinct branch.—F. J. **Meggitt**: A tapeworm parasitic in the stickleback (*Gasterosteus aculeatus*).—Dr. W. **Nicoll**: Trematode parasites obtained from animals that died in the society's gardens during 1911–12.

Paris.

Academy of Sciences, March 2.—M. P. Appell in the chair.—F. **Wallerant**: The polymorphism of camphor. Crystals of camphor deposited at the ordinary temperature from an alcoholic solution are rhombohedral. Fused camphor may take three crystalline forms, so that camphor is at least quadrimorphous.—C. **Moureu** and A. **Lepape**: The helium from fire-damp and the radio-activity of coal. Fire-damp from Anzin has been previously shown by the authors to contain 0·04 per cent. of helium, and as the amount of crude gas evolved a day is estimated at 30,000 cubic metres, this corresponds to 12 cubic metres of helium a day. The amounts of radium and thorium in the ash of the coal have been determined, in this and other coals yielding fire-damp containing helium, and do not correspond to such large proportions of helium. The larger part of the gas is not derived from the radio-active material of the coal, and must be regarded as fossil helium.—André **Blondel**: The effect and production of the higher harmonics in the transport of electrical energy at high potentials.—P. **Sabatier** and A. **Mailhe**: The ester oxides of carvacrol. A study of the direct dehydration of carvacrol by the action of thorium oxide upon the vapour at temperatures between 400° and 500° C.—M. **Gambier**: Algebraic curves of constant torsion, real and not unicursal.—F. **Jager**: The application of the method of Fredholm to the tides of a basin limited by vertical walls.—E. **Mazurkiewicz** and W. **Sierpinski**: An ensemble superposable with each of its two parts.—A. **Pchéborski**: A generalisation of a problem of Tchébischeff and of Zolotareff.—C. **Gutton**: The specific inductive capacity of liquids. According to Voigt's hypothesis, the force which acts on an electron deviated from its equilibrium position in an electric field should not be exactly proportional to the deviation, and hence the specific inductive capacity ought to depend on the intensity of the field. In measurements made with toluene the deviations observed in the specific inductive capacity were of the same order as the experimental error. A slight diminution with increase of field was noticed with bromonapththalene, 4·72 to 4·69.—Maurice **de Broglie**: The spectra of the Röntgen rays. Rays emitted by antikathodes of copper, iron and gold.—J. de **Kowalski**: An explosive luminous phenomenon in rarefied nitrogen. The author confirms the observations of Strutt that nitrogen free from the smallest trace of oxygen is transformed into active nitrogen in a discharge in electrodeless tubes. A curious explosive phenomenon is described which is attributed to a temporary combination between the active nitrogen and traces of mercury vapour unavoidably present to form mercury nitride, the latter decomposing spontaneously.—H. **Labrouste**: A molecular transformation of thin layers on water.—F. **Baud**, F. **Ducelliez**, and L. **Gay**: A calorimetric study of the system water-monomethylamine.—H. **Gault**: A new method of preparation of tricarballylic acid. Oxalocitric lactone cannot be distilled under reduced pressure without decomposition. The liquid obtained by distillation is not, as was supposed by Wislicenus and Beckh, the unchanged lactone, but proves to be ethyl $\alpha\alpha\beta\gamma$-propane-tetracarboxylate. With dilute mineral acids a quantitative yield of crystalline tricarballylic acid is obtained.—Enrique **Hauser**: A new method for the detection and determination of gaseous hydrocarbons dissolved in mineral waters. After adding potash to the water it is shaken with air and the latter analysed.—M. **Piettre** and A. **Vila**: Observations on fibrinogen and the oxalated plasma.—W. **Kopaczewski**: The influence of acids on the activity of dialysed maltase. The observed effects cannot be explained exclusively by the concentration of the acid ions.—Mlle. Jeanne **Weill**: The amount of fatty acids and cholesterol in the tissues of cold-blooded animals.—Paul **Fallot**: The tectonic of the sierra of Majorca.—Emile **Belot**: An attempt at a physical theory of the formation of the oceans and primitive continents.—F. **Malméjac**: The importance of the estimation of chlorides for the control and evaluation of drinking water.—A. **Boutaric**: The thermal state of the atmosphere.

BOOKS RECEIVED.

Om Forandringer i Ringkobing Fjords Fauna. By A. C. Johansen. Pp. 144. (Kobenhavn: Bianco Lunos Bogtrykkeri.)

Wissenschaftliche Ergebnisse der Deutschen Zentral-Afrika-Expedition, 1907–8. Band v. Zoologie iii. Lief. 1. Orthoptera. By J. A. G. Rehn. Pp. 223. (Leipzig: Klinkhardt und Biermann.) 8.40 marks.

DIARY OF SOCIETIES.

THURSDAY, MARCH 12.

ROYAL SOCIETY, at 4.30.—Note on a Functional Equation Employed by Sir George Stokes: Sir James Stirling.—The Mercury Green Line $\lambda = 5461$ as Resolved by Glass and Quartz Lummer Plates and on its Zeeman Components: Prof. J. C. McLellan and A. R. McLeod.—The Electrical Condition of a Gold Surface During the Absorption of Gases and their Catalytic Combustion: H. Hartley.—The Diffusion of Electrons through a Slit: J. H. Mackie.—The Rate of Solution of Hydrogen by Palladium: Dr. A. Holt.—The Dispersion of a Light Pulse by a Prism: Dr. R. A. Houston.

ROYAL INSTITUTION, at 3.—Heat and Cold: Prof. C. F. Jenkin.

CONCRETE INSTITUTE, at 7.30.—Forms for Concrete Work: A. Graham.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—The Design of Rolling Stock for Electric Railways: H. E. O'Brien.

FRIDAY, MARCH 13.

ROYAL INSTITUTION, at 9.—An Indian State: Sir Walter R. Lawrence, Bart.

MALACOLOGICAL SOCIETY, at 8.—Diagnosis of Four New Land Shells from German New Guinea: C. R. Boettger.—Characters of Three New Species of Ennea from Southern Nigeria: H. B. Preston.—A Synopsis of the Family of Veneridæ. II.: A. J. Jukes-Browne.

ROYAL ASTRONOMICAL SOCIETY, at 5.—(1) Correction of Errors in the New Lunar Theory; (2) The Terms in the Moon's Motion Depending on the Node; (3) The Perigee and Eccentricity of the Moon, 1750—1901; (4) The Determination of the Node, the Inclination, the Earth's Ellipticity, and the Obliquity of the Ecliptic, from Greenwich Meridian Observations of the Moon, 1847—1901: E. W. Brown.—Baxendell's Observations of Variable Stars: R. Bootis, R. Cancri, R. Coronæ, S. Coronæ, H. H. Turner, and Mary A. Blagg.—Micrometrical Measures of Double Stars in 1913: Rev. T. E. R. Phillips and H. F. Acocks.—The Spectra of Hydrogen and Helium: J. W. Nicholson.—The Total Light of the Stars: S. Chapman.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Lightning Conductors and their Tests: F. H. Taylor.

ALCHEMICAL SOCIETY, at 8.15.—Roger Bacon: R. Rowbottom.

PHYSICAL SOCIETY, at 8.—Time Measurements of Magnetic Disturbances and their Interpretation: Dr. C. Chree.—The Ratio of the Specific Heat of Air, Hydrogen, Carbon Dioxide and Nitrous Oxide: H. N. Mercer.—The Asymmetric Distribution of the Secondary Electronic Radiation produced by X-Radiation: A. J. Philpot.—A Lecture Experiment on the Irrationality of Dispersion: Prof. S. P. Thompson.

SATURDAY, MARCH 14.

ROYAL INSTITUTION, at 3.—Recent Discoveries in Physical Science: Sir J. J. Thomson.

MONDAY, MARCH 16.

ROYAL SOCIETY OF ARTS, at 8.—Surface Combustion. I: Prof. W. A. Bone.

TUESDAY, MARCH 17.

ROYAL INSTITUTION, at 3.—Modern Ships. The War Navy: Sir John H. Biles.

ROYAL STATISTICAL SOCIETY, at 5.—The Sizes of Businesses, Mainly in the Textile Industries: Prof. S. J. Chapman, and T. S. Ashton.

ZOOLOGICAL SOCIETY, at 8.30.—(1) The Annelids of the Family Nereidæ collected by Mr. F. A. Potts in the N.E. Pacific in 1911, with a Note on Micronereis as a Representative of the Ancestral Type of the Nereidæ; (2) The Genera Ceratocephale Malmgren and Tylorrhynchus, Grube: L. N. G. Ramsay.—The Structure and Development of the Caudal Skeleton of the Teleostean Fish, *Pleuragramma antarcticus*: A. K. Totton.—Report on the Mollusca collected by the British Ornithologists' Union Expedition and the Wollaston Expedition in Dutch New Guinea: G. C. Robson.—The Mechanism of Suction in the Potato Capsid Bug (*Lygus pabulinus*, Linn.); P. R. Awati.—Coleoptera Heteromera collected by the British Ornithologists' Union Expedition and the Wollaston Expedition in Dutch New Guinea: K. G. Blair.—The Malay Race of the Indian Elephant: R. Lydekker.—Fauna of Western Australia. I. The Onychophora of W. Australia. II. The Phyllopoda of W. Australia: Prof. W. J. Dakin.

INSTITUTE OF METALS, at 8.—Annual General Meeting.—President's Inaugural Address: Sir Henry J. Oram.

ILLUMINATING ENGINEERING SOCIETY, at 8.—A Comparison between Illumination Estimates and Performance in Practice: W. C. Clinton.

INSTITUTION OF CIVIL ENGINEERS, at 8.—*Concluding Discussion:* Rail steels for Electric Railways: W. Willox.—Rail-corrugation and its Causes: S. P. W. D'Alte Sellon.—*Papers:* Some Recent Developments in Commercial Motor-vehicles: T. Clarkson.—Comparative Economics of Tramways and Railless Electric Traction: T. G. Gribble.

MINERALOGICAL SOCIETY, at 5.30.—An Occurrence of Bornite Nodules in Shale from Mashonaland: F. P. Mennell.—Augite from Bail Hill, Dumfriesshire: A. Scott.—(1) A Sulpharsenite of Lead from the Binnenthal; (2) Gmelinite and Chabazite from Co. Antrim: Dr. G. T. Prior.

WEDNESDAY, MARCH 18.

ROYAL METEOROLOGICAL SOCIETY, at 7.30.—Climate as Tested by Fossil Plants: Prof. A. C. Seward.

AERONAUTICAL SOCIETY, at 8.30.—Lessons Accidents have Taught: Col. H. C. Holden.

ROYAL SOCIETY OF ARTS, at 8.—House Flies and Disease: E. H. Ross.

INSTITUTE OF METALS, at 10.30 a.m.—First Report to the Beilby Research Committee, dealing with the Solidification of Metals from the Liquid State: Dr. C. H. Desch.—Bronze: J. Dewrance.—Vanadium in Brass: The Effect of Vanadium on the Constitution of Brass containing 50—60 per cent. of Copper: R. J. Dunn and O. F. Hudson.—The Quantitative Effect of Rapid Cooling on Binary Alloys. II: G. H. Gulliver.—Crystal Protomorphs and Amorphous Metal: Prof. A. K. Huntington.—First Report of the Nomenclature Committee.—The Influence of Nickel on Some Copper-Aluminium Alloys: Prof. A. A. Read and R. H. Greaves.—Muntz Metal: The Correlation of Composition, Structure, Heat Treatment, and Mechanical Properties, etc.: Dr. J. E. Stead and H. G. A. Stedman.—The Micro-Chemistry of Corrosion. II: S. Whyte and Dr. C. H. Desch.

ENTOMOLOGICAL SOCIETY, at 8.—(1) A Contribution to the Life-History of *Agriades thersites*; (2) A New Form of Seasonal (and Heterogoneutic) Dimorphism: Dr. T. A. Chapman.

THURSDAY, MARCH 19.

ROYAL SOCIETY, at 4.30.—*Discussion:* Constitution of the Atom. Opener: Sir E. Rutherford.

ROYAL INSTITUTION, at 3.—Heat and Cold: Prof. C. F. Jenkin.

CHILD STUDY SOCIETY, at 7.30.—The Dramatic Impulse in Children: Prof. J. J. Findlay.

INSTITUTION OF MINING AND METALLURGY, at 8.—Annual Meeting.

INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Discussion on Electric Battery Vehicles.

ROYAL SOCIETY OF ARTS, at 4.30.—Indian Water Gardens; Mrs. Patrick Villiers-Stuart.

LINNEAN SOCIETY, at 8.—The Bearing of Chemical Facts on Genetical Constitution: Dr. E. F. Armstrong.

FRIDAY, MARCH 20.

ROYAL INSTITUTION, at 9.—Fluid Motions: Lord Rayleigh.

INSTITUTION OF MECHANICAL ENGINEERS, at 8.—The Chemical and Mechanical Relations of Iron, Tungsten and Carbon, and of Iron, Nickel, and Carbon: Prof. J. O. Arnold and Prof. A. A. Read.

JUNIOR INSTITUTION OF ENGINEERS, at 8.—Aeroplanes as Engineering Structures: W. H. Sayers.

SATURDAY, MARCH 21.

ROYAL INSTITUTION, at 3.—Recent Discoveries in Physical Science: Sir J. J. Thomson.

AN ELIZABETHAN COOKERY-BOOK.

A Proper Newe Booke of Cokerye. Edited by Catherine F. Frere. Pp. clxiv+124. (Cambridge: Heffer and Sons, Ltd., 1913.) Price 7*s.* 6*d.* net.

WHETHER cookery-books should rank as literature is a question upon which opinions may well differ. Charles Lamb, we fear, would have stigmatised the majority of them as among the books which are no books. But whatever exceptions he might have been induced to make, one of them would certainly have been Miss Frere's work. And this because of his reverence for things ancient and of good repute. It would have quickened his instincts as a bibliograph, and he would have chuckled over the evidence of the playful imagination, delicate wit, and subtle humour with which the editor has embellished the setting of her antique and historic jewel. He would have appreciated, too, the element of comedy in the fact that although Miss Frere, as she frankly confesses, has never had the opportunity of acquiring the art of cookery, she should yet have been fated to edit no fewer than four books on the subject.

The origin of the present work may be told in a few words. The good and learned Matthew Parker, Archbishop of Canterbury from 1559 to 1575, and a former Master of Corpus Christi College, Cambridge, from which he had been ejected during Queen Mary's reign, presented a great collection of valuable manuscripts, as well as many printed books, to his old College and to the University Library, concerning which Dr. Berne, the then Vice-Chancellor, wrote of "the singular beauty that the comely order of Your Grace's books doth bring to the University Library, to the great delectation of the Eye of Every man that Shall Enter into the Said Library." Among the printed books given to the College is a little volume bound in vellum, in which, wedged in between political and learned tracts, is a black-letter octavo of twenty-seven pages, entitled "A Proper Newe Booke of Cokerye." This, with the approval of the Master and Fellows, Miss Frere has caused to be reprinted, furnishing it with an admirable introduction, many excellent annotations, and a useful glossary-index.

The original Cambridge edition is dateless, but was probably published during Parker's tenure of the See of Canterbury. According to Hazlitt, the book was often reprinted before 1546, and was, in fact, a recension of the "Book of Cookery" of 1500, of which there was a reprint by John Byddell about 1530. This was often reproduced, with modifications, and under various names, down to 1650, much of it being embodied in the household books of those days, as, for example, in Thomas Dawson's "Good Huswife's Jewell," of 1596.

Of the original author nothing is known, not even his, or her, name; but one may surmise that the compilation was in all probability the work of a monk, to whom the occupation, we may take it, would not be uncongenial. Authoresses, especially of works on cookery, were not plentiful in those days. Even the classical work of Mrs. Glasse, a book of a much later date, was, according to Boswell, written by a mere man, Dr. Hill.

As we turn over the leaves of the "Proper Newe Booke," with its quaint recipes, couched in the "corrupted phonetic" of the golden age of English prose, we gather, as our author says, "a little rushlight illumination on the culinary mysteries of the once busy kitchens, roofless and empty to-day, and on the hospitalities, feasting, and revels of the now silent dining halls of long ago."

Matthew Parker was a large-minded man, who, living in spacious times, did things in a spacious way. Although an abstemious man himself, and not overburdened with the temporalities of his see, he exercised an almost boundless hospitality, both at Canterbury and at Lambeth, and we can well imagine that Mistress Margaret Harlestone, his devoted wife, who, "for her husband's credit," says Strype, "had all things handsome about her—ordering her housekeeping so nobly and splendidly that all things answered that venerable dignity," must have been sorely exercised at times "to avoid the shame of her Lord's table," especially when, as occasionally happened, his Royal Mistress, in one of her many Progresses, intimated her intention of dining with him, together with the whole of her Privy Council. We fancy at such a time there must have been much searching through the scanty pages of the "Proper Newe Booke."

But to the general reader of to-day, perhaps, the most enlightening, as well as the most interesting portion of Miss Frere's book is her introduction, in which she conjures up a vivid picture of "the gay company that rejoiced and feasted, the fighters and revellers, the grave statesmen, prelates, and lawyers, the admirals, bold sea captains, knights, and ladies, the great lords and princes" that revolved, as about a sun, around their imperious Queen, every inch a Tudor, who combined all the strength of will and masterfulness of her father, with, at times, some of the womanly traits of her luckless mother. Very sympathetic, too, is the word-picture Miss Frere draws of the great archbishop—of his courage, his loyalty, his devotion to duty, his broad catholicism, his steadfastness, integrity, and liberality. It needed such a man to steer the reformed Church through those troubled times, when practically every ruler in Europe was conspiring with a disloyal faction at home to bring England once more under the heel of the Papacy.

But if Miss Frere has an eye for the picturesque, she has also a pretty wit, and enlivens her narrative from time to time with frequent sallies of humour and many a good story. We shall not anticipate the reader's pleasure by repeating these, strong as is the temptation. It must suffice here to say that Miss Frere, by her book, has added to the gaiety of gourmets, if not of nations. M. D. W.

APPLIED ELECTRICITY.

(1) *A Primer on Alternating Currents.* By Dr. W. G. Rhodes. Pp. viii+145. (London: Longmans, Green and Co., 1912.) Price 2*s*. 6*d*. net.

(2) *Single-Phase Commutator Motors.* By F. Creedy. Pp. x+113. (London: Constable and Co., Ltd., 1913.) Price 7*s*. 6*d*. net.

(3) *The Development of the Incandescent Electric Lamp.* By G. Basil Barham. Pp. viii+198. (London: Scott, Greenwood and Son, 1912.) Price 5*s*. net.

(4) *Allgemeine Elektrotechnik. Hochschul-Vorlesungen.* By Prof. P. Janet. Autorisierte Deutsche Bearbeitung von F. Suchting and E. Riecke. Erster Band. Grundlagen Gleichstrome. Bearbeitet von F. Suchting. Pp. vi+269. (Leipzig and Berlin: B. G. Teubner, 1912.) Price 6 marks.

(1) DR. RHODES' book can scarcely be recommended to those students of limited mathematical knowledge for whom it is avowedly written. Throughout, the author seems to employ trigonometrical functions whenever he can get an excuse for doing so, while in many cases he omits vector diagrams which would probably be of more assistance. The book is open to the criticism of being too academic and out of touch with real things. For instance, we might mention the calculation of iron losses from formulæ instead of reading them off directly from the experimental curves; the "design" of a transformer by assuming a certain flux density and then putting in enough iron to get a specified iron loss without any regard as to whether that iron is required or not; the elaboration of formulæ for the efficiency of synchronous machines taking account only of the copper loss; and, finally, the combination of the fluxes produced by the different coils of a polyphase motor by adding them algebraically, after rectification for some obscure reason, instead of taking account of their directions in the usual manner. The reader's confidence in the remainder of the book is scarcely restored by the hazy "due to the influence of the rotor currents," which is advanced as an explanation of the discrepancy between the known facts and the results of this curious proceeding.

(2) Mr. Creedy writes on a subject which he has made his own, and he introduces us to some new and fertile ideas in connection with it. His book requires a very close study to master it, and we cannot but feel that the reader's path would have been much easier if the author had given a *continuous* exposition of his method as applied to a single type of machine, instead of explaining it in snippets with other matter between.

So far as fluxes are concerned, he makes his case fairly clear, but when he applies his ellipses to E.M.F.'s he is less convincing. He employs space diagrams to combine E.M.F.'s in series, for which only time-phase matters, and although the latter does depend on the instantaneous position of the coil, his description brings forward no reason why his construction should give the correct result. The statement as to the equality, at synchronous speeds, of the transformer and motion E.M.F.'s in two mutually perpendicular axes should be proved, particularly as the student will have some difficulty in imagining a winding which will give a constant harmonic distribution about a fixed axis while it itself rotates.

Here and there the book is marred by the use of loose expressions which make a difficult subject still more difficult. Thus, we have "rotating ellipse" to describe a curve which is fixed but the radius of which is supposed to rotate. A greater attention to the agreement between the lettering of the diagrams and the text, and to the suitable juxtaposition of corresponding connection and vector diagrams would have been a help to the reader.

In spite of these little defects, we are strongly of the opinion that this book should be on the shelves of all who are interested in the subject.

(3) The account of the early incandescent lamps and of the carbon and tantalum filaments which Mr. Barham gives will be read with much interest by many outside electrical circles. If only the remainder of the book had been similar, we should have had little but praise for it. But the second half of the book, dealing mostly with tungsten lamps, lacks perspective, and wearies the reader. Even the author seems to feel, in one place, that

the matter is too much an echo of the claims and hopes of the various inventors, as recorded in their patent specifications, and too little an account of processes in actual use in the factories which turn out tungsten filaments on a commercial scale. In fact, very few even of those readers who wade through the whole ninety or so pages about these lamps will have gained the faintest idea of these processes. A reduction of this portion of the book would have given space for a description of the Nernst lamp and its properties, which lamp certainly deserves more than a casual mention.

(4) The last of the books before us can be recommended to those who would prefer to read the matter in German. The ground taken up is, for the most part, thoroughly discussed from the theoretical point of view, and the British reader will probably come across some instructive ideas which are new to him. In places there is a tendency to ignore facts which do not lend themselves to a simple theory, and there is a leaning to the physical side of the subject rather than to the engineering side. There are also some statements which give the reader quite a wrong impression, because they are not accompanied by a statement of the very special conditions to which they apply. For instance, we are told that the E.M.F. of a ring armature is independent of the number of poles, while the power is proportional to that number, in such a way that the reader would take the statement to apply to a given armature, whereas it would only apply if the size of the armature were increased along with the number of poles so that each of the latter might be kept of a constant size. The book does not contain, as a knowledge of English books with equivalent titles might lead one to expect, any structural details or views of machines. Still, it is well worth reading, and certainly merits a more substantial binding than the publisher has given it.

PLATO dreamed of a dialectic that should be the science of the sciences, and philosophers have often assumed that philosophy is the essence of knowledge, into which are distilled the results of empirical research. Metaphysical logic may be considered to assist science by suggesting new modes of generalisation, new points of view for classified facts. Darwin's theory of natural selection was a philosophical view; so is Bergson's estimate of mind. Every *-ism* is of this nature; Weismannism and Mendelism, neo-Darwinism and Pragmatism, are examples. Mathematics is equally suggestive of new generalisations; the work of Galton and of Karl Pearson are cases in point. The $\Phi\iota$ formula of Mr. William Schooling is perhaps the most recent. But it is arguable that all such generalisations are ultimately themselves suggested by new facts, and simply show the mind's plasticity of reaction to new environments. It is arguable that they are inevitable and obvious, once given the particular concatenation of facts suggesting them, but that the discovery of new concatenations of facts is not at all beholden to philosophical suggestion. It is said that the inductive idea suggested to Bacon a new mode of research; on the contrary, it was the increase in observed facts and new concatenations of facts that suggested the inductive idea.

The study of forms of thought develops with the material for thought, witness the developments introduced by Poincaré and Bertrand Russell. The latter's analysis, in (1) "The Proceedings of the Aristotelian Society," of the notion of cause is a refreshing proof of philosophical vitality. The word "cause," he says, "is so inextricably bound up with misleading associations as to make its complete extrusion from the philosophical vocabulary desirable." He well points out that advanced sciences like gravitational astronomy, even physics in general, never employ the term "cause." "The reason why physics has ceased to look for causes is that, in fact, there are no such things. The law of causality, I believe, like much that passes muster among philosophers, is a relic of a bygone age, surviving, like the monarchy, only because it is erroneously supposed to do no harm." What scientific laws do, instead of stating that one event A is always followed by another event B, is to state *functional relations* between certain events at certain times (these are *determinants*), and other events at earlier or later times, or at the same time. No *a priori* category at all is involved.

One of the most elementary philosophical ideas is that of purpose in evolution. Another is evolution. Mr. Arthur Lynch criticises the latter (papers of the Aristotelian Society) in an interesting and anecdotic essay. Very much in point is one of his texts, viz., the remark of Kirchhoff: "There is only one science (mechanics)." But Mr. Lynch's plea for a wider and deeper application of the idea of an all-pervading Purpose is unconvincing, though rhetorical.

The idea of Will dominates the psychology of the day; it belongs, of course, to the Purpose-idea. We could wish that some critical philosopher, such as Mr. Russell, would subject it to a merciless analysis. The same may fitly apply to the philosophy of chance and probability. The papers on these subjects read before the Aristotelian Society show the over-elaboration which often precedes the simplification of an idea. In the first volume of "The Encyclopædia of the Philosophical Sciences" (2) there is a similar elaborate treatment of logic. Prof. Losskij thus states the "new conception of consciousness which is leading Philosophy out of the *cul-de-sac* of psychological Idealism": "Consciousness is the sum-total of everything which stands in a certain unique *relation* to the Ego. . . . Every fact of consciousness is made up of at least *three moments*; every such fact depends for its existence upon the presence of an Ego, of a content of consciousness, and of a relation between the two." This is the old logic writ large. Prof. Couturat more hopefully applies mathematics to the principles of logic. His notion of "propositional functions" is worth serious consideration. The plan of the Encyclopædia is suggested, no doubt, by the inconsistencies of the previous works. It consists, "not of brief articles summary in character, dealing with a great variety of topics, . . . but of original and relatively exhaustive discussions of fundamental aspects of each main subject." The index, significantly, is of authors only.

(3) Mr. Reinheimer agrees with the late M. Novikow in emphasising positive factors in evolution against such negative factors as selection by survival. According to Darwin, death is a main factor; nutrition and work, according to Mr. Reinheimer, are more important. His thesis is a good one; biological cooperation, similar to economic cooperation, must be taken into account. Nutrition represents stored-up organic capital. It is parallel to reproduction. He has interesting observations on the fallacy of in-feeding, which is parallel to in-breeding. The book is suggestive, but, as a key, it only unlocks a side-door of the subject. Some elaboration of the orthogenesis doctrine seems more likely to open the main portal.

(4) Mr. Jamyn Brooks has already received careful critical consideration. In "The Science of the Sciences" he undertakes to correlate the three principal sciences of "Chemistry, Physics, and Metaphysics, or Matter, Force, and Mind." Thus, in his first prefatory sentence, he shows confusion, which becomes worse confounded as the argument proceeds. If he has a new idea, he ought to explain it, but when about to explain he goes off at a tangent to something else. The one idea I have gathered is the existence of mental æther, corresponding to material! The author's notion of construction and expansion as primary motion, and of translation as secondary, is not new. As for the testing of the hypothesis, continually mentioned, it fails to materialise.

(5) Herr Meyer, on the evolution of mind, brings together the latest results of animal-psychology, and treats of them in reference to the human mind. His expository method has the merit of being general; he abstracts the insect's mental life and applies it, in comparison with man's, to the forms of thought, such as space and time. This is a big book, closely reasoned and most comprehensive.

(6) The distinguished botanist, the late Prof. Potonié, has written a charming series of "easy-chair" essays on science. The popularisation of science, the art of explanation, the power of habit, dogma and criticism, knowledge and belief, imagination and science, the concept of purpose, are old subjects treated with freshness. In subjects which bring science and society into relation he is not afraid to speak out.

A. E. Crawley.

OUR BOOKSHELF.

Das Relativitätsprinzip; die jüngste Modenarrheit der Wissenschaft. By Leo Gilbert. Pp. 124. Wissenschaftliche Satyren. Band I. (Brackwede i. W: Dr. W. Breitenbach, 1914.) Price 3 marks.

The satire as a means of propaganda for scientific ideas is not of modern usage. Fechner was probably one of the last scientific satirists. Its revival in the present instance is the result of the considerable amount of mystification to which the electromagnetic principle of relativity established by Lorentz, Einstein, and Minkowski has given rise. The description of this principle as "the latest fashionable craze in science" is rather cutting, but as the book is well written and easily read, we can imagine that it will increase rather than lessen the general interest in the work of those eminent theoretical physicists. That the more extravagant conclusions resulting from the extreme adaptations of the principle should be held up to ridicule is quite wholesome, as it reveals the weak points in the argument and prevents the unwary from carrying it too far.

After all, "relativity" is only one among many possible interpretations of the result of a more or less isolated experiment. It asserts that no electrical or optical experiments can ever reveal absolute motion, or show any variation in the velocity of light. It is Einstein's merit to have pointed out the alarming consequences which would result from these two simple propositions. Our notions of time and space become almost interchangeable, and the "present moment" becomes meaningless without considerable restriction so soon as relative motion is involved.

Leo Gilbert burlesques these innovations with much humour and ingenuity, and will no doubt largely prevent them being taken too seriously. Since Einstein himself has practically abandoned the principle of the apparent constancy of the velocity of light in all circumstances, and even his mathematical methods have failed to deal with accelerated motion, there is little left of the imposing mathematical superstructure, and what "craze" there was has given way before a sober appreciation of an interesting speculation on its merits. While enjoying the fun of the satire, we cannot say that the author is at all fortunate where he endeavours to furnish an alternative explanation.

Gipsy Coppersmiths in Liverpool and Birkenhead. By Andreas (Mui Shuko). Pp. vi + 66 + plates. (Liverpool: H. Young and Sons, 1913.) Price 1*s.* net.

THIS book is a collection of newspaper articles describing the manners and adventures of a band of gypsy coppersmiths, which appeared in Liverpool and Birkenhead in 1912. The writer would have been better advised not to reprint his material in this fragmentary form, but to take the opportunity of preparing a connected narrative. These people were commonly known in this country as Hungarians, but they were really cosmopolitan nomads from Eastern Europe. They settled in Liverpool, where they claimed superiority over the local gypsies, and, though they were lavishly supplied with money and jewelry, professed to make their living by repairing copper cauldrons. They can scarcely be described as attractive. They were most unwilling to give estimates of the cost of work entrusted to them. Like all Orientals they loved bargaining, made preposterous demands of payment for work entrusted to them, refused to be bound by any contract, and tried to enforce their claims by bullying and that form of coercion known to Hindus as "sitting *dharna*." They were shameless beggars, and one of their boys stole the ring of their English friend, and flourished it in his face as they departed by train *en route* to Buenos Ayres. In spite of all this, they had a remarkable sense of personal dignity, and their kindness to one of their boys stricken with epilepsy, for whose treatment sorcery combined with the best medical advice was used, was remarkable. On the whole, we can readily imagine that the people of Liverpool easily reconciled themselves to the departure of their visitors.

Prehistoric Times: as Illustrated by Ancient Remains and the Manners and Customs of Modern Savages. By the late Rt. Hon. Lord Avebury. Seventh edition, thoroughly revised and entirely reset. Pp. iii + 623. (London: Williams and Norgate, 1913.) Price 10*s.* 6*d.* net.

THIS, the seventh edition, "entirely reset," was revised by Lord Avebury only a few months before his lamented death. The author was a pioneer in the popularisation of the study of archæology. It is pleasant to be reminded: "This (the Drift period) I have proposed to call the 'Palæolithic' Period," and "For this (the Stone Age) period I have suggested the term 'Neolithic.'" The present edition is specially enriched with coloured illustrations of Palæolithic paintings. For the wide range of its information, and the fairness with which divergent views are discussed, the book well deserves the improved lease of life now given to it as a popular text-book of archæology. Its defects are those of its class. For certain reasons, one had been led to expect that in this edition the author would have set a fashion in works of the kind in including a summary of the astronomical evidence which is but rarely detached from archæological objects. The Stonehenge evidence, it is true, is now too well impressed on the popular mind to be overlooked (pp. 133-4), but it is severely isolated. It is in the interests of young readers or teachers of this text-book that one points to the latter half of the following passage as a questionable statement. "In this country we still habitually call the megalithic monuments 'Druidical,' but it is hardly necessary to mention that there is really no sufficient reason for connecting them with Druidical worship" (p. 126). JOHN GRIFFITH.

A Text-book of Organic Chemistry. By Prof. A. F. Hollemann. Edited by Dr. A. J. Walker, assisted by Dr. O. E. Mott. Fourth English edition, partly re-written. Pp. xviii + 621. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1914.) Price 10*s.* 6*d.* net.

THE first English edition of this work was reviewed in NATURE on June 18, 1903 (vol. lxviii., p. 149). One of the chief characteristics of the present issue is the additional space allotted to the applications in organic chemistry of physicochemical methods. The section on tautomerism has been re-written, and the chapters on the benzene derivatives have been re-arranged.

LETTERS TO THE EDITOR.

New Units in Aerology.

IN NATURE of February 5, p. 629, is a reference to the new edition of the "Observer's Handbook" of the Meteorological Office, and complimentary mention of the proposed extension of c.g.s. units. On this side of the Atlantic, we have not yet seen the book, but feel that Dr. Shaw and his associates have with characteristic progressiveness done well in opening the campaign for the use of rational units. It will be hard for the present generation to depart from the old notation; but for those who are to follow, the adoption of these units means clearer conceptions of atmospheric motion, fewer mistakes, and great ease of compilation. Briefly, the units are those proposed by Köppen at Monaco in 1909, and advocated by V. Bjerknes at Vienna in 1912. Temperature is given in degrees Centigrade on the absolute scale, and pressure is recorded in *bars* and decimal parts thereof, as decibar, centibar, and millibar.

We began using these units at Blue Hill Observatory, January 1, 1914, and within a fortnight had our attention directed by Prof. Kennelly to the fact that unknown to meteorologists at home (and presumably abroad), the *bar* was in use and had an established meaning among chemists and others. If we continue its use without definition we only add to the confusion already existing.

So far back as 1888 the word *barad* was proposed by a committee of the British Association as a suitable term for the unit of pressure, one dyne per sq. cm. In 1903 Prof. T. W. Richards[1] independently suggested that the pressure of one dyne per sq. cm. be called a *bar*. He also suggested *megabar* for a c.g.s. atmosphere. So far as I can ascertain this is the first clear-cut definition of an absolute atmosphere. Ostwald in 1899 had the idea and advocated the use of one million of the units as a standard pressure, but gave no name to the large unit. Richards has used the bar consistently in his work, likewise Kennelly[2] and others. It has been definitely adopted by the International Congress of Physicists, independently of Richards's proposal under the name *barie* (see Guillaume's "Récents Progrès du Système Métrique," Paris, October, 1904).

It seems almost unnecessary to argue that the smaller bar should be the basic unit and not some multiple. And again, it is doubtful if bar is the most appropriate designation for the pressure of an absolute atmosphere. *Aer* is a more significant word. Megabar is not altogether inappropriate, and, as we have seen, is established in the literature of chemistry, and cannot readily be displaced. The megabar in the notation of the aerologist means the pressure of a million atmospheres, a magnitude not often dealt with; while on the other hand we sometimes need to express pressures smaller than the millibar of the aerologist. Now the bar of the chemist and physicist lends itself nicely to the measurement of these feeble pressures, since it is divisible down to its millibar, *i.e.* the thousandth of a dyne per sq. cm.

To contrast the two systems, I have made the following table, and at the suggestion of Prof. Richards have restricted it to the terms in common use.

Chemist and physicist (To be used by all hereafter)	Aerologist (To be abandoned)	Remarks
—	1 megabar	A million atmospheres; beyond direct measurement
1 megabar	1 bar	The absolute atmosphere; equal to 750·1 mm. Hg, or 0·987 of usual sea-level atmosphere. One megadyne per sq. cm. acting through 1 cubic cm. does 1 megerg of work.
1 kilobar	1 millibar	1 kilodyne per sq. cm.
1 bar	?	1 dyne per sq. cm. acting through 1 cubic cm. does 1 erg of work.

There could be no objection to giving the term megabar or absolute atmosphere some convenient nickname, such as "Aer," if megabar seems too ponderous. Prof. Richards has also suggested that for historical reasons the pressure of ten absolute atmospheres might be named after some pioneer in meteorology as Guericke or Torricelli or Pascal; but this need not be dwelt upon at present.

Fortunately we can change from the aerologist's system to that of the chemist by writing kilobar for millibar, and by substituting "aer" for "bar." This we are doing in the handy conversion tables now in course of preparation at this observatory.

Now is the time to agree upon a logical and available system. The megabar atmosphere seems to me to be the more appropriate; but perhaps some of the readers of NATURE can suggest something better.

Weather Forecasting.

MR. MALLOCK quotes in NATURE of February 26 (p. 711) a sentence of the late Sir G. Airy concerning the amassing of millions of useless meteorological observations. Unfortunately, in scientific work a vast amount of work which is not immediately productive has to be done. Indeed, it is not possible to foresee with accuracy what the result of any particular investigation will bring forth. But I do not think that this feeling will deter scientific minds from working, for each advance beyond the frontiers which limit our knowledge makes up for the disappointment resulting from many apparently unsuccessful expeditions.

It is acknowledged that in this country, indeed in this latitude, the weather depends largely upon travelling cyclones which reach us from the Atlantic. Now our knowledge of the nature and origin of cyclones is very limited, and recent researches of the upper atmosphere have shown that a good deal of accepted theory concerning them is unsound. In spite of the millions of observations which have been, and are being, taken, we have no detailed information concerning the conditions obtaining in any one cyclone, and the changes which have occurred in it during its passage over the land or sea. In these circumstances it is not surprising that weather forecasting should be difficult and uncertain. Now whilst such a lamentable want of knowledge concerning atmospheric disturbances exists, it surely cannot be maintained that we already have too much information, and that further research is undesirable.

The main question really is as to the direction such further research should take. Dines enters a plea for further research concerning the condition of the upper atmosphere. Considering that it is this kind of work which has led to such great changes in our views concerning the theory of cyclones, etc., it is reasonable to suppose that still further investigation in this direction would lead to further advances, and that, therefore, the work is one which deserves encouragement in a practical way. My own plea, which gave rise to this discussion, was for better daily charts. At the present time millions of observations are practically buried so far as the individual meteorologist is concerned. A large part of these could be put on the charts and rendered available for all. My suggestion as to the Daily Weather Charts was, that the *wind provinces* should be put in. I found that, even with the information now published, it was possible to do this with fair accuracy during a period of about ten weeks. With a few more wind observations plotted on the diagrams it would be possible to do this accurately. Then the isotherms and humidities of each wind province could be put on the chart. The isobars run from one wind province to another in continuous curves. This is not the case with the isotherms—they terminate more or less abruptly, as do the humidity curves, at the borders of the wind provinces. The winds and isotherms taken together, therefore, render it possible to draw the wind provinces with some accuracy.

It seems probable that daily charts with all the details that have been enumerated plotted on them would not entail great expense, would very likely teach us a great deal concerning cyclones and anticyclonic areas, and prevent so much valuable detail of atmospheric change being buried on the shelves of our institutions and societies.

R. M. DEELEY.

Abbeyfield, Salisbury Avenue, Harpenden, February 28.

The Doppler Effect and Carnot's Principle.

So many objections, based on the Doppler effect, have been made to my application of Carnot's principle to each particular frequency in full radiation, that it seems necessary to show that the two methods are not mutually inconsistent.

According to the Doppler effect, when a beam of light q_1 per sq. cm. per sec. moving with velocity c is directly reflected by a mirror moving with velocity nc in the same direction, the frequency of every component in the beam is reduced by reflection in the ratio $(1-n)/(1+n)$, which according to Wien's displacement law is also the ratio T_2/T_1 of the temperatures of the reflected beam q_2 and the incident beam q_1. The net expenditure of energy by the radiation per sec. per sq. cm. is q_1-q_2, which reduces to $4nq_1/(1+n)^2$, since the energy density varies on reflection as the square of the frequency. Part of this energy $(q_1+q_2)n$, is left in the space nc vacated by the mirror per second. The remainder, $2nq_1(1-n)/(1+n)$, is equal to the work done by the radiation pressure p, namely, pnc per sec. per sq. cm. We thus obtain $p=2q_1T_2/cT_1=2q_2T_1/cT_2=2\sqrt{q_1q_2}/c$, which is true for every component separately, and gives in the limit $p=2q/c$ when the motion is slow, and the incident and reflected beams become equal.

The energy left in the medium, $(q_1+q_2)n$, does *not* give rise to a volume of stationary vibration, unc, where $u=p=2q/c$, as commonly assumed, because the frequencies of each component before and after reflection are essentially different on account of the Doppler effect. In order to find the stationary vibration, or the intrinsic energy-density u in the state of equilibrium, we must combine each incident ray with a reflected ray of *the same frequency, before* taking the limit. For any component q in the incident beam, the energy-stream of the component having the same frequency in the reflected beam is $q-(dq/dT)_\nu dT$, where $dT=2nT$ when n is small, and $(dq/dT)_\nu$ is the rate of increase with temperature of an energy-stream of constant frequency ν. The net energy supplied of a particular frequency is $2nT(dq/dT)_\nu$ per second, and is equal to $(u+p)nc$. But since $p=2q/c$, this reduces in the limit to exact agreement with Carnot's principle, $T(dp/dT)_\nu=u+p$; which applies correctly to the equilibrium state.

H. L. CALLENDAR.

Ligament Apparently Unaltered in Eocene Oysters.

DURING the examination of some large specimens of *Ostrea bellovacina*, Lam., from the Woolwich beds, sent on February 20 to this office by Mr. A. G. Davis, of Beckenham, a very interesting case of the preservation of what appears to be organic tissue in an unaltered state has come to light.

The ligament in the two specimens examined has a remarkably fresh appearance, and in its aspect and texture compares so closely with that of a recent oyster as to suggest that the fossil specimen has undergone no change, except that it is somewhat softer and the fibres are less coherent.

The whole of the ligament has been removed from one specimen and preserved in spirit, and a portion will be embedded in paraffin and sections cut for microscopical examination.

The specimens were obtained from the lowest bed of the following section :—

Excavation for Sewer in the High Street, Beckenham.

	Soil	3 ft. 0 in.
Oldhaven and Blackheath Beds	Buff coloured sand with scattered pebbles; Pale grey sand with seams of clay, the lower part ferruginous, with wood and iron pyrites	9 ft. 0 in.
	Cyrena and Ostrea bed with some pebbles	1 ft. 0 in. to 1 ft. 6 in.
Woolwich Beds	Bluish grey clay with broken Cyrena; Bluish grey sandy clay with Ostrea	2 ft. 0 in.
	Bluish grey mudstone and muddy sand slightly cemented. Ostrea, Modiola, etc.	Base not cut through

The preservation of organic tissue in fossils is so extremely rare that this instance is worth recording. Further examination is being made.

Geological Survey, Jermyn Street, S.W., March 13.

Experiments Bearing upon the Origin of Spectra.

IN connection with Prof. Strutt's letter under the above title in NATURE of March 12, it may be of interest to direct attention to some previous work of Prof. Lenard's which contains results bearing on the same subject. Lenard (*Annalen der Physik*, vol. xvii., 1905, p. 197), as a result of a study of the light emission of the electric arc and the Bunsen flame containing metallic salts, showed that the principal and subordinate series are emitted by different distinct regions of the luminous source, and are thus due to different centres of emission. Further, he demonstrated that the centres emitting the different series behave differently in an electric field, and came to the conclusion that while the centres which emit the principal series are neutral metallic atoms (as has been also contended by Wien for the canal rays), the centres of the subordinate series are atoms rendered positive by the loss of one or more electrons, one for the first series, two for the second, and so on. This theory is strikingly borne out by Prof. Strutt's experiments, all of which seem to be explicable by it; in any case, this independent confirmation seems to place beyond doubt the different electrical state of the centres emitting the different series.

The First Description of a Kangaroo.

I HAVE just read in NATURE of February 26 (p. 715) a letter by Mr. W. B. Alexander concerning the discovery of Australia and the first description of a kangaroo. It is stated there that the first discovery of this animal was made, not by Sir Joseph Banks on Captain Cook's first voyage in 1770, but by Pelsart in 1629. May I be allowed to point out that a description of a kangaroo is to be found at a much earlier date, viz., in the "Decades" of Peter Martyr, published shortly after 1500. Unfortunately this book is not accessible to me at present, so I must only point to numerous publications of Mr. Edward A. Petherick, of the Federal Government Library, Melbourne, concerning the discovery of Australia, who claims this honour for Amerigo Vespucci. According to Mr. Petherick, Peter Martyr states that in 1499 a southern coast was discovered (probably by Vespucci) in which trees grew of such magnitude that sixteen men standing around one could scarcely encompass it (this would correspond to south-west Australia, between King George's Sound and Cape Leeuwin). Amongst these big trees was found a monstrous beast, with the head of a fox, the hands of a man, the tail of a monkey, and that wonderful provision of nature, a bag in which to carry its young. The beast so described was caught alive with its young, but during the long voyage both died. The carcase of the dam was taken to the Court of Ferdinand and Isabella in the year 1500. This description is not as detailed as that by Pelsart; nevertheless it cannot easily be doubted that it refers to a kangaroo, which seems to have been known for the first time so far back as the end of the fifteenth century.

The coast in question is supposed to have been discovered by Diego de Lepe, whose pilot was Vespucci.

The Movements of Floating Particles.

WILL any physicist be good enough to explain the following to an ignorant amateur? If a clean saucer be half-filled with a decoction of tea on the surface of which bubbles or unwetted shreds of ash (as from the consumed paper round the lighted end of a cigarette) are floating but not in a continuous layer, then if the decoction, after coming to rest, be gently rocked the floating particles will partake of its perpendicular, but little, if at all, of its lateral motion. Sunken particles, on the other hand, will partake of the lateral motion. Again, if the saucer be gently tilted the fluid will flow away, but each floating particle will remain stationary, and will be deposited under its original position.

Why do not the particles partake of the lateral motion? Does the surface of the decoction form an incompressible, but flexible, film, which (in the saucer) may be added to but not subtracted from, under which the rest of the fluid slides with little friction. And when the fluid flows away does this film remain behind to form that portion of the fluid that wets the saucer? Or do solid, but invisible, particles come up and form a continuous sheet on the surface? Against the latter supposition is the fact that particles dropped on the advancing edge of the decoction remain stationary. Particles floating on the surface of ordinary tap water move with it much more freely; water in which table salt has been dissolved behaves like tap water. But even in sea water we see froth left behind by receding ripples.

G. ARCHDALL REID.

"Netherby," 9 Victoria Road South, Southsea. March 13.

KINEMATOGRAPHY AND ITS APPLICATIONS.[1]

MR. TALBOT is to be congratulated on having produced a book which must appeal strongly to the interest of the general reader, even though he may have no intention whatever of becoming a "kinematographer." A word here on this terrible term. It may be correctly derived from the Greek, while it certainly admits of many pronunciations, variously wrong, but the frequent collision with these six syllables when otherwise interested must impress upon the reader of Mr. Talbot's book the desirability of finding some new word of one syllable, not derived anyhow, such, for instance, as the mechanic and the electrician have found in the words crank and boost, so that neither attention may be arrested nor printing ink and paper wasted.

The main purpose of the book is to show what has been done in many different fields and the nature and cost of the apparatus which an amateur would be likely to use, rather than to give instruction in the details of the art. Incidentally, the commercial value of lucky-chance films of the amateur is pointed out, but it is not very clear what the cost of the unlucky-chance miles of film that will be worth nothing is likely to be.

On first opening the book the reader will see a picture of a fine cow which appears to have suffered at the hands of the cattle-maiming gang. Closer inspection will show that the injury is a door in the side of the beast, which, according to the legend below, is 15 ft. high. It was made by Messrs. Newman of *papier-mâché*, so that the operator might get inside with his camera with the intention of taking lions and other beasts unawares. Passing on from this testimonial to the credulity of the savage beast, we find numerous full-page or half-page enlargements of single pictures taken from the strip, so perfect in focus and detail that it is scarcely possible to believe that it has all been derived from a miniature $1 \times \frac{3}{4}$ in. only in size. A reference to some of these only will indicate the great variety of subject which is open to those who practise this new art. There are lions at lunch in the jungle, a polar bear diving in the arctic sea, birds feeding their young, a vulture preparing to fly, and taken at such close quarters that every feather is clearly defined, eighteen successive photographs taken during a single beat of a pigeon's wing, and fifteen of the opening of a convolvulus, both from the Marey Institute, two X-ray films from the same institute by M. Cavallo, one of sixty pictures showing digestion in the intestine of a frog, and thirty of the movements of the gizzard in a fowl, and others from the same quarter.

Then by the aid of the microscope and the "ultra-microscope," smaller forms of life may be seen in motion. For instance, there is the head of a spiny monster which is nothing more than a blue-bottle eating honey from off a needle, and there might have been, but are not, illustrations

[1] "Practical Kinematography and its Applications." By Frederick A. Talbot. Pp. xii+262+plates (London: W. Heinemann, 1913.) Price 3s. 6d. net.

of the blood corpuscles, phagocytes, and microbes in human blood in a state of violent activity and warfare. Then there is a group of pictures taken from an American film, which was produced with the object of showing the actual movements of a highly-skilled mechanic, so that those who take too long about their work might learn how to avoid useless movements. There is an account of the beautiful instrument of M. Bull described in NATURE of July 28, 1910 (vol. lxxxiv., p. 112), by means of which stereoscopic pictures may be taken at the rate of 2000 a second of such objects as a fly flying; and the somewhat similar apparatus of Prof. Cranz is also described. There is also an account of the most startling development of kinematography. It is called the "Life Target." In this device a moving picture is projected on the screen; it may be, for instance, of cavalry crossing the screen or of an elephant charging straight at the spectators. These are provided with rifles and shoot at the screen. The explosion wave, by suitable mechanism, causes the film to be arrested for an instant only, when the bullet hole is clearly seen as a white spot, which disappears when the film continues its movement. Other interesting pictures show the hatching of a chick, a fight between a lobster and an octopus, and many other things.

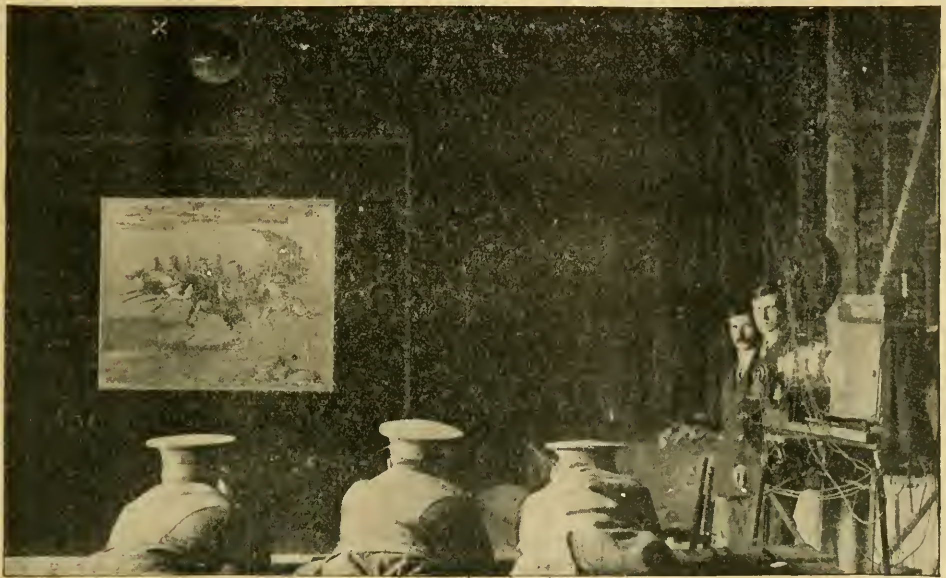

FIG. 1.—Soldiers firing at the "Life Target." The picture on the screen is thrown from the projector at right, and the picture is held stationary by the action of the report of the rifle caught by the microphone (marked ×) upon the lantern mechanism. From "Practical Kinematography and its Applications."

A very good account is given of the construction of several of the simpler machines, and in particular of the "Aeroscope," or moving-picture camera, in which air previously compressed in a light tubular reservoir by means of a bicycle pump drives a minute engine and so moves the mechanism at the desired rate, while the operator, having both hands free, may hold the machine up over his head in a crowd and secure at close quarters some stirring incident. It is with this instrument that Mr. Cherry Kearton has obtained some of his most wonderful results.

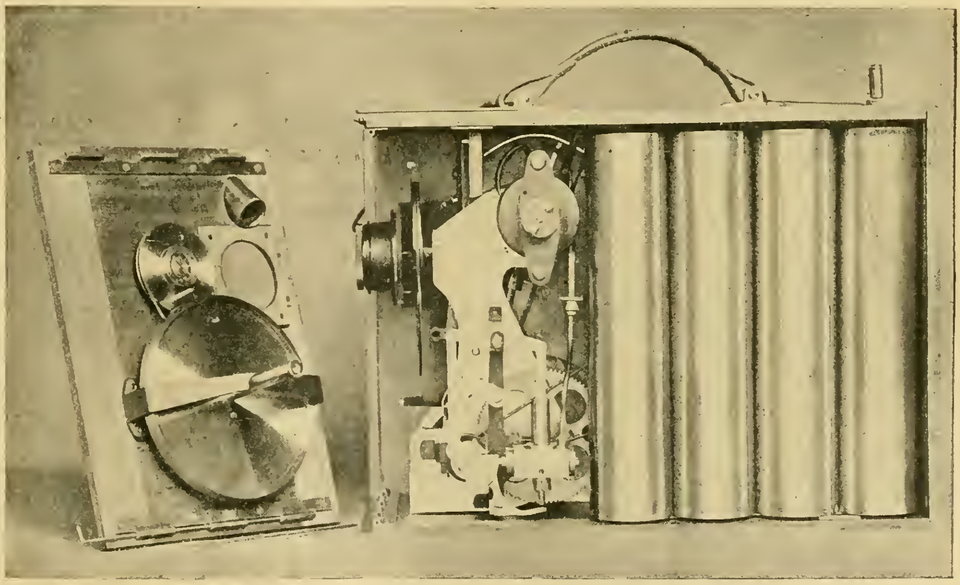

FIG. 2.—The compressed air reservoirs of the "Aeroscope" camera. One charge is sufficient to expose 600 ft. of film. From "Practical Kinematography and its Applications."

The methods used for developing and printing, of course, are described, but, curiously, no mention is made of colour work, whether two colour such as is so popular at the Scala Theatre, or three colour as represented a year or two ago at the Royal Institution by M. Gaumont, with such amazing fidelity to the colours of Nature.

Space is not available for more than a bare recitation of some of the things described or illustrated; sufficient, however, has been said to show that a most interesting and attractive book has been produced.

On p. 171 reference is made to a difficulty met with when photographing live microbes in consequence of their being killed by the heat from the concentrated beam from the powerful arc lamp. The use of a water cell in the beam is described as a method of reducing this trouble. While the ever-repeated fallacy of alum solution finds no place here, the author or Dr. Comandon, whose work is being described, do not appear to have known of the use of freshly-prepared solution of $FeSO_4$, of such a strength that its colour is just visible, as an effective heat absorber.

C. V. BOYS.

EARLY FOSSIL BRACHIOPODS.[1]

THE work before us, which treats of the Cambrian brachiopods of the whole world, must arouse the admiration of all who understand the difficulties of a comprehensive palæontological study of such magnitude. It is a splendid monument to the ability and perseverance of its eminent author, whose previous reputation as an investigator of the Cambrian faunas was so widely established as not to need the further proof afforded by these two handsome volumes. It is a matter both for surprise and congratulation that Dr. Walcott has found opportunity, amidst his many activities, to bring to completion a task so overwhelming: small wonder that it has occupied his available time for ten years or more.

If the wealth and good preservation of the Palæozoic Brachiopoda found in North America has provided an abundance of material favourable for study, how worthily have the palæontologists of the United States utilised their advantages! It may be granted that they owe some measure of their success to generous practical support and to freedom from conservative traditions in the matters of outlook and treatment of their subjects: these are advantages denied to most workers in Europe. Yet no consideration of such favouring circumstances can diminish our indebtedness to those brilliant investigators in the United States who have contributed so largely to the rapid advancement of modern palæontology in all its branches. For models of comprehensive systematic work, for suggestive and original phylogenetic studies, and for inspiring aid in applying the facts of palæontology to many problems of philosophic biology, we in Europe have become more and more accustomed to look westward. Dr. Walcott is one among several of his compatriots who have advanced our knowledge of the Palæozoic brachiopods in an extraordinary degree.

It is impossible for a single reviewer either to criticise in detail a work of such wide scope as the present monograph or to do justice to its merits. It must therefore suffice to indicate briefly some of its special features. In this book are described "44 genera, 15 subgenera, 477 species, and 59 varieties of Cambrian Brachiopoda," and "3 genera, 1 subgenus, 42 species, and 1 variety of Ordovician Brachiopoda." The descriptive part of the text occupies nearly 500 pages; yet, bearing in mind that this will remain the standard work of reference on the Cambrian brachiopods of all countries for many years to come, the author appears to have erred on the side of brevity. There are instances where the specific characters might with advantage have been set out more fully and the comparative observations amplified, though the appearance of an unduly meagre treatment may sometimes be owing to limitations in the material itself. The whole descriptive portion of the work affords ample evidence of the author's extensive knowledge and scholarly thoroughness. The 76 figures, chiefly in half-tone process, which are scattered throughout the text are clearly reproduced, while the letterpress is very well printed and edited.

The various tables in which are set forth synonymic references and the geographical and stratigraphical distribution of the brachiopods, are outstanding features of the work. The table of synonyms, giving the names now adopted set in a column alongside those previously applied to the same species, will be of great service to all workers in this field of study. Geographical distribution is shown in a synoptic table arranged according to continents and faunal provinces (pp. 114–122). Another elaborate table, giving the detailed stratigraphical distribution of the Cambrian and some Ordovician species, occupies 34 pages. This is arranged alphabetically according to states or countries, and contains a vast amount of concisely arranged information. Here are included summaries of many local or regional sections, with references to individual localities which are described in detail on subsequent pages: also lists of the brachiopods found at the various horizons and certain leading species of other classes.

The section of the work headed "Zoological Discussion" (pp. 291–326) is of importance to all students of the Brachiopoda. Here are to be found terminological definitions and an account of the morphological characters of the shells; also short chapters on evolution and classification, which strike us as unduly condensed. The bibliography (pp. 13–26) is very full, and should prove of great help to other workers. We miss here a reference to Mr. F. R. C. Reed's memoir on "The Cambrian Fossils of Spiti" (Palæontologia Indica), published in the summer of 1910, and the species of brachiopods there recorded are omitted from the descriptive portion of the text. Presumably that work appeared too late to be utilised;

[1] "Cambrian Brachiopoda." By Charles D. Walcott. Monographs of the United States Geological Survey, vol. li.: part i., pp. 872+76 figs.; part ii., pp. 363+civ plates. (Washington: Government Printing Office, 1912.)

but if this be the case, two years seems a too generous allowance of time to be occupied in passage through the press, to the exclusion of belated additions, even in the case of an elaborate monograph such as that under review. The volume of text concludes with a full and well-planned index, while there is the useful luxury of a second index at the end of the volume of plates.

Special praise must be accorded to the plates, upwards of 100 in number, which illustrate this work. These are well reproduced in collotype process from beautifully executed drawings, mainly by Miss Frances Wieser, of the United States Geological Survey. The careful and detailed work of the artist is a fine achievement. To many who have little acquaintance with the Cambrian brachiopods beyond the scanty assemblage found in our own country, the perusal of this volume of plates will prove a revelation. It is indeed astonishing to find that such a profusion of species had been evolved and such elaborate specialisation had been attained by many of them in those remote ages. One can only picture in imagination the long and slowly evolving lines of precursors of which no trace has yet been found.

Dr. Walcott deserves the warmest thanks of all palæontologists and geologists for a treatise which must long remain a classic. The public department which has issued the work in such handsome form is also to be congratulated. What higher service can such a department perform than thus to give practical encouragement to arduous scientific labour? F. L. K.

THE TRANSMISSION OF PLAGUE BY FLEAS.

THE third Plague Supplement of the *Journal of Hygiene* maintains the high standard both of research and of editing set by the previous numbers. It contains eight good articles, chiefly by S. Rowland and R. St. John Brooks, on the bacteriology of plague and by A. W. Bacot on the rat flea. The former articles deal with the influence of cultivation in serum-containing media upon the virulence and immunising properties of the plague bacillus; upon the facility with which it is ingested by human leucocytes; and upon its virulence—all points of importance in regard to bacteriology in general. Mr. Bacot's most laborious and well-set-out researches upon the influence of temperature and humidity upon the pathophores and on the effect of vapours as insecticides deserve much commendation; but perhaps the most interesting article is by him and Prof. C. J. Martin on the mechanism and transmission of plague by fleas. They sum up a very careful paper by the following remarks:—

"Under conditions precluding the possibility of infection by dejecta it was found that two species of rat fleas, *Xenopsylla cheopis* and *Ceratophyllus fasciatus*, fed upon septicæmic blood, can transmit plague during the act of sucking, and that certain individuals suffering from a temporary obstruction at the entrance to the stomach were responsible for most of the infections obtained, and probably for all. In a proportion of infected fleas the development of the bacilli was found to take place to such an extent as to occlude the alimentary canal at the entrance to the stomach. The culture of pest appears to start in the intercellular recesses of the proventriculus, and grows so abundantly as to choke this organ and extend into the œsophagus. Fleas in this condition are not prevented from sucking blood as the pump is in the pharynx, but they only succeed in distending an already contaminated œsophagus, and, on the cessation of the pumping act, some of the blood is forced back into the wound. Such fleas are persistent in their endeavours to feed, and this renders them particularly dangerous." R. R.

NOTES.

WE announce with deep regret the death on March 16, as the result of a motor accident, of Sir John Murray, K.C.B., F.R.S., the distinguished naturalist and oceanographer.

THE Right Hon. Sir Francis Hopwood has been appointed by the president and council of the Royal Society to a seat on the general board and executive committee of the National Physical Laboratory, in succession to Sir Arthur Rücker, F.R.S., resigned.

WE notice with regret a Reuter message from New York reporting the death on March 16 of Prof. E. S. Holden, director of the Lick Observatory from 1888 to 1898, and author of a number of papers and other works on astronomical subjects.

THE death is announced, on March 7, at seventy-three years of age, of Prof. Antonino Salinas, professor of archæology at the University of Palermo and director of the Archæological Museum.

PROF. J. G. ADAMI, F.R.S., Strathcona professor of pathology and bacteriology, McGill University, Montreal, has been awarded the Fothergill gold medal of the Medical Society of London for 1914, for his work on pathology and its application to practical medicine and surgery.

THE death is announced, in his sixty-seventh year, of Dr. E. J. Houston, one of the inventors of the Thomson-Houston system of arc lighting. He was twice elected president of the American Institute of Electrical Engineers, and was the author of more than fifty books, mainly on electricity and allied subjects.

PROF. F. KEEBLE, F.R.S., professor of botany, University College, Reading, has been appointed director of the Royal Horticultural Society's garden at Wisley, with the view of making it of more general practical service. Mr. F. Chittenden will remain in charge of the educational section, and Mr. S. T. Wright will continue to act as superintendent of the garden.

MISS A. CANNON, whose critical examination of Harvard College Observatory photographs has led her to the discovery of many new variable stars and other objects of interest, has been elected an honorary member of the Royal Astronomical Society. At the meeting of the society on Friday last, the president, Major E. H. Hills, in announcing the council's decision, remarked that Miss Cannon had acquired remarkable skill in distinguishing the type to which a star spectrum belongs and had completed the classification of 150,000 stars in this way.

MR. MARCONI appears to have secured some remarkable results with his new wireless telephonic apparatus. According to the daily newspapers, experiments have been carried out from Italian warships off the Sicilian coast, and on one occasion signals were received from Canada, 4062 miles away, by means of wireless telephony. In another experiment communication was set up between two ships forty-five miles apart, and the connection continued uninterruptedly for twelve hours. On March 14 the wireless telegraphic station at Nauen, near Berlin, exchanged clear signals with the Windhuk station in German South-West Africa, a distance of more than 6000 miles.

WE regret to announce the death, on March 15, of Dr. Harry Burrows, senior lecturer on chemistry at the Sir John Cass Technical Institute, at the early age of forty-two. Dr. Burrows received his academic training at the Royal College of Science and at Heidelberg University, and was a research scholar and subsequently an assistant demonstrator at the Royal College under Sir William Tilden. For the past ten years he had been on the staff of the Sir John Cass Technical Institute, where his successful work as a teacher was valued and appreciated both by the governors of the institute and by the students. Dr. Burrows contributed several papers to the Transactions of the Chemical Society.

THE Faraday Society has arranged a general discussion on optical rotatory power, to be held in the afternoon and evening of Friday, March 27, in the rooms of the Chemical Society, Burlington House, London, W. Prof. H E. Armstrong will preside at the afternoon session, and will deliver an introductory address. Prof. Percy F. Frankland will preside at the evening session. Papers on various aspects of the subject will be read by Prof. Hans Rupe (Basle), Prof. H. Grossmann (Berlin), Prof. Leo Tschugaeff (St. Petersburg), Dr. Darmois (Paris), Dr. T. M. Lowry, Mr. T. W. Dickson, Mr. H. H. Abram, Dr. R. H. Pickard, Mr. J. Kenyon, and Dr. T. S. Patterson.

THE Royal Society for the Protection of Birds has issued a manifesto signed by the president (the Duchess of Portland) and other ladies of distinction in favour of the Importation of Plumage Prohibition Bill now before Parliament. The manifesto says :—"The present Bill is the result of careful and prolonged investigations. The export of the plumage of wild birds has been prohibited from India, and from the majority of the Crown Colonies. The United States of America and the Commonwealth of Australia have sifted the question, and passed laws prohibiting both export and import. A strong feeling in favour of legislation on these lines is growing in Germany, France, Austria, Holland, Sweden, Denmark, and Belgium. Attempts to regulate the traffic would be futile on account of the insurmountable difficulties with respect to laws and their enforcement in the countries from which a large proportion of the birds come; therefore, the most effectual way to preserve wild birds is by the enactment of laws prohibiting importation in support of the regulations which forbid export."

THE report of the Royal Society for the Protection of Birds, presented to the meeting held at the Westminster Palace Hotel on March 5, shows that the growth of the society has been well maintained. Further funds are required if the society is to do the work which lies before it. "The watchers' committee is continually asked to undertake fresh work and accept new responsibilities; educational work could proceed far more rapidly were there funds for its support; it is probable that the work at the lighthouses will demand large additional outlay; and the legislative work before the society for 1914 is the heaviest it has yet had to encounter." The work at the lighthouses, it may be explained, takes the form of erecting rails on which flights of migrants may perch.

UNDER the powers of the Ancient Monuments Consolidation and Amendment Act, 1913, the following Advisory Boards have been appointed for England, Scotland, and Wales :—*England*—Mr. Lionel Earle (chairman), Lord Burghclere, Lord Crawford, Sir Aston Webb, Mr. R. Blomfield, Sir C. Hercules Read, Mr. C. P. Trevelyan, Prof. F. J. Haverfield, Prof. W. R. Lethaby, Mr. R. A. Smith. *Scotland*—Sir John Stirling-Maxwell, Bart. (chairman), Sir Herbert Maxwell, Bart., Mr. A. O. Curle, Dr. G. Macdonald, the Hon. Sir Schomberg K. McDonnell, Sir James Guthrie, Sir Robert Lorimer, Mr. J. R. Findlay. *Wales*—Sir E. Vincent-Evans (chairman), Lieut.-Col. W. E. Ll. Morgan, Mr. W. Edwards, Sir E. Stafford Howard, Mr. E. Neil Baynes, Prof. R. C. Bosanquet, Dr. W. E. Hoyle, Prof. J. Edward Lloyd. Mr. C. R. Peers, Chief Inspector of Ancient Monuments, is also a member of each board.

THE death is announced of Mr. George Westinghouse, the inventor of the air brake. Born at Central Bridge, Schoharie County, New York, in 1846, he was educated at public and high schools, and at Union College, where he graduated Ph.D. The air brake which has made his name famous throughout the world was invented in 1868. It has been computed that Mr. Westinghouse's genius as an inventor has brought into being undertakings with a capital of 130 millions of dollars, giving employment to 50,000 skilled artisans. He founded works in many American centres, as well as in Manchester and London, at Havre, and in Germany, Russia, Austria, and Italy. Among the decorations bestowed on him were the Legion of Honour, the Order of the Royal Crown of Italy, and of Leopold of Belgium. He was also the recipient of the Edison gold medal in 1912, and in the following year of the Grashof gold medal, conferred annually by the engineering profession of Germany in memory of Franz Grashof.

A PARAGRAPH in the *Times* of March 12 records the arrival at the Natural History Branch of the British Museum of a consignment of specimens illustrating the whales of the Antarctic. They were obtained by the museum taxidermist who accompanied the late Major Barrett-Hamilton to South Georgia, and were brought home *gratis* by Messrs. Salvesan, of Leith, their united weight being about 8 tons. The specimens—which represent three species, namely, the blue or Sibbald's rorqual (*Balaenoptera sibbaldi*), the common finner (*B. musculus*), and the southern humpback (*Megaptera lalandei*)—include the whalebone, flippers, a trunk-vertebra, and ear-bones. Plaster casts of the flippers are now being made, which will in due course be placed on exhibition. The blue rorqual was the second largest specimen on record, measuring close on 100 ft. in total length. To this species pertains the aforesaid vertebra, which is of enormous dimensions, largely exceeding those of the vertebræ of the sauropod dinosaurs from the Wealden of the Isle of Wight.

THERE is something reminiscent of a Latin-American frontier dispute in the controversy which has arisen regarding the base in the Weddell Sea of the respective Antarctic expeditions of Sir Ernest Shackleton and Dr. Koenig, but the parallel unfortunately does not hold good so far as to suggest arbitration by an impartial umpire. It is admitted on Dr. Koenig's side that, before his expedition was spoken of, Sir E. Shackleton had expressed in general terms his hope of undertaking a journey from the Weddell Sea to the pole. Dr. Koenig, on the other hand, produced detailed plans before Sir E. Shackleton did so, and the question turns simply on a point of opinion whether the latter's previous general statement gives him a basis of claim to priority, or not. The Royal and Imperial Geographical Society in Vienna has committed itself to the negative opinion, and there the matter appears likely to rest: either side may claim what it will but cannot enforce any claim upon the other; so that so far as concerns work in the Weddell Sea area (for the published statements do not make it clear that a crossing of the Antarctic continent is part of the Austrian, as it is of the British, scheme) science may be compelled to fall back upon any satisfaction and value which it may be possible to derive from a comparison between independent sets of observations in the same field.

THE concluding meeting of the Optical Convention was held on Thursday, March 12, in connection with the meeting of the Optical Society of that date. The report presented contained many points of special interest, conspicuous among which was an experiment made by the Board of Education in accommodating the exhibition of the Optical Convention in the buildings of the Science Museum at South Kensington. The experiment appears to have given complete satisfaction to the committee and members of the convention. We believe that it is regarded as having been successful by the authorities of the museum, and as it is very evident that such an employment, when practicable, of our public museums must tend materially to enlarge their usefulness, it may be hoped that the precedent will not be lost sight of in the future. From another point of view the report must have been equally satisfactory to the members of the convention, for it appears that in the result the committee has been able to wind up the business without making any formal call upon its guarantors. The most important outcome of the convention was the formation of a technical committee charged with the duty of establishing an effective cooperation between the users of scientific instruments on one hand, and the manufacturers of such instruments on the other. The report of that committee, which was the most interesting feature of the proceedings, shows that the committee found some very useful work ready to its hand in connection with a communication from the War Office referring to the standardisation of the cells and other parts of telescopes and binoculars. A sub-committee has been formed to consider the matter, and it is hoped that through the instrumentality of the Optical Society, and with the cooperation of British manufacturers of telescopes and binoculars, the necessary work of standardisation will soon be carried out.

IN connection with the Panama-Pacific International Exposition in San Francisco next year, there will be an International Engineering Congress, during the week September 20–25, 1915, in which engineers throughout the world, representing all branches of the profession, are invited to participate. The congress is to be conducted under the auspices of five engineering societies, namely, the American Society of Civil Engineers, the American Institute of Mining Engineers, the American Society of Mechanical Engineers, the American Institute of Electrical Engineers, and the Society of Naval Architects and Marine Engineers. Colonel G. W. Goethals, chairman and chief engineer of the Isthmian Canal Commission, has consented to act as honorary president of the congress. The general field of engineering to be covered by the congress has been divided into ten groups or branches, which, together with the special field of the Panama Canal, will constitute eleven divisions or sections, as follows:—(1) The Panama Canal; (2) Waterways and Irrigation; (3) Railways; (4) Municipal Engineering; (5) Materials of Engineering Construction; (6) Mechanical Engineering; (7) Electrical Engineering; (8) Mining Engineering and Metallurgy; (9) Naval Architecture and Marine Engineering; (10) Military Engineering; (11) Miscellaneous. The offices of the committee of management of the congress are at Foxcroft Buildings, San Francisco, Cal., U.S.A.

MR. B. QUARITCH, of 11 Grafton Street, London, W., is about to publish an elaborate work entitled "British Flowering Plants," in four volumes, royal quarto, at twelve guineas if ordered before the date of publication, March 28, or fifteen guineas after that date. The main feature of the work consists in three hundred coloured plates, reproduced from water-colour drawings by Mrs. Perrin. Copies of the first volume of the work, together with the original drawings, and the plates for the book, are on view (March 13-27) at the Dudley Gallery, 169 Piccadilly, where we inspected them on Saturday last, and were equally struck by the beauty of the original drawings and the remarkable fidelity of the plates reproduced from them. Thirty of the plates consist of floral dissections, but those inspected were somewhat too small and lacking in detail to be of much service to the student; such analytical illustrations are usually better done in black and white, except where they are on a large scale, as in the well-known coloured sections of flowers given in Dr. Church's "Types of Floral Mechanism." The British flowering plants are receiving a large amount of attention from artists and photographers at the present time, and the appearance of so many attractive books is a welcome sign of increasing interest in our wild flowers, while it should swell the numbers of field naturalists.

Mr. Arthur MacDonald, of Washington, D.C., has sent us a leaflet entitled "The Study of Man," the object of which is to urge the desirability of laboratories to investigate the bodily and mental characteristics of the criminal, pauper, and defective classes. This leaflet he has sent to the Home Secretary, Mr. McKenna, with a letter directing his attention to the importance of such work as a means of throwing light on the causation of crime, and as likely to furnish a more rational basis for methods of reform. With Mr. MacDonald's object we are in complete agreement, but in fairness to the Home Office it must be said the claims of the anthropological and psychological study of criminals have already met with some official recognition, as is evidenced by the recent publication in the form of a Blue-book of "The English Convict," by Dr. Goring, the deputy-medical officer of Parkhurst Prison. Yet the contents of this memoir are perhaps the most convincing indication that could be brought forward of the need for the establishment of laboratories, each equipped, not necessarily with costly and elaborate apparatus, but certainly with a properly qualified staff. For Dr. Goring's results clearly demonstrate the importance of the problems depending for their solution on work of this nature, while at the same time the poverty of the psychological data which he had at his disposal indicates the need for more advanced experimental work as to the mental nature of criminals.

In the issue of *Man* for March Sir H. H. Johnston discusses the origin of the horse-shoe arch. He suggests that it and the Mahràb, or holy recess, in the Mohammadan mosque, were based on a Phœnician sex-cult introduced into the West by Phœnicians, and that the horse-shoe arch, under their influence, may have arisen independently in southern Spain as it likewise arose in Cœle-Syria and southern Tunis. "But if so," he adds, "it is perplexing to find it as a pre-Islamic feature in Visigothic buildings of *northern* Spain, whither the Phœnician influence can have scarcely penetrated."

Prof. Arthur Keith's discourse on an anthropological study of some portraits of Shakespeare and of Burns, delivered at the Royal Institution on February 20, is printed in the issue of the *British Medical Journal* for February 28. In the case of Shakespeare, Prof. Keith uses a terra-cotta mask recently found in one of the midland counties, the bust in the church at Stratford, and the Droeshout portrait; for Burns a cast of the poet's skull in the possession of Mr. Barrington Nash, and portraits by Raeburn and Nasmyth. Examination of the head of Shakespeare proves him to be a representative example of the short-headed type, not of the early British breed, but of the round-headed race which entered Britain in the Bronze period, about 2000 B.C. His brain capacity was more than 1900 cm., as compared with 1477 in an average Englishman. Burns, on the contrary, represents an exceptional example of the long-headed type, with a brain capacity of 1730 cm., at least 200 cm. above the average of his countrymen. His skull displays a close analogy with those found by Prof. Bryce in Arran cairns. He sprang from families settled round the Firth of Clyde, and he is thus a direct descendant of the long-headed people who lived in England and Scotland during the later Neolithic period. We may call Shakespeare a "Celt" in the sense in which this term is used on the Continent, while Burns comes from the western fringe, usually called "Celtic," but really pre-Celtic. "Is it possible," asks Prof. Keith, "that we may explain the extraordinary difference in the working of their brains by the diversity of their racial origin?"

The third All-India Sanitary Conference, held at Lucknow on January 19–27, was attended by delegates from all parts of India and Ceylon, including the Portuguese possessions. Sir Harcourt Butler, in his presidential address, reviewed the work that is being carried on in the study and practice of Indian sanitation, but pointed out that progress is necessarily slow in a land where the habits and prejudices of centuries are arrayed against the sanitary reformer, and where it is impossible to benefit fully by the discoveries of the secrets of disease and mortality until the people are educated to receive and profit by the results of scientific investigation. An introductory address to the opening meeting of the research section was given by Sir Pardey Lukis, Director-General of the Indian Medical Service, who reviewed the present state of knowledge concerning the etiology and prevention of the more prevalent Indian diseases. A number of important papers were read before the conference, and led to interesting discussions on various problems of sanitation and disease, while affording striking evidence as to the energy and thoroughness with which investigations upon such problems are being carried on by the medical officers of our Indian Empire.

At the last meeting of the Entomological Society of London, a communication was received from Mr. J. C. Hawkshaw on the subject of the cocoon spun by the larva of *Lyonetia clerkella*, a small moth of the family Tineidæ. The cocoon is slung like a hammock between silken threads attached to the surface of a leaf. On each side of the area bounded by the supporting threads, a fine web is spun 3 or 4 mm. wide, and very loosely attached to the leaf. If any attempt is made to detach the cocoon with the point of a knife or similar instrument, the cocoon and webs become a shapeless mass, which sticks persistently to the point, and is with difficulty transferred to any other object. Mr. Hawkshaw suggests that this structure serves as a protection against ants, which are constantly seen to be searching the trees inhabited by the Lyonetia. An ant wishing to seize the cocoon would first have to wade through the loose, flattened web, which forms an outwork in the defence, and in this its legs would become hopelessly entangled. If the ant ventured further, its head and antennæ would also become entangled, and would carry the whole away with it. The assailant would probably be quite unable to bring its biting apparatus to bear on the cocoon. A specimen was exhibited in illustration, in which the supporting strands and flanking webs were clearly seen.

THE list of the zoological gardens of the world drawn up by Capt. S. S. Flower, and apparently published at Cairo by the Egyptian Government, has been revised, and a new issue printed, bearing date January, 1914. Inclusive of a few large private collections, such as that of the Duke of Bedford at Woburn Abbey, the number of establishments of this nature known to the compiler is 166.

ACCORDING to an illustrated article by Dr. F. A. Lucas in the January number of the *American Museum Journal*, the late Mr. E. T. Booth, whose well-known collection of British birds is now the property of the Corporation of Brighton, has the best claim to be the founder of the plan of exhibiting in museums groups of animals mounted amid artificial imitations of their natural surroundings. He was followed by Mr. Montagu Brown, then curator of the Leicester Museum, and soon after by the late Dr. R. B. Sharpe, in the Natural History Branch of the British Museum, where a group of coots formed the commencement of the splendid series of exhibits which is now the delight of visitors to the bird gallery. The rise and progress of the practice—especially in America—are fully described in the article, of which a continuation is promised.

PAPERS on various groups of insects from the Philippines and Japan form the greater part of vol. viii., No. 4, of Section D of the *Philippine Journal of Science*. In one of these, dealing with Japanese termites, Mr. Masamitsu Oshima reproves Mr. N. Holmgren for having given new specific names to certain members of that group, previously named by himself in Japanese. Whether technical names proposed in languages unfamiliar in western Europe should be accepted may, perhaps, be open to argument, although it would be somewhat difficult to decide where to draw the line. In papers written in Russian the names of new species and genera are frequently printed in English characters, which at least renders them legible by zoologists of other nationalities. If this was not done in the case of the Japanese papers, the argument for the rejection of the names is strengthened. The names proposed, both by Oshima and Holmgren, were published in 1912, but only the latter appear in the *Zoological Record* for that year, although some of Oshima's publications are quoted in the volumes for 1909 and 1911.

IN an article in *The Indian Forester*, December, 1913, p. 568, Mr. H. M. Glover directs attention to the difficulty of protecting the forests of *Pinus longifolia* in the Panjab from disastrous fires. The accumulation in a few years of fallen needles, dead wood, and old grass render such forests very inflammable; and the fires which are inevitable, owing to the carelessness of the natives, are very fierce, and cause much damage. Mr. Glover advocates, as the result of numerous experiments, the running of a slow fire over limited areas in these forests during winter, when the soil covering is much less inflammable than in the hot weather. Such fires do no harm to pines more than 6 in. in diameter, as stems of this size are covered with a protective thick bark. This method has proved very efficacious, the artificial firing being done during December, January, and February, over areas well under control, from which young growth is absent. Burnt-over sections can be artificially seeded, as seedlings come up in profusion when the refuse has been destroyed.

As a supplement to the paper on the monthly and annual rainfall normals at Indian stations (NATURE, June 26, 1913), the director-general of observatories has recently published a volume containing averages of the monthly and annual number of rainy days at all stations where records for at least five years are available. For some purposes this summary is perhaps even more valuable than the previous one, as it shows whether the monthly amounts were distributed over several days instead of possibly being due to torrential downpours. In the absence of any discussion of the normals it may be interesting to quote the average annual number of rain-days referring to some of the extreme values at stations quoted in the issue of NATURE above-mentioned:—Cherrapunji (Assam), 159·1; Málcompeth (Bombay), 122·3; Launglon (Burma), 145·6; Rújanpur (Panjab), 7·7; Rohri (Bombay), 6·3; Jhatput (Baluchistan), 6·1. The definition given of a rainy day is one on which 0·1 in. or more rain is recorded. This differs materially from the definition for a rainy day in this country, viz., 0·01 in. or more.

THE January number of *Le Radium*, which reached us at the beginning of the present month, contains a valuable collection of tables of radio-active constants brought up to date by M. L. Kolowrat. It is proposed to publish the table annually in order to keep readers supplied with the most trustworthy data. References to the original authorities are given, and the tables are accompanied by a few pages of explanations and remarks.

PART 2 of the *Verhandlungen* of the German Physical Society for 1914 contains a communication from Dr. G. Wiedmann and Prof. W. Hallwachs, of the Technical High School, Dresden, on the part played by the surrounding or absorbed gas in the production of the photo-electric effects exhibited by metals. Although the observations of Prof. Hallwachs and his pupils have all tended to show that the gas plays an essential part in the phenomenon, the idea that the photo-electric process is due to the metal only seems still to persist. With a view of showing how far such an opinion is out of touch with the actual facts the authors have by repeated distillations of potassium got rid of the large amount of hydrogen dissolved in the metal, and have shown that the reduction of the gas is accompanied by a decrease of the photo-electric action. After the fourth distillation the effect was reduced from a current giving 850 mm. deflection to one too small to detect. The result amply confirms the view that the effect is due to the gas absorbed by the metal.

THE inaugural lecture delivered by Dr. W. C. McC. Lewis, the successor of Prof. Donnan in the Brunner chair of physical chemistry at the University of Liverpool, has been issued in pamphlet form, with the title, "Physical Chemistry and Scientific Thought." It is mainly devoted to the significance of research from the purely scientific aspect, especially in connection with some of the problems of physical chemistry.

SINCE Wöhler's first synthesis of a natural organic compound, the chemist has succeeded in building up nearly all the natural compounds from their constituent elements in his laboratory; indeed, the synthesis of the sugars, the polypeptides, the alkaloids, uric acid and its derivatives are some of the greatest triumphs of the chemist. Much of the success in this field is due to the genius of Emil Fischer, and though he has celebrated his sixtieth birthday he shows no signs of relaxing his labours, being now responsible for another great achievement. The importance of the nucleus in the cell needs no emphasis, and therefore the value of the recent work, more particularly of Levene and his collaborators, in America, on its chemical composition has been widely recognised. In brief, the nucleic acids are composed of glucosidic compounds of purine derivatives combined with the carbohydrates to which phosphoric acid is also coupled. The synthesis of such a glucosidic compound of sugar and purine has long been essayed, but it is only now brought to a successful conclusion. Once the principle of the method of making them has been made clear all kinds of purine derivatives can be coupled with the carbohydrates, and when phosphoric acid has been introduced into the molecule the complete synthesis of the nucleic acids will have been achieved.

Engineering for March 13 gives an illustrated account of the new water supply scheme for New York. The actual water supply is derived from the Croton River by impounding this river and its tributaries thus providing 325 millions of gallons a day. The population has increased very rapidly, and the present consumption amounts to more than 500 millions of gallons daily. The additional water supply system, now under construction, is derived from the various watersheds of the Catskill Mountains, from which 800 millions of gallons daily could be obtained. The Esopus watershed is the only one to be developed at present, and has necessitated the construction of a great dam at Olive Bridge. This dam consists of a central masonry portion 1000 ft. long, and rising to a height of 210 ft. above the bed of Esopus Creek. Each end of the masonry is flanked by an earthen wing, which together are about 3600 ft. in length. The greatest thickness at the base is 200 ft., while the top, which is traversed by a roadway, is 26 ft. in width. The up- and down-stream faces are formed by concrete blocks of large dimensions, while the great bulk of the interior masonry is made of cyclopean concrete. Expansion joints are provided, and run through the entire thickness. The roadway on the top of the dam will be 20 ft. higher than the water level, and thus will be free from the action of ice and waves.

THE directors of Messrs. Pathé Frères have agreed to permit the Research Defence Society to hire any nine of their excellent medical and biological films for the modest fee of two guineas. Nine films afford ample illustration for a lecture of an hour's duration, and as a kinema machine can be hired in most large towns, it should prove possible, in view of the generous concession of Messrs. Pathé Frères, to arrange lectures in support of the work of the Research Defence Society at a comparatively small cost. Further particulars of this promising scheme for educating the public in the value of modern medical research can be obtained from the honorary secretary to the society, Mr. Stephen Paget, 21 Ladbroke Square, London, W.

MESSRS. LONGMANS AND CO. announce as in preparation, "Principles of General Physiology," by Prof. W. M. Bayliss. In the volume special attention will be given to reactions in colloidal systems, oxidation, action on surfaces, secretion, excitation, inhibition, nutrition, etc. Messrs. Longmans and Co. also give notice of a new series of monographs on physiology which will be under the editorship of Prof. E. H. Starling. The following volumes are in preparation:— "The Involuntary Nervous System," Dr. W. H. Gaskell; "The Physiology of Reflex Action," Prof. C. S. Sherrington; "The Conduction of the Nervous Impulse," Dr. K. Lucas; "The Physiological Basis of the Action of Drugs," Dr. H. H. Dale; "The Secretion of Urine," Prof. A. R. Cushny; "The Contraction of Voluntary Muscle," Dr. W. M. Fletcher; "The Cerebral Mechanisms of Speech," Dr. F. W. Mott; "The Chemical Mechanisms of Integration in the Animal Body," Prof. E. H. Starling.

OUR ASTRONOMICAL COLUMN.

ELECTRIC WAVES AND THE COMING TOTAL SOLAR ECLIPSE.—It is hoped that the forthcoming total solar eclipse of August 21 will be fully utilised to study the effect of the propagation of electric waves, as this event affords an exceptional and important opportunity of adding to the existing knowledge of the propagation of electric waves in sunlight and in darkness and across the boundaries of illuminated and unilluminated regions. The total eclipse track passes across Greenland, Norway, Sweden, Russia, and Persia to the mouths of the Indus; in Russia the duration of totality will be a little more than two minutes. A circular, distributed by the British Association committee for radio-telegraphic investigation sets forth details of this special kind of investigation and this committee would be greatly aided in the organisation of this piece of research if those possessing the necessary facilities and willing to make observations during the eclipse would communicate with the honorary secretary, Dr. W. Eccles, University College, London, W.C., at the earliest possible date. The committee proposes to prepare and circulate special forms for the collection of statistics of signals and strays, especially within the hemisphere likely to be affected by the eclipse. It will endeavour to make provision for the transmission of special signals at times to be indicated on the forms. It will also offer for the consideration of the authorities controlling stations near the central line a simple programme of work. The discussion of the observations, and the comparison with meteorological data will be carried out by the committee, and digests of the statistics, together with the conclusions drawn from the analysis, will be published in due course.

THE CURIOUS METEORIC DISPLAY OF FEBRUARY 9, 1913.—A brief account was given in NATURE of September 18 last (vol. xcii., p. 87) of what was described as an "extraordinary meteoric display," which was observed over a very extensive line in Canada and America. The display took the form of a procession of meteors, brilliant and coloured, and was compared with a fleet of battleships or airships proceeding at night across the sky. The Journal of the Royal Astronomical Society of Canada for November–December, 1913 (vol. vii., No. 6, pp. 404 and 438) publishes some further information and correspondence relating to this extraordinary display which will be read with great interest. In the first instance, Mr. W. F. Denning communicates an interesting discussion, having gone over the work again, after Prof. Chant's investigation, with the result of obtaining a good general agreement with the latter's conclusions. Even so experienced an observer as Mr. Denning describes the fall as "unique." The further information is supplied by Col. W. R. Winter, of Bermuda, who has been able to collect additional facts since his first report. It shows that the general appearance of the display at Bermuda differed considerably from that observed in Canada, for most of the large leading bodies had disappeared while the number of trailers and groups had greatly increased. Prof. Chant discusses these various opinions and new observations in the article in question.

THE GENERAL DISPLACEMENT OF LINES IN THE SOLAR SPECTRUM.—Some results of a comparison of arc and solar wave-lengths of certain iron lines appear in Bulletin No. xxxvi. of the Kodaikanal Observatory by which Mr. Evershed has been led to a new interpretation of the general displacement of lines in the solar spectrum towards the red. The completion of the electric installation has enabled use of the arc to obtain spectra of the sun and laboratory source of light on the same plate, thus permitting more accurate determination of absolute and relative shifts of the lines in the solar spectrum. Some of the plates have been measured by the positive on negative method recently noted in this column. Mr. Evershed's determination of the difference between sun and arc agree, in the main, very well with the figures which MM. Fabry and Buisson have obtained by the interference method. The pressure explanation of the origin of the shifts is now found to be quite incompatible with the observations in three different directions: (1) King's low-level lines show *least* shifts in the sun; (2) the lines showing greatest shifts under pressure in the laboratory show least shift in the sun; and (3) the lines in the red do not show the greatly increased shifts they would be expected to if Duffield's exponential law were followed. It is found that lines in the red show the least shifts, and that the strong (high-level lines) are most affected. These two facts receive adequate explanation on the supposition that in the higher levels there is a movement of descent with a negative acceleration. The motion for the strong lines amounts to 0·93 km./sec., while for the weak lines it is less than 0·3 km./sec. The director is to be congratulated on the early advantage he has taken of the increased facilities afforded by the completed electric installation.

ORIGIN OF PLANETARY SURFACE FEATURES.—M. Emile Belot has communicated to the French Academy of Sciences a tentative theory of the mode of formation of the external features of some planetary bodies, more especially those of the earth (*Comptes rendus*, vol. clviii., p. 647). Whilst one does not feel by any means compelled to accept all the suggestions there put forward, the paper is nevertheless intensely interesting, and contains some highly original ideas regarding the development of the heart-shaped figure of the earth and the formation of land areas based on the hypothesis of a relative movement of translation of the earth (also the moon and Mars, which are regarded as resembling the earth) in the primitive nebula, the movement being in the direction of the axis of rotation from south to north. M. Belot regards the main land features as cognate with water. He supposes, indeed, that they were formed by the deposition of material carried by surface torroidal currents flowing away from the south pole, completing a stupendous circulation generated by the resistance offered by the nebula to the movement of translation. The vertical cool descending current in the Antarctic region marked that as the site of the condensation of the water of the ocean.

SMOKE ABATEMENT IN EUROPE AND AMERICA.

THE movement for lessening the evils of smoke, both factory and domestic, is extending and increasing in weight and importance. In our own country, the health authorities of sixteen cities have commenced to make accurate observations upon the extent and character of the soot- and dust-fall, by a standard method and apparatus.

Classes for the instruction of stokers and engineers in the scientific principles of combustion are now included in the curriculum of the majority of the larger technical schools and institutes; and a movement is in progress to obtain higher wages and a better status for the men who have passed satisfactorily through these courses of training, and have obtained a certificate of efficiency. Glasgow has made most progress in this direction, and has also carried on for several winters a series of popular lectures, designed to bring home to the general public the losses and evils arising from smoke, and the best methods of minimising these, both in the works and in the home. The classes and lectures have been carried on in Glasgow, by the West of Scotland Branch of the Smoke Abatement League; in Manchester, Liverpool, and other towns and cities, the classes are run by the local education authorities.

In Germany, the Hamburg "Verein für Feuerungsbetrieb und Rauchbekämpfung" continues to flourish, and can show a membership of nearly 500 members, the majority of whom own boilers or other heating appliances, and are thus large users of fuel. The officers of the Verein are now directing their attention to the emission of smoke from steamers lying in the port of Hamburg, and are seeking to extend the benefits of their system of supervision to the Mercantile Marine.

In America, the most notable event of the past twelve months has been the publication by the Mellon

Institute of Industrial Research in the University of Pittsburg of a series of bulletins dealing with the results of the inquiry into the black smoke problem in that district of the U.S.A. Five bulletins have been issued so far: No. 1 deals with the "Outline of the Investigation," No. 2 is a "Bibliography," No. 3 discusses the "Psychological Aspects of the Problem," No. 4 deals with the "Economic Cost of the Smoke-Nuisance in Pittsburg," and No. 5 with the "Meteorological Aspect of the Smoke Problem."

Bulletin No. 4 contains the following summary of the losses annually incurred in Pittsburg, as a result of the damage and dirt produced by smoke:—

	£
(1) Cost to the smoke-maker, by imperfect combustion	304,150
(2) Cost to the individual: laundry and dry-cleaning bills	450,000
(3) Cost to the householder: painting, cleaning, and decorating	466,400
(4) Cost to the proprietors of wholesale and retail stores: cleaning, lighting, depreciation of stock	735,000
(5) Cost to the owners of office buildings, hotels, and hospitals	43,400
Total	£1,998,950

This estimate, it must be noted, covers the losses per annum in one American city alone, the population of which at the present time is about 350,000. Calculated for each head of the population, the loss is therefore about 5*l.* 13*s.* per annum.

Assuming that London is only suffering pecuniary losses from the smoke evil to one-half the extent of Pittsburg, the total will represent a loss of well over ten million pounds per annum, or more than double the estimate given by the Hon. Rollo Russell, in a paper read at the Building Trades Exhibition and Conference, held in London in 1899.

J. B. C. K.

THE AFRICAN MAMMAL FAUNA.

FROM a zoological point of view the year which has just come to a close will be noteworthy on account of the extraordinary number of new specific and subspecific names applied to members of the African mammal fauna. In the case of the larger forms a great proportion of these names have been proposed as the result of the detailed examination of the vast series of East African mammals collected during the Roosevelt expedition, by Mr. E. Heller, who, in various issues of the Smithsonian Miscellaneous Collections, has described as new a number of local races of monkeys, antelopes, and Carnivora. To some of these reference has been already made in NATURE, with mention of the very slight differences by which many of the new races are distinguished. The same naturalist has also, during 1912 and 1913, made several well-known antelopes the types of new genera, separating, for instance, the lesser kudu as Ammelaphus, and Hunter's hartebeest as Beatragus, the latter term being formed by combining "B.E.A.," the initials of British East Africa, with the Greek *τράγος*—a combination which would have made the classically educated naturalists of a previous generation recoil with horror.

Local races of the arui or North African wild sheep have been described in "Novitates Zoologicæ," by the Hon. Walter Rothschild, who has also, in the December issue of the *Ann. Mag. Nat. Hist.*, given names to various local races of antelopes, among these being the Congo representative of the giant eland, which appears to be the largest form of that species. A new race of the ordinary eland, as well as various monkeys, have been named by Dr. P. Matschie, respectively in the *Sitzber. Ges. nat. Freunde* and the *Revue Zool. Africaine*; while several local forms of antelopes have received new names from Mr. E. Schwarz in the *Ann. Mag. Nat. Hist.* Nor does this exhaust the list of antelopes, as Mr. Gilbert Blaine, in the journal last cited, has named a new gazelle from Erythrœa, as well as two races of reedbucks.

Among the smaller mammals particular interest attaches to the description of a second species of the remarkable insectivorous genus Massoutiera from the Algerian Sahara, by Mr. O. Thomas, in vol. xx. of the "Novitates"; while various new African bats and shrews have been named by the same writer in two issues of the *Ann. Mag. Nat. Hist.* By far the largest number of additions to the list of African Micromammalia has, however, been made by Mr. Austen Roberts, who, in vol. iv., part 2, of the Annals of the Transvaal Museum, has described as new no fewer than twenty-eight species and subspecies from the Transvaal and neighbouring South African States.

Although many of the races to which separate names have been applied during the year are undoubtedly worthy of recognition and distinction, those based on minute and unimportant colour-differences make the thoughtful naturalist wonder where the splitting process is to end, and what advantage accrues to science when it is carried to the excess which is now in vogue.

R. L.

THE INSTITUTE OF METALS.

WE have received a copy of the tenth volume of the Journal of the Institute of Metals, containing, principally, an account of the papers read and discussions at the autumn meeting of the institute, held at Ghent in September last. The volume reflects the flourishing state of the institute, which has now held its first meeting abroad, and with marked success.

The most important feature of the volume is the second report to the corrosion committee, in which Dr. Bengough and Mr. Jones, of Liverpool University, give an account of their work on this subject. This has included laboratory experiments and also trials with an experimental condenser erected with the funds collected by the corrosion committee. This somewhat costly form of investigation has, however, fully justified itself, and its continuance is assured by the further financial support received from some of those most interested in condenser-tube corrosion. The report constitutes an important forward step in our knowledge of the corrosion of brass by the process of "de-zincification." It is shown that in a simple 70/30 brass this occurs normally in contact with sea-water, particularly if the temperature is raised to the vicinity of 40° C. A white zinc-salt, of the nature of a basic chloride, is formed, and acts as a species of catalytic agent, leading to the continued solution of zinc with constant re-formation of the basic chloride. Muntz metal is found much inferior to brass in this connection, but a brass containing 1 per cent. of tin, or, better still, 2 per cent. of lead, is found to resist this form of corrosion far better than a pure zinc-copper alloy. A remarkable result brought out by the report is the negligible influence exerted on dezincification by local electric cells, such as those formed by adherent particles of other metals or of carbon.

Among the other papers may be mentioned a further contribution to the theory of an amorphous intercrystalline cement, by Dr. Rosenhain and Mr. D.

Ewen, which deals with the nature and causes of the brittleness of even the purest metals at temperatures near their melting points. Mr. H. Garland, of Cairo, contributes a paper on the micro-structure of ancient Egyptian metal specimens, showing that the metastable structure of cored solid solutions has persisted through many thousands of years. Prof. Hoyt deals with the constitution of the "kalchoids," by which repellent name he denotes the alloys of zinc, tin, and copper, while Prof. Guertler, of Berlin, contributes a discussion of the relation between alloy constitution and specific volume. All the papers attain a very high standard of scientific and technical interest.

HYDROLOGY IN THE PACIFIC.[1]

IT is a "far cry" to the Sandwich Islands, and equally a "far cry" to the days of Captain Cook with his intrepid crew, pioneers in the exploration of Polynesia. Many changes have taken place since the black day in 1778 when the renowned navigator came to his tragic end on the snowy sand beach of Hawaii. The modern traveller who wanders so far will find the Hawaii of to-day a fully civilised community, the streets of the principal town of which, Honolulu, besides being laid with tramways and electric mains, are so covered with a network of telephone wires as to give the impression of a huge spider's web amid the palm-trees.

The Sandwich or Hawaiian, Islands are eight in number, forming a chain about 400 miles long, distant some 2,000 miles from the North American continent and from the United States, of which they constitute a territory. The principal unit is Hawaii, which gives its name to the group, and is in area more than double any of the others. The capital lies on the island of Oahu. The industry is chiefly agricultural. Practically the whole of the exports—99 per cent.—are products of the soil (rice, sugar, taro, etc.), and of these 93 per cent. are either absolutely dependent on irrigation for growth, or require the application of water at some period or other to stimulate their development, and produce the most satisfactory yield. Such being the case, the administration and conservation of the water resources of the islands are matters of obvious and fundamental importance, in regard to which the United States Government shows no sign of neglecting its responsibilities. The volume just published is an account of the investigations made during the period 1909–11 into the conditions and factors influencing the flow and economic development of the surface waters. It is replete with statistical data and full of strange names of streams and places, the pronunciation of which (Awaawapuhi, Puuwaawaa, Kukuihaele, for instance), though no doubt musical enough when correctly rendered, seems to be beset with difficulty for the uninitiated. B. C.

THE RESEARCH CHEMIST AND THE TEXTILE INDUSTRY.[2]

THE textile industry of this country shows a gross value amounting to the considerable total of 333,000,000*l.*; materials to the value of 235,000,000*l.* were used in their manufacture; and 1,253,000 persons were employed in their manipulation. The power used amounted to 1,987,000 h.p., and 77 per cent. of the firms engaged in their work made a return that they had used during the same period 8,137,000*l.* worth of coal. These figures indicate that there must be under modern conditions an ever-increasing call for research chemists in this industry. If the standard that one chemist is required for every 2000 persons employed in the textile industry were set up, there would be room for no fewer than 620 highly trained chemists, who would each be dealing with an "average gross output" of the value of more than 500,000*l.* per annum.

When it is remembered that a Continental combine in the aniline dye industry employs more than 600 chemists, the above estimate of ultimate requirements cannot be considered unreasonable. The effect of this army of chemists working in the interests of the textile industry would naturally lead to astonishing developments and to considerable improvements in detail.

The student who enters a works on the research side, after having received a university education (or having equivalent qualifications), will, undoubtedly, possess a knowledge of chemistry which will rank as an immediate asset. In a way, the college training will also have prepared him for actual working conditions by indicating their nature.

In addition to this knowledge of theory, the student will make immediate use of any experience he may have gained in ordinary analytical operations. It will often be necessary to devise new methods of analysis, or, at least, modify old ones, before they can be utilised in industrial investigation. A knowledge of the principles which underlie such work is, therefore, a very necessary equipment for the young investigator. This also involves a training which has a special value to those entering this, and most other, industries. In many cases, work will rest on the borderland of industrial research, where the actual analysis of certain products can replace actual experiment in very few cases. It is the latter which counts. The former is generally of secondary value.

The research chemist will probably enter the works at an early age. If he has finished his college course at twenty, a year or two of teaching work will do no harm. It will consolidate his knowledge of theory under the stress of imparting it to others. Better still, if it is possible to determine, at that stage, the direction of his future work, he may engage in a post-graduate course of research. The actual time of coming in contact with works conditions should not be delayed beyond the age of twenty-two years, for the mind must be capable of readily adjusting itself to industrial conditions, which are naturally different from those surrounding the student in a college laboratory.

The introduction of a time factor in its relation to cost of production will alone have a great influence. Work in the factory may be practically continuous in its operation. The young chemist will, therefore, quickly realise that he has to deal with entirely new conditions. These will at once claim his interest by reason of their novelty and importance. He will soon be engaged in the attempt to control, or modify, operations proceeding on a scale possibly measured in tons, or thousands of yards.

The raw material will enter at one end of the factory. At the other end, it will leave in a more or less "finished" state. This operation may, in some cases, take months to complete, during which time the material may be subjected to innumerable processes which may possibly modify both its physical and chemical properties. The chemist will endeavour to understand, and so control, these operations that, during transit through the works, material may receive a minimum of treatment to produce a maximum effect; for this generally means satisfactory working conditions, and low cost of production.

[1] "Water Resources of Hawaii, 1909–11." Prepared under the direction of M. O. Leighton by W. F. Martin and C. H. Pierce. Pp. 552+11 plates +3 maps. (Washington: Government Printing Office, 1913.)

[2] From lectures delivered before the Institute of Chemistry, October and November, 1913, by W. P. Dreaper.

What general effect can the successful investigator have on the methods and processes employed in work of this nature? He must aim at a position under which determining methods of working are being constantly modified in detail; or even in nature. Under the most successful conditions he may, in time, find himself working three years in advance of those who are not taking full advantage of modern methods of investigation. It is difficult for an industrial chemist to hide from his experienced rivals a process or method which can be detected in the finished product by ordinary, or even special, means. Many improvements are, however, of such a nature that they cannot be detected in this way, and then the above condition may be found to apply. In most cases this standard is a reasonable one to aim at. More than this can scarcely be expected, unless the Patent Law comes in to protect ideas and methods for a longer period. When this is realised, there is obviously no finality to work of this nature, and as a result a condition of continual change will probably be set up in the factory.

It is surprising to what an extent secret working has in some cases secured a monopoly. Especially is this so, when the effect of a process, or use of a machine is not self-evident or easily traced in the finished article. Under such conditions, and more particularly where an industry has not adopted a scientific control, a certain sequence of operations has been known to remain the monopoly of a firm, or a limited number of firms, over many years—as witness the Turkey Red industry.

Even where a close examination of the finished product might suggest, to the experienced investigator, the method of treatment employed, its presence is often overlooked or unsuspected because of difficulties in the way of identification or analysis. A slight and inexpensive change in manufacture may add 10 per cent. to the apparent value of a textile material. What this means on a large output can easily be imagined, as the ordinary net profit on manufacture may be somewhere between 20 and 35 per cent.

The research chemist is, therefore, constantly trying to improve or devise methods of investigation which will enable him to keep in touch with the work of those who, for the time being, may be regarded as his competitors; and the methods utilised to this end are based more often upon personal experience than published results. Such processes generally deal with the recognition of certain physical or chemical changes which occur when the material is subjected to tests corresponding to those in actual practice. Owing to their value to the investigator, such methods are not generally disclosed. Work in this direction, or modifications in accepted processes of analysis, and in the proper interpretation of results, are often carefully guarded, until through some change in procedure, they no longer retain their original value. Many such examples will occur to the technical chemist.

The aim of the chemist in this respect is to obtain some clue of a physical or chemical nature which will suggest to the experienced investigator the nature of superior working methods. Such methods of obtaining an insight into hitherto unknown processes or applications are of considerable value. They can only be successfully used by the investigator who has a practical knowledge of manufacture in addition to an ordinary laboratory experience. Thus, to the industrial research chemist, analysis may have a different meaning to what it has to the general consulting chemist. It is a means to an end which possibly may be the discovery of the nature of a process. Analysis is also utilised to obtain the correct working conditions of a new process, or the better control of an old one.

It will be gathered from these remarks that procedure must in many cases be empirical in its nature.

The research chemist often has to watch ordinary manufacturing operations over extended periods before any plan of control or improvement can be devised. Light is sometimes thrown upon such a position by the occurrence of irregular results in the daily output, or a systematic examination of the effects produced by accidental, or predetermined, variations in working conditions. Many problems have been successfully investigated by such means. Such variations, as they occur in everyday practice, may often lead to important improvements, or even suggest new processes. Thus, the research chemist will soon realise that his right place is in the works. He will use the laboratory mainly to follow up ideas in detail.

The introduction of new methods naturally calls for an immediate re-examination of the conditions of working of existing processes. This may often secure to them an extended lease of life, as in the case of the collodion method of preparing artificial silk. In these days of costly apparatus for plant, this factor must not be lost sight of. It is the first point to consider when the chemist finds he has to deal with, and equal, the results obtained, by the introduction of a more efficient process, leading to the production of a better or cheaper product.

The successful worker must, however, go further than this. Experience indicates that important results have generally been obtained by striking out boldly in a new direction. The risk connected with such pioneer work can always be minimised by working on a moderate scale, and making sure of the details of every step as it occurs in a natural sequence. With long experience, it is sometimes possible to experiment at once on a large scale with a reasonable chance of success, but this course should never be followed by the beginner. Such conditions are comparatively rare, and generally governed by some secondary consideration, such as the prohibitive cost of new apparatus, as compared with the utilisation of that already available in the works.

In industrial research, it is sometimes more important to know what not to do than the reverse. This restraining influence must be developed equally with originality. In this, the worker will naturally be guided by instinct, which may be defined as the tempering of past experience by an untiring caution.

Once more, the young chemist may be urged to spend most of his time in the works, only working in the laboratory when some work requires systematic investigation. Many manufacturers have objected to this procedure in the past, but with tact, such opposition, where it still exists, can generally be overcome. The industrial chemist who remains in his laboratory will be hopelessly left behind in the race for progress.

It is impossible to say how far the chemist should experiment in the laboratory, or when he must carry out the necessary investigation in the works itself. In the latter case, it is well to leave such labour as does not entail exact measurement in the hands of the workman. The chemist must, however, *know how to carry on such work*, and in cases of difficulty, be able to do so under the eyes of the workman. This is sometimes a rather trying experience to the novice, but it must be faced.

Be careful, when starting experimental works, and reasonably certain that all data which can be obtained on a laboratory scale are already secured. Only then should the establishment of experimental works be attempted. Much can be done in the way of experimental plant, etc., in the laboratory with 100*l*. An experimental works will probably absorb anything between 3000*l.* and 10,000*l.* before any important results or improvements can be obtained.

It sometimes happens that preliminary operations of a seemingly innocent nature induce material changes which cause endless difficulties in subsequent treatment. These disturbing causes will be entirely overlooked if the chemist does not carry his investigations back to the raw material and examine processes on the broadest lines.

In the process of mercerising the fibre must be kept under a condition of strain during at least one part of the process; and a long staple cotton (Egyptian) must be used if the treatment is to have its maximum effect. The mere chemical operation of mercerising was, in itself, ineffective (Figs. 1 and 2).

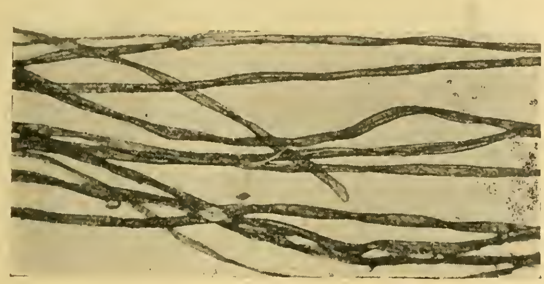

FIG. 1.—Cotton fibres (× 100).

Thus, it is evident that the modern chemist must be prepared to carry his investigation to the extreme limits of experiment, or satisfactory results will not be obtained. Also that he must extend his work beyond the realm of chemistry proper. A more general knowledge and scheme of working are necessary if the laboratory is not to remain a mere adjunct to the engineering department. The term, "chemical technologist," is one which possibly best describes the qualifications of the industrial investigator, and the knowledge he must possess.

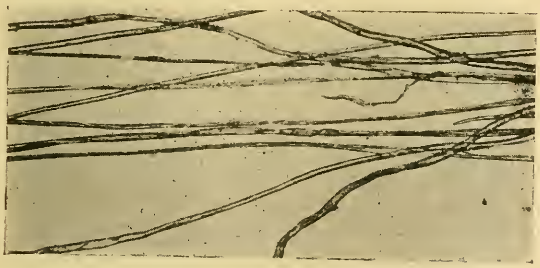

FIG. 2.—Cotton fibres after mercerising under tension (× 100).

When the student considers such processes, he will realise that the difficulties and nature of modern industrial research are closely concerned with detail. This is always so. Many problems of similar importance undoubtedly still exist in the textile industry, but these will be solved only by the trained investigator who attends to this essential point.

Thus, success is often closely associated with the art of carrying existing processes a stage further. It is with the careful working out of additional detail that it is associated.

In numberless cases, progress is only secured by following up a seemingly unimportant point. This being so, the importance of a training, be it self-inflicted or otherwise, which qualifies a man to deal with such problems is evident. In its absence, progress can only be realised by the more slowly working aid of rule-of-thumb.

The presence of this factor has given the rule-of-thumb man great power in the past, for he has at his command a wonderfully accurate instrument in the trained eye. The chemist with all his apparatus is in some cases no match for him.

The investigator, sooner or later, realises the essential value of empirical methods, and if he is wise lets the worker know that he does so. In this way, the chemist gains the worker's confidence, and the latter more clearly realises the true aim of research. Once this position is established, the workman will naturally direct attention to any variations in working which may occur, or make suggestions of distinct value. The workman has a great advantage. His mind is continuously concentrated on one operation. Thus, it often happens that only by a careful study of deviations from the normal will the research chemist be able to report progress. His aim is to explain and control, the workman's to manipulate.

Facts which are but "curiosities" to the workman, and have remained so for many years in some cases, must be carefully investigated in detail by the chemist. They often represent the starting point for improvement—a first aid to progress, when all other means have failed. Time given to such investigation is never lost, for experience in the ways of processes is a commanding asset to the industrial chemist.

Where operations are conducted on a large scale there is a greater chance of recognising such conditions. An improvement when applied on a larger scale has also a greater value. It is, therefore, better for the young chemist to get into a large works; unless he is compelled to enter a single department, in which case the greater freedom in a small works may be more valuable in spite of restricted output.

Attention may be directed to a list of the probable actions which may be involved during dyeing operations, which I advanced some time ago.

(1) A solution state of the dye within certain limits of aggregation as determined by the laws of solution.

(2) A fibre state corresponding to this state of aggregation and of a permeable nature.

(3) Localisation of dyestuff within the fibre area through surface concentration effects.

(4) Localisation of salts, acids, etc. (assistants), within the fibre area from the same cause.

(5) The direct entrance of dye aggregates by molecular migration, with subsequent reformation of aggregates within the fibre area.

(6) De-solution, due to surface concentration effects ("salting out"), or secondary attraction, between the fibre substance and the dyes.

(7) Primary or chemical action, which may play some part at this stage, and may even in some cases take the place of, or cause, de-solution phenomena.

(8) De-solution effects in the case of basic dyes, which may lead to alteration in constitution, and the production of basic salts in a state of high molecular aggregation (insoluble) within the fibre area.

In recent years, Perrin has suggested that the action of dyeing is a purely electrical phenomena, and this suggestion has been followed up in some detail by Gee and Harrison in this country.

It is only in certain cases that the chemist has a voice in the purchase of textile fibres, when certain physical or even chemical factors are recognised as being in question.

The need for such supervision may be seen in the agitation which has been actively carried on by trade associations and others concerning the methods used in South Africa in the dipping of sheep.

For some reason best known to the authorities, a sheep dip is officially recommended which consists of a mixture of slaked lime and caustic soda. The effect of this on the wool itself is sufficiently injurious, for the selling price of South African wool to be materially affected, and endless trouble introduced in subsequent manufacturing processes.

It is said that the breaking strength tests show a loss of 18 per cent. in the treated wool. Although wool buyers and English chambers of commerce have protested since 1899 against this treatment, it is still carried on, and the directions, issued in the *Government Journal of the Union of South Africa* so recently as March, 1913, still recommend its use, and give particulars of its preparation.

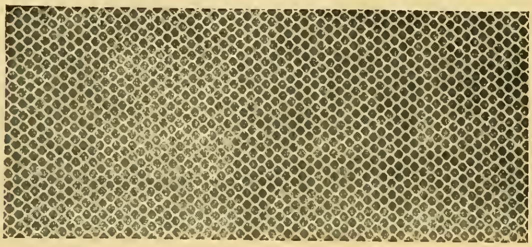

FIG. .—Artificial cellulos fabric (natural size).

This example must be the only one which can be discussed on the present occasion. Many of the methods used to determine certain differences in the nature of raw materials which count in the subsequent manufacture, as they have been noted, or even controlled, by chemists, are considered to be of a more or less secret nature.

Although we are not directly concerned with the rebleaching of goods, the use of electrolytic bleaching liquors may be strongly recommended for the laundry trade. As the sodium hypochlorite leaves the electrolyser it gives better bleaching with weak solutions than the older bleaching liquor does with strong ones. Two of the best-known types of electrolysers are those of Kellner, and that sold by Messrs. Mather and Platt. In the modern type, the original salt or brine solution passes in a serpentine course between the platinum or carbon electrodes. The salt employed in the solution is never entirely converted on grounds of economy, and care has to be taken to adjust the cost of current to that of the salt to secure economical results. Under present conditions, the cost of electrical energy must be low, but in view of the many advantages which the use of the sodium salt gives the bleacher, the new process will obviously be put to more extended use.

FIG. 4.—Artificial silk thread (×80).

It is a mistake, however, to imagine that the chemist's work in the textile industry is chiefly concerned with the adulteration of material and supplying the public with something which is not what it appears to be. Such work is mainly constructive, and its influence has been for good. Extraordinary results have been achieved in the last twenty years in the direction of actual improvements in manufacture as well as in the cheapening of production.

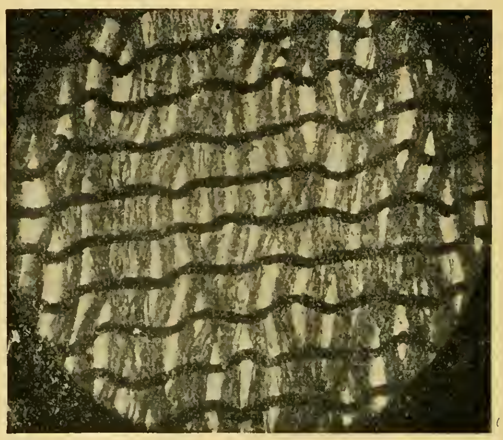

FIG. 5.—Crêpe de Chine, satisfactory finish (×30).

The manufacture of artificial fabrics direct from a solution of cellulose is a case in point (see Fig. 3), or that of artificial silk as shown in Fig. 4.

The use made of the microscope is seen in Figs. 5 and 6, where the difference in certain finishing operations is clearly disclosed and explained.

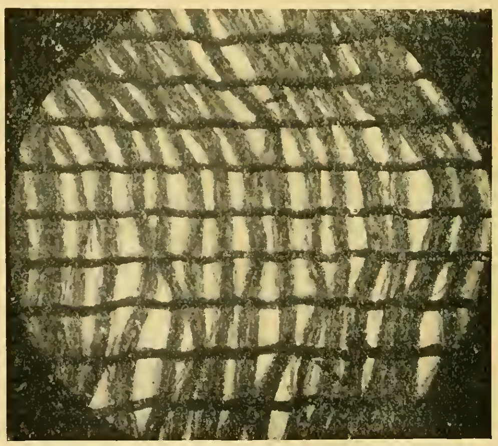

FIG. 6.—Same material, unsatisfactory finish (×30).

It will be gathered from the remarks made generally in these lectures that the influence of moisture, in its relation to the many operations of finishing adopted in this industry, is paramount. It is probably the most important influence which the investigator has to consider. The presence of moisture in a fibre gives rise to many conditions, which seem to indicate that it is present in more than one condition. This materially adds to the difficulty in determining its true influence. The fact that all the fibres take up moisture, and that this influences them in different ways, is one of the most perplexing problems met with in this industry. It will probably be many years before this matter is properly understood. or explained scientifically; but when this is achieved, light will undoubtedly be thrown on many phenomena which are so obscure to-day; and which, under present conditions, can only be dealt with on empirical lines.

The relative position of the chemist and engineer in the works has given rise to discussion in the past, and still shows signs of not being altogether understood.

The opposition to the chemist which is said to exist in some quarters has probably been much over-estimated. In the majority of cases the chemist obtains all the necessary aid he may require from the engineering department. As a matter of fact, the engineer always seems interested in the chemist's work. This is due, no doubt, to the different method of attack adopted by the latter, which, in itself, fully justifies the presence of the chemist in any works.

Under normal conditions the engineer frankly helps the chemist in his experimental work, and this aid is of real service in many ways. Quite apart from his previous training, the chemist will pick up a fair knowledge on the engineering side in the works, which will be particularly useful in cases where he subsequently acts as manager of a department, or even of the works itself

The chemist should be just as anxious to make friends with the engineer as with the heads of other departments; and the best way to gain experience and knowledge in this direction is to keep in touch with any new experimental plant which may be in course of erection.

In some cases, work will develop in directions which are not naturally covered by any existing department. If the operations involved are complicated, it may be better for the process to remain under his direct management or control. In this case, one or more experimental departments may, in time, be associated with the laboratory.

It is then necessary to borrow men from the engineering department, and to direct their operations. When this happens, the work of the chemist becomes still more general in its nature, and additional experience is gained in the management of men and processes.

Where experimental work is rapidly translated into full-scale operations under normal conditions, the control will pass to one of the works departments. This should be encouraged, for the chemist is then more free to continue research in any other directions which may present themselves. But he must always be ready, and able, to resume temporary control if things go wrong, or where further developments are in progress.

The evidence that a merely chemical training is insufficient is fast accumulating, and may be emphasised. The chemist may, for weeks, be working in directions which are physical or even mechanical in their nature rather than chemical. The important point is that *his method of attack is based on a past training in chemistry*; and that, because of this, it will be different from that adopted by the engineer. In this its value rests. This is the point I have tried to emphasise in these lectures. Also that success in almost every case depends upon attention to detail. Thus, an inferior mind may sometimes succeed when once a main idea has been grasped. These are the points I would especially bring to the notice of the young chemist who is entering the textile industry on the research side.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

BIRMINGHAM.—The council of the University has appointed Prof. Charles Lapworth emeritus professor of geology in recognition of his services during his occupation of the chair of geology. The Senate recently signalised his retirement by the presentation of an address and a gift of plate, and on March 11 another presentation was made to him by a large number of his old students. Prof. Boulton was in the chair, and Dr. Walcot Gibson, who spoke on behalf of the old students, gave happy expression to the affectionate esteem in which Prof. Lapworth is held by all who have had the good fortune to come under his influence.

CAMBRIDGE.—The Observatory Syndicate has appointed Prof. A. S. Eddington, Plumian Professor of Astronomy, to be director of the observatory.

Mr. A. V. Hill has been appointed to the Humphrey Owen Jones Lectureship in Physical Chemistry.

DR. PRAFULLA CHANDRA RÂY has been appointed to the Sir Taraknath Palit professorship of chemistry in the Presidency College, Calcutta, and Mr. C. V. Raman to the Sir Taraknath Palit professorship of physics in the same institution.

IT is announced in the *London University Gazette* that a course of eight lectures on the rate of the blood-flow in man in health and disease will be given in the physiological laboratory of the University, South Kensington, by Prof. G. N. Stewart, professor of experimental medicine, Western Reserve University, Cleveland, U.S.A., at 5 p.m., on Tuesdays, from May 5 to June 23 next. The lectures are addressed to advanced students of the University and to others interested in the subject. Admission is free, without ticket.

AN article on careers for university men, by Mr. H. A. Roberts, the secretary of the Appointments Board in connection with the University of Cambridge, contributed to the *Cambridge Magazine* in 1912, has been issued in pamphlet form by Messrs. Bowes and Bowes, of Cambridge, at the price of 6*d*. net. The account given of the work of the Appointments Board at Cambridge shows the usefulness of such an agency in bringing together employers of labour and university men who desire appointments. Graduates will find invaluable the information here brought together as to public posts open to suitable university men, and the facts as to the salaries to be expected at the beginning of a career should save much disillusionment later.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, March 12.—Sir William Crookes, president, in the chair.—Sir James **Stirling**: Note on a functional equation employed by Sir George Stokes.—Prof. J. C. **McLennan** and A. R. **McLeod**: The mercury green line $\lambda=5461$ as resolved by glass and quartz Lummer plates and on its Zeeman components.—H. **Hartley**: The electrical condition of a gold surface during the absorption of gases and their catalytic combustion. At the suggestion of Prof. W. A. Bone, the author has carried out experiments on the electrical conditions of a gold surface during its absorption of hydrogen, carbon monoxide, and oxygen, respectively, at temperatures between 300° and 400°, in order to establish certain data relative to surface combustion phenomena. The results have proved (1) that the metal acquires a *negative* charge during the catalytic combustion of gases in contact with it (thus confirming previous unpublished observations by Bone and Makower), which effect is probably antecedent to the actual combustion, and primarily due to "occlusion" phenomena; (2) that the metal becomes *negatively* charged (0·5 to 1·5 volts) during the occlusion of the combustible gas (hydrogen or carbon monoxide), and *positively* charged (0·8 volt) during the occlusion of oxygen; and (3) that such electrical effects are probably due to occluded gas which is *leaving* (rather than *entering*) the surface. The experiments indirectly lend support to the view that the well-known electronic emission from incandescent solids is probably dependent upon the occlusion of gas.—J. H. **Mackie**: The diffusion of electrons through a slit.—Dr. A. **Holt**: The rate of solution of hydrogen by palladium. The rate of solution of hydrogen at constant (atmospheric) pressure by palladium in the form of black, thin and thick foil has been examined. The rate curves in the case of palladium black are simple and of continuous curvature, but for the foil a more or less pronounced discontinuity of curvature is always observed. The discontinuity is accounted for by considering that the gas is dissolved in two different forms of the metal, the rate of solution being different in the two forms. Palladium black is believed to consist almost wholly of one form, and hence gives a simple rate curve, whilst the foil (which is mainly crystalline) contains both varieties of metal, and so gives two rates, the first rate passing into the second when solution in both forms becomes equally rapid.—Dr. R. A. **Houstoun**: The dispersion of a light pulse by a prism. A light pulse of a form giving the Wien energy distribution is incident on a prism, and expressions are derived (1) for the disturbance in the region immediately behind the prism where the different colours overlap; and (2) for the disturbance in the focal plane of the telescope. The first expression holds only for a particular law of dispersion, but the second is for any law of dispersion. They are both in accordance with results obtained by Lord Rayleigh by considerations of stationary phase and hydrodynamical analogy, but they go further. For example, it is definitely stated how the amplitude varies in the front and rear of and throughout the train of waves given rise to by the pulse in the different parts of the spectrum.

Geological Society, February 20.—Dr. Aubrey Strahan, president, in the chair.—Annual General Meeting.—President's address: As his main subject, the president referred to that part of the work of George Darwin and Wallace which bore on the history and age of the earth, and commented on the vagueness of the evidence on which estimates of the rapidity of denudation in past times are founded. Before attempting estimates of primeval time, it should be shown that some degree of precision is attainable in calculating the amount of denudation effected in post-Glacial times, and the time required to effect it. It is now possible to distinguish the features in the landscape which are due to post-Glacial erosion. River-gorges, dissected plateaus, fans, and deltas of gravel are presented for consideration. In some there seems to be a possibility of estimating the bulk of the material which has been moved, and the rapidity with which the transporting agents are working. Fans spread on the flat bottoms of valleys by tributary streams, or deltas formed in lakes, are of common occurrence. In all cases it would be of value to determine a relation between three factors, namely, the size of the fan or delta, the discharge of the stream, and the character of the ground from which the material was derived. Dammed-up rivers give opportunities for observing the amount of material transported by rolling. The distances over which rivers are now transporting material should be ascertainable by observing the composition of recent alluvial deposits. Few roll gravel directly into the sea, for the gradients in the lower parts of their courses are too low for transportation and favour deposition. An investigation on English rivers has been proceeding for some years, with the object of ascertaining (1) the discharge, (2) the suspended and dissolved impurities, (3) the rainfall, (4) the areas of the basins, and (5) the character of the rocks. The rivers suitable for the investigation are limited to those with a single definite mouth. Fen-rivers have a number of outlets, and cannot be gauged. The amount of material now being rolled by the Exe, for example, is determined from records of dredgings. Rainfall is dealt with by the British Rainfall Organisation, as also the methods of eliminating the error in calculating average rainfall, due to the preponderance of rain-gauges in the lower ground. It was concluded that, although in this country a hydrographic survey may not be essential on the ground of utility, yet more systematic observations on the work of denudation are within the reach of geologists.

February 25.—Dr. A. Smith Woodward, president, in the chair.—Rachel W. **McRobert**: Acid and intermediate intrusions and associated ash-necks in the neighbourhood of Melrose (Roxburghshire). The age usually assigned to the igneous intrusions is a late period in the history of the "plateau-eruptions" of Calciferous Sandstone times. The igneous rocks occur as laccolites and sills, as dykes, and in volcanic necks. The chief rock-types present in the area are porphyritic and non-porphyritic sanidine-trachytes, quartz-trachytes, riebeckite-felsites, quartz-porphyries, basalts, and volcanic agglomerates. The salient features of the suite of rocks described are the high content of alkalies, and the presence of soda-bearing minerals such as riebeckite, ægirine-augite, primary albite, and soda-orthoclase. Nepheline was found to be absent from most of the rocks.—A. **Vaughan**: Correlation of Dinantian and Avonian. The results are given of applying the time-scale deduced from the South-Western Province to the Belgian sequence, and shows that the faunal succession is practically the same in both provinces. If the midland and northern developments of England and Wales are compared with that of Belgium, striking identities are observed. The lateral variation of Mid-Avonian lithology is exhibited in a diagram. Correlation of the Belgian sequence with that of the South-Western Province demonstrates that the periods of partial emergence took place consecutively and not simultaneously. The palæontological section contains descriptions of several gentes that are common in Belgium, but rare in Britain. The facts concerning migration and evolution are importants results of extending the area of observation.

Linnean Society, March 5.—Prof. E. B. Poulton, president, in the chair.—Miss K. **Foot** and Miss E. C. **Strobell**: Results of crossing *Euschistus variolarius* and *E. servus*, with reference to the inheritance of an exclusively male character. The specific character is a distinct black spot on the genital segment of *E. variolarius*, which is wanting in the female, and entirely absent from *E. servus*. The authors explained the methods adopted during five consecutive summers, for raising these Hemiptera in captivity. Detailed accounts are given of the history of their specimens, their crossing, and the results in the F_1 and F_2 generations. The exclusively male character, the genital spot, can be inherited without the aid of the Y-chromosome or of the X-chromosome. The genital spot does not behave as a Mendelian unit; neither the spot nor its absence is dominant in the F_1 hybrids; F_2 generation shows even greater variability.—C. F. M. **Swynnerton**: Short cuts by birds to nectaries. Certain birds, and some individuals more than others, apparently disliked being besprinkled with pollen, and tended always to enter flowers by breaches made by themselves or their predecessors. Other birds tried, contrariwise, to enter the flowers by their natural openings and so to be of use to them for cross-fertilisation excepting in the case of individual flowers that happen, through inconvenience in their own or the bird's position, etc., to offer some difficulty. If these were insufficiently protected as well, they were often either pierced or the openings already made in them by the more indiscriminating birds were utilised. Insects also tended to utilise the breaches made by birds, and so probably in large part failed to counteract the latter's discriminative influence. In most cases the eliminative effect, if any, of the damage was not traced. In two instances it was (for individuals) immediate and clear, flowers of a certain type being bodily removed.

Mathematical Society, March 12.—Prof. A. E. H. Love, president, in the chair.—Prof. W. **Burnside**: The rational solutions of the equation $x^3+y^3+z^3=0$ in quadratic fields.—Prof. H. **Hilton** and Miss R. E. **Colomb**: Orthoptic and isoptic loci of plane curves.—G. H. **Hardy**: The roots of the Riemann ζ-function.—Dr. T. J. I'A. **Bromwich**: Normal coordinates in dynamics.

MANCHESTER.

Literary and Philosophical Society, February 10.—Mr. R. L. Taylor in the chair.—R. F. **Gwyther**: The specification of the elements of stress. Part III.—The definition of the dynamical specification and a test of the elastic specification. A chapter on elasticity. The author proposed to simplify the methods current in the treatment of stresses in an elastic body in treatises and papers on elasticity. The chief point of the paper is that full attention should be paid at the outset to the dynamical (or Newtonian) conditions and that the elastic (or Hooke's) conditions should not have the exclusive prominence given to them which has been the established practice.

February 24.—Mr. F. Nicholson, president, in the chair.—M. **Copisarow**: Carbon: its molecular structure and mode of oxidation.—J. B. **Hubrecht**: Studies in solar rotation. An account of a spectrographic determination of the solar rotation, as observed at Cambridge. Photographs were taken showing the displacement of the absorption lines due to the rotation of the sun. The law which has been found by earlier investigators to govern the solar rotation was on the whole confirmed. Two new points, however, appear to be definitely established for the period of observation (fourteen days): (1) that there is a difference in the rotation velocities of the northern and southern hemispheres of the sun amounting to about 54 metres a second; (2) the latitude law expressing the retardation of the rotation away from the equator was found to be more complicated than usual for the period of time in which the observations were made.

DIARY OF SOCIETIES.

THURSDAY, MARCH 19.

ROYAL SOCIETY at 4.30.—*Discussion:* Constitution of the Atom. Opener: Sir E. Rutherford.
ROYAL INSTITUTION, at 3.—Heat and Cold: Prof. C. F. Jenkin.
CHILD STUDY SOCIETY, at 7.30.—The Dramatic Impulse in Children: Prof. J. J. Findlay.
INSTITUTION OF MINING AND METALLURGY, at 8.—Annual Meeting.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Discussion on Electric Battery Vehicles.
ROYAL SOCIETY OF ARTS, at 4.30.—Indian Water Gardens; Mrs. Patrick Villiers-Stuart.
LINNEAN SOCIETY, at 8.—The Bearing of Chemical Facts on Genetical Constitution: Dr. E. F. Armstrong.
ROYAL GEOGRAPHICAL SOCIETY, at 5.—A Geographical Study of Portuguese East Africa, South of the Zambezi: E. O. Thiele.

FRIDAY, MARCH 20.

ROYAL INSTITUTION, at 9.—Fluid Motions: Lord Rayleigh.
INSTITUTION OF MECHANICAL ENGINEERS, at 8.—The Chemical and Mechanical Relations of Iron, Tungsten and Carbon, and of Iron, Nickel, and Carbon: Prof. J. O. Arnold and Prof. A. A. Read.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—Aeroplanes as Engineering Structures: W. H. Sayers.

SATURDAY, MARCH 21.

ROYAL INSTITUTION, at 3.—Recent Discoveries in Physical Science: Sir J. J. Thomson.

MONDAY, MARCH 23.

ROYAL GEOGRAPHICAL SOCIETY, at 8.30.—Lost Explorers of the Pacific: B. Thomson.
ROYAL SOCIETY OF ARTS, at 8.—Surface Combustion: Prof. W. A. Bone.

TUESDAY, MARCH 24.

ROYAL INSTITUTION, at 3.—Landscape and Natural Objects in Classical Art. I. Early Greece and its Precursors: A. H. Smith.
VICTORIA INSTITUTE, at 4.30.—The Number of the Stars: Dr. S. Chapman
ROYAL ANTHROPOLOGICAL INSTITUTE, at 8.15.—Bellingshausen's Visit to Ono-i-Lau: Sir Everard im Thurn.
INSTITUTION OF CIVIL ENGINEERS, at 8.—Some Recent Developments in Commercial Motor-vehicles: T. Clarkson.—Comparative Economics of Tramways and Railless Electric Traction: T. G. Gribble.

WEDNESDAY, MARCH 25.

GEOLOGICAL SOCIETY, at 8.—The Geology of Rockall: Prof. J. W. Judd.—The Composition of Rockallite: Dr. H. S. Washington.

THURSDAY, MARCH 26.

ROYAL SOCIETY, at 4.30.—*Probable Papers:* The Nature of the Tubes in Marsupial Enamel and its Bearing upon Enamel Development: J. H. Mummery. Oxidation of Thiosulphate by Certain Bacteria in Pure Culture: W. T. Lockett.—The Production of Anthocyanins and Anthocyanidins: A. E. Everest.—Variations in the Growth of Adult Mammalian Tissue in Autogenous and Homogeneous Plasma: A. J. Walton.—(1) The Decomposition of Formates by *B. coli communis*; (2) The Enzymes which are Concerned in the Decomposition of Glucose and Mannitol by *B. coli communis*: E. C. Grey.—Description of a Strain of *Trypanosoma brucei* from Zululand. I: Morphology. II: Susceptibility of Animals: Surg.-General Sir D. Bruce, Major A. E. Hamerton, Captain D. P. Watson, and Lady Bruce.
ROYAL INSTITUTION, at 3.—The Progress of Modern Eugenics. I: The First Decade, 1904–1914: Dr. C. W. Saleeby.
CONCRETE INSTITUTE, at 7.30.—Discussion on Reports of the Science and Reinforced Concrete Practice Standing Committees on: (1) A Standard Specification for Reinforced Work; (2) Advice to Superintendents of Concrete Work; (3) Standard Connections and Joints in Reinforced Concrete.
INSTITUTION OF ELECTRICAL ENGINEERS, at 8.—Current Limiting Reactances on Large Power Systems: K. M. Faye-Hansen and J. S. Peck.
INSTITUTE OF CHEMISTRY, at 8.—Explosives: W. Macnab.

FRIDAY, MARCH 27.

ROYAL INSTITUTION, at 9.—Improvements in Long Distance Telephony: Prof. J. A. Fleming.
JUNIOR INSTITUTION OF ENGINEERS, at 8.—Harmonigraph as Applied to Advertising: A. Forbes.
FARADAY SOCIETY, at 5.—Discussion on Optical Rotatory Power.—Introductory Address: Prof. H. E. Armstrong.—Some Contributions to the Knowledge of the Influence of Certain Groups on Rotatory Power: Prof. H. Rupe.—New Studies in the Rotatory Dispersion of Tartaric Acid and Malic Acid: Prof. H. Grossman.—The Existence of Racemic Tartaric Acid in Solution: Dr. E. Darmois.—Anomalous Rotatory Dispersion: Prof. L. Tschugaeff.—Normal and Anomalous Rotatory Dispersion: Dr. T. M. Lowry and T. W. Dickson. At 8.15.—An Enclosed Cadmium Arc for Use with Polarimeter: Dr. T. M. Lowry and H. H. Abram.—The Relations between the Rotatory Powers of the Members of Homologous Series: Dr. R. H. Pickard and J. Kenyon.—The General Behaviour of Optically Active Compounds as Regards the Dependence of Rotation on Temperature Dilution, Nature of Solvent, and Wave Length of Light: Dr. T. S. Patterson.
PHYSICAL SOCIETY, at 5.—A New Type of Thermogalvanometer: F. W. Jordan.—An Instrument for Recording Pressure Variations due to Explosions in Tubes: J. D. Morgan.—The Direct Measurement of the Naperian Base: R. Appleyard.—An Experiment with an Incandescent Lamp: C. W. S. Crawley.

SATURDAY, MARCH 28.

ROYAL INSTITUTION, at 3.—Recent Discoveries in Physical Science: Sir J. J. Thomson.

THEODORE ROOSEVELT AS NATURALIST.

Theodore Roosevelt. An Autobiography. Pp. xii+647. (London: Macmillan and Co., Ltd., 1913.) Price 10*s.* 6*d.* net.

THE autobiography of Theodore Roosevelt is a very interesting book to the politician or to the political anthropologist; but here I am rightly restricted to reviewing only that part of the book which touches on natural science.

When Mr. Roosevelt entered upon office as President, he found the American Government as represented by Congress and the Senate, comparatively indifferent to the conservation of beauty in the United States—beauty in the form of magnificent trees, magnificent wild beasts, remarkable and beautiful birds, and romantic landscapes. American Senators and Congressmen did not see—any more than British Chambers of Commerce see—that all such things were assets of great national value, of economic importance, indeed. The destruction of bird life throughout the United States was already causing far-reaching plagues of insects, which consumed fruit and vegetables on the extravagant scale in which all natural movements are carried out in North America. American politicians did not appreciate the frightful damage which was being done to the whole North American Continent—Canada as well as the United States—by the unchecked forest fires and the lumberman's lust for destruction amongst the timber of the United States' forests, without any thought of simultaneous measures being taken for reafforestation.

Mr. Roosevelt was not, of course, the first or the greatest pioneer in a movement which has already had most beneficial results in the conservation of beauty and natural resources, and has culminated in the attempt of the United States to set right the bird question throughout the world. Already in the 'eighties and 'nineties of the last century the idea of national parks had come into existence. The Yellowstone region was set apart as a reserve in which natural phenomena, natives trees, and native wild beasts could continue to exist for the wonderment and delight of a new generation. The Yosemite Valley and the big trees of California had been similarly protected from unreasoning destruction. But Theodore Roosevelt, though he had won his spurs as a hunter (and the best book that he wrote about wild life, by-the-by, is not his excellent work on East Africa, but "Outdoor Pastimes of an American Hunter"), had, by the time he became Vice-President, conceived a great love for the natural beauties of a landscape and the presence therein of bird and beast.

During his seven and a half years' tenure of the United States Presidency Mr. Roosevelt established, or caused to be established, fifty-one national bird reservations in seventeen of the United States, as well as in Porto Rico, Hawaii, and Alaska. Amongst these reservations was the celebrated Pelican Island rookery in Indian River, Florida—now world-famous from the beautiful scenes depicted by photography and kinematography; the Mosquito Inlet reservation in Florida (chiefly for the protection of the manati), the reservation of the Klamarth lake and marsh in Oregon (chiefly for the wild ducks, geese, and swans of the western United States); the Tortugas Quay, Florida, for studying the habits of sea-birds and migratory birds; and the great bird colonies (for the protection of albatrosses and petrels) on the Island of Laisan in the Hawaii group, in which direction he intervened after the appalling revelations of bird slaughter by the plumage hunters were made known through the efforts of Dr. Hornaday, Mr. James Buckland, and others. His influence brought about the creation of five national parks—in Oregon, in South Dakota, Oklahoma, North Dakota, and Colorado, and the organisation of four big game reserves in Oklahoma, Dakota, Montana, and Washington, and game laws and game reservations in the vast territory of Alaska.

Mr. Roosevelt also secured the enactment of measures which in the United States not only saved the remains of the bison from extermination, but have led to the gradual increase in numbers and possible future existence of this remarkable bovine. But he has not yet succeeded in making the American Republic call the bison by its right name, instead of the misleading title of buffalo. He is, I fear, rather an advocate for the retention or adoption of a whole series of American misnomers—elk instead of wapiti; bob-cat instead of lynx, mountain-lion instead of puma. In most cases these American terms are the more to be regretted since, with the exception of the puma, nearly all the great mammals of North America had representatives in the fauna of temperate Eurasia, and the English names for these creatures (wapiti, it is true, is Canadian) have a great ancestry going back to the earliest development of Aryan speech in the days of improved stone implements.

What Mr. Roosevelt did for forest preservation is set forth somewhat meagrely in the book under review. Since his quitting the Presidency there has been a set-back under the four years of Mr. Taft, when the recalcitrant party in the Senate got its way, and the lumbermen were once more permitted to destroy unreasoningly. Mr. Roosevelt thoroughly appreciates the fact that the re-afforesting of the United States is a matter of vital importance for climatic reasons, as well as for others, and that the disforesting of these vast territories either by the woodman's axe or by the forest fires, would be a legitimate cause of complaint for the adjoining Dominion of Canada, as the climate of Canada would be affected disadvantageously.

H. H. Johnston.

AMERICAN TEXT-BOOKS OF BIOLOGY.

(1) *A Laboratory Manual of Invertebrate Zoology.* By Dr. G. A. Drew. Second edition, revised. Pp. ix + 213. (London and Philadelphia: W. B. Saunders Company, 1913.) Price 6*s*. net.

(2) *A Text-book of Biology.* For Students in Medical, Technical, and General Courses. By Prof. W. M. Smallwood. Pp. xiv + 285 + xiii plates. (London: Baillière, Tindall and Cox, 1913.) Price 10*s*. 6*d*. net.

(1) DR. DREW'S manual gives directions for the study of ninety-two invertebrates. The accounts of the various types selected for examination are noteworthy for the attention devoted to the reactions of the living creatures, and for the questions designed to test whether the student understands the functions of the several organs and comprehends the adaptations exhibited. In this second edition, the author has cited, at the end of the description of most of the types, a few of the chief memoirs dealing with those types. This is an excellent feature of the book, for the student who follows the lead given will be introduced to the literature of the subject and to the means of becoming acquainted with some of the best methods of modern zoological research. Little consideration is devoted to the larval stages and life-cycles of the types studied, and a detailed account of the internal anatomy of many of the types is not given; the author's intention has evidently been to single out the external features for special study in relation to adaptation. There are descriptions of twelve Polychætes, but of only two insects—a grasshopper and a bee; an account of one of the Diptera, *e.g.*, a mosquito, might have been added with advantage. The descriptions are carefully done, there being very few mistakes. In the section on Gregarina, the organism is said to encyst and form a spore-producing individual—a rather misleading statement. This portion of the life-cycle might have been treated in more detail, and reference made to the formation of gametes and of spores and sporozoites. The poison ducts of Lithobius open on the outer (not on the inner) sides of the second maxillæ.

An appendix contains precise instructions for making permanent preparations of organisms or of parts of them, and there is a useful glossary of terms employed in the book.

The student who works intelligently through the series of types selected for study will acquire a good general knowledge of the structure and chief adaptations exhibited by invertebrates.

(2) Prof. Smallwood has produced an interesting and readable volume, intended chiefly for medical students. Taking the frog as a convenient type, the author describes the physiology of movement, digestion, circulation, and metabolism, and then proceeds to outline the histology of the tissues, the structure of the nervous system, and the development (external features only). A brief account of Hydra and a very short sketch of the Protozoa follow. Succeeding chapters deal with the biology of cells and of yeasts and moulds, parasitism, some biological factors in disease, evolution, variation, heredity, and animal behaviour in its relation to mind. The chapters on variation and animal behaviour are especially interesting, as the illustrative examples are drawn from recent literature. The volume ranges over a wide field, and the accounts of some of the subjects are necessarily brief; in a few cases they are too brief to be of much value to the average student. The account of malaria will not give the student a very clear idea of the life-cycle, for, although the author states that the number of parasites becomes very great, he does not indicate the manner in which this large increase in number is brought about. But the author obviously intends his book to be supplemented by other instruction in the laboratory and lecture-room.

Several mistakes have been allowed to pass, *e.g.*, Bothriocephalus is cited as a type of the Round-worms, sea-anemones are included under Hydrozoa, malaria is stated to occur in frogs, and there are mis-spellings, *e.g.*, Wiederscheim, Unchinaria, etc.

The book contains 243 figures and 13 plates; the illustrations are nearly all well chosen and excellently reproduced, but the figure of Stomoxys represents a fly of entirely different aspect—certainly not a Stomoxys.

SUPERNATURAL RELIGION.

(1) *Modern Substitutes for Traditional Christianity.* By Edmund McClure. Pp. viii+145. (London: S.P.C.K., 1913.) Price 2*s.* net.

(2) *Modern Rationalism as Seen at Work in its Biographies.* By Canon Henry Lewis. Pp. x+418. (London: S.P.C.K., 1913.) Price 4*s.* net.

(3) *All Men are Ghosts.* By L. P. Jacks. Pp. ix+360. (London: Williams and Norgate, 1913.) Price 5*s.* net.

(4) *The Latest Light on Bible Lands.* By P. S. P. Handcock. Pp. xii+371. (London: S.P.C.K., 1913.) Price 6*s.* net.

(5) *The Divine Mystery.* By Allen Upward. Pp. xv+309. (Letchworth: Garden City Press, Ltd., 1913.) Price 10*s.* 6*d.* net.

THE realities of spiritualistic belief are, so far, psychological, subjective. The pathetic paradox about its "apologetics" (science though this styles itself) is that it claims for its realities not only an objective, but a physical, existence. The apologist who condemns "mechanistic" and "materialistic" conceptions of the universe in the same breath introduces a series of super-mechanism and super-matter. Science can do nothing with spiritual entities until they are proved to exist objectively; when this is proved, then they become part of the subject-matter of science, and, therefore, part of the "stuff" of the universe. Matter and mechanism are good terms, but the spiritualist rages at them. The world-substance must be designated by some convenient term; one may serve as well as another; but it is absurd to object to a term because its popular significance suggests solidity and excludes mind.

It is a curious fact that the religion of Western Europe, which from its birth has had an uninterrupted career of success, should have been, from the first, "apologetic." Christianity certainly marked a development of the social consciousness; but it seems as if this apologetic attitude represented a certain mistrust of the spiritualistic material which this last of the old-world religions, and the first and only of the new world, carries with it, apparently as an essential content. The religious impulse is a fact of the emotional life, and with the majority of men requires expression. But Buddhism and Confucianism prove that the religious impulse may be satisfied with a subject-matter that is not supernatural or spiritualistic. If this is so, and if the Christian consciousness is at all mistrustful of traditional supernaturalism, then there is inevitably an air of insincerity about apologetics.

(1) Canon McClure, in an interesting sketch of some modern variations of the supernaturalist point of view, uses the language of science. Miracles, for instance, are "like the mutations or the 'sports' of modern Darwinism." This is good metaphor, but "metaphors are not reasons." He quotes an instance of a frequent temptation to use new scientific discoveries, which have changed our views of matter, as an argument for the objective reality of the supernatural:—

"The very active 'things' which give the atom being are called electrons, and the point of interest to religiously minded people is this, that we have, in these electrons, according to an investigator of world-wide reputation, the nearest analogy to the concept of a disembodied spirit, that is, a charge of electricity pure and simple."

This seems childish; at least, it has no bearing on the argument, and does not help us "to recognise more fully than before that nature and revelation are not in antagonism." The neo-vitalism of Bergson is metaphysical, not scientific. It is regarded by Canon McClure, together with James's similar speculations, as a strong buttress to traditional Christianity. The old religion is better and saner than the modern "substitutes"; why, then, should apologists waste time in trying to prove the material reality of the subject-matter of its creed? The permanence of the religious impulse is not, as this author thinks, a proof of the "validity" (*i.e.* material reality) of supernatural entities; it is a proof of the validity of the religious impulse. This, surely, is enough. The mysticism of Eucken, and the superman of Nietzsche, "theosophy" and "Christian science," "secularism" and "rationalism," are well described and "refuted." It is curious that they should need refutation by a Christian apologist.

(2) Canon Lewis treats of the life and death of famous "rationalists" or "agnostics" by way of showing that the religious temperament produces finer characters than does the agnostic. Voltaire, Paine, J. S. Mill, Renan, Bradlaugh, Spencer, Nietzsche, Goethe, Schopenhauer, George Sand, Shelley, Huxley, George Eliot, Sidgwick, Romanes, and others are described, with emphasis on their moments of dissatisfaction and despair, and with full details of the meannesses of which one or two were guilty. Canon Lewis seems to think that disbelief in the objective reality of certain tenets of Christianity proves a lack of "heart and soul." It proves nothing of the kind; but merely that the person has thought for himself, instead of taking his thinking at second-hand.

(3) "Supernaturalism" has a permanent interest for the imagination. The "ghost story" is as

popular to-day as it was with primitive man. The author of "Mad Shepherds" is an artist. Possibly he is a "believer" (the term always implies materialistic belief) in spirits. His stories of "Panhandle and the Ghosts," "All Men are Ghosts," and "Farmer Jeremy," are fine art, showing an obsession by, and yet a scientific control of, the ghost idea.

"'May it not be that Primitive Religion is the only religion that has ever existed, or will exist, in the world?'

'Panhandle,' I cried, 'you are a ghost!'

'Hush!' he answered, 'we never use that term in addressing one another. . . .'"

"The Magic Formula" is an entirely charming story of child psychology.

(4) Certain exigencies of commission make Mr. Handcock's readable account of archæological discovery in Palestine, Babylonia, Assyria, Egypt, and Syria into a popular illustration of the Hebrew tradition. Thus we find such statements as "the life of Gilgamesh, the hero of Babylonian folklore, whose history presents parallels to many ideas expressed or implied in the Old Testament." "Khammurabi, probably the Amraphel of the Book of Genesis"; "the cause of Israel's migration to Egypt." It has still to be proved that Israel ever was in Egypt; that Khammurabi, and many other historical persons, are really mentioned in the Hebrew books; and that the cosmogony of *Genesis* is anything more than a digest of the Babylonian. The book is an excellent introduction to Mesopotamian and Egyptian archæology, though its particular bias may lead the novice to a wrong perspective. The author is fair enough; the monuments, he admits, "do not do more than mention a few isolated facts out of all that are recorded in the Bible." With the exception of the statement of Menephthah that "Israel is desolated," the first event in the history of Israel or its ancestors certainly attested by the inscriptions is "the invasion of Judah by Shishak under Rehoboam, and the first Israelites whom they mention by name are Omri and Ahab."

(5) Mr. Allen Upward has insight, and has written a suggestive book on the development of religion. The main idea—the Divine Man or Genius—and the stages of his career from medicine man to Messiah, are adaptations from "The Golden Bough"; but the author has had personal experience of savage thought and custom in Nigeria. He has also a sound knowledge of modern thought in general and of the "higher criticism" in particular, and his work, though eccentric in parts (lexicographers will dispute some derivations), has value as an attempt to trace the genesis of Christianity. The central theme, the idealisation of man and the practical work of prophet, priest, and king, is an interesting interpretation of history. But that it has been a predominant factor in the development of culture remains to be proved.

A. E. CRAWLEY.

OUR BOOKSHELF.

A Manual of Petrology. By F. P. Mennell. Pp. iv+256. (London: Chapman and Hall, Ltd., 1913.) Price 7*s*. 6*d*. net.

THE writing of a clear and concise introduction to the study of petrology is fraught with extreme difficulty owing to the fact that the phenomena exhibited by rocks and rock-minerals are seldom capable of simple explanation, and thus the author is often led to assume a wider knowledge of cognate subjects on the part of the elementary student than is likely to be possessed. This book is framed upon a previous work by the same author, entitled, "An Introduction to Petrology"; in fact, a large portion may be regarded as a reprint. The author, however, has rejected much that was in the older publication, and has added new, well-selected matter, but the discussion of the phenomena presented by mineral sections when viewed in polarised light still leaves much to be desired.

Chapters i. to iii. are elementary in character, and deal with the general properties of minerals; the introduction of several tables, such as those dealing with specific gravity, colour, and refractive index, will be helpful to the student.

In chapters iv. to vii. the general characters of the rock-forming minerals are given, and often some simple means of differentiating any one from others which it resembles superficially. The number of species described, however, is slightly larger than is needed in a work of this kind.

The greater portion of the book deals with the classification of igneous rocks and their nomenclature, but mainly with the description of rock-types. The nomenclature has been reduced to its simplest form, and tedious description of unimportant variations have been avoided. The igneous rocks are followed by a brief account of sedimentary and metamorphic rocks.

The book is illustrated with 124 text-figures. Many of the illustrations are excellent, but a few of the figures, such as 66, 77, 86, 119, and 123, might be discarded without prejudice. The book may be described as well planned and methodically carried out; and it gives a good idea of the general nature and scope of the science.

Logging: the Principles and General Methods of Operation in the United States. By Prof. R. C. Bryant. Pp. xviii+590. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1913.) Price 15*s*. net.

THIS text-book on forest utilisation, well printed and fully illustrated, is a very useful addition to the scanty literature on the subject in the English language. The author, who is a professor in the

Yale Forestry School, had formerly practical experience in the lumber camps of the United States and Philippines; and in consequence has been able to give a readable account of the numerous logging methods which are actually in operation. The book should prove suggestive to owners of timber lands in our own Colonies and to Indian foresters.

The first part is general, and comprises chapters on the resources and protection of the forests of the United States. The original woodland area is estimated at 850,000,000 acres, containing about 433,000,000,000 cubic feet of timber. The existing forest has shrunk to 550,000,000 acres, estimated to contain 210,000,000,000 cubic feet, of which the Federal and State Governments control about one-fourth. The second part deals with felling of timber, and contains chapters on labour, tools, organisation of the camp, careful utilisation of the tree, etc. The third part is devoted to transport by land, and is very complete, giving an account of aerial cables, railways, timber slides, and shutes, etc. The rude but efficacious system, by which railroads are often built in the forests of the Far West, is carefully described. The fourth part, transport by water, treats of floating, rafting, flumes, sluices, etc. Another part entitled "Minor Industries," deals with tapping for turpentine, harvesting of tanbarks, etc. A glossary of terms used in logging, tables of wages, timber values, etc., complete this admirable text-book.

Foods and Household Management. A Textbook of the Household Arts. By Prof. Helen Kinne and Anna M. Cooley. Pp. xv+401. (New York: The Macmillan Company, 1914.) Price 5*s*. net.

A FULL treatment is provided in this volume of the production, cost, nutritive value, preparation, and serving of a great variety of foods. The relation of these topics to general household management is made clear, and a careful study of household accounts, methods of buying, and ordinary housewifery is included. Though some parts of the book deal particularly with American conditions, most of the chapters make a direct appeal to teachers of domestic subjects in this country, and the volume deserves their attention.

The Continents and their People. South America. By J. F. Chamberlain and A. H. Chamberlain. Pp. ix+189. (New York: The Macmillan Company, 1913.) Price 3*s*.

THIS beautifully illustrated reading book will serve admirably to supplement the ordinary text-book in use by children studying the geography of South America. The physical and human aspects of geography are presented in such a way as to interest young pupils and to encourage them to trace the connection between the two. There are only three maps in the book; one is an old-fashioned coloured plate, another a photo-relief map of the continent, and the third a sketch map showing rainfall.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

The Movements of Floating Particles.

IN reply to Mr. Archdall Reid (March 19, p. 60) I should say that the effects which he describes are the natural behaviour of a contaminated surface. A greasy contamination of the right order of magnitude tends to spread itself uniformly over the surface. If when the liquid in the saucer sways over to one side, the surface layer went with it, the contamination would be concentrated upon that side and diluted upon the other. Such a displacement is resisted. The invisible surface contamination remains nearly equally distributed, and the fact is witnessed by the visible particles floating upon it.

R.

Weather Forecasts.

IN NATURE of February 26 Mr. Mallock verifies the forecasts for London during 1913. He selects four characteristic types accompanying shifts of wind, and finds that the verification did not exceed 58 per cent. The temperature forecasts were even less accurate, being correct only 161 times; and while the given percentage is 52, a truer value, including doubtful and "no" forecasts, would be 44. He then, very properly, raises the question, reduced to its simplest terms, "Is the daily chart with its many entries worth while?" Personally Mr. Mallock thinks it extremely improbable that trustworthy forecasts can be made. Many meteorologists share this opinion. Two deductions can be drawn, either the chart does not contain data suitable for trustworthy forecasting, or the men who forecast are not competent. The latter we can quickly dispose of, for there is no difference of opinion regarding the honesty and professional skill of the staff of the Meteorological Office; and incidentally we may acknowledge the steady rise of the office under Dr. Shaw's progressive leadership to a commanding place among the meteorological services of the world.

Then is the weather chart inadequate? Yes. Moreover, it will be so for years to come. On the other hand, too much may be expected, and a method of verification applied that is entirely too rigorous. Weather is not the only subject on which forecasts are made, and if these were rigorously tested there would be many verifications below 50 per cent. Not long ago, the writer had gently to remind the editor of a metropolitan daily "that the forecaster in his statements concerning things that had not yet happened was more accurate than the Press (in general) in its statements concerning things that had already happened." Errors in law, medicine, and engineering are neither unknown nor infrequent.

To ask for a definite statement of weather conditions twenty-four hours in advance, is asking much in view of the number of indeterminate variables that are operative. Pressure, temperature, air motion, and precipitation are not definite, regular processes, but often erratic and complicated. From our knowledge of the laws of gases we may indeed work out certain functional relationships, but we are still far from determining actual interferences due to circulation, absorption, and radiation.

Shall the chart then be abandoned, and shall we cease troubling ourselves with millions of useless observations to be added to millions already existing? No. It is an honest effort, and granting that there is surplusage of certain data, the chart is still worth while. Besides, there are some by-products of great value. To illustrate, a strict verification of the wind shifts at San Francisco, a city where the lower air circulation is marked, might show a high percentage; but this would not be a fair test of the worth of the weather chart. Rather, some by-product, as that of frost protection. In the first week of January, 1913, the general forecaster warned the orange-growers 480 miles away of impending trouble. Each community was warned not once, but day after day, and night after night. Fruit worth 10,000,000*l*. was in jeopardy. Half was saved because of ample, accurate warnings coupled with improved methods of heating, covering, and protecting. Overtopping the vast saving, was the demonstration that protection was effective. The story of the campaign against frost extending over a period of sixteen years and culminating in the struggle of January, 1913, is one of the most inspiring chapters in the history of horticulture. The forecaster not only gave warning, but developed the principles of protection. At least five basic patents for covering, heating, and mixing the air were obtained and donated to the public.

Again, a certain railroad system of the west coast in competition with all steam railroads of the United States was awarded the Harriman Memorial safety medal. In five years not a single passenger's life has been lost through collision or derailment of trains in a total equivalent movement of 8,000,000,000 passengers one mile. What has this to do with the weather chart? Only this, that during those five years at times of greatest strain, during heavy rains when road-beds wash out, and derailments most easily occur, the actual head of the whole system kept in closest touch with the weather office. Time and time again the patrols on thousands of miles of roads were doubled on the judgment of the forecaster, based on the chart.

Yet, in San Francisco, it has been known to turn out fair when rain was indicated, or some sudden drizzle from the sea mar a forecast of fair weather.

And the conjecture of De Morgan which Mr. Mallock quotes, "that Sir George Airy would not have given $2\frac{1}{2}d$. for the chance of a meteorological theory formed by masses of observations," remains a conjecture.

Origin of Structures on the Moon's Surface.

The difficulty raised by the Rev. O. Fisher (Nature, February 26, p. 714) with regard to the origin of the moon by fission from the earth has been answered already in part in Sir George Darwin's own writings. The length of the day when earth and moon revolved once a day was calculated by him at first as about 5 hours, the figure used by Mr. Fisher. Afterwards, Darwin showed that taking solar tidal friction into account, this period should be reduced to something of the order of $2\frac{1}{2}$ hours, when the two bodies would be almost in contact (see Darwin, "Scientific Papers," vol. ii., pp. 323, 364). It may not be amiss to quote here his cautious estimate of this result:—"The whole subject is full of difficulties, and the conclusions must necessarily remain very speculative."

The Isothermal Layer of the Atmosphere.

It is a commonplace observation that "truths of science, waiting to be caught," are often simultaneously and independently "caught" by two or more investigators. One of the most remarkable coincidences of this kind appears never to have been definitely pointed out as such. This is the recent Gold-Humphreys (or Humphreys-Gold) explanation as to why the stratosphere is vertically isothermal; viz., because of equality in that region between emitted and absorbed radiation. This discovery is probably destined to remain conspicuous in the annals of meteorology for two reasons; first, because of its intrinsic importance, and, secondly, because of the following remarkable chronological parallelism in its independent development by two investigators:—

Gold.	*Humphreys.*
Preliminary account read at the Dublin meeting of the British Association for the Advancement of Science, September 2–9, 1908.	Preliminary account read at the Hanover meeting of the American Association for the Advancement of Science, June 29–July 3, 1908.
Preliminary account reported in Nature, October 1, 1908.	Preliminary account reported in *Science*, August 21, 1908.
Final paper received by the Royal Society of London, October 5, 1908.	Final paper sent to the *Astrophysical Journal*, October ?, 1908.
Final paper read before the Royal Society of London, December 10, 1908.	Final paper read before the Philosophical Society of Washington, D.C., October 10, 1908.
Final paper published in the Proceedings of the Royal Society of London, A 82, February 16, 1909.	Final paper published in the *Astrophysical Journal*, vol. xxxix., January, 1909.

It would be difficult to find a more interesting chronological parallel. It is particularly pleasant to add that the principals, who up to the time of the publication of their papers were strangers to each other, have since then become well acquainted and the best of personal friends.

Unidirectional Currents within a Carbon Filament Lamp.

During the past two months I have shown to some scores of people the effects described by Dr. Eve under the above heading, in Nature of March 12. His explanation of the slow creep of the displaced filaments back to their original positions does not seem to me wholly satisfactory. Other factors governing the phenomenon are the electromagnetic attractions between the current bearing loops and the plastic yielding of the heated filament. It was a search for the latter effect which first directed my attention to the other phenomena.

The negative discharge from a Wimshurst machine also alters the luminosity of the filament, and I have observed in some cases (using a modified Fleming valve), the complete stoppage of the thermionic current. These two latter effects are now being systematically investigated.

THE ARCHÆOLOGICAL SURVEY OF NUBIA.[1]

WHEN it was decided to heighten the Aswân Dam, the Egyptian Government also made provision for the thorough examination of the whole tract of country that would be immersed in the enlarged reservoir south of the First Cataract. An account has already been given in NATURE (1911, vol. lxxxvi., p. 283) of the surprising richness of the harvest of historical and archæological results, which Dr. Reisner's precise methods and skill in interpretation were able to rescue from this unpromising and poverty-stricken site during the first six months' work in 1907–1908. For in that short time not only were the main outlines of Nubia's chequered history and strange vicissitudes unveiled, but also, incidentally, considerable light was shed upon many points that hitherto had been obscure in the history of Egypt and the Sudan.

FIG. 1.—Cemetery 87. Groups of C-group superstructures. Grave 24, pottery in position at foot of superstructure. From "The Archæological Survey of Nubia. Report for 1908–9."

So successfully was this work accomplished during the first season's work of the Survey (where, fortunately, the materials brought to light in the neighbourhood of the First Cataract supplied a summary of the whole history of Nubia) that the other three seasons' work could be devoted to filling in the details of the story.

It was very fortunate that it was possible to put together the historical framework at the very commencement of the work, for during the following season Dr. Reisner, who had organised the whole undertaking and set the high standard of scientific accuracy and thoroughness for his successor to live up to, had to relinquish the personal control of the survey in order to resume his work in Syria and at the Giza Pyramids for the Harvard University and the Boston Museum. Happily Mr. Cecil Firth, who had been intimately associated with Dr. Reisner for several years, was available to carry on the work in the spirit and with the thoroughness with which it was begun. In the volumes lately issued the results of the second season's work (mainly Dr. Reisner's) have been fully presented with a conciseness and lucidity distinctive of Mr. Firth's writing.

The district with which the first season's work was concerned chanced to be especially rich in Predynastic and Early Dynastic remains, and thus enabled us at the outset to begin at the beginning and appreciate the condition of Lower Nubia when it was ethnically and archæologically a part of Egypt. The second season equally fortunately yielded most information concerning the succeeding period, when a distinctively Nubian culture was manifesting itself; and these data, which form the outstanding feature of the volumes before us, follow naturally upon the Early Dynastic and Egyptian phase of Nubia's history.

From the time of the Third Dynasty there was a rapid decline of Egyptian influence in Nubia, associated with a degradation of its essentially Proto-Egyptian culture and the infusion of negro blood into its population. "The condition of the country, owing to its isolation from Egypt, had reached a very low ebb, perhaps the lowest in its history, and it is not surprising to find it suddenly displaced by, or incorporated in, a new and vigorous barbaric civilisation which is very obviously southern in its origin, and in no way related to that of contemporary Egypt. It would appear that there was a considerable influx from the south of a slightly negroid population, which brought with it a peculiar culture and art which has very marked affinities with that of Predynastic Egypt in its earliest stage" (pp. 13 and 14). The new and precise information concerning this people which suddenly made its appearance in Lower Nubia "at some time between the Old and the Middle Kingdoms," *i.e.* roughly about 2500 B.C., is the outstanding distinctive feature of this report. Both in the physical characters of the people and the nature of their culture, which is so admirably described in these volumes, this Middle Nubian people is nearly akin to the earliest Predynastic Egyptians; but the two branches of the race became separated the one from the other, and developed independently, one in Egypt, the other further south under the influence of contact with the negro population of Africa. When the latter people, after a separation of perhaps nearly ten centuries, moved north and came into contact

[1] "The Archæological Survey of Nubia. Report for 1908–9. By C. M. Firth. Vol. i., part i., Report on the Work of the Season, 1908–9. Part ii., Catalogue of Graves and their Contents. Pp. vi+209. Vol. ii., Plates and Plans accompanying vol. i. 56 plates+xx plans. Cairo: Government Press, 1912.) Price L.E. 2 (for the two volumes).

with the Egyptians, their culture seems strangely alien, for it retained many features that had been extinct in Egypt for centuries, but now reappear strongly tainted with the effects of negro influence. After reading the masterly interpretation of these data relating to the first appearance of a distinctively Nubian culture in Lower Nubia, it is easy to understand how these puzzling facts have so far misled all other recent writers who have discussed Nubian archæology.

A very interesting feature of this report is the account of the superstructures that are found in association with these Middle Nubian graves, sometimes in the form of "a low dome of stonework (Fig. 94), composed of circular corbelled courses, somewhat analogous to the mud-brick corbel vaults of the Protodynastic period in Egypt" (p. 14), sometimes a simple cairn of stones roughly thrown together or more extensive circular walls of stone surrounding the grave, often with a little 'chapel' for offerings on the east or north-east side. As the derivation of these types

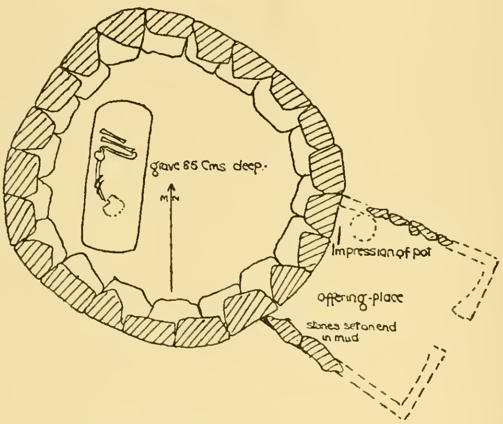

FIG. 2.—Cemetery 87. Grave 61. From "The Archæological Survey of Nubia. Report for 1908–9."

of superstructure from known Protodynastic Egyptian forms is unquestioned, it is very instructive to note that precisely similar circular stone monuments (with offering chapels) have puzzled writers on Algerian archæology (see MacIver and Wilkin's "Libyan Notes," 1901, Chapter xii.), who have not hesitated to class them with the megalithic group of structures in that region.

Limitation of space alone prevents a complete enumeration of all the other important features of these volumes. Further light is thrown upon the destruction of this characteristic Nubian culture, which flourished between the Sixth and Thirteenth Dynasties, by the Egyptian colonisation which followed the military expeditions of Usertesen III. And here, as elsewhere in Mr. Firth's report, it is clearly shown how the facts brought to light in these archæological investigations corroborate and supplement the known historical evidence.

There is now much more precise information concerning an interesting group of negroid people which made its appearance in Nubia between the second and sixth centuries A.D. They appear to be Nubas from Kordofan, perhaps the Nobadae brought into Nubia under Diocletian to check the incursions of the Blemmyes, who in turn were probably the nomadic kindred or descendants of the Middle Nubians who had taken to the Eastern Desert.

The interesting mud-brick forts at Koshtamna, built originally somewhere about the time the famous Giza Pyramids were being erected in Egypt, and frequently repaired and extended in subsequent ages, are fully and lucidly described. So also is the fortified Byzantine town of Sabagura.

There is also much new information concerning the Ptolemaic-Roman and Byzantine periods in Nubia.

The main part of the report consists of the detailed field notes, illustrated by numerous excellent woodcuts and a large volume of photographs and maps. This magnificent record of Prof. Reisner's and Mr. Firth's characteristically thorough survey of an extensive tract of difficult country will be indispensable to everyone who wants to understand the real history of the Nile Valley.

G. ELLIOT SMITH.

THE CRIMINAL AND THE CRIME.[1]

MR. GORING'S Blue Book on the English convict is unquestionably a product of immense patience and industry. In a preface contributed by Sir E. Ruggles-Brise, it is stated that, "In 1901 Dr. Griffiths, Deputy Medical Officer of Parkhurst Prison, formed the idea of subjecting a large number of prisoners convicted of certain similar offences to accurate measurements in order to ascertain whether these showed any deviation from what may be described as the normal, *i.e.* non-criminal persons." Under the encouragement of the Prison Commissioners, especially of Sir Bryan Donkin and Sir H. Smalley, and through the labours of several medical officers, the work grew in scope and magnitude. Ultimately it was placed in the hands of Dr. Goring, who was detached from duty with the view of tabulating the material at University College, with the assistance, and under the direction of Prof. Karl Pearson.

"It soon became apparent that the scope of the work had grown, perhaps inevitably, far beyond its original purpose, viz.: the refutation or confirmation, of the various theories that had been promulgated concerning the existence of the criminal type. It will be seen that the work now embraces a wide range, including not only an analysis of the physical and mental conditions of convicts, but also the data for speculation on very difficult and contentious questions as to the relative influence of heredity, environment, etc. Although the commissioners had not contemplated in the first instance a work of this magnitude, they feel it only fair to Dr. Goring that the work should be published on his own lines, and that

[1] "The English Convict. A Statistical Study." By Dr. C. Goring. Pp. 440. (London: His Majesty's Stationery Office; Wyman and Sons, Ltd., 1913.) Price 9s.

the public should be in possession of the mass of information collated, and statistically tabulated by him, and of the conclusions he draws therefrom. It must also be explicitly understood that the commissioners are not in a position to endorse all the conclusions at which he arrives, or to criticise the method employed in attaining them, as any attempt in this direction would involve an elaborate discussion of matters on which the highest scientific authorities differ."

Part I. of Dr. Goring's work is devoted to an examination of the theories of the late Prof. Cesare Lombroso and his followers. These are shown, we think, quite conclusively to be erroneous. The matter is one eminently suitable for statistical handling. Lombroso stated that criminals are mentally and physically abnormal. A large number of convicts have been examined, and the abnormalities have not been found.

No evidence has emerged confirming the existence of a physical criminal type such as Lombroso and his disciples have described . . . there is no such thing as a physical criminal type (p. 173) . . . there is no such thing as a mental "criminal type" (p. 246).

In chapter i. of part II. we find another statistical summary which must be accepted unless, as is very improbable, it can be shown that the facts are not correctly stated. Convicts as a class are physically and mentally inferior to the general population. They are, on the average, shorter, lighter, and stupider. Thieves, burglars, and incendiaries are especially defective. Criminals convicted of violence or fraud are little, if at all, inferior. A third

indisputable statistical fact has emerged from the investigation. It is that the family incidence of crime is not fortuitously distributed, it is not entirely independent of lineage; that criminals do not occur equally in *all* families of the general community, but tend to be restricted to *particular stocks* or sections of the community: to those stocks tainted with criminal ancestry. And we have found that the intensity of this limitation, the intensity of this parental resemblance in criminal propensity, ranges between 0·45 and 0·6 (p. 364).

But the greater portion of part II. consists of debatable matter. Statistics are not merely summarised, they are interpreted. The inferences are not immediate, but mediate. It is probable that the very facts on which Dr. Goring relies would be used by opponents as foundations for quite contradictory conclusions. Facts very similar actually have been so used times without number. For instance, a generation ago the British Association appointed an anthropometric committee to ascertain the statures and weights of persons engaged in different occupations, in accordance with the principle that—

"The occupation of an individual explains not only the direct effects of physical or mental work on the constitution of the body, but the kind of nurture or sanitary surroundings to which he may have been subjected." The Committee found "the most obvious facts which the figures disclose are the check which growth receives as we descend lower and lower in the social scale."

Dr. Goring's comment is—

"The figures disclose no such check upon growth as an obvious fact. The facts actually revealed are that, as we descend lower and lower in the social scale, the means of stature and weight diminish in value. There is no evidence that the diminution is caused by a check upon growth due to environmental conditions. An inference from these facts of equal validity with the Committee's deduction would be that descent in the social and economic scales of life is associated with a physical inferiority of human stock; in other words, that the professional man, labourer, and artisan, &c., breed their own kind, who in turn pursue the calling of their fathers, *i.e.* the work most suited to their social station, and to their particular type of physique" (p. 193).

Here we have the old dispute as to whether nature or nurture is the stronger. Dr. Goring sets himself the task of "disentangling the influence of *heredity* from a complication of *environmental* influences" (p. 337).

"As seen in the above table, 177, the parental correlation for sexual crimes and crimes of wilful damage to property, is from 0·45 to 0·5; for stealing it is from 0·48 to 0·58. We would assume then from this evidence, that the intensity of the inherited factor in criminality is from 0·45 to 0·5, and the intensity of criminal contagion is anything between 0·05 and 0·1" (p. 367). "Our second conclusion, then, is this: that relatively to its origin in the constitution of the malefactor, and especially in his mentally defective constitution, crime is only a trifling extent (if to any) the product of social inequalities, of adverse environment, or of other manifestations of what may be comprehensively termed the force of circumstances" (p. 371).

In these and many other passages, Dr. Goring appears to maintain strongly that the criminal is born, not made; that parentage counts for much, and training for little; that the child of a criminal has, on the average, the "proclivity" or "diathesis" so strongly developed that he will be a criminal no matter what the circumstances in which he is reared. With some surprise, therefore, we read near the end of the work:—

"But this fact of resemblance does not argue absence of the influence of environment in the development of human beings. It is as absurd to say that, because criminal tendency is heritable, a man's conviction for crime cannot be influenced by education, as it would be to assert that, because mathematical ability is heritable, accomplishment in mathematics is independent of instruction; or that, because stature is heritable, growth is independent of nutriment and exercise. Our correlations tell us that, despite of education, heritable constitutional conditions prevail in the making of criminals; but they contain no pronouncement upon the extent to which the general standard of morality may have been raised by education. We know that to make a law-abiding citizen two things are needed—capacity and training. Within dwells the potentiality for growth; but without stands the natural right of each child born into the world—the right to possess every opportunity of growing to his full height" (p. 373).

This passage is a little vague. Probably instead of "conviction for crime" Dr. Goring means "proclivity for crime," or "chances of conviction for crime." He seems clearly of the opinion that "training" is necessary to make of a normal individual a law-abiding citizen. Presumably such a man may be trained to lawlessness also. He has the capacity for both. In which case the special "proclivity" or "diathesis" of criminals can be nothing more than mere stupidity, mere incapacity to be trained. As expressed by Sir Bryan Donkin:—

"They are, it seems, innately unable to acquire the complex of characters which are essential to the average man, and, according to their surroundings, they follow the path of least resistance. This path is more often than not, but by no means always, the path of unsocial or criminal action" (p. 7).

In conclusion Dr. Goring states:—

"Our tables of figures speak for themselves, we have said; but we do not claim that they utter the last word. . . . A long intimacy with the material discussed in the present Report leads us to believe that better material could, with the experience now attained, be procured; but we are convinced that, at least to a first approximation, our data represent the fundamental interrelationships of criminality" (p. 373). In a note he adds:—"The inquiry, which of all others is most urgently needed, must not be limited to an examination of prisoners and their official records; but must extend beyond the prison walls, and into the homes and haunts of the offenders when at large; and into that wide and most interesting field of research where the experiments of the modern reformatory system are dealing with the child-criminal of the race" (p. 373).

SIR JOHN MURRAY, K.C.B., F.R.S.

THE tragic accident by which Sir John Murray lost his life on March 16 has deprived the world of one of the foremost naturalists of the day, and has sent a thrill of sorrow through the hearts of all who knew him. Though he had passed the allotted span of threescore years and ten, he still so abounded in youthful spirits and enthusiasm, was so active alike in body and mind, so full of work and of plans for further enterprise, that it is hard to believe that a career so distinguished in its past and bearing such continued promise for the future, has been suddenly brought to a close.

Of Scottish parentage, he was born in Canada in 1841, and received there the early part of his education. But in his youth he came to Edinburgh, and at the University there, under J. H. Balfour, P. G. Tait, G. J. Allman, and A. C. Brown, he received the training in physical and natural science that formed the groundwork of his lifelong labours. He soon showed the bent of his disposition towards marine studies, and at the same time his love of personal adventure, by taking, in the year 1868, a voyage in a Peterhead whaler to Spitsbergen and the Arctic seas. In the same year there began that series of pioneering cruises in the *Lightning* and *Porcupine*, by which, during the summers of 1868, 1869, and 1870, Wyville Thomson and W. B. Carpenter obtained so much new information regarding the distribution of life in the ocean. Deep-sea exploration became then a leading preoccupation among the naturalists of this country.

Eventually the general interest in this subject found vent in an application to the Government for a vessel and funds to prosecute the study of the ocean all over the globe. The memorable expedition of the *Challenger* was accordingly organised, which lasted from 1873 to 1876. Wyville Thomson, who had been elected in 1870 to the Chair of Natural History in the University of Edinburgh, was appointed director of the civilian scientific staff of the expedition. Recognising the brilliant promise of John Murray, he chose him to be one of the three naturalists on his staff. To this momentous choice the young aspirant to scientific distinction owed the opening which led to all the varied labours which have made his name so widely known.

When Wyville Thomson died in 1882, Murray, who had proved his remarkable qualities during the course of the expedition, was charged with the editorship of the scientific results of the cruises of the *Challenger*. This was a task the greatness of which is probably not generally appreciated. No ordinary skill, knowledge, tact, and patience were required to allocate the vast pile of collections to the different specialists all over the globe, to keep these writers up to their engagements, and, within reasonable limits of time, to see that the printers and engravers were supplied with material, to supervise the masses of proof-sheets, and, by no means least of all, to battle with an unsympathetic Treasury that grudged the heavy expense necessarily required for the publication of the work of the most completely organised expedition that had ever sailed the seas. Year after year the labours of the editor went on, until some fifty massive quarto volumes were issued. That Murray should have emerged with triumphant success from so prolonged and so trying an ordeal was a striking proof of the strength of his character and the vigour of his scientific enthusiasm.

Besides taking an active part in the dredging and the general biological work of the expedition, Murray specially devoted his attention to the working out of certain parts of the materials obtained. He was more particularly interested in the investigation of the deposits that are accumulating on the floor of the ocean. The ample store of materials which he succeeded in gathering together was subsequently carefully studied by him in concert with the late Prof. Renard, of the University of Ghent, and the conjoint work of the two observers was published as one of the thick quartos of the *Challenger* Reports. This monumental volume possesses a high scientific value, coupled with the historical interest that it gave to the world the first detailed revelation of the nature and distribution of the deposits that are gathering on the floor of the deep sea, and the impressively slow rate at which some of these deposits are being formed.

A further inquiry arising out of the operations of the *Challenger* expedition was the question of the origin of coral islands. The fascinating explanation of these islands proposed by Darwin had been generally accepted by men of science, though some doubts had been thrown upon its universal application. Murray, who was not always disposed to accept the conclusions of his predecessors without subjecting them to rigorous investigation, was led to entertain more than doubts as to the general applicability of Darwin's theory. He ultimately came to the conclusion that the extensive oceanic submergence which the great naturalist's explanation demanded could not be proved from coral reefs. He propounded another view in which he was supported by the late Alexander Agassiz, who undertook many cruises over different oceans, visiting most of the coral regions and obtaining an unrivalled acquaintance with their various features. According to this view, coral reefs have grown up on submarine volcanic peaks, which in many cases have been covered with thick accumulations of calcareous organisms, so as to be brought up within the limits of the growth of reef-building corals. The problem probably cannot be solved by any one universally applicable hypothesis. Whether or not subsidence has played a part in the formation of coral islands there can be no doubt, from the full narratives of Agassiz, that proofs of elevation are conspicuously obvious in many of the groups of these islands.

Sir John Murray's latest expedition took place only four years ago, when at his request the Norwegian Government lent him a surveying vessel, the *Michael Sars*, together with its scientific staff, for a summer cruise of four months in the North Atlantic Ocean, while he himself undertook to defray all the other expenses. The cruise proved highly successful, but perhaps its most important result has been the preparation and publication of a work on the "Depths of the Ocean," the joint production of Sir John himself and Dr. Johan Hjort. This handsome volume is undoubtedly the best and most authoritative treatise on the subject to which it is devoted. It places clearly before the reader the main incidents in the history of the investigation of the deep sea, and it describes the methods of research and the general scientific results obtained, with fresh illustrations from the experience gained in the cruise of the *Michael Sars*. Sir John had already been recognised as one of the chief founders of the modern science of Oceanography, and in this admirable volume he has left what will long be the leading manual on the subject.

It was at his instance that upwards of five-and-twenty years ago the British Government was led to annex Christmas Island, a lonely volcanic peak in the Indian Ocean, which seemed never to have been disturbed by man. He sent out some competent observers to study its geology and natural history, and these visitors found it to be rich in phosphatic deposits. He thereupon formed a company, which obtained a concession to work these accumulations. With the wealth that accrued to him from this source, he has been a generous supporter of scientific investigation in many directions. One of the undertakings which he set on foot and financed was a thorough bathymetrical survey of the freshwater lochs of Scotland by practised observers. The results of this investigation have been published in a series of six volumes. There is probably no other country of which the depths and other features of its lakes have been so fully made known.

Sir John Murray's devotion to science and his sagacity in following out the branches of inquiry which he resolved to pursue were not more conspicuous than his warm sympathy with every line of investigation that seemed to promise further discoveries. He was an eminently broad-minded naturalist to whom the whole wide domain of Nature was of interest. Full of originality and suggestiveness, he not only struck out into new paths for himself, but pointed them out to others, especially to younger men, whom he encouraged and assisted. His genial nature, his sense of humour, his generous helpfulness, and a certain delightful boyishness which he retained to the last endeared him to a wide circle of friends who will long miss his kindly and cheery presence.

ARCH. GEIKIE.

PROF. E. S. HOLDEN.

PROF. HOLDEN, whose death was announced with regret in our last issue, was better known to the astronomers of the last generation than the present. He will be remembered as one who, by his energy and position, encouraged the enterprise and activity that have characterised the development of astronomical research in the United States. It was his fortune, thirty years ago, to be placed at the head of the Lick Observatory, the optical equipment of which was then superior to any that existed. Also the position of the observatory had been selected with care and at considerable expense. He had to construct a programme and to pursue it with such ardour and success that the results should justify the costly erection of the gigantic refractor in a spot remote and difficult of access. In his work as a pioneer he had little to guide him, for though telescopes had gradually increased in power, they had been employed mainly in doing more perfectly what small telescopes had attempted. We may claim that the Lick telescope in his hands was a success. It is, of course, difficult to separate the work of a director from that of the subordinates selected to carry it into effect. The one provides a programme, but the performance must be largely in the hands of the lieutenants.

Prof. Holden was fortunate in the choice of his assistants and in the apportionment of their work. His assistants all increased their reputation under his direction, and demonstrated the capacity of the instrument entrusted to their charge. Barnard added an inner satellite to the Jovian system; Burnham's double-star work remains unsurpassed; Keeler's successful demonstration of the meteoritic constitution of Saturn's rings and his determination of the motion in the line of sight of the planetary nebulæ would have made the reputation of any observatory. Naturally some credit for these successes attaches to Prof. Holden. But his own activities contributed not a little to the high estimation in which the observatory was held. Foremost, perhaps, should be placed his monograph on the nebula of Orion, a useful and painstaking piece of work. Of more originality were his studies of the physical constitution of the sun and its surroundings, the outcome of several eclipse expeditions, some earlier than the appointment to the Lick Observatory. Planetary markings and close examination of the surfaces of such minute discs as those of Jupiter's satellites or the planet Uranus also engaged his attention. The helical forms of nebulæ were the subject of intimate study, and in other directions Prof. Holden displayed equal energy and ability.

Considering the difficulty of getting a new observatory into efficient working order, increased as these difficulties were by the inaccessibility of the situation, it will be admitted that the twelve years' direction from 1885 to 1897 accomplished much useful work. In the latter year Prof. Holden resigned the position of director of the Lick Observatory, and his scientific activities apparently ceased. W. E. P.

NOTES.

The Bakerian Lecture of the Royal Society will be delivered by Prof. A. Fowler on Thursday next, April 2, upon the subject of "Series Lines in Spark Spectra."

We announce with regret the death on March 23, at sixty-eight years of age, of Prof. G. M. Minchin, F.R.S., formerly professor of mathematics, Royal Indian Engineering College, Coopers Hill.

We regret to see the announcement of the death on February 17, at sixty-two years of age, of Dr. G. J. Burch, F.R.S., formerly professor of physics at University College, Reading, and the author of a number of papers upon electrical subjects and physiological optics.

The eighth annual meeting of the British Science Guild will be held at the Mansion House on Friday, May 22, at 4 o'clock p.m., when the Lord Mayor, the Right Hon. Sir T. Vansittart Bowater, Kt., will preside. The annual dinner will be held at the Trocadero Restaurant on the same date, at 7.30 p.m., under the chairmanship of the president of the guild, the Right Hon. Sir William Mather, P.C.

The enormous drain on the mammalian life of the world caused by the fur-trade is strongly emphasised in the following extract from an article in the *Times* of March 19 on the London spring fur-sales:—"Yesterday there were sold in the morning 183,754 skunk skins; in the afternoon 136,623 American opossum and 80,242 raccoons, as well as 3,602 civet cats. To-day will be offered 430,401 skunks, and to-morrow 2,500,000 musquash of various classes. In all there will be sold more than 4½ millions of musquash skins; and it is no wonder that the once familiar musk-rat 'houses,' which used to dot every lake and pond all over the United States, looking like great mole-hills sticking up from among the rushes, are growing scarce." During the three weeks of the sale it is probable that 10 or 12 million skins will have been sold.

The discovery of ancient human remains in German East Africa by Dr. Hans Reck, of the Geological Institute of Berlin University, may prove to be an event of some importance to anthropologists. The report of the discovery, published in the *Times* of March 19, leaves us in some doubt as to the antiquity and racial characters to be assigned to these East African human remains, but apparently they are of mid-Pleistocene date, and show the distinctive features of the negro. If such prove to be the case, we must conclude that the negro race was already evolved in Africa at an earlier date than is now generally supposed. The *Times* report also informs us that the man thus discovered had thirty-six teeth—four more than is given to human and anthropoid races. The teeth are also said to show marks of filing; it would indeed be a remarkable fact if the habit of filing the teeth, so common in modern African races, should have been in use at the early date assigned to these prehistoric remains.

The International Phytopathological Conference summoned by the French Government in conjunction with the Italian Government to meet at the International Institute of Agriculture was inaugurated by his Majesty the King of Italy on February 24, and was brought to a conclusion on March 5, in the presence of all the fifty delegates, who represented the thirty-five States which took part in the conference. By the proposed International Convention adhering States pledge themselves in the first place to take whatever legislative and administrative measures are necessary to prevent the distribution of all diseases of plants in their own countries, but specially to organise an effective service of supervision over nurseries, gardens, glasshouses, and other establishments which carry on a trade in living plants. The measures which adhering States would pledge themselves to take include (*a*) the erection of one or more institutes for scientific studies and research; (*b*) the organisation of an effective service of supervision over nurseries, including the packing and dispatch of plants; (*c*) the issue of phytopathological certificates. They would bind themselves only to admit plants accompanied by phytopathological certificates issued by or from a competent official authority, except in the case of plants which are imported for scientific research at an institute authorised by the Government.

March bids fair this year to establish a record for rainfall, and at Greenwich, where the aggregate rainfall to the morning, March 23, was 3·54 in, the total for the whole month has only been greater in two years during the last century, from 1815. The heaviest record fall is 4·05 in. in 1851, and in 1905 the measurement was 3·57 in.; the latter was exceeded by rain during the day, March 23, and there are nine days which seem likely to be wet, to secure a total of 0·52 in., which will render the present month the wettest March on record for the last one hundred years. At Greenwich there have in all only been eight years with the March rainfall more than 3 in. since 1815. Rain has fallen every day in the month to March 23, with the exception of March 1 and 2, and on March 8 and 9 the aggregate rainfall was 1·43 in., whilst the average for the whole month is 1·46 in. At Camden Square the total rain for the month to March 23 is 4·12 in., which is 0·43 in. more than in any previous March during the last fifty-five years. On March 22 the shade temperature at Greenwich was 29°, which is as cold as any previous reading since January 25, and the terrestrial radiation temperature on March 22 was 18°, which is lower than any grass temperature since January 24. The Greenwich records for the sixty years 1850–1909 show that frost has occurred in thirty-one years on March 22, so that the chances are in favour of frost on that day, whilst on March 20 frost has only occurred in twelve years, which gives the chance of 5 to 1 against frost.

A COMPLIMENTARY banquet was given by members of the medical profession to Surgeon-General Gorgas, sanitary officer of the Panama Canal Commission, on Monday, March 23. Sir Thomas Barlow (president of the Royal College of Physicians) occupied the chair, and the company included many distinguished representatives of medical science. Earlier in the day Surgeon-General Gorgas delivered a lecture before the Royal Society of Medicine on his sanitary work in Panama. In the course of his lecture he said that one-third of the canal zone is low and marshy, and had the reputation for four hundred years of being one of the most unhealthy regions in the world. It is probable that more white men have died there from tropical diseases than at any other place within the tropics. The French began work on the canal in 1880, the Americans in 1904. During the intervening twenty-four years it had been discovered that malaria and yellow fever are transmitted from one human being to another by the mosquito—malaria by the anopheles, and yellow fever by the stegomyia. These discoveries enabled health conditions at Panama to be controlled. Had the Americans known no more about these two diseases in 1904 than did the French in 1880, he did not believe that they could have done any better.—The degree of Doctor of Science, *honoris causâ,* was conferred upon Surgeon-General Gorgas at a special Convocation of the University of Oxford on Tuesday, March 24.

ON Wednesday, March 18, a portrait of Sir William Ramsay, painted by Mr. Mark Milbanke, was presented to the University of London, University College, on behalf of a committee of subscribers, consisting mainly of former colleagues and past students, by Prof. J. Norman Collie. Prof. Collie directed attention to the scientific achievements of Sir William Ramsay. While an assistant in Glasgow, Sir William Ramsay, together with Prof. Dobbie, discovered the fact that a certain number of acids obtained by oxidation of compounds obtained from bone oil and coal tar were identical with the products obtained by oxidation of the alkaloids. After that, when he was professor at University College, Bristol, he brought out a very large amount of extremely interesting work in physical chemistry. On coming to London and University College, his first great discovery, made in conjunction with Lord Rayleigh, was that of argon; and this was followed soon afterwards by the isolation of helium from clevite. Following up these two discoveries, Sir William Ramsay, after five years' hard work with Prof. Travers, succeeded in finally obtaining from the atmosphere three more elements—neon, krypton, and xenon. After this, Sir William Ramsay investigated the emanation that comes off from the element radium. This he obtained in the pure condition above mercury, and noticed that it gradually decomposed and that helium resulted. The portrait was accepted by the Vice-Chancellor of the University (Dr. W. P. Herringham) and by the chairman of the managing subcommittee of University College (Dr. J. Bourne Benson). A replica of the portrait was presented to Lady Ramsay, on behalf of the subscribers, by the Provost of the college in token of the esteem and affection in which Sir William and Lady Ramsay are held at University College. The gift was briefly acknowledged by Lady Ramsay and Sir William Ramsay.

IN the *Times* of March 17 E. Naville gives a further account of his remarkable discoveries at Abydos. He has found a great rectangular reservoir, which is shown to belong to the period of the temple of the Sphinx, when building with enormous stones without ornament came into fashion. This he believes to be the oldest stone monument, in the architectural sense, in Egypt. Some of the pyramids may be older, but, except for the inner chambers, they are without architectural plan. This reservoir was used for the storage of water in high Nile; and it is a remarkable fact that the beginning in architecture is neither a temple nor a tomb, but a gigantic water-work, showing that even in this early period the people had carefully observed the laws of the rise and fall of the Nile, and of the processes of infiltration.

IN the *National Geographic Magazine* for February Mr. W. J. Showalter contributes an interesting article, illustrated by a fine series of photographs, showing how the opening of the Panama Canal has been delayed by the earth slides, particularly in what is known as the Culebra Cut. It was only with the deepening of the canal bed in 1910 that these obstacles became really formidable; in all some thirty million cubic yards of material have been removed. Mr. Showalter describes the geological conditions of the area, with eleven groups of bedded rock and six of igneous formations, the result of volcanic action and uplifting of marine strata. The engineers now intend to check erosion in the Culebra Cut by covering the banks with vegetation, and the ships of the future will pass between banks of tropic green, except at those places where the living rock defies the efforts of the forester.

IN his presidential address to the Society for Psychical Research (published in the current number of the society's Proceedings), Prof. Henri Bergson asked "what would have happened if modern science, instead of setting out from mathematics to turn its attention towards mechanics, physics, and chemistry, instead of bringing all its forces to converge on the study of matter, had begun by the consideration of mind—if Kepler, Galileo, and Newton, for example, had been psychologists." He answered that our psychology would have been almost inconceivably different from what it is. "Foreign to every mechanistic idea, not even conceiving the possibility of such an explanation, science would have inquired into, instead of dismissing *a priori*, facts such as those you study. Vitalism," he continued, "is a sterile doctrine to-day. It will perhaps not be so always, and it probably would not have been so had modern science at its origin taken things at the other end."

THE current number (February, 1914) of the *Journal of Genetics* contains papers dealing with several aspects of the problem of heredity. Mr. R. K. Nabours writes on inheritance in Paratettix, an American genus of locusts. In addition to *P. texanus*, Hanc., he found eight varieties which differ in their colour patterns, and are given new specific names. The inheritance of these colour patterns in crosses is found to be Mendelian in the sense that segregation occurs in the F_2 offspring, the species *P. texanus* being recessive to all the others. In the F_1 the colour patterns of both parents are equally developed, so that there is no phenomenon of dominance. In the experiments, five "unexpected individuals" appeared, which seem to have been due to germinal changes. Long and short wings were found not to be inherited, but to be controlled by environment. Mr. Richardson contributes a note on inheritance in strawberries, and Mr. Salmon describes sterile male dwarfs in the hop. In continuing his studies on the effects of environment on parthenogenetic and sexual reproduction in Cladocera, Mr. Agar concludes that "there is no justification for retaining the hypothesis of an inherent reproductive cycle," the transition from one type of reproduction to the other being entirely under environmental control. Dr. C. J. Bond describes an hermaphrodite Formosan pheasant having the secondary sexual characters of a male on the left side and of a female on the right, and suggests an explanation based on hormones. The utility of the paper on reduplication series, which deals with highly questionable Mendelian hypotheses, is problematical.

THE revived interest in the study of Thysanoptera among English entomologists is shown by the publication of two important papers in a recent number of the *Journal of Economic Biology* (vol. viii., No. 4) on British species of the order, by Mr. C. B. Williams and Mr. R. S. Bagnall respectively. A number of new species are described in each paper. Mr. Williams also describes some new forms from the West Indies.

THE lately issued part of the *Bulletin of Entomological Research* (vol. iv., part 3, 1913) is mostly occupied by two papers combining geographical and economic interest. Dr. J. J. Simpson describes his journeys for entomological research in British West Africa, giving much ecological information and a map to show the ascertained range of five species of Glossina in Sierra Leone. Mr. A. D. Peacock discusses the "Entomological Pests and Problems of Southern Nigeria," describing the principal insects that injure the staple crops of the country—cotton, cocoa, maize, yams, and rubber. The stages of the red "cotton stainer"—a heteropterid bug, *Dysdercus superstitiosus*, are described and illustrated with coloured figures; excellent illustrations of other harmful species are also given.

IN the February number of *Naturen* Dr. A. W. Brøgger discusses certain "kayaks" discovered in Scotland and the isles—two of them so long ago as the seventeenth century—which have been regarded as of a Scandinavian, or rather Finnish, type. Dr. Brøgger states, however, that this is altogether wrong, and that the kayaks, together with the associated paddles and other implements, closely resemble those used at the present day in Greenland. How they reached Scotland and the Orkneys is briefly discussed.

THE greater portion of the third part of vol. iv. of the Annals of the Transvaal Museum is occupied by papers on the results of the zoological section of the Percy Sladen Memorial Expedition to Great Namaqualand in 1912–13, of which section Mr. Paul Methuen was in charge. Mr. Austin Robert supplies the list of mammals collected, while the reptiles and amphibians are discussed by Messrs. Methuen and John Hewitt, and the arachnids by Mr. Hewitt. New species in each of the three last-mentioned groups are described.

As the result of a fifteen weeks' sojourn in South Georgia during the Antarctic summer of 1912–13, Mr. Cushman Murphy (Bull. Amer. Mus. Nat. Hist., vol. xxxiii., p. 63) was led to believe that old males of the sea-elephant had become exceedingly scarce, and that not sufficient were left to impregnate the females. According, however, to the taxidermist who accompanied Major Barrett-Hamilton, this was a temporary deficiency due partly to the visits of a sealing vessel belonging to the Compaña Argentina de Pesca, and partly to an unprecedented slaughter of some 600 males in a single season. During the past season fair-sized and large males are reported to have been relatively numerous.

WE have received from the secretary of the Commission on Zoological Nomenclature, in conformity with the instructions of the congress which require that a year's notice be given before any official exceptions to its rules can be allowed, a memorandum praying for the retention of the old generic names Doliolum, Pyrosoma, Salpa, Cyclosalpa, Appendicularia, and Fritillaria, signed by the following workers on Tunicata:—C. Apstein, A. Borgert, G. P. Farran, G. H. Fowler, R. Hartmeyer, W. A. Herdman, J. E. W. Ihle, H. Lohmann, W. Michaelsen, G. Neumann, C. Ph. Sluiter, F. Todaro. How far the present confusion would be worse confounded by conformity to the new rules may be seen by the fact that what every zoologist knows as Pyrosoma would be called Doliolum, and a new name would have to be coined for the well-known plankton key-form at present termed Doliolum.

IN the *Izvestiya* of the Imperial Academy of Sciences of St. Petersburg (February, 1914) Madame H. I. Poplavska publishes some preliminary results of her botanical researches in the neighbourhood of Lake Baikal. The fauna of the lake exhibits such peculiarities that Prof. Berg has defined it as a subregion of the holarctic region, but the flora has hitherto aroused little interest. The lake affects the distribution of rainfall and the temperature, the summers being much colder in the neighbourhood of the lake than in the surrounding parts of Siberia. Consequently the climate is similar to that of alpine regions and lofty peaks, and the flora is adapted to such conditions. Madame Poplavska mentions several forms peculiar to the Baikal area, some of which differ in so many points from their allied forms in other regions that they may be considered independent species, while others, not having as yet fully adapted themselves to local conditions, show few divergences, and can only be styled varieties. The habitat of these forms and their relation to allied species do not support the view that they are a relict flora.

COUNT DE MONTESSUS DE BALLORE examines the so-called luminous phenomena of earthquakes in a paper published in the latest bulletin of the Seismological Society of America (vol. iii., pp. 187–90). Referring to Galli's catalogue of 148 earthquakes during which luminous phenomena were reported, he shows that the time-intervals between these phenomena and the earthquakes are very variable and sometimes considerable, the accounts come indifferently from the epicentral areas and from distant regions, and the lights appear more frequently from the atmosphere than from the ground. In the great catalogues of Chinese earthquakes, luminous phenomena are never described as attending earthquakes. Two cases are examined in detail. The lights seen during the Valparaiso earthquake of 1906 were probably due to a thunderstorm, and those during the earthquake of November 16–17, 1911, in Germany and Switzerland to meteors. The author concludes that, in the present stage of our knowledge, the existence of luminous earthquake phenomena should be neither affirmed nor denied, but that all the facts at our disposal tend to a negative conclusion.

THE current number of *Symons's Meteorological Magazine* contains an interesting account by Mr. A. H. Hignett of the peculiar behaviour of a cyclonic whirl or tornado which did an immense amount of damage in Cheshire on the evening of October 27 last. It lasted only a few minutes, and its track was about 150 yards wide. It was accompanied by vivid lightning, heavy rain, and a loud noise, said to resemble that of "hundreds of motor-cars crashing through the trees." On entering the county of Cheshire from the north of Shropshire and travelling in a northerly direction, it seems to have risen in the air and passed over about seven miles of country without doing any damage, and then to have descended and struck a tree standing alone in a field smashing it to pieces. It then apparently rose again for about $1\frac{1}{4}$ miles, and afterwards descended and travelled along the foot of the Peckforton Hills (600–700 ft. above sea-level), destroying trees and buildings in its track, and eventually passed into Lancashire near Runcorn. The wind is described as warm, but in South Wales, where the cyclone occurred earlier in the day, it was said to be icy cold. This bounding motion of the whirl is probably by no means an isolated case, and seems to point to another danger to which aviators may be exposed.

DR. P. W. BRIDGMAN, of the Jefferson Physical Laboratory, Harvard University, whose high-pressure research is well known to our readers, has communicated to the American Academy a paper on the technique of high-pressure experimenting which will be of great service to all who wish to follow him in dealing with physical measurement under pressures of ten to thirty thousand kilograms per square centimetre. He gives details of his methods of packing, the construction of his pistons and cylinders, and the connection of his pipes, valves, and pressure gauges. The paper appeared in the February number of the Proceedings of the American Academy.

NO. 209 of the Scientific Papers of the Bureau of Standards deals with the recent determinations of the latent heat of fusion of ice by Messrs. Dickinson, Harper, and Osborne, of the bureau. The natural or artificial ice was cooled in a cryostat to either $-0{\cdot}7°$ C. or $-3{\cdot}78°$ C. before insertion in the calorimeter. Its weight was determined while suspended in the cryostat. Both the electrical method and the method of mixtures were used in measuring the heat of fusion. The former method allows the temperature of the calorimeter to be kept nearly constant during the melting of the ice, and the cooling correction is therefore small. Ninety-two samples of ice were tested, commercial can, plate, and natural ice, and ice made in the laboratory from air-free distilled water were used, and the heat of fusion found to be the same for each to within one part in 1000. The final result is 79·63 calories per gram.

IN the third of his six lectures on new problems of theoretical physics, recently published (in German) by the Ernest Kempton Adams Fund of Columbia University, Prof. W. Wien discusses in an illuminating manner the various electronic theories of the conduction of heat and electricity through metals. The practically infinite conductivity at the absolute zero, rendered probable by the researches of Kamerlingh Onnes, is explained if we assume that the distribution of molecules at the lowest temperatures is perfectly regular, so that the displacement of electrons along certain lines encounters no resistance. The irregularity of distribution induced by rise of temperature and consequent thermal agitation reduces the free path of the electrons, and hence also the conductivity. There is some evidence to show that it is only the mean free path, and not the number of electrons or their mean velocity, which is affected by temperature. Indeed, the lecturer inclined to the belief that even at the absolute zero all electrons have an irreducible kinetic energy, such as is required by the persistence of both diamagnetism and photo-electric effects at the lowest temperatures, not to speak of the expulsion of electrons by radio-active substances in entire independence of the temperature. The question as to whether canal-ray ions emit light in the charged or the uncharged condition is discussed in the sixth lecture. Bärwald showed in 1911 that a magnetic field stops but a small portion of the light emission, whereas most of the positive ions are deflected. This tells in favour of the view that the luminous bodies are uncharged. Even Reichenheim's observation that the whole of the luminous emission from an alkaline-earth anode may be deflected does not invalidate this view, since in this case the mean free path was very small, and every atom was probably charged at least once in the course of its passage.

The increasing adaptation of enzymes to chemical purposes is well illustrated by the utilisation of urease, by Dr. R. H. Aders Plimmer and Miss R. F. Skelton (*Biochemical Journal*, vol. viii., p. 70), in the rapid estimation of urea in urine. The action of the urease of the soy bean has quite recently been shown to be entirely specific; in the communication cited details are given of a process by means of which a rapid and accurate method of estimation is afforded of a substance the analytical determination of which has always presented some difficulty and uncertainty.

During the past few years several active principles have been isolated from ergot which account for most of its peculiar physiological properties; certain other effects have, however, been observed which have not been satisfactorily explained hitherto. In the current number of the *Biochemical Journal* (vol. viii., No. 1) Mr. Arthur J. Ewins describes the isolation from ergot of traces of acetylcholine, a base which produces a peculiar inhibitor effect on the heart, suggesting that caused by muscarine, which had been frequently observed to characterise the use of ergot. That this base is responsible for the effect was shown not merely by its actual isolation from ergot, but by the fact that the synthetic base, prepared from choline, has an identical physiological action.

The following books relating to science are announced by Gebrüder Borntraeger, of Berlin:—"Die wichtigsten Lagerstätten der 'Nicht-Erze,'" Prof. O. Stutzer, Teil. ii., Kohle, Allgemeine Kohlengeologie, illustrated; "Ueber die Bedingungen der Gebirgsbildung," Dr. K. Andrée, illustrated; "Beiträge zur chemischen Petrographie," Prof. A. Osann, Dritter Teil; "Geologischer Führer durch Nordwest-Sachsen," Dr. E. Krenkel, illustrated; "Praktikum der chemischen, biologischen und bakteriologischen Wasseruntersuchung," Prof. O. Emmerling, illustrated; "Geologische Charakterbilder," edited by Prof. H. Stille, illustrated, Heft 18, 19, 20.

The following new books are announced by C. Griffin and Co., Ltd.—In *Biology*.—Practical Field Botany, A R. Horwood, illustrated; in *Chemistry*—A Text-Book of Inorganic Chemistry, edited by Dr. J. Newton Friend, in nine volumes; Elementary Practical Chemistry, for Medical and other Students, J. E. Myers and J. B. Firth; The Storage of Petroleum Spirit, Major A. Cooper-Key; The Petroleum Technologist's Pocket Book, Sir Boverton Redwood and A. Eastlake, illustrated; Oil Chemists' Pocket-Book, Dr. H. Ingle and J. A. Sutcliffe; The Raw Materials of the Enamel Industry and their Chemical Technology, Dr. J. Grünwald, translated by Dr. H. H. Hodgson; in *Engineering*—An Introduction to Town Planning, J. Julian, illustrated; in *Geology*—A Text-Book of Geology, Prof. J. Park; in *Medical Science*—A Practical Handbook of the Tropical Diseases of Asia and Africa, Dr. H. C. Lambart, illustrated; in *Metallurgy*—The Metallurgy of the Non-Ferrous Metals, Prof. W. Gowland, illustrated; Practical Assaying, Prof. J. Park, illustrated; in *Technology*—Clay and Pottery Industries, being vol. i. of the Collected Papers from the County Pottery Laboratory, Staffordshire, by several authors, edited by Dr. J. W. Mellor, illustrated; in *Miscellaneous*—Roberts-Austen: Addresses and Scientific Papers, together with a Record of the Work of Sir William Chandler Roberts-Austen, K.C.B., F.R.S., compiled and edited by S. W. Smith, illustrated; Memorials of Henry Forbes Julian, compiled and edited by his wife, Hester Julian, illustrated.

OUR ASTRONOMICAL COLUMN.

The Forthcoming Total Solar Eclipse.—While the various official and private expeditions are making preparations for observing the total solar eclipse of August 21 next, steamship companies are offering enticing pleasure cruises which include a brief stay on the line of totality on the Norwegian coast. As the last total solar eclipse visible in England took place so far back as the year 1724, and as 1927, the time for the next one, is as yet some time off, the opportunity to view the eclipse of this year should not be lost. The Royal Mail Steam Packet Company's ocean yachting steamer, *Arcadian*, twin screw, and 8939 gross tonnage, is timed to leave Grimsby on August 15 and Leith August 16, and will take up a position near Alsten, north of Torghatten Island, well on the central line. The Norway Travel Bureau of the Great Northern Railway Company has also arranged a special cruise. Passengers leave Newcastle-on-Tyne by the ss. *Venus* on August 15, and join the special steamer *Mira* at Bergen on August 17, a position being taken up at Stokka on eclipse day. It is stated that if a party of seventy-five to eighty members of the Royal Astronomical Society and the British Astronomical Association would avail themselves of this facility no other passengers would be accepted, and the itinerary would be varied to meet the requirements of the party, and the stay at any place in the eclipse zone prolonged.

A Monthly Report on Mars.—Prof. W. H. Pickering has commenced the publication of a series of monthly reports on the appearance of the planet Mars. The first of these was printed in the January number of *Popular Astronomy* (vol. xxii., No. 1, 1914). The observations described are made at the Jamaica Astronomical Station of Harvard College Observatory, situated near Mandeville, at an altitude of 2100 ft., The instrument employed is an 11-in. Clark refractor, and the magnification generally used 660. Prof. Pickering states that the changes on Mars cannot be described as conspicuous except when the planet is viewed under very exceptional conditions, but in their general character they may be detected by careful study, even by those who are not fortunate enough to reside in those portions of the world where the seeing is habitually good. It is in order to emphasise this constant change, unlike changes seen on Jupiter, but resembling more those which occur on our earth, that Prof. Pickering proposed the issue of this monthly bulletin. The present report describes as an introduction the general nature of the nomenclature to be used, and this is generally of a meteorological type, the observations being described under the four headings, snow, clouds, colours and shading, canals and lakes. The observations here dealt with cover the interval from July 27 to October 30, 1913.

A METEORITE FROM ZULULAND.—Prof. G. H. Stanley gives a very interesting description and analysis of a meteorite which fell in the N'Kandhla district of Zululand (*South African Journal of Science*, vol. x., No. 5, January, 1914). The meteorite was observed to fall on August 1, 1912. The first occurrence noted was the usual sound of an explosion, which attracted attention over a considerable area, and a rapidly moving body was seen which left a spiral trail of smoke and at the same time appeared to produce a rumbling or crackling sound. While possibly more than one was found, Prof. Stanley has only been able to locate one definitely, and this forms the subject of his communication. It fell near the junction of the Buffalo and Tugela Rivers, on the Pokinyoni hill in the N'Kandhla district, within a few yards of a native woman. The meteorite weighs nearly 38 lb., and consists almost entirely of nickel-iron alloy, and is therefore classed as a siderite; it is coated with a skin of magnetic oxide exhibiting flow lines, and shows also a profusion of "thumb marks." The communication is accompanied by numerous photographs of the specimen, and also several photographic sections. The complete analytical results are given in percentages as follows: iron, 89·28; nickel, 10·68; silicon, 0·004; sulphur, trace; carbon, 0·030; phosphorus, 0·057; traces of aluminium, magnesium, platinum, and chlorine. The presence of manganese, cobalt, or chromium could not be detected.

A SOLAR OBSERVATORY FOR NEW ZEALAND.—In our issue of July 3, 1913 (p. 460), we announced that Mr. Thomas Cawthron, of Nelson, New Zealand, had offered to build, equip, and endow a solar physics observatory in New Zealand. From a short article in the *Times* of March 23, we learn that Mr. Cawthron is prepared to give 50,000*l*. for this purpose. Mr. J. Evershed, director of the Kodaikanal Solar Observatory in India, who has visited New Zealand to advise as to the erection of the Cawthron Observatory, has spoken highly of the suitability of Nelson, from the geographical and climatological points of view, for the purpose of researches in solar physics.

THE INSTITUTE OF METALS.

THE spring meeting of the Institute of Metals was held in the building of the Institution of Mechanical Engineers on March 17 and 18. The afternoon of the first day was devoted to formal business and to the delivery of the presidential address by the newly elected president, Sir Henry J. Oram, Engineer-in-Chief of the Fleet. The morning and afternoon of the second day were devoted to the reading and discussion of reports and papers. The attendance of members at the meetings was unfortunately rather small, but a large number assembled for the annual dinner, which proved a particularly successful function.

The presidential address was chiefly devoted to the evolution of the Admiralty condenser tube, the various steps being described which have led to the present satisfactory position, in which the number of failures from either corrosion or splitting is as low as one in 60,099 per annum; the steps in question consisted mainly in the imposition of increasingly stringent conditions and tests, and in inducing manufacturers to work to these. Sir Henry Oram also directed attention to the steady decrease in the quantity of non-ferrous metals employed in warship machinery, steel taking the place of brass, bronze, and copper wherever possible. Such a state of affairs points to the need of vigorous progress in non-ferrous metallurgy in order that alloys may be produced which are capable of rendering services to which iron and steel are not applicable.

The nomenclature committee, appointed by the Institute of Metals, but including representatives of the principal technical societies and institutes in this country, presented its first report. The committee was appointed for the purpose of formulating, if possible, a rational system of nomenclature for alloys which should abolish the existing confusion. In its first report the general lines to be followed are laid down; these consist in the construction first of a "systematic nomenclature," in which every alloy is described by the names of its constituent metals, in English, arranged in ascending order of their numerical importance in regard to composition by weight. This logical but cumbersome system is not intended for ordinary daily use, and for this purposes a system of "practical" nomenclature is to be set up, the names comprised in this system being defined as simple verbal abbreviations of the terms of the systematic nomenclature.

The committee has so far presented definitions only of the terms "brass" and "bronze." Brass is defined as an abbreviation for the systematic term "zinc-copper," and therefore when used alone denotes an alloy consisting substantially of zinc and copper only, and containing more copper than zinc. If other metals are present in notable proportions, their names are to be prefixed, so that an alloy containing, say 1 per cent. of tin, would be called "tin-brass." Similarly the term "bronze" is defined as equivalent to "tin-copper." Dr. Rosenhain, as chairman of the committee, in presenting the report, claimed that an important step would be gained if the recommendations in regard to the terms "brass" and "bronze" were widely adopted, because much of the present confusion centred around those very terms; he therefore appealed for the steady support of all concerned on the ground that even if the system put forward by the committee were not the ideally best one, what was really essential was uniformity of nomenclature. In the discussion, Sir H. J. Oram, on behalf of the Admiralty, several important manufacturers and consultants, and some professors and teachers of metallurgy promised their cordial support of the committee's recommendations, so that the committee may approach its further task of defining other alloy names with considerable confidence in the ultimate success of its labours.

Dr. Desch, in his first report to the Beilby Prize Committee, presented a valuable and interesting summary of existing knowledge on the solidification of solids from the liquid state in particular reference to the freezing of metals and Quincke's "foam cell" hypothesis. The report contains a great quantity of information and a useful bibliography; Dr. Beilby commended the impartial and judicial attitude of the reporter, but Dr. Rosenhain likened it to a judge's summing-up, which must, ultimately, be followed by a sentence, and this was unlikely to be in favour of Quincke's hypothesis. Thanks to the further generosity of Dr. Beilby in providing the necessary funds, the committee is in a position to invite a further report on fresh experimental work from Dr. Desch.

A paper by Dr. J. E. Stead and Mr. Steadman, on the "Muntz metal" brasses, dealt with the effects of heat treatment. In this respect the paper was shown —in the discussion—to have been largely anticipated by the much earlier work of Bengough and Hudson, but the paper gave rise to an interesting discussion. This dealt principally with a brass rod which had become disintegrated while in use as a floor-bolt in a high-tension electric power station. The bolt passes through the floor inside a procelain tube, and electrical leakage gives rise to the formation of nitric oxides in the air-space of the insulator tube. In the case described by Dr. Stead, and also in a similar one mentioned by Dr. Rosenhain in the discussion, the brass rod either had some minute cracks, due to slight hollow drawing, when first put in, or these were developed while the rod was in service. The nitric acid gases penetrated into these fissures and produced basic salts of zinc and copper which, by their increased volume, widened the cracks and ultimately led to the complete disruption of the rods. An initially sound, *annealed* brass rod suffers no such damage in the same conditions.

Other interesting papers, by Prof. A. Read and Mr. Greaves, on the influence of nickel on the alloys of aluminium and copper, by Mr. Dewrance on bronze, and by Messrs. Whyte and Desch on the micro-chemistry of corrosion, were read and fully discussed, the eminently successful meeting only terminating late in the afternoon.

AN EELWORM DISEASE OF RICE.

THE appearance of a rice-disease in eastern Bengal so serious that in certain districts the cultivators were in 1911 on the verge of ruin calls for special notice, since rice is, of all important cereals, the one perhaps least subject to serious disease. The matter is dealt with by Dr. E. J. Butler, mycologist to the Agricultural Research Institute at Pusa (Bihar), in a recent pamphlet (Bulletin No. 34, "Diseases of Rice"; Calcutta : Superintendent Government Printing, India, 1913).

The disease in question (called locally "ufra," from a word meaning "above," owing to a belief that atmospheric conditions are responsible for it) has existed long, but has only recently acquired such an intense form as to call for a special inquiry. From Dr. Butler's researches the active cause appears to be an eelworm, *Tylenchus angustus,* closely allied to the nematode which causes tulip-root in oats and other cereals. This Bengal worm, however, differs in its mode of attack from the Tylenchus of wheat and oats. It never enters the tissues of the rice-plant, but confines its ravages to epidemic organs wherever these are sufficiently soft and unsilicified to allow the entrance of the "spear" with which its mouth is armed. The inflorescence, the tissue above the nodes, and the growing point, are such weak places, and here the eelworm, both in mature and in larval stages, was abundantly found in all the plants exhibiting "ufra." The results of the attack of such large numbers of Tylenchus are discoloration of the stem and leaves, arrest of the inflorescence, sterility, and mouldiness. The extent of the damage is not accurately known, but in some districts is estimated to amount to half the normal crop.

This "ufra" disease is of a highly infectious quality. The eelworms swim through the submerged paddy-fields from one rice-plant to another, which they ascend and attack. Like their allies, these nematodes exhibit great powers of resistance to drought, but little to continued submergence; and hence it is somewhat difficult to account for their abundance in such flooded districts as the rice-growing lands in the Noakhali (eastern Bengal) district. Further investigations are needed on the bionomics of these parasites.

With regard to preventive measures, the only hopeful indication at present is the behaviour of transplanted rice in contrast to that of broadcast paddy. Dr. Butler shows that the former, though susceptible of attack by inoculation, is not attacked under ordinary conditions, and advocates an extension of the transplanted crop, the improvement of natural drainage, and the more systematic burning of the stubble. The importance of taking adequate prophylactic measures is seen in the geographical position of the infected area. On one side of it is the enormous paddy area of Bengal, on the other the Irrawaddy Delta, which supplies practically the whole of the export rice of India. "A serious disease of rice," says Dr. Butler, "is one of the greatest calamities that could befall the people" in the infected districts, "(where nearly three-quarters of the cultivated area is under paddy), for no other food crop can replace it."

METEOROLOGY IN NETHERLANDS' EAST INDIA.[1]

THE volume of observations before us contains the hourly readings made at the Batavia Observatory during the year 1910, which is the forty-fifth year of this uninterrupted series of hourly observations. Investigation of the upper air by balloons and kites has been regularly carried on, and important results were obtained. Several of the registering balloons attained heights exceeding 15 km. The number of ascents of pilot balloons amounted to 163; many were followed by means of theodolites to a height exceeding 10 km. The record height reached was 31 km. (on September 12, 1912).

The observations at secondary stations include (*a*) monthly and annual means of air-pressure reduced to the period 1866–1911. The influence of the high mountain range of Sumatra is shown in the deflections of the isobars in the direction parallel to the ridge; in the Indian Ocean, to the south-west of the island, there is a relative air-defect in the west monsoon, and an excess of pressure in the east monsoon. Dr. v. Bemmelen (director) also points out that in the west monsoon the isobars show a remarkable curvative over the sea between Borneo and Sumatra. (*b*) Sunshine observations 1909–11 : the tables give distinct evidence of the way the cloudiness increases with height above sea-level, and that insolation is stronger during the east monsoon in East than in West Java. A further discussion of results is postponed until more data are available. (*c*) Observations of temperature and relative humidity at the agricultural station at Tjipetir, Java, 1906–11. Owing to deficiency of sunshine in the afternoon, the maximum temperature is shifted towards the morning hours.

With respect to the climate generally, Dr. van Bemmelen remarks that rainfall is the ruling factor in the archipelago, as other meteorological elements are almost constant; the average yearly rainfall at Batavia is a little more than 70 in. The study of changes of weather is of little practical importance, as these are trifling, while a storm-warning service is unnecessary, as cyclones do not pass over the area in question. Although it is at present considered unnecessary to construct daily weather charts, the director thinks it would be of great scientific interest if the conditions could be followed by means of synoptical grouping for either weekly or monthly periods. In connection with this view, mercury barometers have been supplied to several places; it is also proposed to establish meteorological stations on a few of the mountains possessing relief of simple form.

EXPLORATION IN PERU.

THE Yale Peruvian Expedition of 1911 made a number of discoveries which, either for lack of time or means, could not at that time be given the attention they deserved. The most important of these finds were the ruins of Machu Picchu, in the Grand Cañon of the Urubamba, below Ollantaytambo, and a small quantity of human bones apparently interstratified with what seemed to be glacial gravel near the city of Cuzco.

FIG. 1.—Machu Picchu. Sacred Plaza. Chief temple, east side, interior. Copyright by the National Geographic Society.

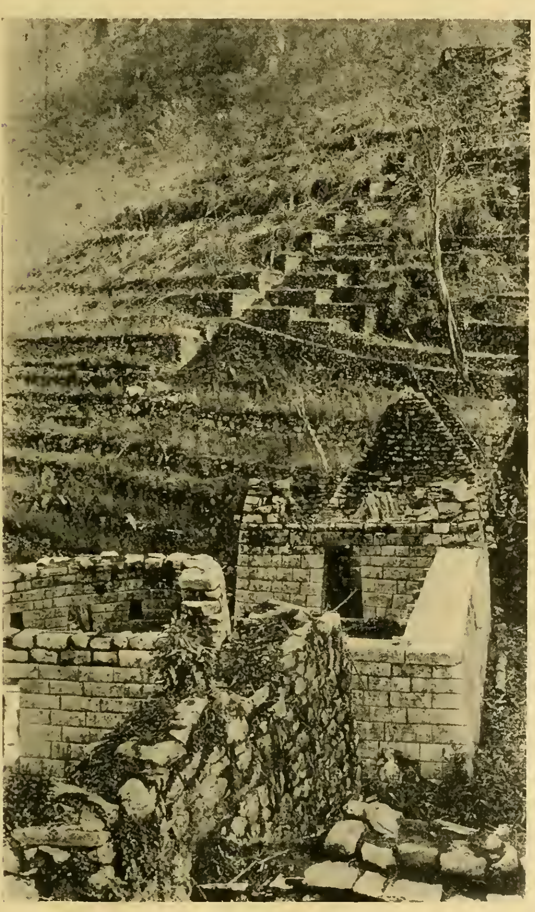

FIG. 2.—Machu Picchu. Princess group. View of round tower and ornamental wall. Shows in distance the agricultural terraces. Copyright by the National Geographic Society.

The Peruvian Expedition of 1912, sent out under the auspices of Yale University and the National Geographic Society, had for its chief objects the further study of these two discoveries and also the completion of certain topographical work planned for 1911, but not finished at that time.

The staff of the second expedition included, besides myself as director, Prof. H. E. Gregory, Silliman professor of geology in Yale University, geologist; Dr. G. F. Eaton, of the Peabody Museum of Yale University, osteologist; Mr. A. H. Bumstead, formerly of the United States Geological Survey, chief topographer; Messrs. K. C. Heald and R. Stephenson, assistant topographers; Mr. E. C. Erdis, archæological engineer; Dr. L. T. Nelson, surgeon; and Messrs. P. Bestor, O. Hardy, and J. P. Little, assistants.

The Cuzco Valley was carefully mapped by Mr. Bumstead and his assistants, and this map will be published in connection with the report on the geology of this valley now being prepared by Prof. Gregory. The geological work undertaken by Prof. Gregory consisted in part of a study ot the gravel deposits near Cuzco, and the relation in age and position of these gravels to the remains discovered in 1911. The result of these researches has not confirmed us in the opinion that the human bones found in 1911 are of very great age. It seems probable, on the other hand, that, owing to recent filling and recutting of the valley, the bones may be of recent origin. Prof. Gregory also carried on a general examination of the structure and stratigraphy of the Cuzco Valley with a view of constructing a geological map of the area tributary to the Huatanay River. The region was found to consist chiefly of sedimentary rock of pre-Tertiary, Tertiary, and Pleistocene age. During glacial times a lake occupied the upper part of the valley.

Not far from Cuzco, in the Apurimac Valley, near Ayusbamba, a small amount of vetebrate fossil material was found and collected by Dr. Eaton. His report on these fossils, which include the remains of both ancient horse and deer, will be published in the *American Journal of Science*.

Anthropometric measurements were made of 145 Indian men in the department of Cuzco, and front and side view photographs were taken of each subject. The Indians represented sixteen provinces and sixty towns. Thirty-eight measurements were taken of each subject. Photographs of many Indian women were also taken in Cuzco and vicinity. The anthropological material collected by Dr. Nelson has been placed in the hands of Prof. H. B. Ferris, Hunt professor of anatomy in Yale University, who is preparing a report which will be published in the near future.

The ruins of Choqquequirau, which had been visited by the present writer in 1909, were reached from the north side by Messrs. Heald, Eaton, and Nelson, of the expedition. A few boxes of bones and potsherds were collected. This party had great difficulty in carrying out its undertaking owing to the fact that no guides could be procured, and the way lay through a very rough country, where scarcity of water and a plague of flies were added to the many other difficulties.

Interesting but not highly important ruins were discovered by the writer near Palcay, in the Aobamba Valley, in the vicinity of an impressive group of glaciers hitherto unmapped and not reported. An interesting feature of one of the groups of ruins in this valley is that it appears to be exactly oriented; its two cross streets seem to run on the true, not on the magnetic, cardinal points.

The topographic cross section of the Andes along the 73rd meridian, begun by Mr. Kai Hendriksen in 1911, was completed in the face of great difficulties by Messrs. Bumstead, Hardy, and Little, and will be published in connection with the report of Prof. Isaiah Bowman, the geographer-geologist of the 1911 expedition.

The most interesting, and in many ways the most satisfactory, results of the 1912 expedition were in connection with the ruins of Machu Picchu. In 1911 the present writer, while engaged in a search for Vitcos, the last Inca capital, discovered a number of hitherto unreported groups of ruins in the valley of the Urubamba and its tributaries. The group known as Rosaspata, near Puquiura, in Vilcabamba, is believed to be that which the chroniclers called Vitcos, the capital where the young Inca Manco, set up by Pizarro, fortified himself after his revolt against the Spanish conquerors. But the ruins of Machu Picchu do not appear to have been connected with the later history of the Incas. These ruins are located on top of a ridge in the most inaccessible part of the Urubamba Cañon some 2000 ft. above the rapids, and some 8000 or 9000 ft. above sea-level.

FIG. 3.—Machu Picchu. Sacred plaza and Intihuatana Hill from boulder caves. Copyright by the National Geographic Society.

The presence here, in a wonderfully picturesque position, of a remarkably large and well-preserved abandoned city practically untouched by the hands of the spoiler, and apparently unknown to the Spanish chroniclers, led us to undertake to clear the city of its extensive jungles and to excavate the ruins. Many difficulties had to be overcome, but we were eventually successful in locating more than one hundred burial caves. The excavation yielded a considerable amount of anthropological material, including human and

FIG. 4.—Machu Picchu Sacred plaza. Chief temple, north wall, interior, showing the cracking caused by the settling of the east wall. Notice the care with which the size of the stones is made to decrease gradually in each ascending tier. The main altar stone is 14 ft. in length. Copyright by the National Geographic Society.

animal bones, a large number of potsherds and a few stone, silver, and bronze implements. Nothing of gold was found, and only half a dozen small silver pins and pendant discs.

The city itself contains about two hundred edifices. Most of the walls are standing and many of the terraces are in good repair. The roofs of the houses disappeared long since, and a large part of the city was completely overgrown with a tropical forest. Trees 2 ft. in diameter were found growing on top of the walls of the houses, and in some cases on the very peaks of the gables. A majority of the houses are of a storey and a half in height with gable ends.

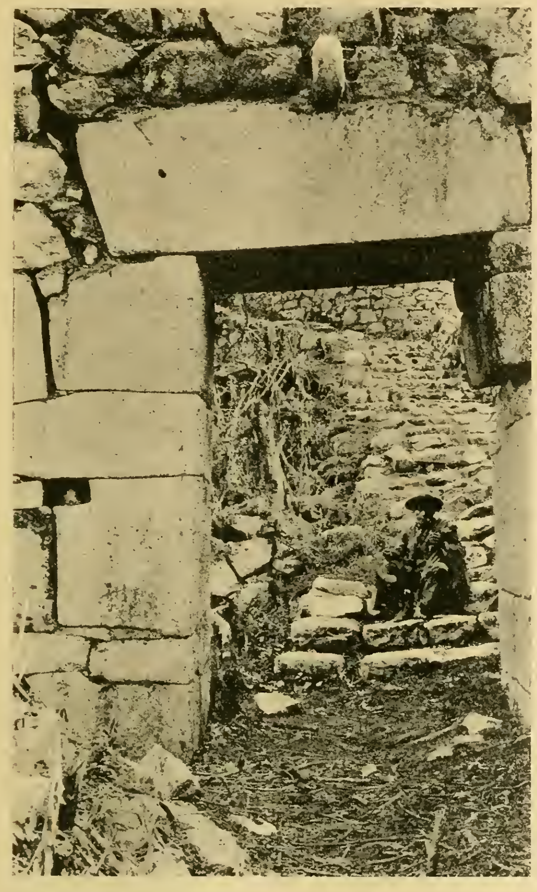

FIG. 5.—Machu Picchu. City gate, interior. Notice the lock hole containing granite cylinder on left and projecting ring stone over the lintel of the doorway. The gate, probably of wood, was either swung from the ring stone or fastened to it and balanced by a log fastened to the stone cylinders in the lock hole on either side of the gateway. A similar device was used also in the entrance doors to each isolated group of houses. Copyright by the National Geographic Society.

Perhaps the most conspicuous features of Machu Picchu are the number of stairways and the large number of windows in the houses. There are more than a hundred stairways, large and small, within the city. Some of them have more than 150 steps. In some cases the entire stairway of from six to ten steps was cut out of a single granite boulder. The water supply must always have been very scarce. We were there during the dry season, and with forty workmen found the available springs only barely sufficient for cooking and drinking purposes. The town may have had a population of two thousand people on occasion.

In the four months of field season, the ruins were practically cleared of all forest growth, and a large part of the débris was burned and removed. From twenty to forty workmen were kept continuously at work under the direction of Mr. Erdis.

One of the most interesting facts brought out as a result of the clearing was that the city was at one time divided into wards, or clan groups, each of which had but one entrance, a gateway furnished with the means of being solidly fastened on the inside. Each one of the clan groups has certain distinctive features, one having its own private gardens, another being distinguished by the ingenuity of the stone work, while still another is marked by having monolithic lintels over the doorways, and unusually steep gables. Machu Picchu contains examples of nearly every variety of architecture known to the Incas and their predecessors on the Peruvian highlands, including fine specimens of the most exquisite stone cutting that can be found anywhere in the New World. One of the most interesting structures is a temple containing three conspicuously large windows. Another is composed of several large blocks of granite, three of them being more than 12 ft. in length. These are shown in the accompanying photographs.

Machu Picchu is in a remarkably good state of preservation, and its architecture has not become confused by Spanish efforts to build churches and villas. The people who lived here were masters of the art of stone cutting. They know how to make bronzes, and they had considerable artistic sense. Their pottery is characteristically Inca in form and ornamentation, but some of the patterns and shapes are practically unknown in European museums.

Just where Machu Picchu comes in the history of the Incas is still a puzzle. It is too early to speak definitely. In many ways it appears to be closely related to Cuzco. One of the buildings bears a strong resemblance to the famous Temple of the Sun, now the Dominican Monastery. It is safe to say that Machu Picchu was essentially a city of refuge. There is no part of the Andes better defended by nature than this Grand Cañon of the Urubamba. Granite precipices, frequently more than 1000 ft. sheer, present difficulties of attack and facilities for defence which cannot be excelled. Furthermore, the natural defences were strengthened by the construction of high walls and a dry moat.

A careful survey of the ruins and the neighbouring cañon was made by Mr. Stephenson. More than seven hundred photographs of the ruins were taken by the writer, who has in hand the preparation of a complete report on the ruins and the material collected at Machu Picchu.

HIRAM BINGHAM.

CIVIL SERVICE ESTIMATES FOR SCIENCE AND EDUCATION.

THE Estimates for Civil Services for the year ending March 31, 1915, are being issued as a series of Parliamentary Papers. The following particulars referring to the money under this heading to be devoted to scientific work and to higher education are taken from the paper entitled, "Class IV.—Education, Science, and Art."

Under the heading, "Scientific Investigation, etc.," we find that the grants in aid for 1914–15 amount to 100,697*l*., which represents a net decrease of 11*l*. on the amount voted in 1913–14.

The grants enumerated under the heading of the Royal Society amount for 1914–15 to 25,550*l*., as compared with 27,150*l*. in 1913–14. This grant includes the usual 4000*l*. in aid of scientific investigation and 1000*l*. for scientific publications; the remainder of the amount is for the expenses of the Magnetic Observatory at Eskdalemuir, and for the National Physical Laboratory. For salaries and other expenses of the National Physical Laboratory the grant for 1914–15 is 7000*l.*, as compared with 12,000*l.* in 1913–14; but the grant for the Aeronautical Section of the National Physical Laboratory, which is given separate mention, is for 1914–15 12,550*l.*, as compared with 9150*l.* in 1913–14.

The following grants remain as they were in 1913–14:—Meteorological Office, 20,000*l.*; Royal Geographical Society, 1,250*l.*: Marine Biological Association of the United Kingdom, 1000*l.*; Royal Society of Edinburgh, 600*l.*; Scottish Meteorological Society, 100*l.*; Royal Zoological Society of Ireland, 500*l.*; Royal Scottish Geographical Society, 200*l.*; International Geodetic Association, 300*l.*; Solar Physics Observatory, 3000*l.*; North Sea Fisheries Investigation, 1250*l.*; International Seismic Association, 210*l.*

The grant to the Edinburgh Observatory is 1637*l.*, an increase of 89*l.* on 1913–14; and the British Antarctic Expedition receives 5000*l.* for the year 1914–15.

The grants in aid of the expenses of universities and university colleges amount for the year under consideration to 287,000*l.*, precisely the same sum as in the previous year.

The vote for science and art in Ireland reaches 145,164*l.*, as compared with 140,450*l.* in the previous year, a net increase of 4,714*l.* The estimate of the amount required for grants under the Irish University Act, 1908, is 124,000*l.*, a decrease of 1800*l.*

The estimate of the amount required to pay the salaries and expenses of the Board of Education and of the various establishments connected therewith is 14,730,621*l.*, a net increase of 70,552*l.* Among the items included in this large sum the following are of interest in this connection:—Technical institutions and evening schools, 638,000*l.*, an increase of 23,200*l.*; university institutions in respect of technological work, 48,000*l.*, an increase of 2000*l.*; Imperial College of Science and Technology, 30,000*l.*; Science Museum, 21,322*l.*, an increase of 2895*l.*; Geological Museum, 3925*l.*, an increase of 176*l.*; and the Geological Survey, 16,828*l.*, a decrease of 1047*l.*

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

GLASGOW.—The first award of the Kelvin gold medal and prize (founded by Lady Kelvin), for the best dissertation in natural philosophy presented for the degree of D.Sc. during the three years 1911–13, has been made to Dr. A. D. Ross, now professor in the University of Western Australia.

The first award of the William Jack prize (founded in honour of Emeritus Professor Jack), for the best dissertation in mathematics presented for the degree of D.Sc. during the four years 1910–13, has been made to Dr. R. J. T. Bell, senior University lecturer in mathematics.

LEEDS.—Mr. Aldred F. Barker, who has been head of the textile department of the Bradford Municipal Technical College for twenty years, has been appointed to succeed Mr. Roberts Beaumont as professor of textile industries. Mr. Barker is an old student of the University, having worked under Prof. J. Beaumont, the first occupant of the chair to which he now succeeds. He has had a considerable experience of actual mill work, and his publications are recognised as standard works on textiles.

Mr. Robert Cattley has been appointed honorary fellow in pathology, and Mr. Lionel Walmsley as honorary curator of the Marine Laboratory, Robin Hood's Bay.

MR. F. J. NORTH, assistant in the geological laboratory, King's College, London, has been appointed assistant keeper in the department of geology in the National Museum of Wales.

A COURSE of lectures on arts of East and West, by Laurence Binyon, will be given at the Battersea Polytechnic, London, S.W., on Wednesdays at 6 p.m., beginning May 6. The lectures are intended for advanced students; admission is free, and no ticket is required.

MR. PERCY COLEMAN, of the Northern Polytechnic Institute, Holloway, who has been appointed adviser in technical education and secretary to the National Board for Technical Education in the Union of South Africa, leaves for South Africa in the R.M.S. *Kinfauns Castle* on April 11.

A SUMMER School in Geography will be held on August 2–22 next at the University College of Wales, Aberystwyth. Prof. H. J. Fleure, lecturer in geography at the college, will give ten lectures on a regional survey of Europe, and eight on England and Wales. Mr. W. E. Whitehouse will give eight lectures on the teaching of geography by modern methods, five on the climate of the British Isles, and five on mathematical geography. In addition to the courses of lectures, practical work will be taken daily. Field classes will be held for practice in the use of simple survey instruments, while excursions will be made to places of interest, which afford material for the study of land sculpture, vegetation, and human facts.

WE learn from the *Times* that in accordance with a resolution passed at the joint meeting of the German and English sections of the King Edward VII. British-German Foundation, instituted by Sir Ernest Cassel, the German Foundation will again, in the year 1914–15, use part of its income in providing studentships to enable university graduates of British nationality to reside in Germany with the object of studying some branch of science or literature, or becoming acquainted with the commercial or industrial life of the country. The work of selection was even more difficult than last year, as the number of candidates was far larger, and most of them had obtained first-class honours in their universities. Studentships of the value of about 175*l.* were on March 21 awarded to Mr. B. Dickins, Magdalene College, Cambridge; Mr. R. A. Frazer, Pembroke College, Cambridge; Mr. S. W. Rawson, Queen's College, Oxford; Mr. G. G. Williams, Christ Church, Oxford; Mr. F. P. Wilson, Birmingham University and Oxford University; Mr. T. Wright, King's College, London University. Studentships of the value of about 100*l.* were awarded to Mr. A. B. Mayne, Balliol College, Oxford; Mr. J. S. Stephens, St. John's College, Cambridge.

SOCIETIES AND ACADEMIES.

LONDON.

Geological Society, March 11.—Dr. A. Smith Woodward, president, and afterwards Dr. H. H. Bemrose, vice-president, in the chair.—E. T. **Newton**: A series of small mammalian and other remains from the rock-shelter of La Colombière, near Poncin (Ain). During the year 1913, Dr. Lucien Mayet and M. Jean Pissot were working systematically at the prolific deposits of this locality, and towards the end of the year made known the discovery of a number of incised bones and stones, representing the human form as well as several animals. The upper part of the deposit is referred to the Neolithic and Magdalenian ages; but below this, at a depth of $6\frac{1}{2}$ ft., a bed (10 in. thick) was found, which yielded the incised drawings above-mentioned, as well as numerous mammalian remains and flint-implements; and this is regarded as of Aurignacian age. Immediately below the last-mentioned bed a deposit of sand and small rock-fragments was penetrated to a depth of 10 ft., and this deposit, also referred to the Aurignacian, was found to contain an enormous number of bones of small mammals and other animals. Some twenty species have already been recognised by the discoverers.—Dr. A. Smith **Woodward**: An apparently Palæolithic engraving on a bone from Sherborne (Dorset). The author is indebted to Mr. R. Elliot Steel, of Sherborne School, for the opportunity of studying a fragment of bone bearing an incised drawing of the fore-part of a horse in the style of drawings already well known from several habitations of Palæolithic man. The specimen was found in an old mound of débris from a quarry in the Inferior Oolite near Sherborne. No associated specimens of any interest were recovered; but at the lower end of the same valley, about a quarter of a mile distant, teeth of mammoth and woolly rhinoceros have been found. Like the only other British specimen hitherto discovered—that described by Prof. Boyd Dawkins from the Creswell caves—the drawing is made on a fragment of rib; and the neck of the horse is fringed by fine lines, which indicate the short hog-mane usual in sketches made by the Palæolithic race.

Royal Astronomical Society, March 13.—Major E. H. Hills, president, in the chair.—Dr. F. W. **Dyson**: Greenwich determinations of the photographic magnitudes of stars brighter than 9·0 m. between declination $+75°$ and the pole. The methods employed and the results obtained were described.—Dr. S. **Chapman**: The total light of the stars. His results showed that the total light of the stars was about equal to that which would be given by 630 stars of the first magnitude. The light given by stars of each magnitude somewhat increased down to the tenth magnitude, the greater number of stars compensating for the decrease of brightness of the individual stars. But below the tenth magnitude this was no longer the case, the light falling off more and more as we descend the scale.—Prof. J. W. **Nicholson**: The spectrum of hydrogen and helium.—H. H. **Turner**: Baxendell's observations of variable stars, edited by H. H. Turner and Miss Blagg. Difficulties had arisen through Baxendell's various ways of naming the stars, but a more serious matter was that there were so many unfortunate gaps in the series of observations. Comparison with the Rousdon observations showed discrepancies, which might be attributed to the attempt to estimate the maximum—always an extremely difficult matter.

Physical Society, March 13.—Dr. A. Russell, vice-president, in the chair.—Dr. C. **Chree**: Time measurements of magnetic disturbances and their interpretation. The paper is a sequel to one read in November, 1910, dealing with the times of commencement of fifteen magnetic disturbances discussed by Mr. R. L. Faris, and supposed by him to support Dr. L. A. Bauer's theory that the commencing movements of magnetic storms travel round the globe at rates of the order of 100 km. a second. The author suggested then that, for an adequate test of Dr. Bauer's theory, data could only be obtained from a number of stations encircling the earth. Shortly afterwards Dr. Bauer issued a circular requesting magnetic observatories to send him their measurements of the times of commencement of the fifteen magnetic storms. Upwards of thirty stations sent in data. A discussion of the data derived from the horizontal force curves has been published by Dr. Angenheister, whose conclusions are unfavourable to Dr. Bauer's theory. The present paper deals with the data from the declination and vertical force curves as well as those from the horizontal force curves. The bearing of the data on Dr. Bauer's theory is discussed.—H. N. **Mercer**: The ratio of the specific heats of air, hydrogen, carbon dioxide, and nitrous oxide. The object of the experiments was to test the accuracy with which γ could be measured, employing small quantities of the gas, with the view of experiments on the variation of γ with temperature. The method employed was to observe with a platinum thermometer of very fine wire the instantaneous fall of temperature corresponding to a given rapid fall of pressure. The apparatus employed was similar to that used by Makower, but it was found that with due precautions an equal degree of accuracy was obtainable with a vessel of only 300 c.c. capacity. A table is given showing the values of the specific heat at constant pressure for the various gases as calculated from the present experiments. The values show good agreement with direct calorimetric determinations.—A. J. **Philpot**: The asymmetric distribution of the secondary electronic radiation produced by X-radiation. Prof. S. P. **Thompson**: A lecture experiment on the irrationality of dispersion. Newton's method of crossed prisms throws an oblique spectrum on the wall. If the prisms used are of identical kinds of glass the oblique spectrum is straight from red to violet; but if different kinds of glass are used, the spectrum is curved by reason of irrationality of dispersion. If a diffraction grating is used instead of one of the prisms, then the curvature observed is that resulting from the irrationality of dispersion of the particular prism employed. To exhibit these effects in the lecture theatre a diffraction grating of 12,000 lines to the inch is employed to cast a horizontal spectrum of the first order, the light from an arc lamp being sent through a small hole. On interposing a prism to disperse the light vertically upwards, the resultant oblique spectrum is finely curved, being concave upwards.

Zoological Society, March 17.—Prof. E. A. Minchin, vice-president, in the chair.—L. N. G. **Ramsay**: (1) The annelids of the family Nereidæ, collected by Mr. F. A. Potts in the N.E. Pacific in 1911, with a note on Micronereis as a representative of the ancestral type of the Nereidæ. (2) The genera Ceratocephale, Malmgren, and Tylorrhynchus, Grube.—A. Kynvett **Totton**: The structure and development of the caudal skeleton of the Teleostean fish, *Pleuragramma antarcticum*.—G. C. **Robson**: Report on Mollusca from Dutch New Guinea collected by the British Ornithologists' Union and Wollaston Expeditions. In general, the collection appears to endorse Hedley's views as to the Oriental affinities of the Papuan molluscan fauna. Though numerically small in species and individuals, the collection has yielded two genera and three new species, the anatomy of all of which is described.—P. R. **Awati**: The mechanism of suction in *Lygus pabulinus*, Linn. This is a Capsid bug injurious to the foliage of the potato, on which it feeds. A detailed description of the morphology and anatomy of those organs of the head concerned in sucking the plant-juices is followed by an account of their mode of action, in part deduced from their structure and arrangement, in part derived from observation of the living insect.—K. G. **Blair**: Report on the Heteromerous Coleoptera collected by the British Ornithologists' Union and the Wollaston Expeditions in Dutch New Guinea. The most interesting feature of the collection, from the point of view of distribution, is the occurrence of *Cissites maxillosa*, Fab., in this region. This beetle has been hitherto regarded as peculiar to the Oriental region, its range extending from Assam to Java, Borneo, and the Philippine

Islands; it has also been found in Ceylon.—R. **Lydekker**: The Malay race of the Indian elephant. The author made the young Negri Sembilan elephant, formerly living in the society's gardens, the type of a new race, *Elephas maximus hirsutus*, subsp. n., characterised by the square, instead of triangular, form of the ear, the early date at which its upper margin is bent over, and the presence in the young condition—at least, in some cases—of a thick coat of black and in part bristly hair.—Prof. W. J. **Dakin**: The fauna of Western Australia: (1) the Onychophora, (2) the Phyllopoda.

Mineralogical Society, March 17.—Dr. A. E. H. Tutton, president, in the chair.—F. P. **Mennell**: An occurrence of bornite nodules in shale from Mashonaland. The ore-body of the Umkondo mine in south-east Mashonaland consists of a bed of shale through which are scattered nodules of bornite, most probably pseudomorphous after concretionary pyrites. The enclosing rocks are of the same age as the Waterberg series of the Transvaal, and contain pseudomorphs after salt in some of the shale bands. The occurrence of copper and salt at nearly the same horizon is paralleled in the Lower Keuper beds of Europe.—A. **Scott**: Augite from Bail Hill, Dumfriesshire. It occurs in crystals, which are black in colour, but yellowish-green in thin sections, and of two types, simple and twinned, and have the axial constants $a:b:c = 0{\cdot}5844:1:1{\cdot}0932$, $\beta = 105^\circ\ 48'$, and refractive indices 1·708, 1·713, 1·728. Sections parallel to the plane of symmetry show the hour-glass structure characteristic of titaniferous augite.—Dr. G. T. **Prior**: A sulpharsenite of lead from the Binnenthal. Analysis of the crystals, on which the prism zone alone was developed, showed that the composition corresponded to the formula, $3PbS.2As_2S_3$, which is that attributed to rathite; crystallographically, however, the crystals seem nearer to dufrenoysite.—Dr. G. T. **Prior**: Phacolite and gmelinite from co. Antrim. In both instances analyses of these minerals, which are varieties of the same species, differing in habit of crystal, showed an excess of hydrated silica over the composition represented by the formula, $(Ca,Na_2)Al_2Si_4O_{12}.6H_2O$.

Royal Meteorological Society, March 18.—Mr. C. J. P. Cave, president, in the chair.—Prof. A. C. **Seward**: Climate as tested by fossil plants. The difficulty of using fossil plants as tests of climate becomes increasingly great in proportion to the degree of difference between the extinct types and their nearest living relations. It is from the examination of petrified plants, the delicate tissues of which are almost perfectly preserved, that data may be obtained throwing light on climatic conditions. This method of inquiry is best illustrated by a consideration of some of the anatomical features of the leaves, stems, and roots of trees which grew in the forests of the Coal period; the form and arrangement of cells in the leaves indicate fairly bright sunlight; large spaces in the cortex of roots point to growth in swamps. The geographical distribution of plants during the latter part of the Palæozoic era affords evidence of the existence of two botanical provinces, a northern province characterised by a luxuriant flora living under conditions more genial than those to which the poorer flora of the southern hemisphere was exposed. The presence or absence of rings of growth in the petrified stems of plants may afford evidence of the occurrence or absence of seasonal changes. A general survey of the Jurassic flora of the world leads to the conclusion that the climate was comparatively uniform, and in Arctic and Antarctic regions much more genial than at the present day. The fossil floras of more recent geological periods furnish clear evidence of subtropical conditions in Europe; in later times the occurrence of northern types in Britain heralds the approach of the Glacial period, and in post-Glacial beds are found fragmentary remains of immigrants from neighbouring floras which have largely contributed to our present flora.

Paris.

Academy of Sciences, March 9.—M. P. Appell in the chair.—H. **Deslandres** and A. **Perot**: The design of an electromagnet capable of giving a magnetic field of 100,000 gauss. The limits of the magnetic field are imposed by the saturation of the iron and the heating of the bobbins. By a special method of cooling the bobbins and modifying their position with respect to the iron core the authors have already obtained a field of 51,500 gauss. For the proposed magnet, keeping the same concentration of ampere-turns, the copper used is to be pure, and strongly cooled petrol to be utilised to carry away the heat generated in the coil. On account of the large consumption of electrical energy it will be necessary to set up the magnet close to a large generating station to reduce the cost of the current. G. **Gouy**: The action of gravity on gaseous mixtures, notably in the terrestrial atmosphere. From a mathematical investigation it is concluded that the action of gravity on the composition of air is too slow to produce sensible effects except in the inaccessible region where the pressure is comparable with that in a Crookes tube.—Paul **Sabatier** and Léo **Espil**: The reduction of nickel protoxide and the existence of a sub-oxide. The reduction of oxide of nickel NiO by hydrogen has been studied at varying temperatures, the reaction being followed by weighing the water formed. Reduction is more readily effected on an oxide which has been formed at a low than at a high temperature, and an increase in the velocity of the current of hydrogen also increases the reduction. The velocity of reduction is an exponential function of the temperature. There are indications of the formation of a sub-oxide, Ni_4O; this is also reduced but at a slower rate than the original NiO.—P. E. **Gau**: General transformations of differential systems.—G. **Armellini**: The general theorem on the problem of n bodies.—Victor **Vâlcovici**: Hydrodynamic resistance in non-uniform movement.—Charles **Rabut**: The calculation of the forces developed by the contraction of cement in armoured concrete.—Th. De **Donder**: The kinematic interpretation of Poynting's theorem.—Louis **Benoist** and Hippolyte **Copaux**: The application of the laws of transparency of matter to the X-rays to the determination of some contested atomic weights. Cases of thorium and cerium. From the opacity to the X-rays the values 232 and 140 are found to be the most probable atomic weights for thorium and cerium respectively.—Georges **Claude**: The light yield of neon tubes as a function of their diameter.—B. **Szilard**: A radium lightning conductor. A small disc carrying a radium preparation is placed beneath the point of the conductor. The electrical effects observed with this in air are described.—H. **Parodi**: An arrangement of rings or brushes capable of replacing the collector in dynamos.—E. **Rothé** and R. **Clarté**: The influence of the state of the atmosphere on the propagation and reception of hertzian waves.—Mme. N. **Demassieux**: Study of the equilibrium between the chlorides of lead and sodium in aqueous solution.—Léon **Guillet**: The alloys of copper, nickel, and aluminium. Measurements of the elastic limit, breaking strain, hardness, and resilience of three sets of alloys containing 60, 83, and 90 per cent. of copper, and varying proportions of nickel and aluminium.—R. **Lespieau**: Passage from the dimethyl ethers of the acetylene glycols to the glycols.—E. E. **Blaise**: The formation of rings from the 1:4 diketones.—H. **Gault**: Oxalacetic ester.

—Georges **Dupont**: The stereochemical isomers of some γ-glycols.—Paul **Brenans**: Iodine compounds obtained from orthonitroaniline and orthonitrosulphanilic acid.—Const. A. **Ktenas**: Metamorphic phenomena at the island of Sériphos.—C. **Gaudefroy**: The dehydration figures of potassium ferrocyanide.—Louis **Matruchot**: Progressive cultural variations of *Tricholoma nudum*.—J. M. **Lahy**: The objective signs of fatigue in professions not requiring muscular effort. The variations in the blood pressure and reaction time were found to give useful indications of this class of fatigue.—Louis **Lapicque**: The economy in food realisable by raising the external temperature. A discussion of a recent note on this subject by Miramond de Laroquette.—E. **Voisenet**: New researches on a ferment contained in waters, the dehydrating agent of glycerol.—G. de **Gironcourt**: The milk ferments in the Touareg.—Paul **Bertrand**: Relations of the imprints of Corynepteris with Zygopteris.—E. **Bénévent**: Glacial action.—Ph. **Flajolet**: Observations made at the Lyons Observatory during the hurricane of February 22, 1914.—E. A. **Martel**: The Beatus-Höhle (Switzerland) and underground water of limestones.—De Montessus de **Ballore**: Luminous phenomena accompanying the earthquake at Rauhe Alb, November 16, 1911.

March 16.—M. P. Appell in the chair.—Ch. **Lallemand**: The twenty-four hours dial. For telegrams and railway time-tables numbering the hours from 0 to 24 has distinct advantages. In the author's opinion there is no advantage, however, in dividing the clock dial into twenty-four hours instead of the usual twelve.—A. **Haller** and Jean **Louvrier**: Syntheses by means of sodium amide. Preparation of some of the higher homologues of mono- and di-methyl camphors, as well as the corresponding camphols. The sodium amide method has been applied to the preparation of ethyl- and diethyl-camphor, methylethylcamphor, propyl- and dipropyl-camphor, benzyl- and dibenzyl-camphor and ethylbenzylcamphor. All these have been reduced to the corresponding camphols, the properties of which are described.—Paul **Sabatier** and M. **Murat**: The direct hydrogenation by catalysis of the diaryl ketones and the aryl alcohols. The preparation of polyaryl alcohols. Benzophenone is reduced by hydrogen in presence of nickel to diphenylmethane; with a more active nickel the reduction can be carried to di*cyclo*hexylmethane. The reaction, which is a general one, is shown to hold for the higher homologues of benzophenone.—Charles **Richet**: Hereditary tolerance of toxic substances in the lower organisms. The lactic acid ferment was grown in presence of toxic substances (potassium arseniate, phosphate, seleniate, nitrate), and after several successive cultures was found to acquire a resistance to the action of the toxic body present.—A. **Laveran** and G. **Franchini**: The infection of mice by means of the flagellæ of the rat flea by the digestive tract.—C. **Guichard**: Asymptotic networks and congruences.—J. **Guillaume**: Observation of the partial eclipse of the moon on March 11, 1914, made at the Lyons Observatory.—F. **Courty**: Observation of the eclipse of the moon of March 12, 1914, at the Bordeaux-Floirac Observatory.—Henry **Bourget**: Observation on the same made at Marseilles.—W. **Blaschke**: The evaluation of double integrals of convex functions.—R. **Jentzsch**: The extension of a theorem of Laguerre.—Henri **Frossard**: The whispering voice and in general the flow of a fluid under pressure in a capsulism going from zero to infinity.—Léon and Eugène **Bloch**: The spark spectra of nickel and cobalt in the extreme ultra-violet. Measurements are given for wave-lengths between 2100 and 1850.—J. de **Kowalski**: The different spectra of mercury, cadmium, and zinc. The metallic vapours were examined at different pressures, governed by the temperature of a piece of metal in a subsidiary quartz bulb. The discharge was produced without electrodes, by surrounding the quartz bulb containing the vapour with several turns of copper wire carrying a high-frequency current. The lines observed varied with the vapour pressure of the metal.—Jean **Timmermans**: Pure propane: the weight of a normal litre. Two sets of density measurements were made, the gas in the first set being prepared by Lebeau's method from propyl iodide and sodium amide, and in the second set by the reduction of propionitrile by sodium. The final purification in both cases was effected by fractional distillation. The mean result (seventeen observations) was 2·01955 grams per litre.—J. **Bancelin**: The absolute measurement of adsorption coefficients. The adsorption was studied on known areas of glass plates, and results are given showing the quantities adsorbed in grams per sq. cm. at different concentrations of the solution.—Eugène Louis **Dupuy**: The magnetic susceptibility of some feebly magnetic alloys. Alloys of silver and antimony, lead and tin, and zinc and aluminium were studied, and the results given graphically, the magnetic susceptibilities being taken as ordinates and percentage composition as abscissæ.—A. **Colani**: Ferrous and chromous metaphosphates.—Marcel **Dubard**: The relations of the principal genera of Mimusopeæ between themselves and with the Sideroxyleæ.—J. **Beauverie**: The chondriome of the Basidiomycetes.—G. **Kimpflin**: The laws of physical growth during childhood and adolescence. A continuous study of 200 children from the age of eleven to sixteen years. Relations between the height, weight, and thoracic perimeter.—L. and M. **Lapicque** and R. **Legendre**: Change in the excitability of nerves caused by an alteration in their myeline sheath. The action upon the nerve of the frog of chloroform, ether, cocaine, strychnine, sodium oxalate, solanine, and morphine is detailed.—A. **Magnan**: The characteristics of the marine birds.—Louis **Léger**: A parasite of the trout, belonging to genus Dermocystidium.—Edgard **Herouard**: Pædogenesic pæcilogony in *Chrysaora isoceles*.—Adrian **Lucet**: Researches on the evolution of *Hypoderma bovis* and the means of destroying it.—J. **Deprat**: The presence of the marine Rhætian with coal, on the western border of the delta of the Red River, Tonkin.—Paul **Fallot**: The stratigraphy of the Sierra of Majorca.—Ph. **Flajolet**: Perturbations of the magnetic declination at the Lyons Observatory (Saint-Genis-Laval) during the fourth quarter of 1913.

THE SYRIAN GODDESS.

The Syrian Goddess; Being a translation of Lucian's "De Dea Syria" with a Life of Lucian. By Prof. H. A. Strong. Edited with notes and an introduction by Dr. J. Garstang. Pp. xiii+111. (London: Constable and Co., 1913.) Price 4s. net.

In view of recent excavation upon sites in Syria, and of the increased interest the ancient cults of that region have for the archæologist, it was well worth while to produce an annotated edition of the well-known treatise "De dea Syria." The editors accept the traditional ascription of the work to Lucian, and there is much to be said for this view; for, although the rest of Lucian's works are written in pure Attic Greek, he may well in his early youth have adopted the Ionic dialect for this treatise in imitation of Herodotus. We should then assign its composition to the middle of the second century B.C. In any case, the record is that of an intelligent traveller who is anxious to make known the facts he has been able to ascertain as to the strange Oriental rites of Syria, and as such it has the very greatest value for the archæologist. Its author describes the cult and temple of the goddess of North Syria, Atargatis, and that of her male consort, at Hierapolis, near Mumbij, on the Euphrates. It has long been recognised that Atargatis was a combination of the Cilician goddess Atheh with Athar, the Aramaic form of the goddess Astarte or Ishtar.

In his introduction Prof. Garstang would trace her descent from a still more remote antiquity, connecting her with the chief goddess of the Hittites, the great nature-mother who appears in the Anatolian rock-sculptures. One of the earliest of her images may well be that mysterious and gigantic figure carved in the living rock on Mount Sipylus, near Smyrna. The fact that Atargatis of Hierapolis is always represented as robed upon coins from the site is in favour of the Hittite comparison; and the descent of her consort from the Hittite and Mitannian weather-god Teshub is rendered probable by the fact that the author of the treatise, "De dea Syria," identifies him with the Syrian Adad. Thus it may well be that much of the cult the author describes had been inherited from the ritual of the Anatolian deity as practised fifteen centuries before he wrote.

Prof. Garstang's notes and introduction give evidence of wide reading in the course of his study of this interesting theme, and the book will form a useful supplement to the collection of material he has already published in his larger work on "The Land of the Hittites." L. W. K.

STONES AND SUPERSTITIONS.

The Curious Lore of Precious Stones. By Dr. G. F. Kunz. Pp. xiv+406+63 plates, and numerous illustrations in the text. (Philadelphia and London: J. B. Lippincott Company, 1913.) Price 21s. net.

Dr. Kunz's wide knowledge and experience in connection with precious and semi-precious stones, and his familiarity with the voluminous literature dealing with the subject, afford a sufficient guarantee to all interested in gems and their "curious lore," that the work he has now produced is one of exceptional value. On the title-page of this handsome volume the subjects to be dealt with in relation to gems are enumerated as "their sentiments and folk-lore, superstitions, symbolism, mysticism, use in medicine, protection, prevention, religion, and divination, crystal-gazing, birth-stones, lucky stones, and talismans, astral, zodiacal, and planetary"—and this long list is far from exhausting the mass of extraordinary and fanciful ideas treated of in the book, and constituting one of the strangest illustrations of human credulity and love of the marvellous.

With regard to the disputed question as to whether precious stones first came to be prized as ornaments or talismans, our author does not attempt to give a decision; he justly points out that the absence of precious stones in the oldest known interments, where shells, etc., appear to be used as ornaments, may be accounted for by the hardness of the stones which prevents easy perforation. Jet ornaments, however, occur with Palæolithic remains, both in the caves of Belgium and Switzerland, and harder stones are found in Neolithic graves. Of the early use of stones as fetishes there is no doubt; life, sex, powers of reproduction, and many extraordinary virtues and influences were ascribed to them at the dawn of history. Magic formulæ concerning stones are found alike in the clay tablets of Sumero-Assyrian age and in Egyptian papyri of very early date. The earliest engraved cylinders of Babylon are ascribed to 4000 B.C., and scarabs of Egypt to 2000 B.C., while amber was found in abundance in the graves of Mycenæ. In classical times magical influences were ascribed to the beautifully engraved gems, partly on account of the materials of which they are composed, and partly from the figures and inscriptions which they bore, and when in medieval times the art of gem-engraving was lost, the gems were still made serviceable by the representations of Greek deities being regarded as those of Christian saints, liturgies being composed by means of which—the old love of ornament and mysticism remaining—the heathen relics were reconsecrated for Christian use.

Of the persistence to recent periods, and even to our own day, of fanciful and superstitious beliefs concerning precious stones, Dr. Kunz gives many amusing illustrations. In a book published in Frankfort as late as 1718, an "airship" is represented which is raised by the supposed action of sunlight upon the "coral-agates" in its roof, a "magnetic action" being thus produced! Napoleon, when in Egypt, found a carnelian seal engraved with Arabic characters, which he wore as a talisman until his death, and it was equally treasured and carried at all times by Napoleon III. The ill-fated Prince Imperial had it on his person in South Africa, and it appears to have been carried off by the Zulus who stripped his body. It is asserted that a well-known noble lady, still living, believes that her diamonds not only have life and sex, but are capable of reproduction; while a recent trial in Paris showed that a wealthy lady became suddenly so overcome by fear of the evil influences of an opal-ring she wore that she slipped it off and put it on the finger of a poor girl who was passing. It is declared that a well-known authoress confesses that she habitually resorts to "crystal-gazing" to recover the thread of a story that she has temporarily lost.

Many very interesting extracts are given by Dr. Kunz from curious and little-known works, which illustrate alike the wildly absurd views held in all ages concerning the various influences exercised by different precious stones on those who wear them, and the cures and other wonders wrought by them, these ideas prevailing not only among the poor and ignorant, but among the educated of all classes and religions. The book, which is admirably illustrated, is as entertaining as it is instructive.

J. W. J.

ANIMAL MORPHOLOGY AND EMBRYOLOGY.

(1) *A Text-book of General Embryology.* By Prof. W. E. Kellicott. Pp. v + 376. (New York: Henry Holt and Co., 1913.) Price 2.50 dollars.

(2) *Zellen- und Gewebelehre Morphologie und Entwicklungsgeschichte.* Unter Redaktion von E. Strasburger und O. Hertwig. Bearbeitet von E. Strasburger, W. Benecke, R. Hertwig, and others. I. Botanischer Teil. Unter Redaktion von E. Strasburger. Bearbeitet von E. Strasburger und W. Benecke. Pp. vii + 338. Price 10 marks. II. Zoologischer Teil. Unter Redaktion von O. Hertwig. Bearbeitet von R. Hertwig, H. Poll, O. Hertwig, and others. Pp. vii + 538. (Berlin and Leipzig: B. G. Teubner, 1913.) Price 16 marks.

(3) *Elementares Praktikum der Entwicklungsgeschichte der Wirbeltiere mit Einführung in die Entwicklungsmechanik.* By Dr. Oscar Levy. Pp. viii + 183. (Berlin: Gebrüder Borntraeger, 1913.) Price 5.60 marks.

(1) THIS is an excellent book to place in the hands of intermediate students of zoology; it gives a clear and interesting account of the more general aspects of embryological science. If the hypercritical reader regards it as somewhat scrappy and superficial, it must be answered that this is unavoidable in a book of its size dealing with so large a subject. The book does not pose as a work of reference; its function rather appears to be to give the student an idea of the present-day point of view of biologists towards the various problems of which it treats, to arouse his interest, and to direct his steps towards the fuller expositions to be found in contemporary literature.

An introductory chapter upon ontogeny is followed by excellent chapters on the cell and cell-division, the germ cells, and the process of maturation or meiosis. In regard to the last-mentioned phenomenon a very good and clear account of modern views is given. A few obvious slips will, no doubt, be corrected in a new edition, *e.g.*, in the legend attached to Agar's figure illustrating the spermatogenesis of Lepidosiren the last six words convey an erroneous statement, and should be excised. Again, in the description of tetrad formation the student will be liable to be puzzled, if not misled, by the wording of the statement that "each of the newly-organised bivalent elements comes out in the form of four small bodies, the tetrads." He may find himself in a similar position when he reads that in cases where tetrad formation takes place "the secondary spermatocytes have the diploid number." Good accounts are given of fertilisation, and of the general features of segmentation, including "cell-lineage," and these are followed by an excellent chapter on the differentiation of the embryo, heredity, and sex determination. In this chapter we welcome particularly the short and clear and critical account of the hypothesis of "organ-forming substances," which will act as a useful corrective to the somewhat prevalent teaching of this hypothesis by uncritical teachers as a well-established theory. As the author puts it, the localised distribution of substances in the egg, upon which this hypothesis is based, is to be regarded rather as a process or result of development than as a primary determining factor of the course of development. A good account is given of the idiochromosome and its relation to sex, and the book ends with a chapter on blastula, gastrula, and germ-layers.

The book is excellently written, and clearly illustrated; it fills an obvious gap in the teaching literature of zoology, and it deserves to have a wide circulation amongst students of that science.

(2) The two biological volumes here under discussion fully maintain the high standard of the great series of volumes entitled "Die Kultur der Gegenwart." The botanical volume is composed of an excellent section on plant histology from the pen of the late Prof. Strasburger, followed by one on plant morphology and development by Benecke.

The zoological volume forms an interesting text-book which will be of use to the senior student as a help towards getting a grip of the current views regarding some of the more important problems of morphology. The volume opens with a charming essay by Richard Hertwig upon unicellular organisms, which gives an excellent sketch of present-day ideas, together with valuable indications regarding future work. Hertwig's essay is followed by a useful sketch of modern histology by Poll, and this in turn by an admirable chapter by Oscar Hertwig on general and experimental morphology and embryology. This commences with a masterly account of the main features of gametogeny and fertilisation—one of the most interesting sections being that in which is given an account of recent experiments in which gametes or zygotes have been subjected to the influence of such substances as radium and mesothorium. An excellent chapter is devoted to parthenogenesis, and the suggestion is brushed aside with scant ceremony that the production of parthenogenesis by artificial means — whether chemical or mechanical—gives any clue whatever to the ultimate nature of the fertilisation process. A witty paragraph is quoted from Bolzmann as to Loeb's work and the exaggerated claims based upon it. How important was the discovery that a process believed to be so essentially vital in its nature was merely chemical! What important consequences the discovery might have when future developments rendered possible its application to the human race—the emancipation of woman to a degree undreamt of by the greatest enthusiast for women's rights! The mere man becomes superfluous; he is replaced by a flask of chemical solution; sex-determination by chemical means follows, and males, now mere useless curiosities, are produced only as occasional specimens for zoological gardens!

A general description is given of the processes of segmentation and gastrulation, and the chapter concludes with a short sketch of the chief results of experimental embryology.

About 150 pages are occupied by a really admirable account by Heider of the morphology of the invertebrate metazoa. It is most clearly and interestingly written, and is illustrated by excellent figures. Naturally, views are occasionally expressed to which some may take exception, but, on the whole, we know of no better general account of the morphology of invertebrates. The subject-matter of the chapter is rightly termed morphology rather than comparative anatomy, confining itself as it does to really important features and ignoring those masses of unimportant detail that so usually make a modern text-book of zoology an effective stifler of all interest in the subject. We notice very few slips. The familiar German misuse of the word splanchnopleure when splanchnic mesoderm is meant catches the eye of the English reader. The frequent reference made to the trochosphere type of larva as an evidence of phylogenetic affinity will not altogether appeal to those who suspect the various larvæ of this type of being simply convergent adaptations to a pelagic existence, while some morphologists of the Cambridge school will look askance at the not unfamiliar attitude towards the primitive and ancestral nature of the lower platyhelminths. But the general opinion will be that Heider has produced a very admirable sketch of his subject.

The remaining two chapters—on vertebrate embryology by Keibel and on vertebrate morphology by Gaupp—are less satisfactory. It seems an error in planning the book to have two such separate chapters, as there can be no morphology worth the name without embryology, and no embryology worth the name without morphology. We are glad to see that Keibel is not overawed by the sanctity of that—in some respects—most highly specialised vertebrate Amphioxus, and that he takes the common-sensible position in regard to the greatly degenerate character of its head region, though we fail to follow him in his somewhat derogatory remarks regarding its gastrulation processes. It seems, by the way, regrettable that Keibel, like many others who are specially interested in the embryology of the higher vertebrates, uses the word gastrulation in a sense which does not seem to be justified. Strictly speaking, the term gastrulation should only be used of forms in which an undoubted gastrula has been shown to be present; to use it in reference to the two-layered condition of a bird or mammal in which there is the greatest reason to doubt that a true gastrula stage exists at all, is simply to court confusion, and leads to such absurdities as the statement that "endoderm," or "ectoderm," is not homologous throughout the series of vertebrates. To give a cell-layer, the name endoderm in the various types of vertebrates is, of course, merely a short way of stating that it *is* homologous in these various types!

(3) Dr. Levy's book affords a short sketch of vertebrate embryology written from a practical point of view. Simple instructions as to laboratory methods are given, stress being very properly laid on the preparation of thick, free-hand sections of embryos—the great instructiveness of which is too often ignored. The chapter on technique is followed by an account of gametes and gametogenesis, then by chapters on early development in amphibia and in the chick, while the remaining half of the book is devoted to organogeny and a short chapter on developmental mechanics.

OUR BOOKSHELF.

The Change in the Climate and its Cause. By Major R. A. Marriott. Pp. 94. (London: E. Marlborough and Co., n.d.) Price 1*s.* 6*d.*; cloth 2*s.* 6*d.*

THIS book is a contribution to the great Drayson Myth, and as such it may appeal to those with whom it is a fair presumption that any theory of orthodox science is wrong, and also to those who take a curious interest in the vagaries of that class of mind.

Major Marriott, like Sir A. de Horsey in "Draysonia," complains that Drayson was not taken seriously. The fact is perfectly true, but the complaint is unjust precisely because General Drayson (not without professional precedents) failed to take seriously the position he was assailing. Astronomy is unique among sciences in its dependence on a single controlling principle, gravitation. It is open to anybody to abolish that principle and coordinate the facts otherwise—if he can. Or he may question the accuracy in detail of a mathematical deduction or demonstrate a false assumption. What he cannot do is to isolate a piece of the whole doctrine, reject the operation of the general law in the particular case on insufficient grounds, and ignore the effect of what he is doing on the whole related theory.

It would be unprofitable to comment on the errors (as we deem them) of the present work. It is pleasanter to mention the one pertinent remark which we have come across. This is the reference to the theory of "planetary inversion" (p. 66). It is quite possible that tidal friction is slowly changing the obliquity of the ecliptic, and thus exercising a secular influence on climate. But the effect is very slow; it is not periodic; and there is little in common between the methods of Mr. Stratton and those of General Drayson and his followers.

The book deals largely with changing climatic conditions, the evidence of geology, and the bearing of the so-called astronomical theory of an ice age. But why are the possibilities limited by the tacit assumption that the radiation of the sun has been constant through geological ages, an assumption not merely unproved, but even improbable? H. C. P.

Perspective made Easy by Means of Stereoscopic Diagrams. By C. E. Benham. (Colchester: C. E. Benham, 28 Wellesley Road.) Price (post free) 6*s.* 2*d.*

THIS set of fifteen stereograms is intended as a substitute for models as used by teachers and students in illustration of some of the rules and principles of perspective projection. When viewed in a stereoscope the diagrams exhibit in relief, amongst other things, the principle of the convergence or parallelism of the projections of parallel lines in space; and the rotation into the picture plane of horizontal and vertical vanishing planes, thus illuminating the constructions relating to vanishing and measuring points for horizontal and inclined lines. An explanation is given in a sixteen-page pamphlet which accompanies the stereograms.

The idea of the author is good, but it is not very efficiently carried out. The views are not always so convincing as they might be, and the descriptions are occasionally lacking in mathematical precision. We also think that the price has been fixed too high. Nevertheless, a teacher would receive some useful suggestions by a study of the diagrams.

A Laboratory Manual of Organic Chemistry for Beginners. By Prof. A. F. Holleman. Edited by Dr. A. J. Walker. Second edition, partly re-written. Pp. xvii+83. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 4*s.* 6*d.* net.

A REVIEW of the first edition of Dr. Walker's translation of Prof. Holleman's little book appeared in the issue of NATURE for May 11, 1905 (vol. lxxii., p. 28). New experiments have been incorporated in the present edition, and some obsolete reactions have been omitted.

Engineering Workshop Exercises. By Ernest Pull. Pp. viii+80. (London: Whittaker and Co., 1914.) Price 2*s.* net.

THIS little book provides instructions to enable technical students and apprentice engineers to perform their workshop experiments and exercises intelligently, and to obtain practice in the use of ordinary engineering tools and appliances. Prominence is given to the value of working drawings, and accuracy is insisted upon consistently. A chapter on screw-cutting and notes on materials are included in the book.

LETTERS TO THE EDITOR.

The Doppler Effect and Carnot's Principle.

IN my letter of March 19 I endeavoured to show that the latent heat absorbed in the production of unit volume of stationary vibration of a particular frequency in a mixed beam of radiation, is not equal to $4q/c$ (where q is the energy stream per sq. cm. per sec., and c the velocity), as would naturally be supposed, but, in consequence of the Doppler effect at the moving mirror or piston, takes the form $T(dp/dT)$, as required by Carnot's principle, where p is the pressure, or the mechanical work per unit volume, and is equal to $2q/c$ for a directly reflected beam under equilibrium conditions. The latent heat, $T(dp/dT)$, may be represented as the sum $(u+p)$ of the intrinsic energy or internal latent heat u and the external work p. As a matter of interpretation, u was identified in my letter with some form of stationary vibration which continued to exist in the medium at the frequency at which it was emitted. Further analysis shows that this is not the case, but that the energy left in the medium conforms exactly to the distribution required by the theory of exchanges. The energy density is $2q/c$ in a directly reflected beam, and is equal to the pressure, but differs from the energy absorbed on emission or evolved on condensation, namely, the latent heat, $T(dp/dT)$, which is the quantity measured experimentally, as previously explained (*Phil. Mag.*, October, 1913, p. 787).

Similarly in the case of full radiation where the energy stream is Q per sq. cm. per sec. in all directions, the energy density is $4Q/c$, and the pressure $4Q/3c$ *for each frequency*, but the latent heat per unit volume is still $T(dp/dT)$ (in place of $16Q/3c$) on account of the Doppler effect, and the energy stream *as measured experimentally* is not Q but $\frac{1}{4}T(dQ/dT)$. With a slight change of viewpoint the consideration of the Doppler effect leads to the exact formulæ and numerical relations already detailed in my previous note (*loc. cit.*), which are now seen to be no longer in conflict with the electromagnetic theory as was at first supposed. Lead and the Final Product of Thorium.

IT is now practically certain that the final product of the uranium family of radio-elements is isotopic, or chemically identical, with lead. The constancy of the ratio between lead and uranium, Pb/U, in the case of primary rock-forming minerals of the same geological age, and its sympathetic variation in the case of minerals of different ages, go far to establish this important conclusion. The recent discovery that all the final products of radio-active disintegration fall into Group iv. B of the periodic classification has naturally led to the further suggestion that each one is isotopic with lead.

If lead, or one of its isotopic equivalents, is the final product of the thorium series, then the estimates of geological time hitherto based on the lead-uranium ratio stand in need of a ruthless revision.

Fortunately this does not appear to be necessary, for mineralogical evidence clearly indicates that the presence or absence of thorium in a uranium-bearing mineral does not affect the lead content, which can generally be adequately accounted for by the uranium alone.

It is easy to calculate the relative rates at which uranium and thorium generate their final products, and assuming that the latter are isotopic, to express a given amount of thorium in terms of uranium, and so to arrive at a "total equivalent quantity of uranium," U_e, which also takes thorium into consideration. If then lead is, chemically speaking, the final product of thorium as well as that of uranium, the ratio Pb/U_e ought to be constant for minerals of the same age, and ought to vary in sympathy with the ages if these should differ. I have examined a large number of analyses of radio-active minerals from this point of view, and neither of the above criteria is found to hold. In many cases a large percentage of thorium may be present, but unless uranium is also present, lead is nearly always absent. In the few examples where lead and thorium occur alone, the ratio Pb/Th is variable and bears no relation to the geological age of the minerals.

However, more fully to demonstrate the bearing of evidence of this kind on the problem, Mr. R. W. Lawson, of the Radium Institute, Vienna, and myself are at present estimating the thorium content of a series of Norwegian minerals of Devonian age which had already been analysed for lead and uranium (Proc. Roy. Soc., A, vol. lxxxv., p. 248, 1911). Other workers are busily engaged on determinations of the atomic weights of the lead from uranium and thorium bearing minerals respectively, and there is therefore some likelihood in the near future of a final settlement of the question whether lead is an end-product of thorium or not. ARTHUR HOLMES.

Science, London, March 18.

Thermions and the Origin of Solar and Terrestrial Magnetism.

PREVALENT opinion seems to favour decidedly the hypothesis that the chief part of the magnetism of the earth or sun is due to the rotation of all, or a considerable portion of, the matter of which it is constituted. Theories of the magnetisation of matter by rotation fall into two classes: one (a) assuming that the substance is magnetic but not necessarily charged, the other (b) assuming that the substance is charged but not necessarily magnetic.

(a) If the matter is magnetic, consisting of molecular systems with individual magnetic moments differing from zero, rotation about a given axis will, on the electron theory, produce a torque on each individual system, causing it to contribute a magnetic moment parallel to the axis of rotation, and thus magnetising the whole body, if originally neutral, along this axis.

(b) Gravitation, or electrical forces, acting differentially on the positive and negative constituents of the matter, or differential centrifugal action, or some other cause, may give rise to a volume-density of electrification throughout the mass of a rotating body, in which case magnetisation, or at least a magnetic field, must result from the convection currents thus formed.

The particular kinds of differential action just mentioned have been proposed before, but I have seen no reference to the fact that an essentially steady electric volume-density must long ago have been produced by the emission of negative electrons from the heated matter of which the earth and sun are composed, and the resulting internal electric field. As the emission increases with the temperature, which increases from the surface inward, it is clear that the volume-density must be of the proper size to account for the polarity of solar and terrestrial magnetism.

It seems probable that both classes of effects are involved in the actual magnetisation in question, though experiment has shown that any effect of class (*a*) is at least exceedingly minute unless the magnetic behaviour of the interior parts of the earth and sun is quite different from that of matter at ordinary temperatures on the surface of the earth.

S. J. Barnett.

A Triangle that gives the Area and Circumference of any Circle, and the Diameter of a Circle equal in Area to any given Square.

It is not possible to measure *exactly* the interminable fraction required for the line BZ in the following figure, but it is quite easy to draw it so nearly that the error is practically immensurable.

First Method.—Draw a line AB = 44, and make BZ = 23. $\frac{23}{44} = 0\cdot52\dot{2}\dot{7}272$, which is a little too long.

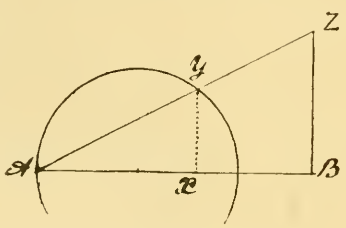
AY will then be short, about 1 in 600,000.
AX will also be short, about 1 in 300,000.

Second Method (with the familiar ratio $\frac{355}{113}$). Make a circle with diameter AB = 11·3, and let AX = $8\frac{7}{8}$. Draw a perpendicular from X to cut the circle in Y. Join AY, and continue the line to Z.

Then the error in AX, the $\frac{1}{4}$ circumference, will be less than 1 in 11,780,000 *in excess*.

The true angle for the line AZ lies between the lines found by the two methods, but the difference is too small for measurement, and in any accurate drawing the lines will appear to coincide.

AX being found, equal to an arc of 90°, a line for any other arc may be found; and the triangle once drawn on a sufficiently large scale, is true for all circles.



Let AB = 1, and at right angles BZ = 0·5227232008+, join AZ } Angle A. 27° 35′ 49·6″+

Then, any circle with diameter upon AB and one extremity at A, will cut the line AZ (or AZ produced) in a point Y, making AY the side of a square equal in area to the circle.

Also, a line from Y perpendicular to AB will cut the diameter in a point X, making AX equal to $\frac{1}{4}$ circumference of the circle.

Again, any square with base upon AB and a corner at A, will, with its side opposite to A, cut AZ in a point Y, making AY the diameter of an equal circle.

T. M. P. Hughes.

5 The Croft, Tenby.

The following remarks may help to explain Mr. Hughes's constructions:—

Let AY be a chord of a circle of which AD is a diameter, and let $\angle DAY = \theta$. Then if the square on AY equals the area of the circle, $(2r\cos\theta)^2 = \pi r^2$, and therefore $\cos^2\theta = \pi/4$, $\tan^2\theta = (4-\pi)/\pi$, and

$$\tan\theta = 0\cdot5227232,$$

very nearly, as stated. Now if we express this approximate value of $\tan\theta$ as an ordinary continued fraction we find the successive convergents,

$$1/1,\ 1/2,\ 11/21,\ 12/23,\ 23/44,\ \text{etc.},$$

where the first of those not written has four digits in numerator and denominator. Hence, as Mr. Hughes has discovered, 23/44 is a very close approximation to the transcendent number $\sqrt{(4-\pi)}/\sqrt{\pi}$. It seems absurd to speak of a mathematical accident, but we do seem to have something of the kind here. Supposing that a/b is a rational approximation to $\sqrt{(4-\pi)}/\sqrt{\pi}$, we should not expect beforehand a solution correct within about $4\cdot10^{-6}$ for values of a, b, each less than 100.

The second construction is obtained by putting, as an approximation,

$$AX : AD = \pi/4 = 355/4\cdot113 = 710/8\cdot113 = 8\tfrac{7}{8}/11\cdot3.$$

It would be easy to make a set-square with its shorter sides in the ratio 23 : 44, and this could be used for the approximate quadrature and rectification of any given circle. It is interesting to see how the same figure solves both problems to the same degree of exactness (practically). I suppose the error in the set-square could be reduced to 0·1 per cent., or less; the question is, what percentage of error is likely to occur in using it. For the rectification we have to draw the perpendicular YX; it seems to me that for the quadrature we are likely to obtain the most accurate results by using a straight edge as well as the set-square; that is to say, we should not try to adjust the set-square without first placing a straight edge along a diameter of the circle. If this is so, the graphical solutions of both problems are likely to be affected by the same percentage of error; because to obtain X, after marking Y, we have only to slide the set-square along the straight edge until a shorter side goes through Y; and if we repeat the manipulation several times, I do not think the error in finding X, regarded as a distance from the true position, can be so much as five times the error in finding Y, or conversely. Of course, by "the same percentage of error" I mean here that the two errors, on the same scale, are of the orders $\pm a\cdot10^{-n}$, $\pm b\cdot10^{-n}$, where a, b both lie above 1, while neither of them is equal to, or exceeds, 5.

G. B. Mathews.

New Units in Aerology.

With reference to Prof. McAdie's letter in Nature of March 19, p. 58, I should like to point out that throughout my "Thermodynamics," published in 1878, a megadyne per square centimetre is used as the unit of pressure, and it is termed a c.g.s. atmosphere. Ever since 1888, when the B.A. committee (of which I was a member), adopted the barad, I have employed in my lectures the above pressure unit under the name of megabarad. The corresponding unit of work, and also of heat, adopted in the book is the megalerg. Megerg to my ear is too cacophonous for use.

Robert E. Baynes.

Christ Church, Oxford, March 25.

PROGRESS IN WIRELESS TELEPHONY.

The attention of telephonic engineers has of late years been very closely directed to the improvement of the line wire in ordinary telephony. Apart from the imperfections of the telephone transmitter and receiver, *per se*, a very considerable effect is produced on the transmitted speech by the line itself if it is at all long. This action, from an electrical point of view, consists in the distortion of the wave form of the current as it travels along the cable, and its rapid attenuation or diminution in amplitude.

When speech is uttered to the mouthpiece of the transmitter, the current flowing into the line is modulated in a complicated manner, but this variation in virtue of Fourier's theorem can be analysed into the sum of a number of currents of simple harmonic or sine wave form placed in certain relative phases and having certain amplitudes. The velocity W, with which any simple harmonic current travels along a cable having a resistance R ohms, an inductance of L henrys, a capacity of C farads, and a dielectric leakance of S mhos per unit of length, provided that the quantities R/pL and S/pC are small compared with unity, can easily be shown to be expressed by the formula:—

$$W=\frac{1}{\sqrt{CL}}\frac{1}{\sqrt{1+\frac{1}{p^2}\left(\frac{R}{2L}-\frac{S}{2C}\right)^2}},$$

where $p=2\pi$ times the frequency.

Accordingly, the greater the frequency, the greater will be the wave velocity. In other words, short waves travel faster than long. The short waves, having also the least energy, attenuate most rapidly.

The result of this is that in the case of telephony along wires the different harmonic constituents of the current get out of step, and degrade unequally. Hence the wave form, and the quality of the received sound, is altered after the wave has travelled a certain distance along the wire or cable. The result is to diminish the loudness and reduce the clearness of the speech heard. Therefore, beyond a certain distance the articulate sound becomes unintelligible.

On the other hand, it is well known that the velocity of electromagnetic waves through space is independent of the wave length, and there is, therefore, in this respect a marked difference between the transmission of electromagnetic waves guided along wires, and free electromagnetic waves diverging through space. As soon as the telephonic or aural method of receiving Morse signals in wireless telegraphy was substituted for the method of employing some form of coherer as a relay to actuate a Morse inker printing them in *dot* and *dash* on paper tape, the suggestion was made that it might be possible to transmit articulate speech by space electromagnetic waves, and not merely Morse signals composed of long and short sounds; and hence to conduct a wireless or lineless telephony.

It was at once recognised that before this could be done it would be necessary to provide a generator of electromagnetic waves giving truly continuous waves, and not merely intermittent groups or trains of rapidly decadent waves. The discovery of the power of the continuous current arc between carbon electrodes to create high-frequency oscillations in a condenser circuit connected between the carbons, held out hopes of making such a generator. It was not, however, until Poulsen discovered the peculiar properties of an electric arc formed in hydrogen or coal gas to enable very high-frequency oscillations to be so generated that progress began to be made. The Poulsen arc-generator consists, as is well known, of a direct-current arc formed with an electromotive force of about 500 volts between a carbon and a copper electrode in an atmosphere of hydrogen or coal gas. A strong transverse magnetic field is also applied to the arc. An inductive circuit, consisting of a coil of wire having in series with it a capacity, the capacity and inductance being so adjusted that the natural frequency of this oscillation circuit is not less than about 50,000, or preferably much higher, even up to 250,000, is then connected between the carbon and copper electrodes. Powerful continuous electric oscillations are then set up in this condenser circuit. These oscillations can be made to set up similar oscillations in an open radiative circuit or antenna, which is inductively connected with the condenser circuit, as in the case of an ordinary wireless telegraph transmitter.

In this manner continuous or uninterrupted electric waves of a wave length which is anything between 1 and 4 or 5 miles, can be radiated from the aerial wire. The reason the hydrogen or coal gas is effective in enabling the arc to create more powerful high-frequency oscillations is that it increases the steepness of the characteristic or volt-ampere curve of the arc, and hence increases the energy which is conveyed to the condenser at each oscillation.

To transmit speech we have then to modify the amplitude of these radiated continuous electric waves sent out from the sending station antenna in accordance with the wave form of the speaking voice. This is done usually by some form of carbon microphone inserted in the base of the sending station antenna. When the diaphragm of the microphone is acted upon by the voice, the carbon granules in it are more or less compressed, and the electrical resistance thereby altered. If then the high-frequency current in the antenna is made to pass through this microphone, the amplitude of the radiated continuous waves will be varied by making speech to the microphone, in such a way as to create waves upon waves, or to alter the wave amplitude in accordance with the wave form of the speaking voice.

At the receiving end all the arrangements are identical with those required in wireless telegraphy when using a telephone and rectifier of some kind to receive audible Morse signals. The receiving antenna is coupled to a closed condenser circuit, and to the terminals of this condenser is attached a Bell receiving telephone in circuit with some oscillation rectifier, such as a crystal or constant detector, viz., carborundum, perikon, or zincite-chalcopyrite, or an ionised gas rectifier such as a Fleming glow-lamp valve. The telephone is then not affected by the rectified continuous oscillations *per se*, but it is affected by the variations in their amplitude produced by the microphone in the transmitter circuits.

Audible and intelligible speech can thus be reproduced at the receiving end. The limitations that present themselves in this transmission are wholly connected with the creation and modulation of the electric waves emitted by the sending station, and chiefly due to the difficulty of designing a microphone which can carry a sufficiently large current without heating. An additional trouble is that of devising a generator which shall be as simple and easily managed as that of a wireless telegraph plant.

As regards the microphone, most workers have employed a number of carbon microphones joined in parallel so as to enable a high-frequency antenna current of, say, 4 or 5 amperes to be passed through them without overheating any one. It is not easy, however, to divide the current equally between the microphones, or to keep them absolutely in step with each other. Another type is the liquid microphone of Majorana, and of Vanni. In Dr. Vanni's microphone a jet of water rendered slightly conducting by acid or salts is allowed to fall on a fixed inclined metal plate, B, and then bounces off on to another inclined metal plate, A, which is in mechanical or electrical connection with the diaphragm of a speaking mouthpiece (see Figs. 1 and 2). Speech, therefore, made to it sets the last-named plate vibrating, and thus breaks up and varies the resistance of the film or column of liquid connecting the two plates. Hence, if this liquid column is in the circuit of the transmitting antenna, any speech made to the diaphragm will vary the electrical resistance in the antenna circuit, and change in a similar manner the amplitude of the radiated electric waves.

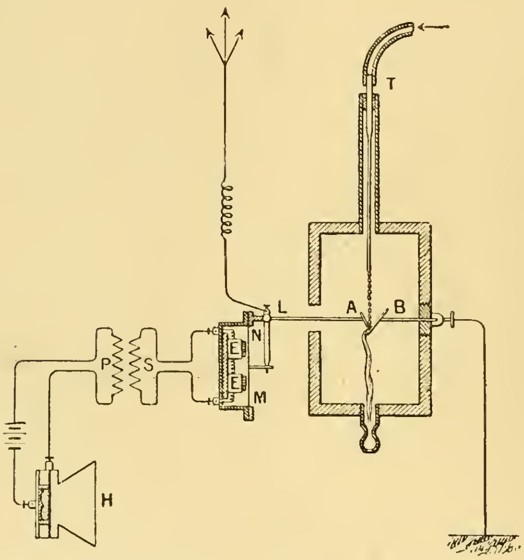


FIG. 1.—The liquid microphone of Dr. J. Vanni.

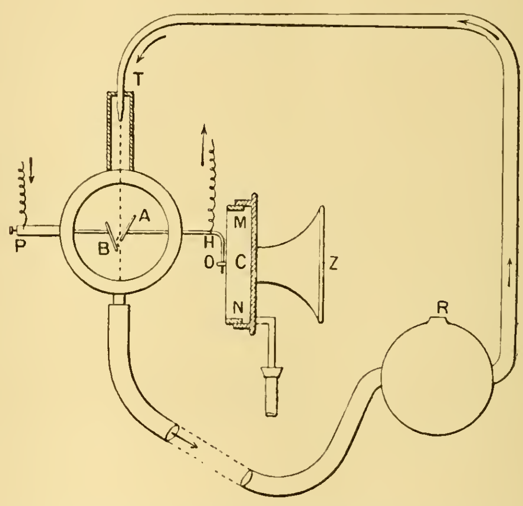

FIG. 2.—Arrangements for circulating the liquid by a rotary pump R in Vanni's microphone.

W. Dubilier has also invented a water-cooled carbon granule microphone, the main diaphragm being moved by the current through a relay microphone to which the speech is actually made. This microphone can pass 700 watts with clear articulation (see Fig. 3). Then with regard to generators, a good many modifications of the arc generator have been produced. The Moretti arc consists of a copper tube kept supplied with water, and another copper rod is brought down so as to strike the arc against the water. When the arc is formed with a continuous current, and is also shunted as above described with a condenser inductive circuit, high-frequency oscillations are set up in the latter. There is a very rapid extinction and re-ignition of the arc, possibly due to some action like that in the Wehnelt interrupter. The writer of this article has also devised recently a new form of arc generator which requires no transverse magnetic field, nor supply of hydrogen or coal gas, as in the Poulsen apparatus. We have, then, in addition, the high-frequency alternator method of creating the oscillations. Fessenden experimented at one time very largely with such machines, devising a form of Mordey alternator which could give a frequency of 80,000 or 100,000. The invention by R. Goldschmidt of a means of multiplying frequency by means of a rotating field alternator made a new departure. By this machine high-frequency continuous oscillations are mechanically created, and their amplitude can be controlled by a microphone placed in the exciting circuit of the machine, so that it is not traversed by the main current.

Furthermore, we have the high speed, smooth disc generator of Mr. Marconi as a means of creating undamped oscillations, and, in addition, a telephonic transmitter has been invented by him which has not yet been described in detail, but was mentioned by him in a recent lecture in Rome. It is known that he has recently directed his attention closely to invention in connection with wireless telephony.

It is also possible to employ spark discharges of a very high spark-frequency, above the limit of audition, as a means of creating what are practically unintermittent oscillations, the separate trains of oscillations being practically in contact with each other. This method depends upon the self-extinguishing power of electric arcs produced between certain metals which are good conductors, such as aluminium and copper. If a pile of plates of these metals with very small air-gaps is built up, and a high electromotive force applied to it, discharges will take place, or small arcs which, when the discharger is shunted by a condenser, can generate high-frequency oscillations. By the aid of these appliances, their inventors and other workers have conducted wireless telephony up to a distance of 1000 kilometres, or, say, five hundred or six hundred miles.

Thus, Dr. J. Vanni, working at Rome, and using a Moretti arc generator, his own liquid microphone, and a form of Fleming oscillation valve as a receiver, has transmitted and received articulate speech between Rome and the Island of Ponza (120 km.), to Maddalena (260 km.), to Palermo (420 km.), to Vittoria (600 km.), and finally between Rome and Tripoli, a distance of 1000 km.

The speech is said to have been clear and singularly free from evidence of distortion of wave form. In addition to this, successful experiments in wireless telephony are said to have been conducted between Berlin and Vienna, a distance of 375 miles, by the Telefunken Company. The stations were the German high-power station at Nauen, to the west of Potsdam, and a receiving station on the roof of the Technological and Industrial Museum at Vienna. The experiments were so promising that it is expected much greater distances can be covered. A very inviting field of work seems to be opening out in connection with the alternator method of generation. With a suitably designed Goldschmidt high-frequency alternation it is said that a small variation in the exciting current will produce very large variations in the amplitude of the radiated waves. Hence the microphone can be placed in the excitation circuit, and need only have a current-passing capacity of a few amperes to be able to modulate a radiation representing a very large horse-power. To transmit articulate speech across the Atlantic will necessitate the power of varying the amplitude of continuous wave radiation representing at least 50 or 100 horse-power. This must be done by means of some microphone which passes not more than, say, 10 amperes. These conditions are not impossible of attainment. Hence Transatlantic wireless telephony may be said to be within the range of practical politics, whilst no improvements yet made in submarine telephonic cables hold out hope of being able within any reasonable time to speak through an Atlantic cable.

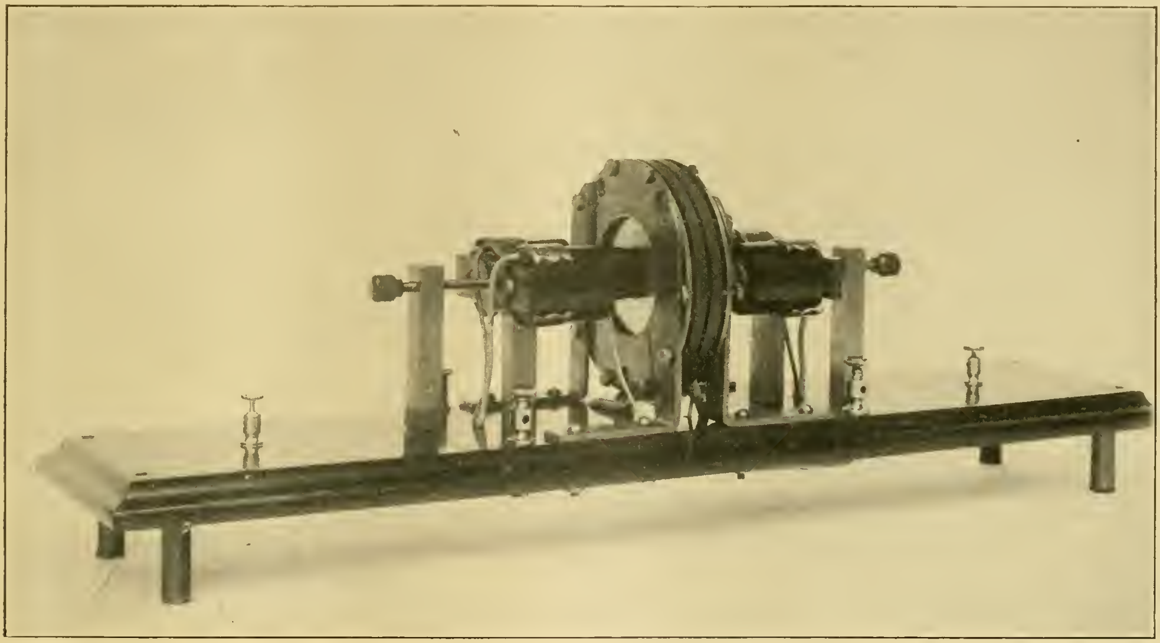

FIG. 3.—Dubilier water-cooled large current microphone.

The subject of wireless telephony is, therefore, one which holds out much promise for future achievement, and it is not surprising that it is attracting the attention of some of the leading workers in radiotelegraphy. J. A. FLEMING.

A BIRD WITH A HISTORY.[1]

A WELL-KNOWN ornithologist here gives us the fruits of many years of careful study devoted to a single species. His study has been diverse: at times it has lain among etymological dictionaries and curious old works on natural history, at times among the publications of

[1] "The Gannet: A Bird with a History." By J. H. Gurney. Pp. li+567+plates. (London: Witherby and Co., 1913.) Price 27s. 6d. net.

modern scientific societies and technical anatomical descriptions, and again in the open air on those rocky islets where the birds congregate in their thousands during the months of the long nesting season.

It is not every bird that deserves to be made the subject of a handsome and expensive monograph, but the gannet, as our author shows, makes more than ordinary claims on the interest and attention of the naturalist. And it is only just that a British naturalist should be the historian in this case, for of the fifteen breeding localities of the gannet, no fewer than nine lie off the coasts of our islands. Moreover, of the estimated total gannet population of 101,000

Gannets on the Bass Rock. From "The Gannet: a Bird with a History."

birds (exclusive of nestlings), 75,000 are allotted to these nine haunts. The British colonies are Lundy Island (recently abandoned); Grasholm, off Pembrokeshire; the Little Skellig and the Bull Rock, off the south-west of Ireland; Ailsa Craig, in the Firth of Clyde; St. Kilda (three colonies); Sulisgeir, to the north of the Lewis; the Stack of Sule Skerry, to the west of Orkney; and the Bass Rock. In the Færöes there is a colony on Myggenæs, while off Iceland there are colonies in the Vestmann Islands and the Eldey group, and a very small one on Grimsey, which is on the north coast, and lies within the Arctic Circle. Across the Atlantic there are colonies on Bonaventure and the Bird Rocks, in the estuary of the St. Lawrence; while there, as here, former sites, long since abandoned, are also known.

Mr. Gurney points out that these colonies, without exception, are on rocky islands, and that no mainland site, past or present, is anywhere known. Furthermore, the great majority of those on this side of the Atlantic lie off westerly coasts; the Bass Rock is, indeed, the only British exception. Apart from these points, there is an interest even in the purely statistical side of the careful census, which Mr. Gurney has been able to make. There are few species the numbers of which can be estimated even approximately, and the figures given in this volume should form an interesting basis for comparison in the future.

The book opens with a discussion of the various vernacular and scientific names which the species has received: both "gannet" and "solan" are dealt with at length. Then come many interesting pages quoting historical references to the gannet, illustrated by quaint figures taken from the works of the early naturalists. The species is justly called "A Bird with a History."

Mr. Gurney devotes a chapter to each of the important colonies, and shows personal familiarity with them in many cases, and an exhaustive knowledge of their literature in all. History is then left for a discussion of the general habits of the gannet, its nidification and incubation, the growth of its nestling, its food and its manner of fishing, its powers of diving and its seasonal movements, and many another question. Nor is its relation to man neglected—its effect on fisheries and its use as food. Finally, the plumage, osteology, and general anatomy are discussed, and appendices are added dealing with its allies, its parasites, its fossil remains, and the like.

We may note the omission from the bibliography of Mr. Kirkman's recent important contribution ("The British Bird Book") to the study of the gannet's habits, but Mr. Gurney has missed little that throws light on the interesting bird which he has made the object of enthusiastic and fruitful study. Many useful maps and beautiful photographs are scattered throughout the work.

A. L. T.

DR. G. J. BURCH, F.R.S.

FEW men of science have had such a varied career as Dr. George James Burch, whose death we announced with regret last week. Born in 1852, he went in 1873 to Cheshunt College to study for the Nonconformist ministry, and in due course became a minister first at Leeds, and later at Oxford. But at Oxford his duties became to some extent uncongenial to him, and this fact, coupled with a very bad breakdown in health, induced him to give up his pastorate, and take up the study of science for which he always had a natural inclination. He was hampered by pecuniary difficulties which would have deterred most men from such a course, and only by the most heroic struggles could he and his newly-married wife keep their heads above water. As a means of livelihood he worked for six hours every day on the subject catalogue at the Bodleian Library, and only after this work was over was he free to study Chemistry for his Oxford degree course. In spite of this double call on his time, he found opportunity to carry out research, and in 1886 he began his work on the capillary electrometer with the late Sir John (then Dr.) Burdon Sanderson, the Professor of Physiology. From 1887 onwards they did a good deal of electro-physiological work together, the mechanical details of the apparatus used being gradually improved by Burch until the final present day form was evolved.

Burch also worked out a method for analysing the electrometer curves, and in December, 1887, wished to publish an account of his discoveries. Burdon Sanderson, who was always cautious about committing himself, dissuaded him from doing so: hence a description of the method was not actually published until 1890, when Einthoven independently described his method, and so deprived Burch of some of the credit of the discovery. In 1892 Burch published a more elaborate paper on the time relations of the excursions of the capillary electrometer in the Philosophical Transactions of the Royal Society, and other papers were published later in the Proceedings of the society.

Meanwhile, Burch in 1891 took up lecturing under the Oxford University Extension Delegacy, and in 1892 he became lecturer, afterwards professor, of Physics at University College, Reading. He still lived in Oxford, and went backwards and forwards to his work daily. This was a great strain on his health, so that in 1909 he broke down and had to resign his position, though he continued to teach in Oxford.

In the last eighteen years of his life Burch devoted most of his spare time to research in colour vision. Among his observations regarding the physiology of vision were a number bearing on the vexed problem of colour sensations. He was a convinced adherent of the Young theory of colour sense. He subjected himself to a series of severe experiments in which the eye was fatigued to certain colours by prolonged intense stimulation by appropriate parts of the prismatic spectrum, and the alteration in the colour of other parts of the spectrum when observed by the fatigued eye was examined. He supplied an interesting memorandum on this subject to the Board of Trade Committee on Sight Tests three years ago. A small book presenting a practical course of instruction in visual physiology embodied the class-work he conducted in the subject at the Physiological Laboratory at Oxford. It is not only extremely lucid, as was everything he wrote, but is strikingly original in scope and treatment, and contains a number of exercises, as, for instance, one on the measurement of visual acuity, devised entirely by the author. His combination of first-hand knowledge of physical and physiological experimentation fitted him to a degree which is quite exceptional for success in this branch of scientific study.

Dr. Burch was elected a Fellow of the Royal Society in 1900. H. M. V.

PROF. G. M. MINCHIN, F.R.S.

The death of Prof. George M. Minchin, F.R.S., on March 16, at sixty-eight years of age, has deprived science of an earnest and versatile investigator, and a wide circle of friends of a companion who will be greatly missed. Always active in body and alert in mind, Prof. Minchin caught the fire of life with both hands, and conveyed its benefits to all around him.

Prof. Minchin was appointed to the chair of mathematics in the Royal Indian Engineering College, Coopers Hill, in 1875, when he was in his twenty-ninth year; and he remained at the College until it closed, when he removed to Oxford, where he died. He took a leading part in the movement for the improvement of geometrical teaching in schools; and his little book "Geometry for Beginners" published in 1898, was an early and very favourable specimen of the methods of the reforming party. He was also the author of works on "Statics," "Uniplanar Kinematics," and "Hydrostatics"; and his treatment of all these subjects was original and distinctive. Less well known in scientific circles, perhaps, except among his friends, is a little volume of verse and prose entitled "Naturæ Veritas" published in 1887. His skill in writing verse was of no mean quality; and a humorous example of it will be found in Nature of April 14, 1898, in a poem entitled "Balnibarbian Glumtrap Rhyme." He was a lover of good English; and this regard for the purity of the language made his many contributions to our columns clear in expression as well as authoritative in opinion.

Probably the work by which Prof. Minchin will best be remembered is that on photo-electricity and selenium cells. He began his experiments on these subjects in 1877, and was led by them to the discovery of many interesting phenomena. He observed that electric currents are produced by the action of light on silver plates coated with collodion or gelatin emulsions of bromide, chloride, iodide or other silver salts, or with eosin, fluorescein, or other aniline dyes, when the plates were immersed in a suitable liquid and one plate was illuminated while the other was screened. In 1891 he exhibited these cells to the Physical Society, and also cells made by spreading melted selenium on metal plates and immersing them in liquids together with an uncoated plate. He found that some cells, termed by him "impulsion cells," had their sensitiveness altered by slight impulses or taps, and also by electro-magnetic impulses, such as are given by electric sparks or a Hertz oscillator at a distance; so that the cells embodied the principle of the coherer used for the reception of Hertzian waves.

The form of photo-electric cell afterwards adopted by Prof. Minchin consisted of two selenium-coated aluminium wires dipping into certain solutions. His "Seleno-aluminium Bridges," described in a paper to the Royal Society in May, 1908, consisted of two plates of aluminium separated by a very thin flake of mica and having a thin layer of sensitive (or conducting) selenium spread across one edge of the mica and the two adjacent portions of the aluminium plates. This further development of his photo-electric work was carried out in the electrical laboratory at Oxford.

Prof. Minchin's application of selenium cells to the measurement of starlight was a notable extension of his experiments. In 1894, in conjunction with Mr. W. E. Wilson, he used his cells to obtain measurable electro-motive forces from the light of planets and stars; and he was thus able to determine the relative intensities of the light of Jupiter, Venus and Sirius. Shortly afterwards, an improvement in the construction of the cells enabled measurements to be made of the E.M.F.'s of the light of Vega, Arcturus, Regulus, Procyon and other stars. A comparison of the results obtained by photo-electric measures with those of photometric measures of stellar magnitude showed close conformity.

Prof. Minchin was an M.A. of Dublin and a member of Queen's College, Oxford. He was elected a fellow of the Royal Society in 1895, and his many friends within the society and without join with the widow and his two children in sympathetic sorrow that the finger of death has touched one who was so rich in the physical and intellectual attributes of life. R. A. G.

NOTES.

We announce with deep regret the death on March 30, in his sixty-second year, of Prof. J. H. Poynting, F.R.S., professor of physics in the University of Birmingham.

Prince Arthur of Connaught has been elected a fellow of the Royal Society, under the statute which provides for the election of Princes of the Blood Royal.

We record with regret the announcement of the death on March 30, in his sixty-fifth year, of the Hon. Rollo Russell, author of a number of works on meteorology and other scientific subjects.

The death is announced, at eighty-one years of age, of Mr. G. Sharman, for more than forty years palæontologist to H.M. Geological Survey at the Geological Museum, Jermyn Street, London.

A handsome brass tablet to the memory of Captain Scott and the southern party of the British Antarctic Expedition was unveiled at St. George's Chapel Royal, Naval Barracks, Chatham, on March 29, by Admiral Sir Richard Poore, Commander-in-Chief at the Nore, and dedicated by Archdeacon H. S. Wood, Chaplain of the Fleet.

Dr. C. H. Browning has been appointed first director of the new Institute of Pathology of the Middlesex Hospital, which has been erected as the gift of Sir J. Bland-Sutton at a cost of between 15,000*l.* and 20,000*l.* Dr. Browning is at present director of the clinical research laboratories in connection with the University of Glasgow.

A strong committee, with the Speaker as president, has been formed in Cumberland, according to the *Times* of March 27, with the object of affording protection to the local fauna. Wherever possible tracts of natural ground will be set apart as reserves, one such tract, Kingmoor, near Carlisle, having been already secured. A "watchers' fund," to provide keepers for such reserves, is being formed, and a close watch is to be kept on nesting ravens, peregrines, and buzzards throughout the county.

In the *Times* of March 27 attention is directed to the lateness of the arrival in this country of spring migratory birds. This lateness is specially notable in regard to a great spring flight of immigrants from Central Europe, which, as recorded by a Norfolk correspondent in the same journal a few days previously, reached Yarmouth on March 11. In normal seasons such flights are usually over by the beginning of the month. A partial explanation may be found in the great drop in temperature which occurred on the Continent between March 10 and March 11, when there was a fall of 13° in the minimum.

The President of the Local Government Board has authorised the following special researches to be paid for out of the annual grant in aid of scientific investigations concerning the causes and processes of disease:—(1) An investigation by Dr. Eardley Holland into the causes of still-births; (2) a continuation of the Board's inquiry into the cellular contents of milk, by Prof. Sims Woodhead; (3) a continuation of the Board's inquiry into the causes of premature arterial degeneration, by Dr. F. W. Andrewes; (4) an investigation by Dr. M. H. Gordon and Dr. A. E. Gow into the etiology of epidemic diarrhœa in children. Announcement of further investigations will be made at a later date.

A wish has been expressed in many quarters that the distinguished services which Prof. Charles Lapworth, F.R.S., has rendered to geology should be commemorated in some permanent manner. The council of the Vesey Club, Sutton Coalfield, of which Prof. Lapworth has been a vice-president for more than twenty-five years, proposes to make a donation from the funds of the club towards such a memorial, and to enable members of the club who desire to be identified personally with the project to participate also, a small committee has been appointed to collect subscriptions. The amount subscribed by members will be handed over in one sum with a list of names only of subscribers. Donations may be sent to Mr. H. H. Sherwood, 109 Colmore Row, Birmingham.

In honour of the memory of the late Henri Poincaré, and in order that his name may be associated with a fund for the encouragement of research in science, the president of the Institute of France, on behalf of the institute, is inaugurating an international subscription with the approval of the family, friends, and admirers of the great French mathematician. It is proposed to arrange for a medal with Poincaré's portrait inscribed on it, and to secure a fund, the proceeds of which will be employed to encourage and assist young men of science engaged in those branches of knowledge with which Poincaré's name is chiefly associated. Donations may be sent to M. Ernest Lebon, secretary and treasurer, 4*bis* Rue des Ecoles, Paris, V.

The tragic death of the late Dr. H. O. Jones and his wife in the Alps in August, 1912, was recorded in these columns at the time (vol. lxxxix., p. 638). We note with interest that a tablet bearing the following inscription has been placed on the walls of Lewis's School, Pengam:—"In affectionate remembrance of Humphrey Owen Jones, M.A., D.Sc., F.R.S., Fellow of Clare College, Cambridge. A distinguished worker in the field of physical chemistry—a former pupil of the school—who while on his honeymoon in the Alps was killed with his wife by falling from the Aiguille Rouge de Peteret on the 15th August, 1912, at the age of 34 years. This tablet is by the staff, boys, and friends of Lewis's School sorrowfully inscribed." In memory of his wife (whose maiden name was Muriel Edwards), who was a distinguished student of the University College of North Wales, a fund of about 70*l.* has been raised by her fellow-students and handed over to the college to found a "Muriel Edwards's Prize" for distinction in chemistry or physics.

The annual general meeting of the Ray Society was held on March 26, the president, Prof. W. C. McIntosh, in the chair. The report of the council commenced with an appreciative notice of the late president, Lord Avebury, and an expression of regret at his death, and stated that three volumes, a "Bibliography of the Tunicata," by the secretary, and vols. i. and ii. of the "British Parasitic Copepoda," by T. and A. Scott, for 1912 and 1913, had been issued during the past year; that the volumes for the present year would be vol. iii. of the "British Freshwater Rhizopoda," by G. H. Wailes, and vol. v. of the "British Desmidiaceæ," by W. and G. S. West; and that the issue for 1915 would be vol. iii., part 1, of the "British Marine Annelids," by the president. The account of income and expenditure showed that the finances of the society were satisfactory. Prof. McIntosh was re-elected president, Dr. DuCane Godman treasurer, and Mr. John Hopkinson secretary.

The following are the lecture arrangements at the Royal Institution, after Easter:—Dr. W. Wahl, two lectures on problems of physical chemistry; Prof. W. Bateson, two lectures on (1) double flowers, (2) the present state of evolutionary theory; Prof. D'Arcy W. Thompson, two lectures on natural history in the classics; Prof. A. Fowler, two lectures on celestial spectroscopy: experimental investigations in connection with the spectra of the sun, stars, and comets; Prof. Svante Arrhenius, three lectures on identity of laws in general and biological chemistry; Prof. Silvanus P. Thompson, two lectures on Faraday and the foundations of electrical engineering; Dr. T. E. Stanton, two lectures on similarity of motion in fluids; Prof. C. J. Patten, two lectures on bird migration; Prof. J. W. Gregory, two lectures on (1) fiords and their origin, (2) fiords and earth movements. The Friday evening meetings will be resumed on April 24, when the Astronomer Royal, Dr. F. W. Dyson, will deliver a discourse on the stars around the north pole. Succeeding discourses will probably be given by Prof. Karl Pearson, Prof. F. Keeble, Mr. R. Mond, Prof. J. C. Bose, and Prof. W. H. Bragg.

In the *Times* of March 25 is announced the discovery at Kolophon, in Ionia, of a remarkable collection of Greek surgical instruments. They exhibit a type of workmanship unequalled in any other extant specimens, and generally reveal the high progress in surgery which the ancients achieved. With two exceptions all the instruments are of bronze, and even in the case of those made from steel a piece of bronze is added, preserved, apparently for ceremonial reasons as a mystic, sacred metal. The collection includes polypus pincers for the removal of growths, an elevator for raising a piece of depressed bone in the skull, a drill-bow for trephining the skull to produce an exit for the evil spirits which were believed to cause madness and epilepsy, a scoop or cuvette for gynæcological work, a cautery and probes of modern type, scales, and cupping vessels. It is to be regretted that this valuable collection has been secured for the Johns Hopkins University, and will shortly be taken to America. Models, however, are being made, and will be on view in London within a few weeks.

The royal medals and other honours of the Royal Geographical Society have been awarded this year as follows:—The Founder's medal to Prof. Albrecht Penck, professor of geography at Berlin University, and director of the Oceanographical Institute; the Patron's medal to Dr. Hamilton Rice, of Boston, U.S.A., who for ten years has been closely investigating a little-known part of the large region of northern South America drained by the headwaters of the Orinoco and of the northern branches of the Amazon; the Murchison grant to Commander H. L. L. Pennell, R.N., who was a member of the Antarctic expedition of 1910, and was specially selected by Captain Scott to command the *Terra Nova* after the landing of the shore party; the Gill memorial to Mr. A. E. R. Wollaston, who has made extensive journeys in many parts of the world for zoological and other work; the Cuthbert Peck grant to Dr. J. Ball, of the Geological Survey of Egypt, who has carried out a large amount of scientific geographical work; and the Back grant to Mr. J. N. Dracopouli, for his careful survey and other work in the Sonora desert of Mexico in 1911–12, and his expedition to the Lorian Swamp and neighbouring regions in 1912–13.

The annual report of the council of the Institution of Mining and Metallurgy was presented at the annual general meeting of the institution on March 26. The report refers to the purchase of the freehold of No. 1 Finsbury Circus, as a permanent home for the institution, and states that the stability of the institution and its future progress have been materially assisted by the gift of 5000*l.* by Lady Wernher, and the further gift of 5000*l.* by Lady Wernher and her co-executors. This sum of 10,000*l.* has been invested as the "Sir Julius Wernher Memorial Fund," and the interest accruing is available for the ordinary purposes of the institution. The council has established as a personal memorial, a "Sir Julius Wernher Memorial Lecture," to be delivered and published triennially. The first lecture will be delivered before the International Congress of Mining, Metallurgy, Engineering, and Economic Geology, to be held in London in July, 1915. The subject of the lecture will be "The Metalliferous Mining Industry in its Relation to the Development of the British Empire," and the name of the lecturer and other particulars will be duly announced. The total membership on December 31, 1913, was 2372, as compared with 2258 in the previous year. "The Consolidated Gold Fields of South Africa, Ltd.," gold medal has been awarded conjointly to Mr. A. J. Clark, and Dr. W. J. Sharwood, for their paper on the metallurgy of the Homestake ore, and its premium of forty guineas to Mr. L. H. Cooke.

A FEW days before his death Sir John Murray was gathering material in the library of the Royal Society of Edinburgh in preparation for his presidential address at the Meteorological Congress, which is to be held in Edinburgh during next September. The sudden and tragic end of a project just begun is infinitely lamentable, and one naturally asks what will become of Medusa Villa as a centre of scientific activity. The terms of Sir John Murray's will have been so far made public as to bring a great relief to all who knew and appreciated the work which was always being carried on under his direct supervision. The books and collections, especially those bearing on deep-sea deposits, oceanography, and limnology, are to be kept together, along with furniture, instruments, fittings, etc., in the Villa Medusa, so that scientific work may be carried on there for twenty years. A certain number of shares in the Christmas Island Phosphate Company (Limited) are to be devoted to this purpose, the dividends being applied in scientific research or explorations or investigations which are likely to lead to an increase of natural knowledge, particularly along the lines indicated above. The carrying out of this project is left in the hands of his children. Very liberal powers are given in regard to special schemes, such as a scientific exploration of Canadian lakes or oceanographic expeditions. Should a case of substantial expenditure arise, it is suggested that the Challenger Society or the Royal Society of London or the Royal Society of Edinburgh might be consulted. Provision is made for the disposal of the collections and the library and the Christmas Island shares after the lapse of twenty years; or the arrangement may be brought to an end at an earlier date if the dividends should seriously decrease. In the obituary notice last week reference was made to the bathymetrical survey of the fresh-water lochs of Scotland. It should have been said that while Sir John planned, directed, and assisted financially the survey of the lochs, a large part of the expense was defrayed by Mr. Laurence Pullar, as a memorial to his son.

FOLLOWING an article on "The Spider Sense," several letters upon this subject have appeared in the *Times* (March 18–26). Certain people, we are told, are able to detect the presence of a spider (or cat) by means of a "sixth sense." The use of the term "sixth sense" indicates the complete innocence of psychology that characterises the whole correspondence. As to the fact, Prof. Meldola (March 26) is fully justified in pointing out that the neglect of the "negative instance" makes the proffered evidence totally unconvincing. Probably many people believe they can tell when they are being stared at from behind, but a recent experimental test revealed no such ability. On the other hand, such sensitivity does not seem *a priori* impossible. Sensory acuity varies greatly in different individuals and in special conditions. Thus some blind persons can perceive objects at a distance. This seems to be an abnormal development of a normal form of cutaneous sensitivity, the sense-organ being the skin of the face and the drum of the ear. Again, remarkable degrees of hyperæsthesia occur in certain stages of hypnosis, and in the present instances there may possibly be something of the nature of hypnotic auto-suggestion. That smell may play some part, as suggested by Mr. Ponder (March 25) is possible. This sense is imperfectly understood; how, for instance, is a hound able to avoid "back-tracking"? Even in the human its potentialities seem very elastic. Helen Keller, having lost her sense of smell for a few days, says: "A loneliness crept over me as vast as the air whose myriad odours I missed." But the existence of the "sense" and its nature should be quite simply determinable by experiment. Mr. C. Sully, assistant lecturer in psychology at King's College, London, will be glad to hear of a suitably endowed person willing to act as subject.

THE *National Geographic Magazine* for February reprints an important report by Mr. F. K. Lane on the conservation of the national undeveloped resources of the United States, particularly in connection with Alaska. This State contains the largest area of unused and neglected land in the country. Its resources are enormous in minerals, forests, and land available for cultivation. Hitherto lack of organisation has impeded development; but if the scheme now formulated is adopted this great national estate will become highly valuable.

THE fourth part of vol. i. of the Sarawak Museum Journal is devoted to an elaborate paper by Mr. Sidney H. Ray on the languages of Borneo. This collection of tribal glossaries was begun by Mr. Ray when he visited Sarawak on his return from the Cambridge Anthropological Expedition to Torres Straits in 1898–9. Additions were made to these by Dr. A. B. Meyer, whose papers on his death in 1911 came into Mr. Ray's possession. He has now published these glossaries with notes on the geographical distribution of the tribal dialects. It may be hoped that these collections will form the basis of a comparative study of this little-known group of languages. The value of the collection, not only to philologists, but also to anthropologists, is much increased by the addition of an extensive bibliography of books and papers on the Borneo tribes and their dialects.

In the Report of the Indian Museum, Calcutta, for 1912–13, Dr. Annandale is enabled to record an increase in the number of visitors, and likewise to chronicle the occupation and installation of the new laboratories and offices on the top of the Chowringhi side of the main building. The whole of the old building has been made over to the Geological Survey.

In vol. x., part 7, of the Annals of the South African Museum, Mr. K. H. Barnard continues his account of the crustacean fauna of South Africa, dealing in the first instance with the marine Isopoda, of which two genera and numerous species are described as new. Of much more general interest is his description of a new species of the genus Phreatoicus from Table Mountain; the genus being the typical representative of a southern terrestrial and fresh-water family of the Isopoda, containing three other genera. Hitherto the Phreatoicidæ have been known only from Australia, Tasmania, and New Zealand, and it is therefore of great interest to find it represented in South Africa, and that, too, by a member of the typical genus. Whether the group will ultimately turn up in South America remains to be seen, but the new discovery affords additional evidence of the community of the fauna of the old "Gondwanaland."

We have been favoured with a copy of a summary, by Dr. Max Fürbringer, of the scientific results of Prof. R. Semon's zoological expedition to the Malay Archipelago and Australasia, as worked out by specialists in the six volumes of the well-known "Zoologische Forschungsreisen," to which this "Schlussübersicht" forms an appendix. Prof. Semon started on his journey from Jena in June, 1891, remaining from the following September until January, 1892, in Australia, and spending from February until May in visiting Easter and other islands, and the south coast of British New Guinea. At the end of October, 1892, he arrived in Java, whence he proceeded to the Mollucas, Celebes, etc., finally returning homeward in April, 1893. On his arrival scientific work was commenced with the least possible delay, so that the "Reisen" embodies the results of some twenty years' labour. How greatly these labours have augmented our knowledge of marsupials, monotremes, Ceratodus, and many other groups, to say nothing of their bearing on the problems of distribution in the Austro-Malay area, is well known to every working zoologist.

An instructive account of experiments on the manuring of grass land in Oxfordshire has been prepared by Mr. G. R. Bland (Bulletin 15, University College, Reading). The work, which was commenced in 1909, has been carried out with special reference to the conditions obtaining with soils of different geological formations, and, in order to allow of comparison in other cases, a geological and a rainfall map of the county are included. The scheme of manuring is, if anything, rather limited in scope, but the general character of the account with regard to yields, profit and loss, botanical composition of the herbage and photographs of certain of the plots, is of great value, and is worthy of imitation by other county workers.

In a contribution to the *Journal of Agricultural Research*, Mr. G. N. Collins describes a drought-resisting adaptation in maize which appears to possess considerable economic value for conditions in semi-arid regions. Experience has shown that, in the case of common varieties, if the seed is planted at the customary depth, many seeds fail to germinate from insufficient moisture; if planted deep enough to come in contact with moist soil, the plants may fail to reach the surface. A study of the varieties grown by the Hopis and other agricultural Indians shows, however, that these varieties possess two special adaptions: (1) a greatly elongated mesocotyl that permits of deep planting, and (2) the development of a single large radicle that rapidly descends to the moist subsoil and supplies water during the critical seedling stage. The productive power of some of these varieties compares favourably with that of ordinary "improved" varieties even when grown under irrigation conditions. On these grounds a further study of some of these special varieties seems desirable.

To restrain a horizontal pendulum from executing its own oscillations during the passage of earthquake-waves, some method of damping is usually resorted to, either the electromagnetic method of Galitzin, the air-damping of Wiechert, or the liquid damping of other seismologists. After three years' work in experimenting with free and damped pendulums, Dr. A. Cavasino concludes (*Boll. Soc. Sism. Ital.*, vol. xvii., pp. 89–101) that a damped pendulum still tends to oscillate with its proper period; that except with violent earthquakes the beginning of the movement is retarded, it may be for several minutes, as compared with that indicated by a free pendulum; and that less than one-half of the earthquakes recorded by a free pendulum are registered by a corresponding damped pendulum.

In the Proceedings of the American Philosophical Society, Philadelphia (vol. lii., No. 208, pp. 31–162), Mr. J. J. Stevenson brings to a conclusion his lengthy monograph on the formation of coal beds. Parts i. and ii. appeared in vol. l., and part iii. in vol. li., of the same journal. Whether geologists accept his views or not—and many geologists will do so—all will be grateful to him for his great labour in gathering together the opinions of others on this much-discussed subject, and for the pains he has taken in collecting evidence from modern deposits of carbonaceous material and from Coal Measures of all ages in all parts of the globe. The author concludes:—"The coal beds and the associated rocks are of land origin; the detrital deposits are those made by flooding waters on wide-spreading plains; the coal beds, in all essential features, bear remarkable resemblance to peat deposits, sometimes to the treeless moor, more frequently to the Wald moor." But, as he very truly says, many matters still await explanation, and he emphasises the fact that no extensive coalfield has yet been closely studied, for in spite of the imposing array of skeleton sections there is an astounding lack of detail respecting many matters which appear to have no important bearing on commerce. Until the topography and geography of the Coal Measures land have been worked out, geologists must be content merely with probabilities concerning the remarkable bifurcation of some coal beds, the variations in subordinate intervals between two approximately parallel coal beds, the presence of huge blocks of transported rock in coal and the associated rocks, the immensely long periods of stable conditions indicated by the thickness of some coals, and with similar problems.

An article, entitled "The Meteorological Service on Mercantile Vessels," appears in vol. ix. (1913–14) of the Italian *Annali Idrografici*. The author, Prof. L. Marini, chief of the meteorological branch of the Hydrographical Institute, points out that although meteorological observations have not been neglected by vessels belonging to the several important shipping companies, they have not hitherto been dealt with on the same scale as observations on land. The publication of pilot-charts of the Mediterranean has been left to other countries, *e.g.* the United States, Germany, and this country. It is now intended that Italy shall take her proper place in such work, and with this view an earnest appeal was made in a circular to the national navigation societies on June 1, 1912, by the Minister of Marine, in which he points out the provisions made for the successful working of the service. A long list of registers received by the institute during the succeeding half-year clearly shows that the appeal has met with a very favourable reception among the seafaring community; we may therefore confidently look forward to some valuable contributions in due course to the meteorology of the Italian seas and adjacent regions.

In the *Popular Science Monthly* for March Dr. P. G. Heineman advances the view that development of automobile traffic will be beneficial to public health in two ways: first, by the provision of dust-proof roads, thus minimising the diffusion of disease germs which are commonly associated with dust, and secondly by doing away with stables which are fertile breeding grounds for flies that act as carriers of disease.

Readers of the *Cornhill Magazine* for March will derive considerable enlightenment from the article entitled "After the Death of Euclid," in which Mr. C. H. P. Mayo endeavours to compare the advantages and disadvantages of the old and new methods of teaching geometry. While admitting that the new method is beneficial in many respects, the author evidently considers that the sacrifice of logical training involved in the change may seriously impair its educational value.

The March number of the Transactions of the Institution of Engineers and Shipbuilders of Scotland contains an important paper by Mr. H. Ollendorff on the utilisation of ground adjoining harbours and railway stations. He shows that by the use of suspension railways enabling the goods unloaded from ships at the wharf to be taken direct into the factory, the cost of transport is so far reduced that the "hinterland" of a harbour can be profitably utilised to about ten times the extent it is at present. On this ground he advocates the provision of suspension railways by public authorities, which at the present time provide cranes for service at harbours.

A paper by Hiromu Takagi on the thermomagnetic properties of magnetite, which appears in the third part of vol. ii. of the Science Reports of Tohoku University, Japan, casts some doubt on the accuracy of the results obtained by Prof. Weiss and Foex for the variation of the magnetic susceptibility of magnetite with temperature. They found that at about 680° C. the susceptibility showed a sudden decrease which they attributed to some change in the internal state of the artificial magnetite used by them. Such changes led Prof. Weiss to postulate the existence of the magneton or atom of magnetism which a substance can possess only in integral multiples. The present experiments on natural magnetite show that the substance neither follows Curie's law—susceptibility inversely as the absolute temperature—nor are there any sudden changes in the curve of susceptibility as a function of the temperature.

In the current number of the *Comptes rendus* MM. Charles Moureu and A. Lepape discuss the cause of the constancy of composition of crude nitrogen (nitrogen with the rare gases) from various sources. The ratios between the nitrogen, argon, krypton, and xenon have been found to be the same in gases derived from fire-damp, thermal springs, petroleum, volcanic gases, or the atmosphere. This constancy of composition of nitrogen from natural sources is regarded by the authors as having existed from the nebular stage of the solar system. The same number also contains some measurements by Georges Claude on the amounts of hydrogen, helium, neon, and nitrogen absorbed by charcoal at low temperatures, $-182\cdot5°$ for nitrogen, $-195\cdot5°$ for the other gases. The amounts of helium and neon absorbed are much smaller than the absorptions of hydrogen and nitrogen. The position of hydrogen is anomalous, since it deviates from the rule that the lower the boiling point the smaller the charcoal absorption.

Railless electric traction systems, otherwise designated the "trolley-bus" or "trackless-trolley," already form in several cities extensions to the tramways systems, and there are numerous applications to Parliament for the authorisation of similar lines. Mr. T. G. Gribble, in a paper on these systems read at the Institution of Civil Engineers on March 24, says that it requires no more current to carry the passenger by railless electric traction than it does by a tramway. The author shows that with a traffic density represented by a $2\frac{1}{2}$ minute service, the economy of construction in favour of railless electric traction is about 44 per cent., and in cost of operation about 7 per cent. The economy increases inversely with the traffic density; with a 30-minute service the economy of construction is about 70 per cent., and that of operation is about 36 per cent.

The annual volume of *Knowledge* for 1913 is now available. The twelve monthly issues of our contemporary together form a handsome book which makes a special appeal to readers interested in nature knowledge. Attention may be directed to the excellent illustrations, the plates particularly being well produced. The price of the volume is 15*s.* net.

SOON after the death of Prof. Henri Poincaré, four appreciative notices of his work in various departments of knowledge were contributed to the *Revue du Mois* by Profs. Vito Volterra, Jacques Hadamard, Paul Langevin, and Pierre Boutroux. These studies have now been published together in a volume entitled "Henri Poincaré: L'œuvre scientifique, l'œuvre philosophique" (Paris: Félix Alcan; price 3.50 francs).

THE annual report of the Board of Scientific Advice for India for the year 1912–13 has been received from Calcutta. The report is divided into sections dealing respectively with applied chemistry, astronomy, and meteorology, geology, geodesy, botany, forestry, zoology, veterinary science, and medical research work. An appendix by Dr. W. R. Dunstan contains the report on the scientific and technical investigations conducted for India at the Imperial Institute during the year ended June 30, 1913.

DR. W. LEIGHTON JORDAN writes, with reference to a paragraph on the origin of planetary surface features and the "heart-shaped" figure of the earth, which appeared in our issue of March 19 (p. 69), that in 1866 he applied the term "cardioid" to the earth's shape, and pointed out that the motion of the earth through space tends to create high land in the Antarctic and deep water in the Arctic region. A description of Dr. Jordan's views upon this subject will be found in his work entitled "The Sling" (London: Simpkin, Marshall, Hamilton, Kent and Co., Ltd.).

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR APRIL:—

April 3. 15h. 6m. Mars in conjunction with the Moon (Mars 2° 0′ S.).
4. 4h. 28m. Neptune in conjunction with the Moon (Neptune 4° 30′ S.).
5. 23h. 0m. Neptune stationary.
6. 19h. 0m. Mercury at greatest elongation W. of the Sun (27° 46′ W.).
10. 15h. 0m. Mars at quadrature to the Sun.
15. 19h. 0m. Neptune at quadrature to the Sun.
17. 22h. 50m. Uranus in conjunction with Moon (Uranus 2° 20′ N.).
18. 12h. 13m. Jupiter in conjunction with the Moon (Jupiter 1° 50′ N.).
20. 22h. 24m. Mars in conjunction with Neptune (Mars 2° 34′ N.).
23. 2h. 33m. Mercury in conjunction with the Moon (Mercury 5° 30′ S.).
26. 18h. 20m. Venus in conjunction with the Moon (Venus 4° 52′ S.).
28. 11h. 11m. Saturn in conjunction with the Moon (Saturn 6° 22′ S.).

A NEW COMET.—A telegram from Prof. Kobold at Kiel reports the discovery of a new comet by Dr. Kritzinger at Bothkamp. The comet is of magnitude 9·5, and was picked up on March 29 at 15h. 29·1m. Bothkamp mean time. Its position is given as R.A. 16h. 11m. 40s., and declination 9° 31′ S., and the daily motion as +3m. 8s. in R.A., and −32′ in declination. It is described as having a tail.

JUPITER VISIBLE BEFORE SUNRISE.—The planet Jupiter can now be well seen in the mornings, and it is important that telescopic observers examine his disc carefully and note the chief features. Last year the equatorial current had increased its rate of movement, its rotation being 9h. 50m. 11s. from a number of spots on the south edge of the northern equatorial belt. Are these markings still visible, and what is their velocity as compared with that determined during the previous opposition?

The great red spot also exhibited a quickening of speed in 1914, the rotation period being 9h. 55m. 35s. It is probable that at the present time the red spot precedes the zero meridian of System II. (see ephemeris for physical observations of Jupiter in Nautical Almanac) about 3h. 40m. It is impossible to tell exactly, however, because the planet has been too near the sun during the past winter for corrective observations to be made. Transits of the red spot and hollow in the southern belt may, however, be looked for at the following times:—

		h.	m.			h.	m.
April 14	...	14	27	May 3	...	15	6
16	...	16	5	8	...	14	14
21	...	15	12	15	...	14	59
26	...	14	20				
28	...	15	58				

Some estimated transits would be valuable in order to determine what the rate of rotation has been during the last six months.

The great south temperate spot now precedes the red spot. The former was no less than about 135° in length during last opposition, and it may ultimately extend all round Jupiter and darken the previously brilliant south tropical zone.

A PROPOSED TOWER TELESCOPE.—From Modena we have received a pamphlet describing a tower telescope to be erected to the memory of Secchi. It is proposed to build at Reggio-Emilia in reinforced concrete a pyramidal structure 35 m. high. Its memorial character is to be expressed by making the work, decorated in what is described as the Chaldeo-Babylonian style, serve as a canopy to a seated effigy of Secchi, whilst at the four corners of the base will be placed gigantic statues of Copernicus, Galileo, Kepler, and Newton. The scientific purpose is to make the tower carry the heliostat and objective of a vertical telescope of the type so successfully employed at Mount Wilson. A sum of 500,000 lire (20,000*l.*) is required, of which about 150,000 lire had already been collected by a permanent committee.

This is not the only project now on foot to perpetuate the memory of an astronomer. An influential international comité d'honneur is inviting subscriptions for the erection of a monument to the memory of Laplace, at his birthplace, Beaumont en Auge (Calvados), Normandy.

ANNUAL REPORT OF THE HAMBURG OBSERVATORY IN BERGEDORF.—The report for 1912 of the Hamburg Observatory in Bergedorf has just come to hand. It shows that great strides have been taken since this site was occupied, in spite of various hindrances regarding the larger instruments. Thus the large reflecting telescope had to undergo a change in the method of mounting the mirror, that used by Common and Ritchey being finally adopted. The report gives a brief *résumé* of the work of the various branches accomplished during the year, and an appendix contains a table giving the corrections to the Norddeich and Eiffel Tower wireless time signals. The report is accompanied by some good reproductions of some of the larger telescopes, and two pictures of the annular solar eclipse of April, 1912, secured by Prof. A. Schwassmann with the Lippert astrographic instrument.

OPTICAL ROTATORY POWER.

THE Faraday Society has adopted in recent years the policy of organising a series of general discussions on physico-chemical subjects, to which investigators of all countries are invited to contribute. The ninth of these discussions, on optical rotatory power, was held in the rooms of the Chemical Society on Friday, March 27. At the afternoon session the chair was occupied by Prof. Armstrong, who contributed an introductory address; the evening session was presided over by Prof. Frankland. Papers were read by Prof. H. Rupe, of Basle, on the influence of certain groups on rotatory power, by Prof. H. Grossman, of Berlin, on the rotatory dispersion of tartaric and malic acids, by Dr. T. M. Lowry and Mr. T. W. Dickson, on simple and complex rotatory dispersion, by Dr. T. M. Lowry and Mr. H. H. Abram on an enclosed cadmium arc for use with the polarimeter, by Dr. R. H. Pickard and Mr. Joseph Kenyon, on the rotatory powers of the members of homologous series, and by Dr. T. S. Patterson, on the dependence of rotation on temperature, dilution, nature of solvent, and wave-length of light. Papers were also communicated by Prof. L. Tschugaeff, of St. Petersburg, on anomalous rotatory dispersion, by Dr. E. Darmois, of Paris, on the existence of racemic tartaric acid in solution, by Dr. G. Bruhat, of Paris, on the rotatory power of tartaric acid, and by Prof. A. Cotton, of Paris, on the constitution of liquid mixtures and their rotatory power.

Two distinct schools of research were conspicuous in the papers and in the discussion. The attempts to find a relationship between chemical constitution and the rotatory power of compounds for sodium light received its greatest impetus from the theory put forward in 1892 by Crum Brown and Guye, to whom, at the suggestion of Prof. Armstrong, greetings were sent from the meeting; this school of research was well represented by Prof. Frankland, who had no difficulty in showing that results of very great value had been obtained from observations made with light of one colour only, that of the sodium-flame. Prof. Rupe gave a masterly summary of his work on the influence of unsaturated groups on rotatory power; this work had also been done mainly with sodium light, but there was no reason to suppose that the results would have been essentially different if light of other colours had been used. Dr. Patterson, in describing his observations on the influence of temperature and of solvents on the rotatory power of the tartrates for sodium light, was able to show that there is an essential unity in the effects produced by these two widely different factors; this unity could be extended to include some features in the behaviour of these liquids towards light of different colours, as recorded by Winther and others.

An element of novelty attached to the description of several series of researches which depended on the measurements of rotatory dispersion—a subject which has come suddenly to the front, both in England and on the Continent, during the course of the last two or three years. The apparatus required for measuring rotatory dispersion was exhibited by Mr. Abram, who also succeeded in showing an enclosed cadmium arc in actual operation. This arc is likely to be of great value in experiments on rotatory dispersion, because it provides a pair of lines, Cd 5086 (green) and Cd 6438 (red), which can be read with the same accuracy as the mercury lines, Hg 4359 (violet) and Hg 5461 (green). Thus it has been used to prove that α-methylglucoside, a compound which contains five asymmetric carbon atoms, obeys strictly the simple dispersion law given by the formula,

$$a=\frac{k_0}{\lambda^2-\lambda_0^2}.$$

This law also holds good for a long series of alcohols prepared and described by Dr. Pickard and Mr. Kenyon, the dispersive power of which remains constant over wide ranges of temperature, and may persist almost unchanged throughout the whole range of a homologous series.

Rotatory dispersion has usually been classified as *normal* when the rotation increases steadily as the wave-length diminishes, and as *anomalous* when in any part of the spectrum the rotation diminishes with the wave-length. The most familiar examples of anomalous rotatory dispersion are (i) tartaric acid, for which a remarkable series of data were recorded in M. Bruhat's paper; (ii) ethyl tartrate, studied exhaustively by Dr. Patterson; and (iii) methyl malate, which has been examined by Grossman in nearly one hundred different solvents. More recently Dr. Pickard and Mr. Kenyon have detected the same phenomenon in the simple esters of their optically active alcohols, and also in the α-naphthylmethylcarbinol,

$$C_{10}H_7.CH(OH).CH_3,$$

when this is examined in the superfused state.

Dr. Patterson protested against a classification which represented ethyl tartrate as showing "normal" dispersion in some solvents and "anomalous" dispersion in others. He argued that it was merely a matter of accident whether the maximum of optical rotation occurred within or without the region of the spectrum used for the polarimetric observations. This contention was supported by Dr. Lowry and Mr. Dickson, who were able to quote cases in which the camera had revealed a maximum beyond the limits of visual observation. They proposed to describe as *simple rotatory dispersion* all those cases to which the formula,

$$a=\frac{k_0}{\lambda^2-\lambda_0^2}$$

can be applied. All cases in which two or more terms are required to express the dispersion, thus—

$$a=\frac{k_1}{\lambda^2-\lambda_1^2}\pm\frac{k_2}{\lambda^2-\lambda_2^2},$$

were to be described as *complex rotatory dispersion*, whether the curves were anomalous or apparently normal in the region investigated. Simple rotatory dispersion may be detected very easily by plotting $1/a$ against λ^2, when the experimental data are found to fall on a straight line. When two terms, with constant values of λ_1^2, and λ_2^2, are sufficient to express the rotatory dispersion of a substance over a wide range of experimental conditions, the "characteristic diagram" of Armstrong and Walker will plot out to a series of straight lines, but this will no longer be the case if three "dispersion-constants," λ_1^2, λ_2^2, λ_3^2, are required.

The cause of anomalous rotatory dispersion was discussed by Prof. Tschugaeff. It can be produced by mixing two substances of opposite rotatory power and unequal dispersion (Biot) or by superposing two partial rotations, as in the camphorsulphonate of menthol (Tschugaeff). It may also be produced by an absorption-band in the visible spectrum (Cotton's phenomenon), or, as R. W. Wood has pointed out, by a band in the infra-red region. The view that anomalous rotatory dispersion is usually caused by the presence of two species of optically active molecules in the liquid was adopted by Armstrong, Grossman, Pickard, and other speakers; in support of the same view, it was stated in the discussion that nitrocamphor, which exists in two isodynamic forms, gives anomalous rotatory dispersion in acetone, and that ethyl tartrate may be fractionated into portions which differ very widely in their rotatory power for violet light, although the differences are small when green or yellow light is used.

LIZARD VENOM.[1]

THE results of a comprehensive study of the poison of Heloderma, undertaken by several observers, under the direction of Prof. Leo Loeb, at the laboratory for experimental pathology, University of Pennsylvania, are published by the Carnegie Institution of Washington in the volume before us.

Heloderma, or the Gila monster, is a lizard attaining the length of 2 or 3 ft., which inhabits the dry regions of Mexico and Arizona. It is of alarming appearance, and regarded by the natives with the utmost dread, although the results of a bite from this reptile are not very serious to man. The two species of the genus are peculiar in that they are the only reptiles other than snakes which possess poison glands in relation to some of their teeth. Unlike the poison glands of snakes, those of Heloderma are situated in the lower jaw, and consist of four independent sacs on each side, which open into separate cup-like depressions of the mucous membrane just external to the anterior mandibular teeth. When the jaw is closed the corresponding teeth project into these depressions and thus both upper and lower sets become bathed with the secretion.

The first article contains a good account of the anatomy and histology of the poison gland, and is followed by one on the histological changes in the gland after stimulation by pilocarpine. Then follow papers on the general properties and action of the venom and on some experiments in immunisation. The general lines followed in these studies are those previously traversed by various observers with snake-poisons, with which Heloderma venom has many similarities. The venom is an albuminous fluid, but the albumen can be coagulated by boiling without destroying the toxic principle. The latter is, however, carried down in the precipitate, to which it apparently adheres. This toxin seems, in fact, to adhere to almost any kind of fine precipitate, and this property has led to difficulty in all attempts to separate the essential poison.

The main poisonous constituent of the venom is a neurotoxin, and death is caused by gradual paralysis and ultimate cessation of respiration. From experiments upon isolated strips of cardiac muscle, the heart does not seem to be directly affected and the fall of blood pressure following the injection of the venom is presumably due to paralysis of the vasomotor centres. The nerve cells of animals killed by the venom show chromatolytic changes similar to those observed by Kilvington and Lamb and Hunter in snake poisoning. The venom has no influence on the coagulation of blood, nor does it produce hæmorrhages. It does not itself hæmolyse blood corpuscles, but, if mixed with lecithin it gives rise to a hæmolytic substance. This, as has been shown to be the case with cobra venom, is presumably due to the action of the lipase it contains upon the lecithin. The subcutaneous injection of subminimal lethal doses is followed by a considerable but temporary leucocytosis. Admixture of the venom with leucocytes and staphylococci does not hinder phagocytosis.

The memoir concludes with an account of attempts to separate an active principle from the venom, using the methods by which Faust obtained a non-nitrogenous active body in the case of cobra and crotalus venoms. These methods proved to be unsuitable, but by dissolving the venom in glacial acetic acid and precipitating, first with weak alcohol and then with stronger alcohols, and ultimately with ether, it was found that the successive precipitates with alcohol contained less protein and more active substance, and that the final precipitate with ether was protein free, but very active.

The above short *résumé* gives some idea of the extent of these researches, although a number of papers included in the volume, of less general interest, have not been referred to.

The work seems to have been carefully planned and performed, but the statements about snake venoms are occasionally inaccurate, as, for instance, the affirmation on p. 56 that the venoms of Hoplocephalus and Pseudechis may be heated without injury, and on p. 60, that the "venom of Viperidæ" does not pass through a Chamberland filter.

C. J. MARTIN.

[1] "The Venom of Heloderma." By Leo Loeb, with the collaboration of a number of workers. Pp. vi+244. (Washington: Carnegie Institution of Washington, 1913.)

CHINESE PALÆONTOLOGY.[1]

THE volume before us contains the palæontological results of the Carnegie expedition to China in 1903–4, and is an important contribution to our knowledge of the Palæozoic faunas of eastern Asia. The principal memoir is by Dr. Walcott, and deals with the Cambrian fossils which were found in large numbers. A total of sixty-three genera and 245 species are described and figured, and of these thirty-six genera and 175 species are trilobites (including five genera peculiar to China) and thirteen genera and thirty-six species are brachiopods. The oldest fossiliferous rocks are referred to the upper part of the Lower Cambrian and contain the Redlichia fauna, so that we are now acquainted with this fauna from Shantung, Yun-nan, Spiti, and western and southern Australia, as well as from the Salt Range where it was first found. It is, however, from the Middle Cambrian that the richest and most varied fauna was obtained in the Chinese provinces of Shantung, Shen-si, Shan-si, and in Manchuria, as was the case in the central Himalayas. A rapid process of evolution under new conditions of environment was originated at this period, accompanied by the more or less complete isolation of parts of the marine area, leading to the formation of local faunas. But on the whole the affinities of the Asiatic Cambrian fauna prove to be with the Cordilleran Province of western North America, and with the Upper Mississippian Province of the United States rather than with Europe. This is emphasised by the absence of the genus Paradoxides in western North America, China, and India, though other genera connect these areas with the Atlantic Province. In the Upper Cambrian a similar relationship is noticeable. From the evidence now available Dr. Walcott recognises three faunal provinces in Asia

[1] "Research in China." Vol. iii., The Cambrian Faunas of China, by C. D. Walcott; A Report on Ordovician Fossils Collected in Eastern Asia in 1903–4, by S. Weller; A Report on Upper Palæozoic Fossils Collected in China in 1903–4, by H. Girty. Pp. vi+375+29 plates. (Washington: Carnegie Institution of Washington, 1913.)

in Cambrian times, and these he terms respectively the Shantung Province (including Manchuria and Shan-si), the Punjab Province (including Yun-nan), and the Siberian Province.

Passing to the description of the new genera and species from China, we cannot help regretting that there is a general absence of individual comparison of the new forms with previously established or well-known species from other lands. It would have been especially valuable to have had their affinities discussed by Dr. Walcott, with his ripe experience and world-wide knowledge of Cambrian fossils. He indeed expresses the opinion that the excellent illustrations of the new species will enable other investigators to pursue such a study as occasion requires; but no plates or figures, however good, can remedy such a defect in the original descriptions, and this omission robs the memoir of much of its value.

The Ordovician fossils described in the second section by Dr. Weller, have been obtained partly from Shantung and partly from Ssï-ch'uan. The former are very poor and few in number, and no specific determinations were found possible, but their stratigraphical horizon is believed to be Middle Ordovician. The fossils from eastern Ssï-ch'uan are quite different in character and in much better preservation. They were obtained from a thick limestone resting conformably on the Cambrian, and consist chiefly of brachiopods and trilobites, some species of which were described in 1901 by Martelli from Shen-si. Richthofen's Ordovician fossils from northern Ssï-ch'uan, collected more than thirty years ago, are regarded as indicating the same geological horizon which Dr. Weller correlates with the Mohawkian (Middle Ordovician) of North America. The fossiliferous Ordovician beds of the central Himalayas, to which he makes no reference, have been regarded as of the same age. There is no similarity to the Ordovician faunas of eastern Yun-nan and Tonkin or of the Northern Shan States, but some species appear comparable or closely allied to Spiti forms; and in south-western Yun-nan it is probable that the Ssï-ch'uan fauna is represented. A conclusion of special interest at which Dr. Weller arrives is that there is a mixture of North American and Baltic forms in China, as in the Himalayas, where, however, the American element seems to be stronger.

The Carboniferous fauna described by Dr. Girty from Shantung, Shan-si, and Ssï-ch'uan is very scanty and of peculiar facies, but seems remotely allied to Russian and Indian faunas, and is considered to be of Upper Carboniferous (Pennsylvanian) age, with the exception of a few very doubtful fossils. The rich Middle and Upper Carboniferous faunas described by Kayser, Loczy, Mansuy, and Deprat from other parts of China appear to be unrepresented.

F. R. C. Reed.

MARINE BIOLOGY.

The life-histories of the Pacific Coast salmon and the halibut caught off the west coast of North America form the subject of two papers just published by Dr. J. P. McMurrich in vol. vii. of the Transactions of the Royal Society of Canada. In this work the author puts the method of scale examination to a somewhat severe test. It is fairly certain that this line of investigation must be regarded only as supplementary to detailed research by means of fishery experiments and statistical studies; such is the experience of most workers in Europe. Yet Dr. McMurrich does not hesitate to describe the conclusions that may be deduced from the study of the scales of twenty-two, or ten, or even three fishes, as "remarkably definite." The species of Oncorhynchus (the Pacific salmon) spawn only once in their lifetimes. The Pacific halibut becomes mature in its eighth year, and then enters upon a period of reproductive maturity. The ova ripen gradually, and "spawning is not a matter of a few days or even weeks, but is prolonged over, it may be, several years." This is too exceptional and improbable a result to deduce from a microscopic examination of the scales of three fishes, especially when the author admits that practically nothing is known as to the life-history of the halibut in North American waters. It is also incorrect to say that planktonic ova of this fish have not been found in European waters. Less, perhaps, is known about the halibut than most other Pleuronectids, but our ignorance is not such an utter blank as is suggested in the paper noticed.

Part i. of the Journal of the Marine Biological Association, published in November, 1913, contains papers dealing with varied aspects of marine biology. Mr. J. H. Orton, in a most useful paper, describes the functioning of the ciliary mechanisms on the gills of Amphioxus, Ascidians, and Solenomya. English writers, apparently accepting as correct the earlier work of Fol, have described food collection as occurring in the endostyle of Ascidians, the solid particles being then conducted along the peripharyngeal grooves, and so into the dorsal groove. Mr. Orton points out that no food-matter at all is taken up by the endostyle. The latter secretes mucus, which is then driven dorsally over the pharynx to the dorsal groove. Essentially the same mode of functioning of the ciliary tracts occurs both in Amphioxus and Ascidians. The pharynx in these animals, and the gills in Lamellibranch molluscs, are not respiratory mechanisms, but organs which function as water-pumps and food-collectors. In the same number of the journal there is an account of some very interesting experiments made by Mr. J. Gray with the object of investigating the chemical and physical changes which occur when the egg of the sea-urchin is naturally fertilised. The entrance of the sperm into the egg raises the electrical conductivity of the latter, the change attaining a maximum within ten minutes of the addition of the sperms to the ripe eggs. The egg-membrane in the unfertilised condition is remarkably impermeable to electrolytes, its surface being polarised. Probably the entrance of the sperm effects depolarisation and increases the permeability of the membrane to ions, but in some fifteen minutes polarisation again occurs, and the egg returns to its electrical state prior to fertilisation. Five other papers in the journal are written by zoologists of University College, Aberystwyth, and deal with sea-anemones, with the habits of the Galatheidea, and with the littoral fauna of Cardigan Bay. Dr. Th. Mortensen writes also on the development of some British Echinoderms. This number of the journal is altogether a very interesting one.

CRYSTALLINE STRUCTURES AS REVEALED BY X-RAYS.[1]

The analysis of crystal structure by means of X-rays depends on the fact that a pencil of X-rays of uniform quality is reflected by a crystal face when, and only when, it meets the face at exactly the proper angle. As we shall see presently, the effect depends on the regularity of the crystal structure according to which the atoms of the crystal are arranged in planes, which are parallel to the face and regularly spaced. There is a certain relation between

[1] From a lecture delivered before the Manchester Literary and Philosophical Society on March 18, by Prof. W. H. Bragg, F.R.S.

the wave-length of the X-radiation, the spacing of the planes, and the proper angle of incidence. If we always use the same rays, and measure the angles at which they are reflected by the different faces of a crystal, natural or prepared, we discover the relative spacings of the many systems of planes which can be drawn regularly through the atoms of the crystal; and hence the actual arrangement of the atoms can be deduced. It is in this way that the structure is analysed.

Let us first consider some details of the reflection effect. The theory is not entirely strange to us, for Lord Rayleigh carefully investigated a strictly analogous phenomenon twenty-five years ago; this was the brilliant coloration of crystals of chlorate of potash. When white light falls on these crystals there is a strong selective reflection of rays the wave-lengths of which are confined within very narrow limits. R. W. Wood has prepared crystals which reflect waves the limits of which are no wider apart than the two D lines of sodium. Rayleigh showed that the effect was due to the existence of regularly spaced twinning planes parallel to the reflecting surface. He pointed out the analogy to other physical problems in sound, and in a Friday evening discourse at the Royal Institution he illustrated the effect by reflecting a high-pitched note by a series of parallel muslin sheets stretched tight and evenly spaced.

Rayleigh showed that in these and parallel cases the reflection must be total provided the number of planes was sufficiently great, no matter how feeble the reflection from each plane. In the present case the wave-lengths of X-rays are many thousands of times smaller than the waves of light which Rayleigh used; and the crystal planes being at atomic distances from each other are also many thousands of time closer than the twinning planes of chlorate of potash.

It is found that pencils of homogeneous X-rays suitable for use in the experiment, are contained in the general mass of radiation issuing from an X-ray bulb. The antikathode of the bulb emits "lines" or rays of definite wave-length which are characteristic of the material of which it is made.

The platinum antikathode gives a spectrum containing five sharply defined and intense lines which stand out well from the general radiation. The osmium spectrum appears to have five similar triplets instead of the five lines of the platinum, the head of each triplet coinciding with a platinum line. Several substances ranging in atomic weight from silver down to calcium emit similar spectra consisting each of two strong lines, increasing regularly in wave-length as the atomic weight decreases. A large number of these have been photographed by Moseley. Bulbs having rhodium or palladium antikathodes have been exceedingly useful in the crystal analysis, as they last well, their line spectra are very intense, and the wave-lengths are of convenient magnitude. The principal rhodium line is really double; and it will serve to illustrate the surprising exactness of the reflection effect when it is stated that the two constituents are just separated by reflection at the cleavage face of the diamond. The glancing angles are then 8° 35′ and 8° 39′.

Let us next consider the application of these principles to the determination of crystal structure. We take first, naturally, the large class of cubic crystals which are not only of high importance, but also of the most simple construction.

The atoms of a crystal can be arranged in the form of a repeated group or pattern. Each group is to be supposed to contain as few atoms as possible consistent with the requirement that the whole crystal can be built by packing these groups together, all the groups being similar and similarly oriented. If a point is chosen similarly in each group it serves to indicate the position of that group relative to other groups. An arrangement of points chosen in this way shows the basal structure of the crystal, and is known as a "space lattice."

There are three space lattices which give cubic character to crystals. In the first the representative points are placed at the corners of a cube; the whole lattice consisting of a repetition of this arrangement in all directions in space. In the second there are representative points at the corners of a cube, and the centre of the cube; in the third at the corners of a cube and at the middle points of the faces. The three are called the cubic, the centred cubic, and the face-centred cubic respectively.

These three types of lattice can be at once distinguished from each other by the X-ray method. Suppose we consider three important types of plane which may be drawn through the atoms of a cubic crystal, that is to say, planes perpendicular to (*a*) a cube edge, (*b*) a face diagonal, (*c*) a cube diagonal. If we draw a diagram or build a model we find readily that the relative spacings of the three sets are different in the different crystals, and this causes corresponding differences in the angles of reflection of some standard line.

Proceeding on these lines we come at once to a case of great importance. Rock-salt or sodium chloride and sylvine or potassium chloride have long been known to be of similar construction, though the nature of the construction has been uncertain until now. X-ray analysis shows, however, that the former crystal has the characteristics of the third class of lattice, and the latter of the first. Moreover, it appears that the elementary group or pattern contains the same number of atoms in each case. There is one obvious way of explaining these facts. Suppose that we place chlorine atoms at the corners of a cube and at the centres of the faces and sodium atoms at the middle points of the edges of the cube and at the cube centre, and take this to represent the structure of rock-salt. Potassium chloride may be derived from sodium chloride by replacing the chlorine atoms of the structure by potassium. Now it appears from a number of mutually supporting indications that the contribution of an atom to the reflection effect depends on its atomic weight only. The atoms of potassium and chlorine are of very nearly the same weight, and can be looked on as equivalent. If this is done the structure of potassium chloride is in effect the simple cubic. But there is a great difference between the weight of sodium and chlorine, and the face-centred arrangement of the chlorine atoms taken separately gives its character to the whole rock-salt structure. All this agrees with experiment. But there is more. The presence of the sodium atoms amongst the chlorine, arranged as a matter of fact on a face-centred lattice of their own, modify the purely face-centred character of the spectra, and experiment shows that the modification is exactly such as theory predicts.

It is impossible in a short account to describe in full the work that has or can be done. Moreover, description is difficult without the aid of a plentiful supply of diagrams or models. It will be sufficient to say that the examination of the positions of the spectra, and especially of the relative intensities of the different orders give information which is gradually being interpreted. The simpler crystals have already been analysed, and the structure of many of the more important cubic crystals is known. The more complex structure of the calcite series has been determined, and something has been discovered of the still more difficult structures of sulphur and of quartz. It must be remembered that in all these cases complete analysis requires not merely the determination of the lattice, but, what is far more difficult, the arrangement of the atoms in the group which is represented by each point on the lattice.

We may consider certain points of more general interest. The structure of the diamond stands out with some prominence. It is interesting to find that the carbon atoms are arranged in the most beautifully symmetrical pattern, each being at the centre of a regular tetrahedron composed of its four nearest neighbours. Rings of six carbon atoms are a predominating feature. Planes perpendicular to a cube diagonal—the diamond is, of course, a cubic crystal—are arranged in a curious way, the spacings being alternately large and small in the proportion of three to one. This leads to the extinction of the second order reflection from these planes. The effect can be readily illustrated optically by ruling a diffraction grating in the corresponding fashion. Zincblende has exactly the same structure as the diamond, but the alternate planes of the kind just mentioned contain alternately zinc atoms alone and sulphur atoms alone. This explains the well-known polarity of the crystal. Iron pyrites has a rather more complicated structure, which explains at once the curious disposition of the striations on its faces. Sulphur has eight interpenetrating lattices, quartz three of silicon and six of oxygen. In each of these two cases there is regular spacing of the lattices along the long axis, but not in other directions.

The atoms of a crystal are not, of course, at rest; the extent of their movements depends on thermal considerations. As the temperature rises the motion increases. According to theory, this must tend to destroy the intensity of the spectra, particularly those of higher order. Experiment confirms the theoretical deduction, and gives some promise of being able to decide between conflicting hypotheses as to the extent of the thermal influence. It is curious to observe the angles of reflection diminish as the crystal expands with heat and the spacings of the planes increase. The method might even be applied to the measurement of coefficients of expansion of crystals.

Lastly, the study of the X-ray spectra emitted by various substances when made the antikathodes of the X-ray bulb gives valuable information respecting atomic structure, and is most skilfully made use of in the investigations which are being conducted in the physical laboratory of the University of Manchester.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

London.—Prof. H. H. Jeffcott has been appointed by the Senate to the chair of engineering tenable at University College, vacated by the appointment of Prof. J. D. Cormack to a professorship at Glasgow. Prof. Jeffcott was educated at Trinity College, Dublin, and is now professor of engineering in the Royal College of Science, Dublin.

The D.Sc. degree in physics has been granted to Dr. E. E. Fournier d'Albe, Royal College of Science and Birmingham University, for a thesis on the efficiency of selenium as a detector of light.

Evidence is to be presented, on behalf of the University, to the Departmental Committee of the Board of Education in regard to external students, without being restricted to the recommendations of the Royal Commission.

Mr. C. A. King has been appointed professor of mechanical engineering in the Civil Engineering College, Sibpur, India.

A free scholarship of the value of 30*l*., tenable at the Northampton Polytechnic Institute (London) is being offered to students. In view of the openings which the calling and craft of optics now offer, this "Aitchison Memorial Scholarship," should prove most attractive to intelligent youths. The subjects of examination include English, mathematics, and elementary physics. Full particlars can be had of the hon. treasurer, Mr. H. F. Purser, 39 Charles Street, Hatton Garden, London, E.C.

A copy has been received from New York City of a volume entitled "A Study of Education in Vermont prepared by the Carnegie Foundation for the Advancement of Teaching at the request of the Vermont Educational Commission." The legislature of Vermont on November 19, 1912, appointed a commission to report on the educational responsibilities of the State. On February 24, 1913, the commission invited the Carnegie Foundation to undertake an expert study of the school system of the State, including the higher institutions of learning. The resulting report provides much information and enumerates the conclusions and recommendations of the foundation. Among other recommendations the withdrawal of State subsidies from all higher institutions not owned and controlled by the State is suggested. Three colleges are now subsidised by the State of Vermont, and these have some 1026 students, 565 of which are provided by Vermont itself, while 400 Vermont students attend colleges in other States. There are in every thousand of population in Vermont three students of higher education. In connection with the University of Vermont, one of the institutions aided by the State, strong courses in the humanities and in the sciences are recommended, as well as the development by the University of the State Agricultural College.

The general and departmental reports for the session 1912–13 of the Bradford Technical College reveal a satisfactory growth in the usefulness of the institution. There was an increase in the attendance over the previous academic year. The arrangement under which advanced students in dyeing from the Leeds University attend a course in the practical dyehouse at Bradford was in work during the session. A number of Bradford students also attended special courses of lectures at the Leeds University. This reciprocal arrangement, having proved satisfactory, is being continued. The head of the department of textile industries reports that although no large increase in the number of day students is to be expected, it is worthy of note that attendance in the department forms a ready entrance into the higher walks of the textile industries in the case of students of ability who lack special influence in the trade. He points out also that the raising of the standard of attainment in the industry is possibly the most important work of the college evening classes, and those who have followed this development recognise the help which the college has rendered to the textile trade of the city in this direction. The work of the materials testing laboratory of the department of engineering is growing at a rapid rate, and at the present time more than one thousand tests per annum are being made for the various Government and corporation departments, and for local firms. This has the effect of bringing the work of the department into close touch with the engineering trade of the district, and a number of interesting problems of a practical character are forthcoming, in the solution of the majority of which the students are permitted to take part.

SOCIETIES AND ACADEMIES.

London.

Royal Society, March 26.—Sir William Crookes, president, in the chair.—J. H. **Mummery**: The nature of the tubes in marsupial enamel and its bearing upon enamel development. In the present paper the author has endeavoured to show that the tubes are dentinal tubes and not an enamel product, and that the penetration of the dentinal fibril results from the late and imperfect calcification of the cement substance between the prisms.—W. T. **Lockett**: Oxidation of thiosulphate by certain bacteria in pure culture. In the course of investigations on the oxidation of thiosulphate on bacterial sewage filters, it was found that the oxidation was due largely to the presence of living organisms. Experiments were undertaken with a view to the isolation of the organism or organisms capable of bringing about this oxidation.—A. E. **Everest**: The production of anthocyanins and anthocyanidins. The question of the production of Anthocyan pigments from the yellow pigments of the flavone and flavonol class is discussed. Evidence is brought forward to show that the Anthocyan pigments must be regarded as reduction products of flavone or flavonol derivatives, and that they are readily produced as glucosides from the glucosides of the yellow compounds without intermediate hydrolysis.—A. J. **Walton**: Variations in the growth of adult mammalian tissue in autogenous and homogeneous plasma. This paper considers the results of experiments performed to obtain information as to the presence in plasma of substances inhibitory to the growth of tissue. Several tissues were used and several plasmata were investigated.—E. C. **Grey**: (1) The decomposition of formates by *B. coli communis*; (2) the enzymes which are concerned in the decomposition of glucose and mannitol by *B. coli communis*.—Surg.-General Sir D. **Bruce**, Major A. E. **Hamerton**, Captain D. P. **Watson**, and Lady **Bruce**: (1) description of a strain of *Trypanosoma brucei* from Zululand. Part i.—Morphology. Part ii.—Susceptibility of animals. Part iii.—Development in *Glossina morsitans*. (2) The Trypanosoma causing disease in man in Nyasaland. Part iii.—Development in *Glossina morsitans*.

Linnean Society, March 19.—Prof. E. B. Poulton, president, in the chair.—Dr. E. F. **Armstrong**: The bearing of chemical facts on genetical constitution. The subjects dealt with were:—(1) The relation of enzymes to colour inheritance in plants; (2) the nature of oxydases; (3) the anthocyan pigments of plants and their mode of formation; (4) other plant pigments; (5) An hypothesis as to the relation between the several members of an epistatic series of pigments.

DUBLIN.

Royal Dublin Society, February 24.—Dr. J. H. Pollok in the chair.—Prof. G. H. **Carpenter** and T. R. **Hewitt**: The reproductive organs and first-stage larva of the warble-fly (Hypoderma). Descriptions with figures of the reproductive organs of both sexes of *Hypoderma bovis* are given, and comparative studies of the ovipositor and external male genitalia in *H. bovis* and *H. lineatum* have been made, very definite specific characters being apparent. The male genitalia of Hypoderma are symmetrical, and apparently more primitive than the corresponding structures in the blow-fly or house-fly, three pairs of gonapophyses being well developed. There are evidently ten segments in the abdomen of the male *H. lineatum*. The newly hatched larva of the warble-fly is exceedingly spiny, and provided with strong mouth-hooks and a sharp median piercer connected with the pharyngeal sclerites. In this stage the larva offers a marked contrast to the almost smooth second instar which is found in the wall of the ox's gullet.—J. E. **Collin**: Notes on the specimens of Borboridæ and some Ephydridæ in the Haliday collection in the National Museum, Dublin. The paper gives details of Haliday's type specimens, accompanied with systematic and synonymic notes. Many of the specimens are still in excellent condition after a lapse of eighty years.

EDINBURGH.

Royal Society, February 16.—Prof. J. Geikie, president, in the chair.—Dr. **M'Whan**: The axial inclination of curves of thermoelectric force: a case from the thermoelectrics of strained wire. The author found that when the thermoelectric force, for a given temperature difference, between strained and unstrained nickel was compared with the load, the relation was represented by a parabola the axis of symmetry of which was inclined to the coordinate axes, thus obtaining for the relation between electromotive force and longitudinal stress a relation similar to that which Mr. Hamilton Dixon had established for electromotive force and temperature.—A. R. **Fulton**: Rupture strains in beams and crane hooks. A modified theory as to the strains in bending as the elastic limits were approached was tested and verified by experiments on the rupture of beams and hooks.—Dr. H. A. **Haig**: A description of the systematic anatomy of a Fœtal Sea leopard (*Stenorhynchus leptonyx*), with remarks upon the microscopic anatomy of some of the organs: Scottish National Antarctic Expedition. The fœtus investigated had attained about one-third of its intra-uterine development, and was 122 mm. in length. The flippers were well formed, as also the nostrils and eyelids. Points of special interest were described in connection with the cerebellum, the heart, the position of the cæcal diverticulum, and the pituitary gland. The placentation of the seals resembled that of the cat or dog, the placenta being of the zonary type. A general survey of the developmental aspects indicated that certain organs of brain, internal ear, and pituitary were, comparatively speaking, more advanced than the same organs of the three-months human fœtus. Further investigation, more especially of the earlier stages, would be of great interest in connection with the pituitary gland and the kidney, the latter organ being of the type in which separate renal pyramids are met.

March 2.—Sir E. A. Schäfer, vice-president, in the chair.—Sir Thomas **Oliver** and T. M. **Clague**: Electrolytic method of treatment for blood poisoning.—Sir William **Turner**: The aborigines of Tasmania. Part iii. The hair of the head compared with that of other Ulotrichi, and with Australians and Polynesians. The paper consisted of a detailed examination of ulotrichous hair—that is, woolly or frizzly hair—as it is found in various African races, in the aborigines of Tasmania, New Guinea, and the Melanesian Islands, and in the Negritos of the Malay Peninsula, etc. The comparison was based upon the author's observations and measurements of the specimens which formed the collection in the anatomical museum of the University of Edinburgh, a collection which had been made over a number of years for the purposes of anthropological study.

MANCHESTER.

Literary and Philosophical Society, March 10.—Mr. Francis Nicholson, president, in the chair.—Prof. Edmund **Knecht** and Miss Eva **Hibbert**: *l*-Pimaric acid from French rosin. The authors described a method of obtaining lævo-pimaric acid from French rosin in a chemically pure state and in considerable bulk. Further, the composition, molecular weight, and the more important physical constants of the acid have been determined. The acid appears to be a derivative of the terpene or the camphene series. If treated for some time to the temperature of the boiling point of aniline (183° C.) the acid is converted into an anhydride resembling ordinary rosin in appearance. On dissolving this in alcohol or glacial acetic acid hydrolysis ensues, and an optically inactive (racemic) acid is obtained, possessing the remarkable property of showing in benzene or alcohol solution molecular weight of its optical isomer. The racemic compound can be resolved into its optically active components by means of *d*-tetrahydroquinaldine.—R. F. **Gwyther**: The specification of stress. Part iv., The elastic solution, the elastic stress relations, question of stability, struts, ties, and test-pieces. The author proposed a general dynamical solution of the elastic problem, but admitted that there are special cases. Certain hypotheses are made in the solution which from the dynamical point of view seem reasonable. Treating the statical case, the solution is found without the necessity of employing these hypotheses. If the statical result is a special case of the general dynamical result no question arises. But on introducing time-factors into the statical solution, the question arises whether the dynamical equations are generally satisfied, whether they are satisfied in some special way or whether they cannot in any circumstances be satisfied by the variation of the statical solution. The relations of stresses when all direct reference to strains is eliminated is considered, and it is shown how each element of stress can be represented in terms of the invariant of the three longitudinal stresses.

March 24.—Mr. Francis Nicholson, president, in the chair.—Faunal survey of Rostherne Mere, Cheshire. (1) Dr. W. M. **Tattersall** and T. A. **Coward**: Introduction and methods. The authors gave an account of the formation of the mere and its physical characteristics, pointing out that the mere was a dissolution basin formed as the result of subsidence of the earth's surface, consequent on the action of underground water in dissolving and carrying away rock-salt from the underlying strata. Accounts of the temperature of the lake and of the chemical composition of the water were given.—(2) R. S. **Adamson**: Preliminary account of the flora. A description of the marginal vegetation of the lake.—(3) T. A. **Coward**: Vertebrata. A list was given of the vertebrates which occurred in and round the mere. The author included only those vertebrates which were in one way or another influenced by the presence of the water, and were therefore factors in the ecology. Five mammals, seventy-six birds, and eleven fish were enumerated.—(4) A. W. **Boyd**: Preliminary list of lepidoptera. One hundred and forty-four species, found by the author during the last three years, were recorded. Three species were new to the Cheshire list. The tendency towards melanism, as is usual in the north of England, was noted in a number of species.

Paris.

Academy of Sciences, March 23.—M. P. Appell in the chair.—A. **Haller** and Ed. **Bauer**: Syntheses by means of sodium amide. The preparation of allyl ketones derived from the alkylacetophenones and pinacoline. It has been shown in a previous paper that the interaction of sodium amide, iodide or bromide of allyl, and acetophenone does not give allylacetophenones but only condensation products. With mono- and di-alkylacetophenones, however, the reaction goes normally, and allyl derivatives are formed. Details of numerous examples of this reaction are given.—Paul **Sabatier** and A. **Mailhe**: The use of manganous oxide for the catalysis of acids. The preparation of fatty and aryl ketones. The oxides of calcium or of iron, although giving satisfactory results in many cases, do not give satisfactory yields of ketones from *iso*butyric and *iso*valeric acids. A study of various oxides from this point of view has shown that manganous oxide, MnO, acts well as a catalyst, is not expensive, preserves its catalytic properties nearly indefinitely, and can be utilised for the production of aldehydes as well as ketones. The vapours of the acids are carried over a 60 cm. column of the MnO maintained at a temperature of 400° to 450° C. Numerous examples of the excellent yields obtained are given.—A. **Lacroix**: The laterites of Guinea.—Charles **Moureu** and Adolphe **Lepape**: Crude nitrogen (nitrogen and rare gases) in natural gas mixtures (see p. 120).—R. de **Forcrand**: Potassium tetroxide. The pure K_2O_4 has been prepared by two methods, and its thermochemical constants determined. The results are compared with those previously obtained for rubidium and cæsium.—A. **Calmette** and A. **Mézie**: The treatment of epilepsy by snake poison. The snake poison used was extracted from *Crotalus adamanteus*, injected in gradually increasing doses. The number of fits per annum was reduced in all the cases detailed, and this improvement was maintained after the treatment was stopped.—Lucien **Godeaux**: Involutions having only a finite number of points belonging to an algebraical surface.—M. **Gunther**: The general theory of systems of partial differential equations.—E. **Baticle**: The partial differential equations of the limiting equilibrium of a sandy mass, comprised between two surfaces of rectilinear profile.—Louis **Benoist** and Hippolyte **Copaux**: Application of the laws of transparency of matter to the X-rays to the determination of some contested atomic weights. The case of beryllium. The transparency of beryllium to X-rays corresponds to the atomic weight 9·1.—Georges **Claude**: The absorption of gases by carbon at low temperatures (see page 120).—A. **Leduc**: The density and atomic weight of neon. Eighteen litres of neon containing some helium and nitrogen as impurities were purified by treatment with charcoal cooled with liquid air. The density found was 0·696, or nearly 3 per cent. higher than the value found by Ramsay and Travers (0·674). From this is deduced that the atomic weight of neon is exactly twenty times that of hydrogen, or 20·15 for O = 16.—Jean **Bielecki** and Victor **Henri**: Contribution to the study of tautomerism. The quantitative study of the absorption of ultra-violet light by the derivatives of acetoacetic acid.—L. **Moreau** and E. **Vinet**: A method of determining traces of arsenic of the order of a thousandth of a milligram. The method is based on the production of a silver mirror in a small glass U-tube containing silver nitrate.—Mil. Z. **Iovitchitch**: The absorption of carbon dioxide from the air by chromium hydroxide.—A. **Joannis**: The constitution of potassium carbonyl. By the controlled action of water vapour upon the compound KCO obtained by the interaction of potassium and carbon monoxide, glycollic acid was obtained, according to the reaction,

$$K.CO-CO.K+H_2O=CH_2.OK-CO.OK.$$

—Félix **Bidet**: The hydrates of the primary amines. Normal and *iso*amylamines and *iso*butylamine combine with water vapour from the air and form well-crystallised hydrates, fusible below 100° C., and possessing high vapour pressures.—Const. A. **Ktenas**: The petrographical relations existing between the island of Seriphos and the neighbouring formations.—J. L. **Vidal**: The adaptation of the vine to the different conditions of life created by pruning at different periods and its consequences on the evolution of the reserve carbohydrates.—M. **Marage**: The action on certain organisms of an artificial current of water. An account of some experiments with the divining rod, in which the flow of water was controlled. For water flowing in pipes the experiments failed, as the person holding the divining twig was unable to detect the flow of water with certainty.—H. **Coutière**: The "ocular tubercles" of podothalmic Crustacea.—P. **Benoit**: The formation of the gonophore in *Tubularia indivisa*.—Bernard **Collin**: The involution forms of ciliated Infusoria in the renal organ of a Cephalopod.—Theodor

Mironescu: The action of some pharmaceutical substances on the development of experimental cancer.—A. **Blanchet**: The activity of the lipodiastase of castor oil seeds at a low temperature. Although the diastatic activity is reduced by lowering the temperature it is not entirely suppressed at -5° C.—L. **Cavel**: The transportation of micro-organisms into the atmosphere by the pulverisation of polluted water. The sprays in actual use in connection with bacterial beds for the treatment of sewage give up organisms to the surrounding air, and may be a source of danger in time of epidemics.—Em. **Bourquelot** and M. **Bridel**: The biochemical synthesis of the β-monoglucoside of glycol with the aid of emulsin.—Paul **Durandin**: The possible existence of oil-bearing strata in French Indo-China.—F. **Jadin** and A. **Astruc**: Manganese in some springs of the Vosges *massif*.

Göttingen.

Royal Society of Sciences.—The *Nachrichten* (physico-mathematical section), part 4 for 1913, contains the following memoirs communicated to the society:—

May 24.—G. **Angenheister**: The velocity of propagation of magnetic disturbances and pulsations (report on the instantaneous records of terrestrial magnetism in Apia (Samoa), Batavia, Cheltenham, and Tsingtao in September, 1911).

June 21.—H. **Bohr**: The significance of power-series of an indefinitely large number of variables in the Dirichlet series, $\Sigma a^n/n^s$.—O. **Faust**: The internal friction of fluids under high pressure.

July 7.—A. **Peter**: Injuries to forest-trees by lightning-stroke over large areas.

July 19.—C. **Carathéodory**: Boundary-adaptation in conformal representation.—L. **Föppl** and P. **Daniell**: The kinematics of Born's rigid body.

August 23.—B. **Meese**: Some observations on the optical constants of potassium and sodium.

November 1.—L. **Bieberbach**: A theorem of Carathéodory.—O. **Mügge**: Shearing-deformations in phosgenite and galena.—R. von **Mises**: The mechanics of solid bodies in the plastic-deformable condition.—G. **Tammann**: The discrimination of racemism from pseudo-racemism.

A VOCABULARY OF EMBRYOLOGY.

Terminologie der Entwickelungsmechanik der Tiere und Pflanzen. Herausgegeben von Wilhelm Roux. Pp. xii+465. (Leipzig: W. Engelmann, 1912.) Price 10 marks.

THE science of embryology has its own evolution. Once upon a time it was no more than a science of observation; its task was to describe the form and structure of the embryo during growth, as the naturalist or the anatomist had described those of the organism when it was grown. Later on, in the light of the cell-theory, in the spirit of Darwinism, and with the help of Wolff's and Von Baer's laws, embryology became dominated by, even subjugated to, the historical method; its chief aim was "to form a basis for phylogeny," and its chief problems dealt with such matters as the retention of ancestral characters in embryonic and larval forms, the explanation on similar lines of functionless or atrophied organs, and the discovery of "homologies" between cells, germ-layers, and organs, even in distantly-related organisms.

Such, so far as it can be expressed in a sentence, was Balfour's attitude towards embryology, and so he defined its aims in the preface to his great text-book, adding, however, the important qualification "as restricted in the present work." One great problem, or class of problems, he expressly excluded, when he spoke of the embryological investigations of certain older writers as being "mixed up with irrelevant speculations on the origin of life." But inquiries into the character and inner nature of organic processes, and speculations on the nature and even the "origin" of life, recur continually to men's minds, and upon such inquiries embryological study has a bearing, which is by no means to be dismissed as irrelevant. So we come to a third, and nowadays important, phase of embryology, in which that science has become not merely a morphological, but a physiological, study, and is accordingly approached from the side of chemistry and of physics, with the aid of the known properties of matter and of energy.

The new and growing conception of embryology as a "dynamic" science, or series of dynamical problems, carries us a long way from the older and simpler embryology, with its "statical" outlook, its concrete description of forms and phases of form. It widens out and out into ways of experiment and analysis undreamed of a generation ago; it leads us, for instance (to name but a few names out of many), to the philosophical inquiries of Driesch, to the wide experimental field of Loeb and his followers, and to the general study of "developmental mechanics," which has been the life-work of Wilhelm Roux.

But "the house that is a-building is not as the house that is built." In the growth of a young science there is a stage when facts are heaped up in apparent confusion, out of which order and simplicity presently emerge. For a while, the workman is kept busy making his own tools, and in the growth of new knowledge and of new ideas language itself has to be strengthened by new words.

Common experience, and the Oxford Dictionary, show us how ill the older vocabulary sufficed to keep pace with last century's growth of ideas, even in the ordinary affairs of men. To natural science Huxley's generation contributed a new language, which we now speak familiarly; and once again, in the narrower field of embryology, we wake up to find that yet another language has become implanted in the old. We had better not ask whether all this new nomenclature be essential; some of it will doubtless pass away while part remains; meanwhile, it has grown by a natural process of evolution, and those must learn it who would master the teaching of the new schools. So Prof. Roux, with a little band of botanists and anatomists, has set himself in a true spirit of helpfulness to put in order the new terminology, and to teach this new language to those who have not learned it by the way.

His book is a book of reference, a means of interpretation, and a bibliographical guide; it is a dictionary, and those who find pleasure in the reading of dictionaries are few. Yet, after all, the book is something more than a book of reference or a mere vocabulary, for many of its paragraphs amount to short essays, where the student will find both information and instruction. This is not only the case in some of the larger articles, such as "Entwickelungsmechanik," "Kampf der Theile," etc., but in others also. Take at random, for instance, a little paragraph on "Scherenumkehr," or "Heterochelie"; here we have a concise introduction to a very singular phenomenon, witnessed among certain crabs, which ordinarily possess, on opposite sides, one large claw and one small one; if the former be chopped off, then the latter grows into a big claw, and the former big claw, after repair, comes to be a little one. The crab is perfectly regenerated, but its new form is a "mirror-image" of that with which it began. The article ends with references to papers wherein this phenomenon is discussed in its many curious modifications.

G

But while we may well be grateful to the writer who has tried in this little book to make a very difficult subject somewhat less difficult, it must be confessed that the book is too condensed, too strenuously logical, and, moreover, too much occupied by questions of priority, to attract the general scientific reader, or, indeed, any but the professed student of its own subject. Prof. Roux has greater powers than are put in action here. Haeckel's "Generelle Morphologie" is now practically obsolete; but it marks an epoch in biological science, and it stands as a monument of clear thinking and lucid scientific expression. Let us hope that some day or other Prof. Roux will give us not only a vocabulary, not only isolated researches, however important, but will crown his labours by the writing of a newer and a better "Generelle Morphogenie." D. W. T.

RUBBER AND RUBBER PLANTING.

Rubber and Rubber Planting. By Dr. R. H. Lock. Pp. xiii+245+x plates. (Cambridge: University Press, 1913.) Price 5s. net.

Dr. R. H. Lock was connected, until recently, with the Botanic Department at Peradeniya, Ceylon. In conjunction with other officers of that department, he conducted a series of very valuable experiments in connection with the tapping of rubber trees.

The book before us contains much that has already been published by the author officially in Ceylon. The diagrams and photographs illustrate many interesting features in connection with Hevea, Manihot, Castilloa, Funtumia, Ficus, and Landolphia, such as is rarely found in a book on rubber.

The book deals with the botanical sources and history of rubber, physiology of latex, the usual planting and harvesting operations, and the various pests and diseases of rubber plants. Each chapter is written in a very easy and popular style, and the subject-matter can be easily understood by the general reader.

The special line of work in the book is that which relates to tapping operations. When dealing with the effects of wounding the bark, the author lays stress upon the fact that any system of tapping which involves the cutting of the whole circumference of the tree at one time is bad. He suggests that in no circumstances should more than one-half of the total circumference of the tree be tapped at one time.

The yield of rubber bears a peculiar relation to the volume of bark on the tree. An instance is quoted of one tree which in three years yielded 240 lb. of dry rubber; the rubber was contained in 70 gallons of latex, equivalent to 20,000 cubic inches. This yield of 20,000 cubic inches of latex was obtained by tapping an area of bark which had contained only 500 cubic inches of latex at the beginning of the experiment. The problem, therefore, resolves itself into one of the origin of the balance of 19,500 cubic inches of latex. The author concludes that the greater part of the latex can only have been produced by secretion of latex in the existing laticiferous tissue, thus suggesting that the latter is an organ for the actual manufacture, as well as storage, of the milky liquid.

It is common knowledge among experimenters in the tropics that the yielding capacity of rubber trees exhibits enormous variation. It is this variation which renders the majority of the public records of experiments valueless. Dr. Lock shows in certain experiments that the highest and lowest average yields for particular operations were respectively 106 and 8 cubic centimetres. The yield per unit of bark removed was in the ratio of 317 to 25—a variation of 1,000 per cent. in yields from trees which to the author appeared to be somewhat similar. In addition to this variation in yield, there is an equally marked variability in composition of the latex according to frequency of tapping, season of tapping, altitude, and so forth.

In the middle-East, the majority of planters tap the same area on the same day, or on alternate days, the intervals between successive tapping operations being regarded as sufficient to enable the latex to accumulate to the desired quantity and degree of concentration. Dr. Lock is probably the first experimenter who has continued experiments for a period of four years, and herein lies the great value of his work. The majority of tapping experiments have usually lasted a number of months, and on that account alone are apt to be highly misleading.

Dr. Lock concludes that, after $3\frac{1}{2}$ years' continuous tapping, the yield from trees tapped once a week may become as great or greater than that from trees tapped at any shorter interval. It was this conclusion which gave rise to a controversy in the columns of the *India-rubber Journal*, which in turn led the Rubber Growers' Association in London to take up experimental tapping on various Eastern estates. Later publications from Malaya do not agree with the result obtained from Dr. Lock in Ceylon, but this might very well be due to the fact that the experiments in Malaya have not been continued for the same period of time.

Altogether, the book can be regarded as being of great value, not only to the practical man on the estate, but also to investigators in this country.

H. W.

WATER SUPPLIES.

(1) *Studies in Water Supply.* By Dr. A. C. Houston. Pp. xii+203. Macmillan's Science Monographs. (London: Macmillan and Co., Ltd., 1913.) Price 5*s.* net.

(2) *Water: its Purification and Use in the Industries.* By W. W. Christie. Pp. xi+219. (London: Constable and Co., Ltd., 1913.) Price 8*s.* 6*d.* net.

(1) DR. HOUSTON has gathered together an epitome of his own researches, which have been scattered among a considerable number of reports and papers. In the first chapter, which deals with sources of water-supply, he directs attention to the remarkably low death-rate from typhoid fever in London during the past few years, a rate which in the year 1911 amounted to only 0·03 per thousand of the population. After discussing the rivers Thames and Lea as sources of water-supply, he proceeds in subsequent chapters to give results of his observations upon the purification of water, finally concluding the volume by a discussion and description of the methods carried out under his direction in the laboratories of the Metropolitan Water Board.

The main conclusions which Dr. Houston draws from a large amount of experimental work may be summarised as follows:—River water exposed to manifold pollutions, and furnishing ample chemical and bacteriological evidence of objectionable contamination, may fail to show any or scarcely any of the microbes of water-borne disease; and he raises the question as to whether we have not exaggerated the value, high as it is, of the sand filter as a factor in our long-continued immunity from typhoid fever, and whether some at least of this freedom may not be due to the fact that the water was not primarily so noxious as it has hitherto been regarded. He is convinced that artificially-added typhoid bacilli die fairly rapidly in stored water, even when such water is of great initial impurity, and that a preliminary storage of water is an important factor of safety. This purification of water under storage conditions is chiefly due to the sedimentation, equalisation, and devitalisation of microbes; and he shows that by the second week the reduction in the artificially cultivated typhoid bacilli added to river water is more than 99 per cent. on the average, and that storage reduces the number of bacteria of all sorts and devitalises the survivors, if sufficiently prolonged.

Taking the chemical and bacteriolegical results together, Dr. Houston demonstrates that the beneficial effect observed in connection with simple continuous flow settlement of water may be considerably enhanced by the use of coagulants, such as aluminoferric, etc. He finds that when a hard water is overdosed with lime a considerable bactericidal effect is produced; and if after a suitable interval sufficient untreated water is added to combine with the excess of lime, a much safer water for drinking purposes is obtained. Speaking generally, these experiments demonstrate that the bactericidal dose of lime for hard waters would appear to be rather less than 1 to 5000, and with very soft waters 1 to 50,000. This method is especially attractive in cases where a water, bacteriologically impure, has in any event to be softened, and where a contaminated river supply has scarcely any available storage accommodation prior to sand filtration.

The author is to be congratulated, not only upon the good work to which the volume bears testimony, but also upon bringing it together in this monograph, and presenting it in a condensed and readable form.

(2) Mr. Christie's small work is mainly composed of a series of articles which appeared in "Industrial Engineering and Engineering Digest" for 1910-1911, and it is to be commended more particularly for its treatment of the use of water in various branches of industry. While much useful information is given upon the subject of the purification of water which would fit it for drinking purposes, this portion of the book is less satisfactorily dealt with than that which is concerned with the use of water for industrial purposes. Indeed, the treatment of the sources of water, its analysis and standards of purity, is fragmentary and unsatisfactory. It is impossible to deal with the subject of the standards of purity of water except in regard to the sources from which the water is derived. More particularly is this necessary with reference to chlorine standards; and the standard given for chlorine in water, of from 3 to 10 parts in a million, is useless and misleading. Extremely few of the drinking water supplies of this country would conform to such a standard. The chapters on water softening, pressure filters, oil filters, and boiler waters are the best contributions to a work which is exceedingly well produced, the illustrations being a noteworthy feature of the publication.

OUR BOOKSHELF.

From the Letter-Files of S. W. Johnson. Edited by his Daughter, Elizabeth A. Osborne. Pp. 292. (New Haven: Yale University Press; London: Oxford University Press, 1913.) Price 10*s.* 6*d.* net.

No teacher of agricultural chemistry can afford to do without Johnson's two books, "How Crops Grow," and "How Crops Feed." If he tries it, he will miss two most valuable sources of help for his lectures. The first was written in 1868, and instantly achieved a most remarkable popularity, being translated into French, German, Russian, Swedish, Italian, and Japanese, besides being revised and adapted for English readers by Church; the second appeared two years later, and was almost equally successful. Neither book is ever likely to get out of date, because each deals so fully with the fundamental experiments carried out by men who were laying the foundation of what has since become a great subject.

The book before us gives an account of the life of the writer of these books, and incidentally throws much interesting light on the opening chapters of the history of agricultural chemistry. Samuel William Johnson was born in 1831 at Kingsboro, in what was then the new country of Northern New York State. In 1849 he had saved enough to justify his entering Yale to study chemistry under Prof. J. P. Norton; from the outset he took a special interest in agricultural chemistry. Four years later (in 1853) he went to Leipzig to work under Erdmann, and then in 1854 to Munich to study under Liebig. He then came to England for a short time to study gas analysis at the Owens College, Manchester. On his return to New Haven he did a good deal of missionary work among farmers to demonstrate the enormous value of chemistry to the agriculturist, and became appointed chemist to the Connecticut State Agricultural Society in 1857. After eighteen years of work, the first agricultural experiment station in the States was founded; in the spring of 1875 the Legislature of Connecticut State passed a measure securing 700 dollars a quarter for two years for the maintenance of a laboratory placed at their disposal by the University at Middletown.

The history of these pioneer days is well told in Johnson's letters, and they make very interesting reading. The editor is to be congratulated on the way the material has been collected and arranged. E. J. Russell.

The Cancer Problem: a Statistical Study. By C. E. Green. Third edition. Pp. 98 + plates. (Edinburgh and London: William Green and Sons, 1914.) Price 5*s*. net.

This book belongs to the all too numerous class of harmful publications on the subject of cancer. The author frankly states he is not a qualified medical man, but this fact will have little weight with the lay public. The sub-title, "A Statistical Study," conveys an entirely erroneous impression as to the scope of the book. It is in reality a plea for the infective nature of cancer, and of the active intervention of coal-smoke as an augmenter of the frequency of the disease. The alleged parasite is likened to the well-known *Plasmodiophora brassicae*, which causes finger and toe disease or club-root in turnips and cabbages. This vegetable parasite is not "almost unknown to pathologists," but has had its alleged claims to resemble a supposed cancer parasite discussed *ad nauseam* by pathologists and botanists of the highest repute. The author argues that coal-smoke manures the soil for this "cancer parasite."

The error of likening cancer to finger and toe disease has been often exposed. As for statistics, none are contributed by the author. His figures state the number of deaths from cancer as a percentage of deaths from *all* causes, and he marvels that 1 in 7 is from cancer in the Strand district, but only 1 in 54 in Stepney. This statement is illuminated by photographs of the roofs of these two districts. No mention is made of Charing Cross Hospital being situated in the Strand district.

The statements as to the cure of cancer are deserving of severe condemnation. Only the harm the book may do has justified any notice being taken of it. It is with regret that the reviewer feels obliged to judge thus harshly what the perusal of the book proves has been a labour of love, carried out with the best intentions; but the pursuit of a hobby ought not to be encouraged to the public danger. E. J. B.

The Socialized Conscience. By Prof. J. H. Coffin. Pp. viii + 247. (Baltimore: Warwick and York, 1913.) Price 1.25 dollars.

Prof. Coffin's purpose in this interesting book is to suggest, using modern psychological and sociological terms, a moral criterion by means of which the different types of moral situations may be met with consistency by ordinary human beings. He applies the criterion to a great variety of questions, including personal relationships, educational agencies, the State and the Church. His chapters are stimulating and thought-impelling.

Descriptions of Land: a Text-book for Survey Students. By R. W. Cautley. Pp. ix + 89. (New York: The Macmillan Company, 1913.) Price 4*s*. 6*d*. net.

All students of surveying in Canada before securing official recognition are required to pass an examination on "descriptions of land," which is one branch of conveyancing. Many lawyers in all countries are ignorant of the elementary principles of surveying, and few surveyors are able to understand the intricacies of a complicated title. Mr. Cautley has written on the subject in a way which should be useful, not only to students of surveying, but also to acting lawyers and surveyors everywhere.

Elementary Commercial Geography. By Dr. H. R. Mill. Revised by Fawcett Allen. Pp. xii + 215. (Cambridge University Press, 1914.) Price 1*s*. 6*d*. net.

Dr. Mill's primer of commercial geography was published first in 1888, and is well known to all teachers of the subject. It is sufficient to say of the latest edition that it has been revised thoroughly by the aid of the latest official publications, and is enlarged by additions to part i., and by more detailed descriptions of countries which have shown recent commercial development.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Funafuti Boring.

It was with great pleasure that I read the clear statement of Prof. J. W. Judd (Nature, March 12) in reply to the letter of Prof. E. B. Poulton (February 26) upon this subject. Especially welcome was his definite statement that all idea of solution of calcium carbonate being the causative factor of lagoon formation was negatived by the study of the bore.

But I would direct a caution to those who might be inclined to read into Prof. Judd's letter a vindication of the correctness of Darwin's theory of atoll formation.

Suppose it is definitely proved that an atoll such as Funafuti is established upon a basis which has certainly undergone a movement of sinking. Such a finding can only establish the "validity" of a statement that a sinking basis may become the site of atoll development; it cannot establish the "validity" of a theory which demands this sinking as the *cause* of the development of the peculiarities of atoll growth; especially in the face of the definite knowledge that typical atoll growth may be established upon a basis which shows either, no evidence of sinking, or actual evidence of rising. It is upon this point that I fear the recent correspondence may mislead.

One other question arises: Has it been definitely proved that the site of Funafuti atoll has undergone a movement of sinking?

A bore made upon the extreme windward edge of an atoll some ten miles in diameter has so inherent a probability of penetrating a talus slope, that the most rigid proof should be furnished of its having penetrated anything else. This proof is, I think, not forthcoming.

The lagoon bores are not sufficiently deep to establish, beyond dispute, the supposition that there has been a movement of sinking. The statement of Prof. Judd would leave quite an opposite impression, for he says that the lagoon bore extended "to a depth of 100 ft. below the limit of growth of the reef-forming corals." The lagoon bores extended to 36 and 41 fathoms below the surface of the water. It is obvious that to make Prof. Judd's statement correct he must allow the reef-builders only $24\frac{1}{3}$ fathoms as their bathymetrical limit. But $24\frac{1}{3}$ fathoms is not the "lowest depth at which, as all naturalists agree, reef-forming corals can flourish."

It is only necessary to mention the dredgings of Basset-Smith on the Lizard and Macclesfield Banks in which twelve species of typical reef-forming corals were obtained from between 31 and 45 fathoms. On open oceanic banks, far from any shore line from which suspended matter may be carried in the water, it is possible that even this may not represent the bathymetrical limit of the true reef-builders; but it is enough that we have positive knowledge of their presence at depths exceeding that of the Funafuti lagoon bores to negative any idea that these bores can prove a downward earth movement. Atoll formations are developed in areas in which upward earth movements are evident; they are also developed in areas in which downward earth movements are evident (though the Funafuti bores cannot be accepted as proving it); and in neither case can such movement be invoked as the cause of their peculiar features. The Funafuti bores showed that "solution" was not the cause of lagoon formation; they did not show that "subsidence" was the cause. It is the study of the coral zooid and the coral colony that alone can reveal the picture of atolls caused by "sedimentation." F. Wood-Jones.

We are quite ready to admit that the evidence obtained at Funafuti does not prove that *all* atolls are formed by subsidence. A stationary volcanic bank, eroded down to the level at which reef-forming corals could begin to flourish, would serve as well for the basis of an atoll as a sinking island; this was well pointed out by the late Admiral Wharton. So, too, would a deeper bank which had been raised to a similar level by the raining down upon it of pelagic organisms, *if it can be shown that such action is capable of producing any considerable thicknesses of rock.* And there are other conceivable ways in which atolls may arise, as was fully admitted by Darwin in his correspondence with Semper.

We claim, however, that Funafuti proves that atolls can be formed by subsidence from the following facts. The upper part of the main boring, as well as several subsidiary borings, show the existing reef to consist of corals in their position of growth, their interstices being filled with broken fragments of coral mingled with smaller organisms. Now, right down to the extreme depth reached, the cores were of precisely similar character; they showed corals in the position of growth surrounded by detritus and small organisms. Thus the hypothesis of a talus—which, so far as I know, was only suggested after the boring was found not to reveal a substratum of foreign rock—falls to the ground.

Although species of corals belonging to genera which are reef-forming have been found at considerable depths, the luxuriant growths of coral, necessary for building up a great reef, have never been shown to take place below 20 to 25 fathoms. This was a conclusion that was certainly accepted by the late Prof. Alexander Agassiz, from the results of his wide experience, as it has been by so many other naturalists. The ingenious method employed in boring in the middle of the lagoon of Funafuti did not admit of large cores being brought up, but the borings were stopped by hard coral-masses, the fragments obtained from these indicating that they belong to reef-making forms. It is fair, therefore, to maintain that the lagoon borings at Funafuti afford valuable evidence in support of that obtained by the main boring.

J. W. Judd.

Zoological Classification.

Zoological classification of the present day is unsatisfactory, and the reason is not far to seek. This condition has resulted from the unnecessary multiplication of genera.

The real object of classification is being lost sight of. The objects aimed at in a classification may be put briefly as follows:—(1) To give to each animal a name, by which it will be known internationally, and (2) to give to animals which resemble one another the same name.

The unit-group of animals bearing the same name is the genus. How large may the genus be? There are at present independent genera which have been created out of a formerly existing single genus. Has the diagnosis of the species been rendered simpler by breaking up the genus, and by giving to each subgenus a new name? Certainly not in several cases.

The subdivision of the older genus has resulted from the more detailed examination of the various species. Such investigation cannot be too minutely carried out, for it is necessary both from the morphological and the diagnostic point of view. But the mistake has been made of giving to the new groupings of species thus revealed names which are so dissimilar from that of the orginal genus, and from each other, as to hide the genus-relationship. The latter is shown when the genera are grouped as a family.

The subdivision of the animal kingdom into groups that receive independent names should not be carried further than is necessary to ensure ready diagnosis of the species. When carried beyond that point the classification is weakened.

What is required at present is the extinction of probably half at least of the genera. The present family-group should in many cases be the genus.

Marine Laboratory of the Fishery Board for Scotland, Aberdeen, March 23.

The Dublin Gorilla.

LIVE specimens of the gorilla are still rarities in British zoological gardens, and it is believed that except for one that has lived for several years at Stuttgart, there is no example at present to be seen on the European continent. A few notes on a young female —probably about a year old—that has now lived for three months in the ape-house of the Royal Zoological Society of Ireland, in Dublin, may therefore be of interest to readers of NATURE.

This little ape—"Empress" is her name—was brought to Europe in company with a young male chimpanzee; in consequence of this companionship she is much tamer and livelier than captive gorillas usually are. In the constant sports which the two young creatures enjoy, the chimpanzee is the more active and spirited, frequently cuffing the gorilla playfully or dragging her along the floor of the house. The gorilla, however, is able to hold her own, and has already developed the habit of drumming on her chest as a challenge; usually she is good-tempered both to her companion and to human visitors. She often climbs leisurely but confidently to the top of the house. The photograph (by Mr. W. N. Allen) shows the little ape in a characteristic attitude, and brings out the distinctive shape and pose of the leg and hindquarters. Her eyes are very expressive, and her almost black face is a great contrast to the pale pink skin of her companion chimpanzee. Both the apes have completely recovered from an epidemic cold that ran through the house in February, and it is hoped that "Empress" may survive in the Dublin Gardens for several years.

G. H. CARPENTER.

Royal College of Science, Dublin.

A Property of Chain-Fractions.

FOR convenience, let $(1;\ a, b, c, \ldots)$ mean the chain-fraction of which $1/a$ is the first convergent, and a, b, c, etc., are the partial quotients. Consider all such fractions which have no partial quotient greater than 9: the greatest of these is the periodic fraction $(1;\ \dot{1}, \dot{9})$, and the least is $(1;\ \dot{9}, \dot{1})$. We have,

$$\alpha=(1;\ \dot{1}, \dot{9})=(-9+\sqrt{117})/2=0{\cdot}9083,$$
$$\beta=(1;\ \dot{9}, \dot{1})=(-9+\sqrt{117})/18=0{\cdot}1009,$$

and any proper fraction outside the limits (α, β) will have at least one partial quotient greater than 9. (The converse is not true.) More generally, one partial quotient at least will be greater than an assigned integer n, if the chain-fraction represents a quantity outside the interval determined by the positive roots of the equations:—

$$\alpha^2+n\alpha-n=0, \quad n\beta^2+n\beta-1=0.$$

As n increases, α becomes more and more nearly equal to 1, and β more and more nearly equal to 0. The curious point is that if we take a proper fraction sufficiently near to 1 or zero, its chain-fraction expansion must contain a partial quotient greater than any integer assigned beforehand, and we can actually (when n is given) assign intervals containing such fractions *and no others*. For instance, when $n=9$, the intervals are

$$\{1, (-9+\sqrt{117})/2\} \text{ and } \{0, (-9+\sqrt{117})/18\}.$$

Thus 0·9089 is within the first of these intervals, and its expansion is $(1;\ 1, 9, 1, 42, \ldots)$.

G. B. MATHEWS.

New Units in Aerology.

IN NATURE of March 19, p. 58, Prof. McAdie discusses the question of the new units in aerology, and says that now is the time to agree upon a logical and available system, considers the megabar atmosphere the more appropriate, and thinks that some of the readers of NATURE may suggest something better.

I have not the ambition to respond to the last suggestion, but, in order to avoid confusion in the future, I beg to direct attention to what has been done in this respect very recently. According to an official report, M. Pérot has presented to the French Minister of Commerce a report upon the reform of the legalised measures and weights. In this we find among the derived units the *Newton* as a unit of force $=\text{Kg m/sec.}^2$, which equals 10^5 dynes. From this is derived another new unit, *Pascal*, as a unit of pressure, 10 Newtons per sq. cm. (10 Newtons = 1 megadyne). I may add that the *Calorie* is proposed at 15° and 1·02 Pascal (=765·1 cm.).

As France may be called the mother-country of the c.g.s. system, the question arises, whether the name *Pascal* might not be substituted for the *modern* megabar (*not* for *ten* absolute atmospheres)?

BOHUSLAV BRAUNER.

Bohemian University, Prague, March 24.

WINELAND THE GOOD.[1]

THE evidence for the pre-Columbian discovery of North America by Norsemen depends essentially on two sagas: the Saga of Eric the Red, the Saga of Thorfinn Karlsefni in Hauksbook; both of which are repeated with modifications in the Flateybook. The dates of the extant MSS. lie between 1300 and 1400 A.D.; the sagas themselves were probably composed about a century earlier; the main event, the discovery of Wineland by Leif the Lucky, occurred in or

[1] "Early Norse visits to North America." By William H. Babcock. Smithsonian Miscellaneous Collections, vol. lix., No. 19. Pp. iv + 214, x plates. (1913.)

about 1000 A.D. Collateral evidence consists mainly in the references by other writers to the events recorded by the sagas, which, it is plain, were regarded as historical narratives.

The numerous vague rumours of a world in the west, as embodied in strange maps and stranger stories, have little bearing on the relatively precise and plain tales of the Norse sea-kings. Those tales which, where not distorted by later fancy, are straightforward as a sailor's log, must be checked by reference to the geographical data recorded in them. This is the most valuable part of the task essayed by Mr. Babcock in his interesting and well-written volume. He is not the first to make the attempt, but the originality and the strength of his attack lie in his reconstruction of the geographical conditions as they probably were nine hundred years ago. Then the seaboard north of the Gulf of Maine was lower than now, whereas south of that point it was higher. The change, which is still in progress, is due to the oscillation of the earth's crust initiated by the withdrawal of the great ice-sheet. By taking this movement into consideration, Mr. Babcock has been able to identify with much plausibility the features and localities mentioned in the sagas.

Let us take only one point in illustration. Karlsefni and his wife Gudrid on their southward voyage saw to the starboard "a bleak coast, with long and sandy shores . . . they called them Wonder Strands, because they were so long to sail by." The interminable sand-dunes of New Jersey and Maryland supply a modern parallel to these cheerless "Furdustrandir," but the voyagers cannot have been further south than Nova Scotia, and no such wonder-strands are found there now. "Conceive," however, says Mr. Babcock, "the Nova Scotia seaboard lowered by the 25 feet or more of its present height, that is, brought down to water-level and dipped a little under—with slight narrowing of the peninsula in its mainland part, and partial obliteration of the eastern side of the now hollow insular terminal part called Cape Breton Island—and you will have something not wholly unlike the long strands of New Jersey or the peninsula east of the Chesapeake, only with the hill country much nearer. It was the first introduction of the surprised northern visitors to the characteristic American coast line."

By such ingenious but not unwarranted use of the scientific imagination does Mr. Babcock identify the various localities of the saga, thus confirming its essential accuracy. The vines that gave a name to Wineland are the fox-grapes of to-day and the apparent wheat "self-sown wherever there were hollows," is interpreted as wild rice, still a conspicuous feature.

It is maintained, then, that Leif Ericsson chanced on America circa 1000 A.D., and coasted as far south as New Jersey; that Eric the Red dispatched Thorfinn and Gudrid three years later, as leaders of a large colonising party; that they passed Helluland (Labrador), Markland (Newfoundland), the Wonder-strands (Nova Scotia), and settled near the mouth of Straumfjord (Bay of Fundy), where Gudrid gave birth to Snorri, the first American-born white man. Disappointed in the hard winter, Thorfinn and a party sailed further south about as far as Mount Hope Bay, but were driven back by Indians. After another winter at Straumfjord, all returned to Greenland.

THE IMPERIAL BACTERIOLOGICAL LABORATORY, MUKTESAR, INDIA.[1]

The Imperial Bacteriological Laboratory, situated at Muktesar in the United Provinces, has been established, and is maintained for the investigation of the diseases of stock in India, and for the preparation of anti-sera and vaccines used for the control of epidemic diseases among animals. The history of the laboratory dates from 1890, when Dr. Lingard was appointed Imperial Bacteriologist, and for some years the work in connection with the diseases of animals in India was carried out at Poona. It was decided, however, to establish a separate institution for this purpose in the hills, and in 1895 a laboratory and a few additional buildings were completed. This first laboratory was destroyed by fire in 1899. The re-building was taken in hand at once, and the present laboratory, much larger than the original structure, was erected and ready for occupation in 1901. The work of the laboratory has increased very rapidly, and it was found necessary to add a wing to the main building four years ago. In addition to the large laboratory there are three smaller buildings for the study of separate diseases, and other buildings for the accommodation of animals, post-mortem examinations, etc., have been added from time to time.

One of the earliest problems to be studied at Muktesar was the preparation of a prophylactic for rinderpest. In 1896 Koch visited Muktesar, and demonstrated his bile method of inoculation against rinderpest. An anti-serum for the disease was first prepared in India by Lingard, and it was first used in field epidemics in 1899, when about 2000 doses were issued. Rinderpest anti-serum is one of the most effective prophylactics known to science, and a striking tribute to its value is to be found in the records of the Muktesar Laboratory. Ten years after its introduction into India half a million doses were issued annually. In 1910 improved methods for the preparation of the serum were discovered, and in the following year a million doses were manufactured. The serum is now supplied to all the provinces of India, to Burma, Ceylon, and the Native States, to the Federated Malay States, and to Egypt. In addition to rinderpest anti-serum, a serum and vaccine for the control of epidemics of hæmorrhagic septicæmia are prepared, as well as a vaccine for black quarter and a serum for anthrax. About 20,000 doses of mallein are issued annually. Pathological specimens are examined, and instruction is given to native veterinary graduates in the practical application of serum and vaccines.

[1] "A Description of the Imperial Bacteriological Laboratory, Muktesar: its Work and Products." By Major J. D. E. Holmes. (Calcutta: Superintendent Government Printing, 1913.)

The officers of the laboratory have carried out numerous investigations in connection with animal diseases. Much of the research work deals with the study of rinderpest, and the results of Dr. Lingard and Major Holmes (the present director of the laboratory) in this field have found practical application in the preparation of rinderpest anti-serum. Investigations on surra were commenced by Lingard at Poona, and continued by him until 1907, when he retired from the service. Holmes directed his attention to the problem of the treatment of surra in equines, and a method has been discovered which, in his hands, has given 75 per cent. of recoveries. The treatment has been successful in animals experimentally inoculated with the disease, and also in cases in which the disease has been contracted naturally. Various other subjects have been studied, and the results of the investigations have been published in scientific journals in India and Europe.

The problem of dealing with infectious diseases of animals in India presents many difficulties which arise from the somewhat peculiar local conditions. Measures of treatment, segregation, and disinfection cannot be imposed without the permission of each individual owner. Formerly a good deal of opposition to serum inoculation for rinderpest was encountered, but this has now almost disappeared, a result which is largely due to the repeated practical demonstrations of the efficacy of serum inoculation in the control of rinderpest epidemics. In dealing with an outbreak of disease it is essential that the measures adopted shall be free from all danger to the lives of the animals treated, and shall in no way interfere with their work. Under these conditions serum therapy has proved to be the safest and most efficient method of operation. Dead vaccines are also used as a preventive measure in districts where disease is seasonally prevalent. Vaccination by means of living or attenuated organisms is not practised, except in the case of black quarter.

A consideration of the subject matter of this pamphlet, and a study of the thirty full-page illustrations, shows that a successful attempt has been made to deal with a subject of great economic importance, viz., the health and well-being of the stock of a great agricultural country. The rapidity of the progress made, since the establishment of the laboratory some twenty years ago, is remarkable, and especially so when one considers the nature of the difficulties which have been encountered.

Percival Hartley.

PROF. J. H. POYNTING, F.R.S.

On the evening of Monday, March 30, surrounded by his family, John Henry Poynting passed quietly away. A memorial service was held in Birmingham on the Thursday following, and was attended by representatives of many universities and learned societies, including Sir J. J. Thomson, Sir Joseph Larmor, Dr. Glazebrook, Sir William Tilden, Prof. W. M. Hicks, Dr. W. N. Shaw, and of course by many colleagues and councillors of the University in which he occupied a chair, as well as by a large number of private citizens and friends. For he was a man universally beloved.

He was born on September 9, 1852, at Monton, near Manchester, son of the unitarian minister of that place. His first education was at home, but the years 1867 to 1872 he passed at Owens College, Manchester, graduating B.Sc. at the London University, and proceeding, in 1872, to Trinity College, Cambridge, where he was bracketed third wrangler in 1876.

He was then appointed demonstrator at Owens College by Balfour Stewart, and began a life-long friendship with Sir J. J. Thomson, who was at that time a student. In due time Poynting became a fellow of Trinity, and in 1880 was appointed to the professorship of physics at Birmingham, which he held to the day of his death.

The four first professors of the Mason College, which was opened by Huxley in 1880 (who delivered, on this occasion, a notable address, reprinted as the first of his collected essays), were Sir Wm. Tilden, Prof. M. J. M. Hill, Dr. T. W. Bridge, who died a few years ago, and Poynting. In this same year Poynting married Miss M. A. Cropper, daughter of the Rev. J. Cropper, of Stand, near Manchester. In 1887 he received the Sc.D. of Cambridge, and in 1888 the fellowship of the Royal Society. In 1891 the Adams prize was awarded to him, and in 1899 he presided over Section A of the British Association at Dover. This meeting was memorable for the clear discovery of the separate existence of electrons, which was announced to Section A by Sir J. J. Thomson on an occasion when many members of the French Association, meeting simultaneously at Boulogne, had come over for friendly fraternisation.

In 1905 Poynting became president of the Physical Society, and was awarded a Royal medal by the Royal Society "for his researches in physical science, especially in connection with the constant of gravitation and the theories of electrodynamics and radiation." In this brief summary an immense amount of work is referred to. The work for which he is locally best known was his determination of the Newtonian constant of gravitation by the very accurate use of an ordinary balance with an adjustable mass under one or other of the pans—a determination which is popularly called "weighing the earth." His account of it appears in the *Phil. Trans.* for 1891. It is a classical memoir of its kind, and very instructive to the physical student, but the papers on electrodynamics eclipse it in value. These were "communicated" to the Royal Society in 1884 and 1885 respectively, their titles being "On the Transfer of Energy in the Electromagnetic Field," and "On the Connection between Electric Current and the Electric and Magnetic Inductions in the Surrounding Field."

The memoir on the transfer of energy aroused universal attention. The paths by which energy travels from an electromotive source to various parts of a circuit were displayed, and their intricacies unravelled, for the first time; *identity* of energy might legitimately be urged as a supplement to *conservation*; and it is to these papers that we owe that fundamental generalisation, connecting mechanical motion with electric and magnetic forces, which is known all over the world as "Poynting's Theorem."

The work on radiation appeared partly in the *Phil. Trans.* for 1904 and partly in the *Phil. Mag.* for 1905. In these memoirs the tangential pressure of radiation is analysed and demonstrated; and it is shown, both theoretically and experimentally, that a beam of light behaves essentially as a stream of momentum, and gives all the mechanical results which may thus be expected, though of a magnitude exceedingly minute. Nevertheless, he goes on to show that these radiation-pressures, however small, are of much consequence in astronomy, and have many interesting and some conspicuous results. A noteworthy part of his radiation memoirs, however, is independent of considerations of pressure or momentum, and gives a means of determining the absolute temperatures of sun and planets, and of space, in a singularly clear and conclusive manner.

It is impossible, in a brief notice like this, to do justice to these great treatises, or to the rest of Poynting's scientific work; it must suffice to mention the titles of a few of his other papers:—"Change of State Solid-Liquid" (*Phil. Mag.*, 1881); "A Double Image Micrometer" (*Monthly Notices, R.A.S.*, 1892); "Osmotic Pressure" (*Phil. Mag.*, 1896); "On a Simple Form of Saccharimeter" (Proc. Phys. Soc., 1881).

Among his publications is a series of text-books on physics, written in conjunction with his friend, Sir J. J. Thomson; but he has also produced smaller and more popular books, one on "The Pressure of Light" (S.P.C.K.), and one on "The Earth" (Camb. Univ. Press). He also took an interest in statistical science, and wrote on "Fluctuations in the Price of Wheat," and on "Drunkenness Statistics of Large Towns."

His public spirit was shown by his accepting the position of a justice of the peace.

He took some interest also in the philosophical aspects of physical science, and his help is acknowledged by Prof. James Ward in connection with the publication of a series of Gifford Lectures. Poynting was strongly inclined, almost unduly, to limit the province of science to *description*, and to regard a law of nature as nothing but a formulation of observed similarities. He wished to abolish the idea of *cause* in physics. In some of this he may have gone too far, but his rebellion against an excessive anthropomorphism which had begun to cling around the notion of natural laws, as if they were really legal enactments to be obeyed or disobeyed by inert matter almost as if it possessed will-power and could exercise choice, some substances being praised as good radiators while others are stigmatised as bad—most gases being admittedly unable to reach a standard of perfection held out to them as Boyle's law, though a few of excessive merit might surpass it,—Poynting's revolt against this kind of attitude to laws of nature, though doubtless more than half humorous, was in itself wholesome. His philosophic views may be read, as a Presidential Address to Section A, in the Reports of the British Association for 1899.

But I must not delay further on his scientific work; the man himself was even more than his work. When the Mason College became the University of Birmingham Poynting was elected Dean of the Faculty of Science; in that capacity his quiet wisdom and efficiency were very manifest, and keen was the regret of all his colleagues when, some twelve years later, failing health necessitated his yielding this office to another. His judgment was as sound as his knowledge, and his conspicuous fairness endeared him to colleagues and the members of his staff. By the latter it is not too much to say that he was regarded with affectionate veneration; one of them writes to me as follows:—

"As to his character it is impossible to give the right impression to those who did not know him well. I consider him a man of very extraordinary ability, which might have carried him much farther if it had been associated with more self-assertion. But it was largely this modesty and self-suppression which created a very unusual degree of affection in those who had the privilege of knowing him intimately. I always associate him in my mind with Faraday and Stokes."

As a lecturer and teacher he was admirable, and the respect in which he was held by his peers was noteworthy. I am glad to remember that so recently as the last meeting of the British Association, some of the greatest physicists in the world, who were staying with me—Prof. H. A. Lorentz, Lord Rayleigh, and Sir Joseph Larmor—went to his house one evening, and met there in his study Sir J. J. Thomson and Dr. Glazebrook, who were staying with him; thus constituting a remarkably representative gathering, and giving him a pleasure which he remembered to the end of his life.

There is much more that might be said; but let his position in the world of science be what it may, we in the University of his mature life knew him well, and know him best as an admirable colleague, a staunch friend, and a good man.

At the Memorial service, the following true words concerning him were spoken by the Rev. Henry Gow, who knew him well:—

We remember that he did work to make him famous throughout the world of science which gave him a high place amongst the discoverers of truth; but we remember much more than that. We remember how he loved life, how interested he was in little things, how he delighted in children, in flowers, and in birds; what confidence and affection he inspired, how free he was from claims of self and from uneasy egotism; how much happiness he felt and gave. We remember his wise judgments, strong character, cheerful courage, his delightful humour, and a certain peaceful beauty and childlike joyousness of spirit behind all his multifarious gifts. He rejoiced to be the friend as well as the teacher of the young. He kept his heart free from all bitterness and disillusion which come so often to us in our later years. He knew and felt always how beautiful and great a thing it was to be alive.

OLIVER J. LODGE.

NOTES.

DR. G. T. BEILBY, Prof. A. Keith, F.R.S., and Mr. J. Swinburne, F.R.S., have been elected members of the Athenæum Club under the rule which empowers the annual election by the committee of a certain number of persons "of distinguished eminence in science, literature, the arts, or for public services."

By the death of Mrs. Huxley on March 5, in her eighty-ninth year, another link with the scientific society of the latter half of the nineteenth century has been snapped. All who had the happiness of knowing Huxley intimately are aware of the reliance which he at all times reposed on the advice and judgment of his lifelong helpmate. Not only in all domestic concerns, but in questions of literary criticism and even of scientific procedure, he never took a step without consulting her, and her wide knowledge and keen literary instincts made her aid invaluable to him. As is well known, the young surgeon of the *Rattlesnake* found a kindly welcome in the house of Mr. W. Fanning, a merchant in Sydney; and the half-sister of the merchant's wife, Miss Henrietta Heathorn, who had come out to Australia four years earlier, won his affections, though eight years had to elapse before the marriage could take place. Strange to say, Mrs. Huxley's health was a constant source of anxiety to her husband; he believed that an Australian medical man had so injudiciously treated a complaint from which she suffered as to have fatally undermined her constitution, but, nevertheless, she has survived Huxley himself by nearly twenty years. Mrs. Huxley wrote some very striking and thoughtful poems, nonsense verses, for the amusement of her children and grandchildren, and laughable stories, illustrated by one of her gifted daughters, with the same object; she will, however, be best remembered by the little work containing judiciously selected passages from her husband's writings, the admirable "Aphorisms and Reflections from the Writings of T. H. Huxley."

THE HON. FRANCIS ALBERT ROLLO RUSSELL, whose death on March 30 we announced with regret last week, was the third son of the first Earl Russell. He was born on July 11, 1849, and was educated at Harrow and at Christ Church, Oxford. As a youth he became interested in meteorological phenomena, and when about fifteen or sixteen years of age he began keeping records of the weather, especially of clouds and optical phenomena. He became a fellow of the Royal Meteorological Society in 1868, and served on the council from 1879 to 1892, and again in 1914, and was a vice-president in 1893–94. He was a fellow of the Royal Sanitary Institute, and served on the council in 1881–82, and again in 1889–92. Mr. Russell was the author of several works and papers on meteorological subjects, and also on matters connected with public health. He took a great interest in the question of London fogs, and was an advocate for the abatement of coal smoke. In conjunction with the late Mr. Douglas Archibald, he made a report to the Royal Society on the unusual optical phenomena of the atmosphere, 1883–6, including twilight effects, coronal appearances, sky haze, coloured suns and moons, etc., which were due to the volcanic eruption of Krakatoa. For his memoir, "The Atmosphere in Relation to Human Life and Health" (148 pp.), which was submitted to the Hodgkins Fund prize competition of the Smithsonian Institution, he was awarded honourable mention with a silver medal. Among his other works may be mentioned "The Spread of Influenza: its Supposed Relation to Atmospheric Conditions" (1891), "On Hail" (1893), and "The Early Correspondence of Lord John Russell," which was published last year.

THE seventieth birthday, on March 25, of Prof. Adolf Engler, the director of the Royal Botanic Garden and Museum at Dahlem, near Berlin, was celebrated in the presence of many eminent German and foreign botanists, by several functions. On the day itself, Prof. Lindau spoke on behalf of the scientific staff of the garden and museum. Prof. Pax, rector of the University of Breslau, with Profs. Diels and Gilg, as its editors, presented to Prof. Engler a copy of the *Fest-Band* of Engler's "Botanische Jahrbücher." The volume forms a supplement to the fiftieth volume of this well-known publication, and consists of more than forty illustrated contributions, largely from his pupils. The volume will be a lasting memorial of appreciation of Prof. Engler's botanical position, not only in Germany, but also in both hemispheres. As a further mark of this appreciation, Prof. Haberlandt presented Prof. Engler, on behalf of hundreds of subscribers, with his life-size marble bust, the work of the sculptor, A. Manthe, while Prof. Wittmack (to whom we owe these particulars, and the celebration much of its success) read the congratulatory address of the Deutscne Botanische Gesellschaft. Following similar addresses from the Vereinigung für angewandte Botanik, and from the Freie Vereinigung, an album of views of all the meeting places of the systematists was presented. Prof. Warming spoke on behalf of the foreign botanists. The presidents of the German Horticulture and of the Dendrological Societies added their felicitations, and it was announced that Prof. Engler had been made an honorary member of several learned societies in Germany, Russia, and other countries. On March 26 there was a banquet at which the official world was represented; and on March 27 the monthly meeting of the Deutsche Botanische Gesellschaft was converted into an "Engler" meeting, and Prof. von Wettstein gave, by special invitation, a lecture on the phylogenetic evolution of the Angiosperm flower.

IN connection with the establishment of a meteorological observatory at Agra for upper-air observations, the *Pioneer Mail* states that the Government of India has decided that the observatory shall be called the "Aerological Observatory, Agra," and that Mr. J. H. Field, Imperial meteorologist, while in charge of this work shall be designated the director of the observatory, and Mr. W. A. Harwood, the assistant-director.

At the suggestion of Mr. R. H. Tiddeman, president of the Yorkshire Geological Society, arrangements are being made by the society to call a conference next autumn, in Leeds, to consider the question of the glacial geology of the north of England. The conference will last a week, and in addition to papers and discussions, excursions will be made during the day to various centres of importance in connection with the glaciation of the north of England. Glacialists from all parts of the country will be invited to attend. A committee has been elected to make all the necessary arrangements.

Through the generosity of M. Spendiaroff, of St. Petersburg, the International Geological Congress presents at each session a prize amounting to about 450 roubles (47*l.*) for the best work in some specified field of geology. The next prize will be awarded at the session in Belgium in 1917 for the best work in petrography giving new light on the general problems of the science. Two copies, at least, of any work presented for the competition must be sent to the general secretary of the last congress, Mr. R. W. Brock, Deputy Minister of Mines, Ottawa, Canada, at least one year before the next session.

The septennial award under the Acton Endowment has this year been made by the Royal Institution to Prof. C. S. Sherrington, Wayneflete professor of physiology in the University of Oxford, for his work entitled "The Integrative Action of the Nervous System," being a synopsis of his elaborate paper published in the Philosophical Transactions of the Royal Society on experiments in examination of the peripheral distribution of the fibres of the posterior roots of some spinal nerves. Previous Actonian awards have been made to Sir George Stokes, Miss Agnes M. Clerke, Sir William and Lady Huggins, and Madame Curie, for achievements in the field of physical science. Prof. Sherrington is the first investigator in experimental biology to receive this distinction for the third of a century.

We regret to learn that the recent fire at Wellesley College, Massachusetts, though happily unattended by loss of life, destroyed the results of several years of research work. For the last six years Prof. Marion E. Hubbard has been investigating the problem of variation and heredity in beetles. The disaster swept away in a few moments all her notes and specimens, as well as a valuable original apparatus she had constructed for the purpose of her observations. Prof. Alice Robertson, head of the department of zoology, similarly lost all the specimens and notes relating to a collection of bryozoa dredged up by the *Albatross* expedition. Prof. C. B. Thompson, of the same department, has lost the results of similar work on dredgings bv the Bureau of Fisheries and the University of California, together with the memoranda of three years' experiments on the brains of ants and a collection of 4000 slides which had taken eight years to prepare.

The programme has just been issued of the annual meeting of the Iron and Steel Institute, to be held on Thursday and Friday, May 7–8. On May 7 the retiring president, Mr. Arthur Cooper, will induct into the chair the president-elect, Mr. Adolphe Greiner; the Bessemer gold medal for 1914 will be presented to Mr. Edward Riley; the president will deliver his inaugural address; and a selection of papers will be read and discussed. On May 8 the Andrew Carnegie gold medal (for 1913) will be presented to Dr. T. Swinden, the award of research scholarships for the current year will be announced, and other papers will be read and discussed. Among the papers that are expected to be submitted for reading and discussion are:—"The Forms in which Sulphides may Exist in Steel Ingots," Prof. J. O. Arnold and G. R. Bolsover; "The Hardening of Metals, with Special Reference to Iron and its Alloys," Dr. C. A. Edwards and Prof. H. C. H. Carpenter; "Influence of Molybdenum upon the Corrodibility of Steel," Dr. J. N. Friend and C. W. Marshall; "The Magnetic and Mechanical Properties of Manganese Steels," Sir Robert A. Hadfield and Prof. B. Hopkinson; and "A New Reagent for Etching Mild Steel," Dr. W. Rosenhain and J. L. Haughton.

The President of the Scientific Association of Rhodesia regrets in his annual address for 1913 that no attempt has been yet made to organise an anthropological survey of the State. He suggests the preparation of tribal and linguistic maps as a preliminary measure. Some good work is being done by the members under the difficulties which attend research in a new country. The report publishes two excellent ethnological and sociological papers on the Matabele, by Mr. P. Nielsen, and the people of the Zambezi valley, by Mr. C. I. Macnamara, which give valuable accounts of tribal organisation, initiation ceremonies, and marriage rites, which deserve the attention of anthropologists.

The fine collection of glacial boulders now preserved in the grounds of Messrs. Cadbury, at Bournville, Birmingham, is described by Prof. C. Lapworth in part ii., vol. xviii., of the Proceedings of the Cotteswold Naturalists' Field Club for 1913. After describing the advance of the ice-sheet into the midlands, and the numerous boulders conveyed by its action into the Birmingham district, the writer states that the collection at Bournville consists of masses of dark igneous Plutonic rock, usually known as felsite or andesite, identical with the rock which forms a large part of the Arenig mountain ranges, several miles west of Bala Lake, in the basin of the river Dee, North Wales, and fully fifty miles, as the crow flies, from Bournville.

To the March *Zoologist* Col. C. E. Shepherd communicates the first part of an article on methods of determining the position of the auditory sacculus and its contained otoliths in various groups of fishes.

In an article on the effect of geographical distribution on the development of species, published in the March number of the *American Naturalist*, Mr. A. C.

Chandler enunciates a law that as the distributional area of any given group of animals increases, the number of species increases in proportion to the genera, that of genera to the families, and so on. The theoretical explanation of this law involves the consideration of problems relating to evolution and species-development.

Three important additions to the Natural History Branch of the British Museum are recorded in the March number of the *Museums Journal*, namely, a series of more than 900 zeolites collected and presented by Mr. F. N. A. Fleischmann, a collection of 800 specimens of plants made in the Eket district of Southern Nigeria by Mr. and Mrs. P. A. Talbot, by whom they were presented, together with descriptions and coloured sketches, and, lastly, a collection of more than 10,000 specimens of Hymenoptera (including 1500 types), brought together by the late Mr. P. Cameron, and purchased from his executors.

The most interesting feature in the March number of the New York Zoological Society's Bulletin is Mr. Townsend's account of the capture and transport of the bottle-nosed dolphins, or porpoises (*Tursiops tursio*) in the New York Aquarium. There is a regular fishery of these cetaceans at Cape Hatteras, N. Carolina, and in November last a small "school" of them was captured and dispatched to New York in special water-tanks. Nine reached their destination in safety, and of these five were alive and in excellent health at the time the article was written. They are kept in a salt-water pond of 37 ft. in diameter by about 7 ft. in depth, and constitute a unique and highly attractive exhibit.

Amphibians and reptiles loom large in the March number of Douglas English's *Wild Life*, Mr. E. G. Boulenger communicating an exquisitely illustrated article on some of the well-known species of European toads, while in a second he figures the first living example of the saddle-backed giant tortoise (*Testudo abingdoni*), of Abingdon Island, Galapagos group, received alive in this country. In a note regarding other giant species the author mentions that about 1760 no fewer than 25,000 of these chelonians were exported from Rodriguez to Mauritius for food in a single year. Little wonder that the species of the former island soon became exterminated. In connection with giant tortoises, it may be mentioned that remains of an extinct species from the Pleistocene of Minorca are described by Miss Bate in the March number of the *Geological Magazine*.

A new serial, of the first number of which we have received a copy, has been started at Buitenzorg, under the editorship of Dr. J. C. Koningsberger, and published by the Department of Agriculture, Industry, and Commerce, with the title of "Contributions à la Faune des Indes Néerlandaises." It is specially intended for papers emanating from the Zoological Museum and Laboratory of Buitenzorg, and the Biological Station at Batavia, which have hitherto appeared in another local publication. The new issue appears, however, as a section of the well-known "'s Lands Plantentuin," dating from 1817. Its contents include an article by Dr. C. P. Sluiter on holothurians collected by Mr. P. N. van Kampen in the Malay Archipelago, and a list of chelonians from the Dutch East Indies in the Buitenzorg Museum.

In a recent number of the *Memorias do Instituto Oswaldo Cruz* (vol. v., part 2), a memoir, illustrated by beautiful coloured plates, is published by Drs. Aragao and Vianna on the disease known as *Granuloma venereum*. The authors deny that a treponeme is the cause of the disease, which is quite distinct from syphilis. They associate the disease with a peculiar bacterium occurring in the cells of the granulomatous tissue. The most striking characteristic of this organism is the possession of a peculiar capsule, for which reason they propose to put it in a distinct genus, Kalymmabacterium (or Calymmatobacterium; the name is spelt in both these ways in the same paragraph). The authors have obtained very remarkable success in the treatment of this disease with injections of tartar-emetic; they state that this treatment has effected a complete cure in every case treated by them, and the photographs given of cases before and after treatment are quite astounding. Full descriptions are given of a number of cases and of the progress of the treatment. Incidentally, it is mentioned that injections of tartar emetic have been found most efficacious in the treatment of leishmanioses in Brazil.

The Carnegie Institution of Washington has published together a paper by Prof. W. E. Castle, "Reversion in Guinea-pigs and its Explanation," and one by C. C. Little, "Experimental Studies of the Inheritance of Color in Mice" (Publication No. 179, issued September, 1913). Prof. Castle shows that some red guinea-pigs when mated with black give blacks, black being dominant, but that other apparently similar reds when mated with blacks give agouti. A series of breeding experiments proves that the cause of the difference is that some reds contain a factor which brings about striping in the hair. It has no effect in the red, from which black pigment is absent, but black, in the presence of the striping factor, becomes agouti. Mr. Little's paper adds some new and probably valuable ideas to the already extensive literature of coat-colour in mice. He points out that yellow, brown, and black pigment are produced by three successive stages of oxidation of a chromogen. He suggests that albinos lack the factor *Y* (yellow) which produces the first stage, and that the higher factors *Br* (brown) and *B* (black) are then unable to act. Brown is produced by the presence of *Y* and *Br*, black by *Y*, *Br*, and *B*. Yellow, which in all the cases he has used is dominant to other colours, is caused by a factor inhibiting the action of *Br* and *B*. There are in addition two classes of "distributive" factors. One of these causes full development of pigment; its absence causes dilute colour. Another is necessary for full development of *Br* and *B*; in its absence the mice are pink-eyed with pale-coloured hair. Both these factors are somewhat variable in intensity. The other pair of distributive factors are that for the agouti barring of the hair, and that which more or less completely inhibits *Br* and *B*, giving dominant yellows. The question of piebalding is also dealt with, and many pages of tables of experimental results are included.

The unexpected discovery of hot springs and evidences of recent volcanic activity in Spitsbergen is described and illustrated by A. Hoel and O. Holtedahl in *Naturen* for January, 1913. The occurrences are in Wood Bay, on the little visited north coast of the main island. The springs have formed characteristic travertine basins, in which a species of Chara is recorded, with a moss and twelve algal species which are equally new to the high arctic flora. The characteristic forms in the moving soils of Spitsbergen, with their walls of stones set in circular cracks, are described by W. Meinardus in the *Sitzungsberichte des Naturhistorischen Verein der preuss. Rheinlande u. Westfalens*, 1912 (published 1913), C, p. 1. A useful bibliography is appended. B. Högbom points out the various features in Spitsbergen that indicate the dryness and the desert-character of present conditions in the island (Bull. Geol. Institution of the Univ. of Upsala, vol. xi., p. 242), and A. Smith Woodward describes Lower Triassic fish-remains from Sassen Bay in the same volume.

The Messina earthquake of December 28, 1908, originated in two foci, both beneath the Straits of Messina, one at its northern entrance, the other between Reggio and Messina. Almost exactly four years later, on December 22, 1912, a strong earthquake occurred, probably within the latter focus. According to Dr. Agammennone, who describes the earthquake in a recent number of the *Rivista di Astronomia*, the shock was not announced by any early tremors; it disturbed an area only 135 miles in diameter; but, though its intensity at Messina was 7 (Mercalli scale), the shock failed to damage buildings erected in accordance with the new regulations.

We are glad to learn that the United States have again decided to send revenue cutters to the vicinity of Newfoundland Banks for the purpose of reporting on the conditions of the ice. The *Seneca* has already taken up her position, and is sending wireless reports to the Hydrographic Office in New York, in addition to which she will make oceanographic observations while cruising in that district. The meteorological charts of the North Atlantic issued by the offices at London and Hamburg for April show that drift ice has recently increased to a considerable extent. Bergs or field ice were seen on or before February 15 nearly so far south as 42° N., and nearly so far east as 41° W. Several ships have had to alter their course, considerably, off the Newfoundland Banks.

The question whether thermometers in the double-louvred "Stevenson" screen, now generally used in this country give true measurements of air temperature has been discussed in *Symons's Meteorological Magazine* for several months past. Mr. W. F. A. Ellison considers that the accuracy that some observers are striving for is fallacious, and that on a sunny day no two adjacent masses of air have the same temperature. An important communication from Dr. John Aitken appears in the March number. He considers that, although the whole mass of air is a mixture of more or less heated patches, the thermometers in the screen in question fairly represent the mean temperature, but that the screen must always read higher than the true temperature, while the sun shines. He points out the important fact that some of the screens in use in the north and south of the country are not similar in construction in all respects.

English readers of Italian scientific journals have often been rather puzzled when they have come across such names as Giuseppe Larmor, Guglielmo Ostwald, or Enrico Poincaré. From a note published in *Isis*, vol. i., part 4, p. 707 (1914), by Aldo Mieli, we are glad to learn that this practice is being discontinued, and he now opens the further question as to how uniformity can be obtained in the spelling of classical names and others possessing different alphabets from ours. Here it is suggested that the nominative case should be universally adopted, and in the case of Greek a uniform system of equivalents for the Greek letters should be adopted. In this list he still adheres to the custom of replacing the Greek *ph* by *f*.

Articles of a semi-popular character *about* mathematics, as distinct from papers *on* mathematics, are not so common as they deserve to be. The February number of the new quarterly, *Isis* (vol. i., part 4) goes a long way to supply this want. Mathematics is represented by three of the five principal articles. M. George Sarton writes on modern tendencies in mathematical history and criticises the recent works of M. Leon Brunschvicg (Paris: Felix Alcan, 1912) and M. Pierre Boutroux (Paris: Hermann, 1913–14), both of which volumes are also reviewed in this number. In Prof. Gino Loria's paper on the glories of British mathematics, which was read at the International Congress of Historical Studies in London in 1913, the author laments the scarcity of literature dealing with the history of English mathematics, and expresses the opinion that many valuable and interesting manuscripts are waiting to be unearthed. Mr. P. E. Jourdain writes on the origin of Cauchy's conceptions of a definite integral and of a continuous function. In addition there are a number of reviews of mathematical books. The subscription to *Isis* is 24 francs per annum, and the offices are at Wondelgem les Gand, Belgium. Messrs. Max Drechsel, of Berne, are agents.

The photographs of the tracks of α and β particles obtained by Mr. C. T. R. Wilson with his cloud apparatus illustrate so well the properties of these radiations, that many teachers will be glad to know the Cambridge Scientific Instrument Company is now producing copies of them in the form of lantern slides. The clearness of the photographs raises the hope that it may be possible to obtain stereoscopic photographs which would enable depth to be estimated, or possibly kinema views which, when run through the lantern slowly, would allow the sequence of events to be followed.

Although the incandescent electric lamp when standardised and used with accurate ammeters has proved the most trustworthy standard of light, the

Bureau of Standards at Washington has selected the Harcourt 10-candle pentane lamp as the best of the gas-flame lamps to serve as a secondary standard. This decision has been arrived at after an extensive test of the various lamps, and the conclusions with regard to the best method of using the standard are embodied in a paper by Messrs. E. C. Crittenden and A. H. Taylor, which appears in the tenth volume of the bulletin. They cover the question of the fuel and the effects of pressure and moisture on the candle-power.

A SUCCESSFUL modification of General Sterneck's pendulum apparatus has been designed and employed by Sig. Vincenzo Reina and Gino Cassinis in the determination of gravity (relative) at Rome, Arcetri (Florence), Livorno and Genoa in Italy, and also at Vienna and Potsdam (*Memorie R. Acc. Lincei*, series v., vol. ix., No. 17, pp. 751–839). In the earlier forms, such, for instance, as those used in the gravimetric survey of the Indian Peninsula, and more recently in Egypt, the pendulum support is a solidly constructed tripod resting on and clamped to a masonry pillar. Although maximum rigidity is aimed at, yet under the alternating strains induced by the swinging pendulums the support is found to be appreciably yielding, and the determination of the effect of flexure constitutes one of the necessary pieces of preliminary work. It is obtained by observing the oscillation of the invariable pendulum induced by a heavier synchronous (variable) auxiliary pendulum swinging in the same plane (method of Schumann). In the Italian modification the means for applying this method is made an inherent feature of the design. The trustworthiness of the correction is increased by securing (1) greater equilibrium in the distribution of parts, (2) that the correction is obtained with the invariable pendulum swinging in the position used in the actual determinations. These improvements are realised by mounting the single perforated agate plate on which the knife edges of the pendulums bear when they are in motion on two consoles, which can be bolted to a vertical surface. Only one invariable pendulum is swung at a time. With this arrangement the effect of flexure is less than one-tenth of that of the tripod type, the maximum correction of nine different groups being -3.9×10^{-7} secs., whilst the minimum was -1.5×10^{-7} secs.

WE have received a reprint of a paper read before the eleventh International Congress of Pharmacy, held at Scheveningen last September, by Prof. Hans Haller, of Leyden, on the application of comparative phytochemistry to systematic botany. Illustrations are given of the growing importance of a knowledge of the chemical substances elaborated by plants in elucidating vexed questions of classification and in throwing light on phylogenetic relations. The field is one which has as yet been little worked, but it will in the future undoubtedly become more and more fruitful.

THE *Società Tipografica Editrice Barese*, of Bari, Italy, announces the forthcoming publication of a series of reprints of scientific and philosophical classics under the title, "Classici delle Scienze e della Filosofia." In some respects this series will resemble the valuable collection already issued by Ostwald in Germany, under the title "Klassiker der exakten Wissenschaften," but the venture will be on an even more ample scale; it will render easily accessible to the student of the historical development of science many classical papers which have hitherto been obtained only with great difficulty. Each volume will contain about 300 pages, and will cost about 3 lire. The whole series is under the general editorship of Messrs. Aldo Mieli and Erminio Troilo. All scientific workers will wish success to this praiseworthy enterprise. The following are specimens of the titles of volumes already issued:—Spallanzani's "Saggio sul sistema della generazione" (1777); Biringuccio's "De la Pirotechnia" (1540), vol. i., and a translation of Descartes's "Principia Philosophiæ." Amongst those to appear at an early date are Francesco Redi's "Esperienze intorno alla generazione degli insetti," Galileo's tracts on motion, and several reprints of the scientific works of Leonardo da Vinci, Volta, Giordano Bruno, and Vico, to mention only a few of those announced as already in the press.

MESSRS. NOVELLO AND CO. have published a second edition of Dr. Jamieson B. Hurry's "Sumer is icumen in." The attractive volume was originally published at the time of the unveiling at Reading Abbey of a memorial tablet, bearing a facsimile of the canon, which, it may be remembered, was written by a monk at Reading Abbey, about the year 1420.

OUR ASTRONOMICAL COLUMN.

COMET 1914*a* (KRITZINGER).—Circular No. 145 from the Central Bureau at Kiel contains the following elements and ephemeris, communicated by Prof. Kobold, deduced from observations on March 29, 30, and 31:—

Elements.

$$T = 1914 \text{ May } 31{\cdot}1816 \text{ M.T. Berlin.}$$
$$\omega = 67^\circ \quad 0{\cdot}95'$$
$$\Omega = 198 \quad 36{\cdot}68$$
$$i = 23 \quad 30{\cdot}86$$
$$\log q = 0{\cdot}09910$$

Ephemeris for 12h. M.T. Berlin.

	R.A. h. m. s.	Decl. ° ′	Mag.
April 8	16 43 30	−3 36·4	10·1
9	46 56	2 53·8	
10	50 24	2 10·2	10·0
11	53 54	1 25·4	
12	16 57 27	−0 39·9	

The ephemeris shows that the comet is reducing its southern declination; it is situated in the constellation of Ophiuchus.

THE NEW SOLAR CYCLE.—The long period of apparent rest which the solar atmosphere has been recently undergoing has now been broken by the comparatively large sun-spot which developed during the course of last week. The sun-spot activity of the last few years has been well summarised in the annual report of the council of the Royal Astronomical Society (*Monthly Notices*, February, 1914). In this we are told that the past year has been a year of minimum activity of sun-spots, more than a century having elapsed since the sun exhibited such complete and prolonged quiescence. The following brief table is gathered from the report above mentioned, and brings out clearly the exceptional nature of the year 1913:—

Year	Days without spots	Mean daily spotted area in millionths	No. of separate groups
1911	183	64	62
1912	246	37	39
1913	320	5	15

It is stated that no year since 1810 has given such a barren record as that just elapsed. The new cycle was indicated last year by two groups in high latitude, the chief criterion for the beginning of a new cycle.

RELATION BETWEEN STELLAR SPECTRA, COLOURS, AND PARALLAXES.—In *Astronomische Nachrichten*, No. 4722, Herr P. Nashan describe the results he has obtained in comparing the colours, spectra, and parallaxes of a number of stars. Dealing first with 101 stars, he divides them first into three classes, α, β, and γ, according as the stars are white, yellow, or red; the parallaxes are also grouped with three divisions as follows:—0·000″ to 0·050″, 0·050″ to 0·100″, and 0·100″ to 0·200″. The comparison shows that the white stars decrease with increasing parallaxes; on the other hand, the red stars increase with increasing parallaxes. The fact that there is a close relationship between the colour and the spectrum of a star has led him to compare the spectra of 246 stars with their parallaxes. The results are best shown as follows:—

Spectrum	No. of stars	Parallax 0″·000–0″·050		0″·050–0″·100		0″·100–0″·150		0″·150+	
		n	%	*n*	%	*n*	%	*n*	%
B	11	7	63·6	3	27·3	1	9·1	0	0
A	28	8	28·5	8	28·5	7	25·0	5	18·9
F	59	19	32·2	22	37·3	15	25·5	3	5·1
G	64	13	20·3	22	34·4	27	42·2	2	3·1
K	70	13	18·6	21	30·0	23	32·9	13	18·5
M	14	3	21·4	2	14·3	5	35·7	4	28·6

Herr Nashan then couples up the B and A stars into a white group, the F and G into a yellow group, and the K and M stars into a red group, and concludes that the relative number of white stars decreases with increasing parallaxes, while the relative number of the red stars increases with increasing parallaxes, a result similar to that obtained with colour alone. The communication concludes with the list of the 246 stars employed, giving their positions for 1900·0, parallax, type of spectrum, and colour.

SERIES LINES IN SPARK SPECTRA.[1]

PREVIOUS work on series lines in spectra has dealt chiefly with lines produced in the electric arc, or in vacuum tubes with discharges of moderate intensity. The lines discussed in the present communication are some of those which are specially developed in the condensed spark, belonging to Lockyer's class of "enhanced lines." The investigation was undertaken in connection with the new lines (λ 4686, etc.) produced in 1912 by passing strong condensed discharges through helium tubes, which always contained an impurity of hydrogen. These lines are of great interest in celestial spectroscopy, and, following Rydberg, they were assigned to hydrogen, to the lines of which they seemed to have a simple relation, while having no apparent connection with those of helium.

[1] Summary of Bakerian lecture delivered at the Royal Society on April 2, by Prof. A. Fowler, F.R.S.

The evidence for assigning the lines to hydrogen, however, was still numerical rather than experimental, and further inquiry was called for, especially in view of the presence of an intermediate set of lines associated with the Rydberg series. A search for other series of this character was therefore instituted in the hope that some generalisation with regard to them might be reached. The well-known spark line of magnesium, λ 4481, was subsequently found to be the leader of a series of this kind, but no relation to other magnesium series was then traced.

The lines of the "4686" series have since become of increased importance, in connection with theories of the constitution of the atom, through the theoretical work of Dr. Bohr, who explains them as being produced during the first stage in the re-formation of helium atoms from which both electrons have been removed by the strong discharges employed. The "4686" and the intermediate series were thus united in a single series of a new type, in which the Rydberg series constant N(=109675) had four times the value associated with hydrogen. A similar modification of the usual formula was found to be applicable to the magnesium series, and also to some lines of calcium, strontium, and barium observed by Lyman in the Schumann region. At this stage a valuable contribution to the investigation was made by the work of Lorenser, from which it results that the enhanced lines of the elements named form groups of series similar to those found in arc spectra. Further calculations have shown that these series are best represented by the Hicks formula with 4N for numerator.

A further experimental investigation of magnesium has resulted in the production of many new enhanced (spark) lines, from which it appears that the "4481" series is the fundamental series of a system of narrow doublets, in which the separation of the pairs is identical with that calculated for the *second* member of the principal series of wider doublets previously known. It has also been shown that the "4481" series consists of very close doublets with constant separation. Two well-defined combination series related to 4481 have also been identified.

From these investigations of enhanced metallic lines it follows that two kinds of series must now be recognised:—(1) Series of the arc type, having Rydberg's "N" for the series constant; and (2) series of the spark, or enhanced line, type, having a series constant equal to 4N. No numerical relations between the two sets of series occurring in the same element have been traced.

The "4686" series produced in helium tubes is of the spark (4N) type, and can no longer be considered to belong to the same group as the Balmer series of hydrogen, which is of the arc (N) type. It is concluded that the lines in question are due to helium, as indicated by Bohr, and it is suggested that they should be designated "proto-helium" lines in accordance with the convenient nomenclature of Lockyer. The "Pickering" lines associated with the "4686" series probably have a similar origin, in which case the series would include intermediate lines nearly coincident with the Balmer lines of hydrogen. Observational evidence on this point is incomplete, but indirect evidence is furnished by the fact that one of the new combination series is related to the 4481 series exactly as the extended Pickering series would be related to the "4686" series of proto-helium.

Dr. Bohr has shown that the slight differences in the observed positions of alternate lines of the "4686" series and those calculated for the principal series of hydrogen by Rydberg are accounted for when his theoretical formulæ are corrected for the mass of the electron (NATURE, October 23, 1913). If the formulæ are correct, the inverse calculation provides a spectroscopic method of determining the mass of the electron. The available observations give the mass of the hydrogen atom in terms of that of the electron as 1836 ± 12, in remarkable agreement with the generally accepted value.

Until other evidence is forthcoming, it may be considered that the line spectrum of hydrogen consists only of the Balmer series, with parallel series in the infrared and extreme ultra-violet. The proto-helium spectrum is of the same simple character, and this simplicity gives the two spectra a special value in theoretical investigations. Bohr's theory implies that arc series in general are produced when only one electron is removed from the atom by the exciting source, and spark series when two electrons are removed.

The change in the character of the series in passing from arc to enhanced lines suggests the possibility of series requiring still greater multiples of the ordinary series constant, but no such series have yet been identified.

PRACTICAL EDUCATION IN SECONDARY SCHOOLS, TRADE SCHOOLS, AND CENTRAL SCHOOLS.[1]

ONE of the most striking features of English education at the present time is the attempt which is being made to give a more practical or vocational bias to the training of boys and girls between the ages of twelve and sixteen years—that is, after the completion of the ordinary primary-school curriculum. So far as day work is concerned, this tendency is operating along two main lines, (*a*) the modification of the traditional secondary-school course by the introduction in some schools of elementary engineering, agriculture, shorthand, typewriting, or of subjects grouped under the general name of "educational handwork" (*e.g.* woodwork, metal-work, domestic subjects for girls); (*b*) the development of schools (central schools, junior technical schools, trade schools) with a pronounced vocational object.

A. *Secondary Schools.*—In the year 1911–12, of the total number (39,726) of new admissions to the secondary schools aided by the Board of Education, no less than 67·7 per cent. came direct from the elementary school. Clearly the great majority of these cannot enter one or other of the learned professions, but must devote themselves on leaving school to some branch of commercial or industrial life. A strong public demand has arisen for a modification of the curricula of these schools so that the education given may be of more direct value to the pupils after leaving school. Employers are demanding better trained assistance; the parents feel that the additional sacrifices they must make in order to keep their boys and girls at the schools after fifteen years of age are not sufficiently justified by the benefits to be derived by their children from an education which is mainly of a literary or classical type. As a result, some secondary schools have specialised to a certain extent, more particularly of course in the higher forms, in engineering subjects, others in science (chemistry, physics, botany, and biology) as applied to agriculture, others in commercial and secretarial work, depending upon the needs and circumstances of the locality. Apparently the results of this specialisation, where it has been attempted, have been satisfactory. The general educational work of the school has gained in interest and vitality by the increased contact with concrete, everyday affairs. Possibly it may help also in checking the exodus of the pupils from the secondary schools at about the age of fifteen, *i.e.* half-way through their full course.

[1] (1) Report of the Consultative Committee of the Board of Education on Practical Work in Secondary Schools [Cd. 6849]. (Wyman and Sons, 1913. Price 1*s.* 9*d.* (2) Report of the Board of Education for 1911–12 [Cd. 6707]. (Wyman and Sons, 1913.) Price 8½*d.* (3) Regulations for Junior Technical Schools in England and Wales [Cd. 6919]. (Wyman and Sons, 1913.) Price 1½*d.*

The Consultative Committee of the Board of Education issued a short time ago a comprehensive and suggestive report upon the development of "educational handwork" of various kinds (woodwork, metal-work, gardening, modelling, and domestic subjects for girls) in secondary schools. The report states (p. 5) that the evidence of the witnesses "leaves no room for doubt as to the necessity and the practicability of giving such work a more definite place in secondary education than it has hitherto occupied, and of associating it so far as possible with the rest of the work of the school." While it is not the function of the secondary school to impart technical instruction, it should provide those of its pupils whose future callings may involve manual work or the utilisation and control of such work with a foundation on which technical instruction may subsequently be built. "Systematic work with the hands is a necessary constituent of a liberal education." To train deftness of hand, although important, is not the sole or even the chief aim of handwork teaching. The principal object is to influence the mind and character of the pupils by developing their common sense, readiness, and adaptability. In addition it brings the work of the school into close relation with the needs of daily life outside the class-room, thus giving school work that reality which is so important for arousing the child's interest. Manual training has a valuable steadying influence upon the over-quick and excitable child, and a stimulating effect upon the child who is naturally slow at abstract mental processes.

The recognition of handwork as a compulsory school subject has been objected to on the ground that it involves the addition of one more item to an already overburdened time-table. Experience shows that a reasonable amount of time devoted to handwork does not lead to any lowering of attainment in other branches of school work, but rather the reverse.

The Committee lays down the following general principles for the teaching of all branches of educational handwork. The encouragement of independence and initiative is of fundamental importance, hence each pupil should be allowed to work at his own pace and be encouraged to select his own work. Classes should be sufficiently small to permit of individual instruction. Constructive practice and theory should go hand in hand. The syllabus should be logical, coherent, interesting, and of a direct culture value. A number of syllabuses which are in actual operation in schools are given in the report. These will be of great value to teachers.

Handwork should be recognised in any general examination scheme for secondary schools. External examinations in this subject are particularly undesirable; the assessment of the progress made by the pupil should be based upon the work done during the course.

The Committee points out that at the present time the educational training, status, and remuneration of handwork teachers are unsatisfactory. These teachers should be on an equality in these matters with their colleagues. This type of teaching should not be handed over to artisans, but to men with a good general education and a special knowledge of educational handwork. The universities should provide increased facilities for this branch of education, and adequate recognition of those who complete successfully the prescribed courses of study.

B. *Central Schools, Junior Technical Schools, Trade Schools.*—In this group of schools the work as a whole has a more pronounced practical or vocational bias than in the secondary schools, this being most marked in the trade schools and least in the central schools. The students in these schools are in nearly every case drawn from the elementary schools. The usual age of admission is twelve or thirteen years, the courses lasting three to four years. The fees are nominal, ranging from 10*s.* to about 2*l.* 10*s.* per annum. There is usually a generous supply of scholarships with maintenance grants awarded by the local education authority.

(1) *Central Schools.*—The last Board of Education report (*i.e.* for 1911–12) states that central schools have been established only in London and Manchester as yet. In London there are thirty-one such schools containing forty-two departments, fifteen for boys, thirteen for girls, and fourteen "mixed"; nineteen of these departments have a commercial bias, sixteen industrial, and seven a "dual" bias. Manchester has six such schools, including three boys' departments, two girls' departments, and three mixed departments.

These central schools are intended to attract at about the age of twelve or thirteen the best boys or girls from the local elementary schools, who have not previously been drafted off by means of competitive scholarships into the secondary schools. The object of the schools is to continue the general education of the pupils and at the same time to prepare the children to go directly at about the age of fifteen or sixteen into business houses or workshops at the completion of the course. The training is to be such, however, that it will not prevent the pupil proceeding by scholarships or otherwise to a place of higher education.

An examination of the curricula of these schools reveals comparatively little difference between them and those secondary schools which have definitely attempted to introduce vocational work into their programme. A typical central school (with a commercial bias) provides throughout the whole course, in addition to the ordinary subjects, such as mathematics, geography, and history, about four hours a week for a modern language, four hours a week to English, science two hours, manual training two hours, and drawing two hours. In the third and fourth years a few hours a week are devoted to shorthand, business correspondence, office routine, and typewriting. In departments with an industrial bias, about ten to twelve hours a week are given to practical work (laboratory work, drawing, woodwork, and metalwork). No attempt is made to specialise for any one particular industry. The practical work for girls consists of elementary science and housecraft. This type of school as a whole, though doing excellent work, suffers somewhat in the public estimation through it being regarded as inferior in prestige to the ordinary secondary school. The training given in the central schools is probably better fitted to the after circumstances of the majority of boys and girls from the elementary schools than is that afforded by the usual type of secondary schools.

(2) *Junior Technical Schools and Trade Schools.*—This class of schools suffers from a bewildering variety of names—junior technical schools, trades preparatory schools, pre-apprenticeship schools, and trades schools. Generally speaking, the junior technical schools provide a wider training in general education and in theoretical work than the trades schools. Again, junior technical schools are understood not to specialise for one particular trade, but to provide a training enabling a boy to enter any branch of a group of industries, such as engineering or the building trades. The trades schools specialise more severely than this in many cases. Actually, the names of the schools are often misleading, so-called "trades" schools being really "junior technical" schools. At the present time the general tendency is in favour of the "junior technical school," with its wider educational outlook and less severe specialisation, rather than the "trades" school proper.

There are about sixteen junior technical or trades schools in London, with about 800 boys and 3000 girls in attendance. In other portions of England and Wales there are about twenty such schools, with, say 1200 pupils, and in Ireland twelve schools with 500 pupils. Scotland relies upon a system of "supplementary classes," which in effect is very similar to the "central schools" described earlier.

The provincial schools are usually designed to provide only for the engineering, building, and metal trades. Manchester has recently established a Day Trade School of Dressmaking. London trade schools cover a wide field of more or less specialised instruction, *e.g.* furniture and woodworking trades, book production, silversmith's work, tailoring, bakery and confectionery, cookery (for *chefs*), and many women's trades. The net annual cost of the trade schools maintained by the London County Council is approximately 15*l.* to 21*l.* a student. There is no definite provision, except at Cardiff, for instruction in commercial subjects along junior technical-school lines.

The curricula of these schools vary considerably. Broadly speaking, each school allows about three to four hours a week for English, three to four hours a week for mathematics or arithmetic, and of the remaining time, about one-third is devoted to theoretical instruction in the theory or sciences, if any, allied to the special trade or industry, and about two-thirds to the practice of the trade or practical work (including drawing office, workshops, laboratory work, or drawing) connected with the industry. Considerable attention is given to continuing the general education of the pupils, with the result that but for the omission of a modern language, the boy of sixteen in the better type of junior technical school is educationally on a level with the average boy of the same age in the secondary school. The physical welfare of the children is helped through the agency of organised games and gymnastics. The pupils are encouraged to organise clubs and societies in order to foster the social life and corporate spirit of the schools.

On the whole this type of school has been very successful, especially perhaps the trade schools for girls in London. Close contact with the trades and industries is secured in many of the schools by the formation of "advisory committees," consisting of representatives of employers and of labour. The pupils are generally keen upon their work, and the tone of the schools is good. There is comparatively little difficulty in most cases in securing positions in industrial life for the boys or girls at the completion of their course. The work done in these schools generally enables the boy or girl to shorten the period of apprenticeship very considerably and to obtain higher wages than they would otherwise have secured.

The success of the relatively few junior technical schools or trades schools which have been established so far points to the probability of a rapid increase in the number of these schools in the immediate future. Broadly speaking, about half a million boys and girls leave the elementary school each year, less than one-tenth of these passing forward to the secondary school, and only about 2000 to the junior technical or trades schools. Of the remainder, a considerable proportion would probably amply repay further systematic full-time education, not of the customary literary type, but of a more practical character, such as is given in the junior technical or trade schools. One point, however, must be watched. The Board of Education, in the recent regulations for junior technical schools, states that these schools are not intended to furnish a preparation for higher "full-time" technical work, this being one of the functions of the secondary school. This would make the junior technical schools a "dead end" so far as further day technical work is concerned. In science and mathematics, the fundamental subjects in technical work, the boy in the junior technical school is ahead of the secondary-school boy. The junior technical school should be another avenue, alternative to the secondary school, by means of which the bright boy could pass from the elementary school to the technical college. This is especially important in the case of the boy who develops somewhat late or whose mental activities only become aroused by contact with things rather than with books.

J. Wilson.

THE INSTITUTION OF NAVAL ARCHITECTS.

The spring meeting of the Institution of Naval Architects opened on April 1 at the rooms of the Royal Society of Arts. The institution's gold medal was awarded to Mr. G. S. Baker, for his paper on methodical experiments on mercantile ship forms. Premiums were awarded to Messrs. A. Cannon and L. Woollard for papers dealing respectively with the effect of loose water on the rolling of a ship, and the effect of water chambers on the rolling of ships. In all fourteen papers were read and discussed during the three days over which the meeting extended.

In a paper dealing with some questions relating to battleship design, Mr. T. G. Owens states that the present tendency in warship construction and design, as exemplified in the later ships of all the principal maritime powers, is towards very large displacements, with the arrangement of all the guns of the primary armament on the centre line, and with the guns of the secondary armament placed in an armoured citadel on, or immediately below, the deck carrying the primary guns. In respect to the above-water armoured protection, there is the usual thick armoured belt, extending, say from 4 to 6 ft. below the water-line, to the height of the main deck, and carried along the length of the vessel for such distance as to protect the machinery and boiler compartments and the magazines. The ends of the ship and the citadel have armour of reduced thickness. In all modern battleships there are horizontal protective decks. Protection against attack from bombs, etc., dropped from aircraft is not yet in the region of practical politics. When the time arrives to arrange measures to meet such attack, they will probably take form in the method advocated by Sir Trevor Dawson, *i.e.* to increase the thickness, and give a greater curvature, or whale-back formation, to the armoured deck.

Mr. W. J. Luke contributed a paper on experiments upon wake and thrust deduction, supplementary to another paper which he presented to the institution in 1910. The present paper has particular reference to experiments with contrary-turning screws on a common axis, with tandem screws, and also of experiments with quadruple screws. It appears from the experiments that the first-mentioned type of screw has not a little to recommend it, and were the engineering difficulties connected with its application to marine propulsion overcome, it would be well worthy of consideration. Tandem screws have nothing to recommend them.

Mr. J. T. Milton read a paper on the present position of Diesel engines for marine purposes, and Prof. W. E. Dalby described some results of trials made on a small Diesel engine in which accurate indicator diagrams were obtained by means of a new form of optical indicator.

Mr. G. S. Baker gave an account of a number of model experiments made to determine the effect of shape of area curve on the resistance at any reasonable speed. This paper gives also a brief account of the work of the year at the William Froude tank. A large proportion of time has been spent on test work for various shipbuilding firms. The resistance of at least five large vessels has been reduced more than 10 per cent. by modifications to the form made at the tank, and several others have been improved in a less degree. The importance and value of these results can be seen from the fact that the saving in cost of coal per annum for a single one of the above five ships would be more than sufficient to support the experimental tank for the same period. The investigation of the resistance and tipping moments experienced by aero-hydroplane floats has been continued. Considerable improvement has been effected in the power required for their propulsion, the tipping moments due to the water forces are now known, and a float which is stable in character and of a low water resistance has been evolved. Ship models have been tested with four different kinds of surface, the paraffin wax being (*a*) bare, (*b*) freshly coated with shellac varnish, (*c*) the same, with blacklead rubbed into a coating of shellac when the latter was "tacky," and then allowed to harden, (*d*) coated with red lead paint. The spots from the four surfaces were indistinguishable, and show that, provided the surface is smooth and free from grit, the same result will be obtained.

Mr. H. Gray gave the results of experience with superheated steam, with special reference to economy and cost of upkeep, based on more than three years' working in engines of both triple- and quadruple-expansion types in the mercantile marine engaged in regular trade, voyage after voyage, to Australia *viâ* the Cape of Good Hope. The system adopted was the Schmidt. None of the steamers have been delayed either in port or on the voyage by reason of superheater defects, notwithstanding the fact that the runs are long—that of the *Port Augusta* being forty-five days without a call at any port. Lubrication of the cylinders and valve faces is of the utmost importance with superheated steam, and it is absolutely necessary to have a trustworthy system of filtration for the feed-water, so as to ensure the abstraction of the oil and to safeguard the boilers from the possibility of any traces of oil being introduced. The author states that the economy of triple-expansion engines of 2000 i.h.p. after being altered to use superheated steam, has been increased about 12 per cent., and of quadruple-expansion engines, about 17·8 per cent.

Mr. C. E. Stromeyer contributed a paper on the elasticity and endurance of steam pipes, and a note on the Foster strain meter, and some data obtained therewith were presented by Mr. W. R. Gerald Whiting.

Dr. K. Suyehiro, professor of naval architecture at Tokio Imperial University, described a new torsionmeter which he has devised. This instrument has some interesting features. The angle of twist of the shaft is measured by the relative rotation of two arms, one clamped to the shaft, and the other carried by a long tube clamped to the shaft at the end remote from the other arm. The first-mentioned arm carries a scale having half-millimetres along one edge and a reading scale along the other. The scale faces the shaft, and mounted on the same arm is a plane mirror, situated half-way between the shaft axis and the scale. Hence a virtual image of the scale will be seen every revolution, coinciding with the shaft axis, and therefore at rest. On the other arm is a concave mirror which forms an image of the reading edge of the scale, also on the shaft axis, and side by side with the first image. Both images are picked up by a reading telescope, and their relative displacement when the shaft is twisted may be read easily. The advantage of the instrument lies in the fact that the scale, as well as the optical parts, rotates with the shaft, and the reading telescope requires but little adjustment. Other types in which the scale does not rotate, require considerable adjustment in a place, viz., the shaft-tunnel, where adjustment is not easy to carry out.

Other papers read dealt with the stability of ships in damaged conditions, and the rolling of ships. Mr. H. E. Wimperis described his instrument for the measurement of velocity of roll, which depends for its action on a small electrically-driven gyrostat.

PAPERS ON INVERTEBRATES.

A REPORT on the Crustacea Schizopoda, collected by the Swedish Antarctic Expedition, 1901–3, has been published, in 4to form, by G. E. C. Gud, of Copenhagen. In his preface, the author, Mr. H. J. Hansen, states that this memoir, which is illustrated by six plates, should be regarded as a further contribution to his account of the Mysidacea and Euphausiacea (the two main groups of the Schizopoda) of the world. A considerable number of new species are named, and revised descriptions of others previously known to science given, but as these appeal only to specialists, they must be passed over without further mention.

Two Calyces of Scyphocrinus. From Proc. U.S. Nat. Mus.

Of more general interest is Mr. R. S. Bassler's description (Proc. U.S. Nat. Mus., vol xlvi., pp. 57–9) of a remarkably fine slab of fossil crinoids from the Middle Palæozoic strata of the Mississippi Valley, north of Cape Girardean, Missouri, which has recently been placed on exhibition in the American Museum. This slab, measuring 4 ft. by 7 ft., contains eighteen complete crowns of Scyphocrinus, two of which are shown in the accompanying illustration, together with a number of bulbs of the so-called Camarocrinus; the latter, as pointed out by Dr. Bather, really pertaining to the former. In some of the specimens the crown, or calyx, retains to some extent its original globular form, but in the majority it has been flattened by contact with the Camarocrinus bulbs. The strong, many-branched arms, are frequently a foot in length.

The first American representative of the umbrella-shaped sponges of the genus Cœloptychium is described by Messrs. Shimer and Powers in vol. xlvi., pp. 155–6, of the Proc. U.S. Nat. Mus., under the name of *C. jerseyense*. As the type specimen was obtained from the Upper Cretaceous of New Jersey, it is strictly contemporaneous, in the geological sense, with the European forms of the genus to which it is provisionally referred. The American species is characterised by the rounded, in place of flattened, margin of the umbel.

Hitherto the number of species of oligochætous annelids known from Jersey was only eleven, all belonging to the earthworm family (Lumbricidæ). A collection, including fresh-water forms, recently received from the island has, however, enabled the Rev. H. Friend, in an article published in *The Zoologist* for December, 1913, to raise the number of known species to fifty, of which three are described as new. Of the fifty species, the Enchytræidæ claim thirty-one, the Lumbricidæ seventeen, and the Lumbriculidæ and Megascolecidæ one each.

R. L.

METEOROLOGICAL REPORTS.

THE report of the Meteorological Service of Canada for the year 1909 (pp. xxi+567 and plates), has been published recently. The large mass of data furnished by this extensive system is arranged in tables giving (1) monthly and annual summaries; (2) bi-hourly and hourly temperature and barometric pressure; (3) mean and extreme temperature, daily range, rainfall, etc.; (4) daily observations from selected stations; and (5) magnetic results at Agincourt Observatory. Some of the results of observations at the Central Observatory at Toronto were quoted in Nature of September 7, 1911. The report includes a brief monthly summary of the weather over the whole Dominion, and tables showing the number of weather forecasts and percentage of fulfilment in each district and month. The general percentage of fulfilment amounted to 86·8, after making due allowance for forecasts only partly verified.

The annual reports of the Philippine Weather Bureau for 1910 (parts 1 and 2), containing hourly meteorological observations at Manila, and for 1909 (part 3), containing observations at secondary stations have recently been published. Father Algué states in the preface to part 1:—"Were it not for a few exceptions, the history of the Weather Bureau for the fiscal year 1910 might have been condensed into the three words, 'Everything as usual.'" This statement practically holds good with regard to all the parts; the most interesting details relating to typhoons, storm-warnings, earthquakes, etc., are contained in the Monthly Bulletins, to which we have frequently referred. The number of earthquakes felt in the Philippines during the fiscal year 1910 amounted to 121, exclusive of many microcosmic movements. The most important far-distant earthquakes recorded were those in Mexico, Baluchistan, and Greenland. A new magnetic observatory has been established at Antipolo, about eleven miles east of Manila, owing to the disturbance caused by the electric railroad at the latter place.

The Central Meteorological and Geophysical Institute of Chile has issued a volume containing hourly observations and means for Santiago for the year 1911, including all the principal meteorological elements, prepared under the direction of Dr. W. Knoche. This is the first time that such values have been published *in extenso* in Chile, and it is intended to continue them regularly for Santiago in future. There are several other stations in Chile, where hourly observations are available; the publication of some of these, or at least summaries from them, would be very valuable, but the large amount of work entailed thereby is said to be more than the limited staff is able at present to cope with.

The nineteenth annual report of "Meteorology in Mysore" for 1911 contains, as usual, daily and monthly results of observations for Bangalore and Mysore, and 8h. a.m. observations, with monthly means for Hassan and Chitaldrug. Synopses of the monthly and yearly results made at those observatories are carefully arranged as before, for the purpose of comparison, by Mr. Iyengar, in charge of the Mysore meteorological department. A useful table giving the means for the nineteen years 1893–1911 shows that the absolute maxima of temperature ranged from 100·2° at Hassan (3149 ft.) to 103·0° at Chitaldrug (2405 ft.). The minima at the same stations were 42·7° and 51·2° respectively. Yearly rainfall ranged from 25·0 in. (ninety-one days) at Chitaldrug, to 35·8 in. (121 days) at Hassan. The mean relative humidity was about 60 per cent. at all stations; excessively low readings were observed occasionally.

The Royal Magnetical and Meteorological Observatory of Batavia has published the results of rainfall observations in the Netherlands' East Indies for 1911 (part ii. of the thirty-third yearly series). The volume contains the monthly and yearly amounts at a large number of stations, the number of rain-days, greatest amounts in twenty-four hours, averages for the period 1879–1911, departures from those values in 1911, and other useful details. These data, in addition to their general scientific value, are of great importance locally, and it has been pointed out elsewhere by Dr. Van Bemmelen that rainfall is the ruling factor which determines the weather in the archipelago, because the remaining meteorological elements are almost constant. In Java the yearly amounts for 1911 varied from 23 in. at Sitoebondo (long. 114° E.) to 177 in. at Pelantoengan (long. 110° E.), and even more in the outside possessions. The greatest rainfall in one day was 10·2 in. at Padang (Sumatra) in November. The fullest information is given respecting the stations, but this volume contains no general discussion of the results.

IMPROVEMENTS IN LONG-DISTANCE TELEPHONY.

THE subject of improvements in telephony is one in which the general public is very closely interested, and a large audience, including many experts, therefore followed with attention the expositions given by Dr. J. A. Fleming, F.R.S., at the Royal Institution on March 27, in which he described the inventions that of late years have enabled a great increase in the practicable distance of telephonic communication to be made, and also rendered possible the use of submarine telephone cables over distances not hitherto attainable. In his opening remarks, Dr. Fleming gave first a brief description of the construction of the modern telephone transmitter and receiver, and of the transformations and sources of loss of energy in transmitting electrically articulate speech between two places. He stated that he would confine attention chiefly to the action of the line of cable, neglecting the imperfections of the transmitter and receiver *per se* owing to limitations of time.

An experiment was first shown with an instrument which projected upon the screen in the form of a line of light, the motion of the diaphragm of a telephone, when sounds musical or articulate where made near it The sound of an open organ pipe was thus seen to produce a smooth wavy or simple harmonic curve, whilst the less pure sound of a harmonium reed or of the voice uttering a vowel sound produced a complex curve, and a spoken sentence an irregular wave line.

The use of the oscillograph in recording photographically or visually the wave form of the electric current sent into a telephone was next explained, and photographs of various vowel and syllabic sounds shown.

A few words of explanation were then given concerning Fourier's theorem in virtue of which any irregular but single valued curve can be resolved into the sum of a number of simple harmonic curves of various amplitudes and phase differences having frequencies in the ratio of 1, 2, 3, etc.

It was then explained that the action of the transmitter on the line was equivalent to the imposition of a complex electromotive force which in virtue of Fourier's theorem could be regarded as the sum of a large number of simple harmonic electromotive forces of various amplitudes, wave-lengths, and phase differences.

Every telephonic cable has four primary qualities, two conservative, viz., its inductance and capacity, in consequence of which it can store up kinetic and potential energy in the form of a magnetic or electrostatic field. Also it has two dissipative qualities, viz., its conductor resistance and dielectric leakance, which convert a part of the energy given to it into heat. Hence an electromotive impulse given to the cable at one end is propagated along it as a wave. The current in the cable at each point is oscillatory, but the current is not, so to speak, at high tide simultaneously at all points in the cable, but successively, the maximum value travelling along the cable with a certain speed. The mode of propagation of a wave along a string or wire was illustrated by various wave models.

In the case of a wire or string of finite length the wave is reflected at the far end, and if the time taken by the wave to travel to and fro is equal to some exact multiple of the periodic time of the impulses, stationary waves are produced on the cord or wire. These effects, together with a demonstration of the laws of string vibration, were proved by the aid of Dr. Fleming's vibrating string apparatus in which a light cotton cord has one end fixed to a slide rest and the other end twirled uniformly with an irrotational motion by an electric motor.

The production of stationary electric waves on wires was also beautifully shown by the use of a long wire coiled into a helix on an ebonite rod. One end of this helix was connected to the earth and the other to a high-frequency oscillator. On adjusting the frequency of the oscillator, stationary electric waves of wave-length equal to some exact multiple or fraction of the length of the helix were produced and shown to exist by the brilliant glow of a neon vacuum tube held near the ventral segments and its non-glow when held near the nodes.

Dr. Fleming then explained that in the case of a telephone wire the velocity with which the waves travel along it is greater the shorter the wave-length, and also that in virtue of the resistance and dielectric leakance, these waves attenuate in amplitude at a rate which is greater for short waves than for long ones. In the case of the helix operated on by high-frequency currents the wave velocity is the same for waves of all wave-lengths, and is inversely as the square root of the product of the capacity and inductance per unit of length. Hence when a complex electromotive force, the result of speaking to a telephone transmitter, is applied to the end of a cable the various simple harmonic waves into which they may be resolved travel along the cable with unequal speed and attenuation. The shorter waves travel fastest, but are worn out soonest. Hence the wave form is distorted by the disappearance of the higher harmonics and the resulting sound is enfeebled by the attenuation.

Dr. Fleming proved these statements by a new and interesting experiment. A complex electromotive force comprising a fundamental wave having a frequency of about one hundred, and including higher harmonics of greater frequency was applied to one end of an artificial cable built on Dr. Muirhead's plan, representing a submarine cable fifty miles in length. By means of a Duddell oscillograph the wave form of this electric oscillation was projected on the screen. A second wire on the oscillograph was then employed to examine the current in the cable at various distances, ten, twenty, thirty, etc., miles from the sending end, and to project on the screen a second curve representing the wave-form at various distances along the cable. It was seen that as the distance increases the wave form is reduced in height and smoothed out so as to show that the higher harmonics are gradually extinguished. In the case of a telephone cable this would mean that the received sound is not only fainter but altered in quality so that the syllable or word is no longer recognisable.

Photographs were then shown, taken by Mr. Cohen at the General Post Office Research Laboratory, showing the distortion of various articulate sounds as transmitted through certain cables. A remedy for this distortion was first suggested by Mr. Oliver Heaviside, who proved mathematically more than twenty-five years ago that if the four constants of the cable were so related that the quotient of the inductance by the resistance was equal to the quotient of the capacity by the leakance, then waves of all wave-lengths would travel at the same speed and attenuate at the same rate.

In all ordinary cables the first-named quotient is much smaller than the second. Hence to remove distortion we may either increase inductance or leakance. Heaviside suggested increasing the former, and Prof. Silvanus Thompson in 1891 suggested increasing the latter by providing the cable with inductive leaks. Practical telephone engineers preferred, however, to decrease the resistance of the cable by increasing the copper section so far as possible. There is, however, a limit to this from the point of view of cost. Also the invention of paper-insulated cables for telephony assisted matters by reducing the capacity of the cable. Nevertheless a very important advance was made by Prof. Pupin, of Columbia College, New York, in 1899 and 1900, when he proved that Heaviside's suggestion could be put into practical form by loading the cable with coils of wire wound on iron wire cores inserted at equal intervals, but so close that at least eight or nine coils are included in the distance of one wave-length of the average wave frequency which is always taken at 800. If the coils are placed farther apart relatively to the wave-length they do more harm than good. Dr. Fleming illustrated this by a very pretty experiment of his own consisting of a string loaded at intervals with beads, one end of the string being fixed and the other twirled round by a motor so as to produce on it stationary waves. When the half wave-length was adjusted to be nearly equal to the distance between the beads, the cord refused to transmit the oscillations.

It was also illustrated by the production of stationary electric waves on a series of helices of wire having loading coils, or coils of high inductance introduced at intervals.

An experiment was also shown with an artificial cable representing forty miles of standard cable into sections of which loading coils could be introduced or cut out as required. It was shown that when the cable was loaded the current flowing out of it at the receiving end was greatly increased when constant electromotive force was applied at the sending end.

It is found then that loading telephone wires by suitable coils of high inductance placed at proper intervals of a mile up to ten or twelve miles according to the cable, greatly reduces the attenuation of the waves, although it is difficult to add sufficient inductance to cure distortion completely.

Dr. Fleming gave a mechanical illustration of this effect. He said, suppose two similar ships were to be launched together side by side down ways of equal inclination and allowed to glide out into the sea as far as they would go until brought to rest by friction of the water. If then one of the ships was loaded with ballast so as to make it much heavier than the other, then, although entering the water with the same speed, the heavily loaded ship would glide out further than the other because it would possess a greater store of kinetic energy. So it is, he explained, with the electric waves on wire. By adding inductance to the circuit the wave energy is increased, and the waves attentuate less for a given distance of travel.

This proposal of Pupin has proved to be a very practical solution of the problem of reducing the attenuation of telephonic waves. Both aerial lines, underground cables, and submarine cables can be "loaded" or "Pupinised" by inserting appropriately made inductance coils at equal distances, and the result is to reduce the attenuation to half or less than a half of that of the unloaded cable, and therefore to reduce the enfeeblement of the sound.

In the case of aerial lines there is no difficulty in inserting these loading coils in the run of the cable. The coils are contained in iron boxes attached to the telegraph posts at intervals of six to twelve miles. The coils themselves consist of an iron wire core wound over with wire, and have generally an inductance of about 0·2 henry, and a resistance of 6 or 8 ohms. In the case of underground cables the loading coils are placed in pits at intervals of two or three miles. Such underground cables consist now of paper-insulated double metallic circuits; a large number of such circuits being included in one water-tight lead sheath. The problem of loading a submarine cable was more difficult to solve because the insertion of heavy iron-cased coils was out of the question. The cable had to be loaded in such manner as not to thicken it up inordinately at any point, and to permit of its being laid in the usual manner and lifted again if necessary for repairs. This particular problem was solved by Messrs. Siemens Bros. by the invention of a particular form of cylindrical loading coil which could be inserted in the run of a cable of the usual double-circuit type at distances of one nautical mile or so. When once it had been shown that such loading was effectual, telephonic engineers in all countries began to adopt it. In the United States the American Telephone and Telegraph Company has equipped with loading-coils lines up to 2000 miles in length. The longest aerial loaded line is that from New York to Denver. It is composed of No. 8 hard-drawn copper wires, the circuits being twisted to avoid cross talk and loaded every eight miles with coils having an inductance of 0·265 henry (see Table I.).

The attenuation constant of the line is thus reduced to less than half of that of the unloaded line, and good speech is possible from New York to Denver. It is the ambition of Mr. Vail, the president, and Mr. Carty, the able engineer of the above company, to complete a loaded line such that speech will be possible from New York to San Francisco, a distance of more than 3000 miles. Another long loaded aerial line just completed is that from Berlin to Rome. This line, with the exception of a short piece of cable through the Simplon Tunnel, is an overhead line of phosphor-bronze, 4·5 mm. in diameter. It is loaded every ten kilometres with loading coils having an inductance of 0·2 henry. It runs from Rome to Milan, thence to Iselle, then through the Simplon Tunnel to Brieg, then to Bâle and Frankfurt, and so to Berlin.

TABLE I.

Loaded Aerial Land Lines.

All values are per mile or per kilometre at 800 frequency.

Line	New York and Denver	Berlin and Rome	Berlin and Frankfurt	London (St. Albans) and Leeds Trunks No. 6	London (St. Albans) and Leeds Trunks No. 7
Length ...	2000 miles	2082 kms.	584 kms.	189 miles	189 miles

Total Attenuation	2·6	2·2	1·12	0·55	0·72
Conductor ...	Copper	Phosphor Bronze	Bronze	Copper	
Weight or Size	435 lb. to mile	4·5 mm. diameter	2·5 mm. diameter	300 lb. to mile	

Dr. Bresig and Dr. di Pirro, who have had the charge of the scientific work in connection with it, find the actual attenuation is closely in accordance with the predicted value, and good speech is possible over the whole distance.

In our own country the longest loaded lines are two trunk lines running from London to Leeds, 200 miles, which are loaded every eight and twelve miles.

The engineer-in-chief, Mr. Slingo, states that the General Post Office has now in operation 30,000 miles of aerial and underground loaded circuits, using 12,448 loading coils; also 45,645 miles more are in course of being loaded, so that before long the G.P.O. will have 75,000 miles of circuits loaded with 30,000 coils. In the United States up to 1912 there were 103,000 miles of loaded circuits in all.

In England one of the longest loaded underground lines is that from Hull to Newcastle *viâ* Leeds, 154 miles in length, which is loaded every 2·5 miles. The Post Office has now under construction an underground loaded line from London to Liverpool *viâ* Birmingham, which will contain fifty circuits, and render communication independent of storms. In the United States a long underground line has been constructed from Boston to Washington, 475 miles, passing through New York, Philadelphia, and Baltimore. A loaded line underground from Berlin to Cologne is in contemplation.

Turning then to submarine cables, we find that at present the General Post Office has three such loaded cables, one from England to France, laid in 1910, one from England to Belgium, laid in 1911, and one from England to Ireland, laid in 1913 (see Table II.). An Anglo-Dutch cable of the same type is being manufactured to be laid between a point in Suffolk and the nearest point on the coast of Holland, a distance of 125 miles.

TABLE II.

Loaded Submarine Telephone Cables.

All values are per nautical mile of loop at 800 frequency.

Cable	Anglo-French Coil loaded 1910	Anglo-Belgian Coil loaded (1911) Side Circuit	Anglo-Belgian Phantom Circuit	Anglo-Irish Coil loaded (1913)
Length in nauts	21	48	48	64
Coil Spacing in nauts	1	1	1	1
Coil Resistance in ohms. ...	6·6	11·5	4·6	6·8
Total Resistance in ohms. ...	20·9	25·7	11·7	21·0
Capacity in mfds.	0·138	0·162	0·314	0·166
Inductance in henrys	0·1	0·1	0·05	0·1
Ratio S/C	120	12	12	12
Attenuation Constant	0·017	0·018	0·0173	0·015
Total Attenuation	0·36	0·86	0·83	0·96
Conductor weight per naut ...	160 lb.	160 b	320 lb.	160 lb.

The Anglo-French uniformly loaded cable has an effective resistance of 8·54 ohms at 1000 frequency, a wire-to-wire capacity of 0·176 mfd., an inductance of 0·0135 henry, and an attenuation constant 0·0185. The total attenuation is 0·39,, the value of S/C is 109, and the conductor weighs 300 lb. to the nautical mile.

These cables were all constructed by Messrs. Siemens Brothers with the cylindrical coils above-mentioned. The Anglo-French and Anglo-Belgian were laid under the direction of Major W. A. J. O'Meara, C.M.G., when engineer-in-chief of the General Post Office, and the Anglo-Irish cable under Mr. W. Slingo, now holding the same position. The French Government also laid from France to England a uniformly loaded cable made by the Telegraph Construction and Maintenance Company, which has a copper core of twice the weight of the Anglo-French cable, and is loaded by being uniformly wound over with one layer of soft iron wire. Each of these cables contains two pairs of wires which can be used as two independent circuits, and also by using each pair conjointly, as a lead and return, can be used to make a third or phantom circuit. These cross-Channel loaded cables have enabled telephonic speech to be transmitted from London to Geneva, London to Berlin, and to cities in the south of France.

Broadly speaking, we can say that by loading cables and lines it has been possible to double or more than double the distance of effective telephonic intercourse, and to speak for 2000 miles overland, 500 underground, and up to 100 miles or more under sea.

It is possible that submarine communication in this manner may be increased to 150 or even 200 miles, and overland to 3000 miles.

Turning then to the question of the abolition of the line by so-called wireless telephony, Dr. Fleming gave a brief description of the apparatus used. The arrangements are closely similar to those employed in wireless telegraphy. At the transmitting station there must be an antenna in which continuous oscillations are set up by a Marconi disc generator, a Goldschmidt alternator, or some form of arc generator, such as that of Poulsen or Moretti.

In the base of the antenna, or coupled to it, must be placed a microphone by means of which the speaker's voice makes changes in resistance of the antenna circuit. The continuous electric waves radiated must have a wave-length of not much greater than five or at most ten miles. If a spark system of wave generation is employed, the spark frequency must not be less than about 20,000 a second.

When the microphone is spoken to, the result is to vary the amplitude of the waves emitted without altering their wave-length. It produces waves on waves. At the receiving end the arrangements are similar to those used in wireless telegraphy with a telephonic and crystal or valve receiver. In this case, however, the receiver hears the words spoken to the distant microphone and not merely dot and dash Morse signals.

Using a very ingenious liquid microphone, Prof. Vanni, of Rome, has transmitted speech for 1000 kilometres. In the United States, Fessenden has similarly telephoned a few hundred miles, and Poulsen in Denmark, Colin and Jeance in France, Goldschmidt in Germany, and Ditcham in England have covered greater or less distances. Mr. Marconi also has recently devised appliances for wireless telephony with which he has conducted demonstrations for the Italian Navy lately. All are agreed that the quality of the transmitted speech is good. Since electric waves through the æther all travel with the same velocity, no matter what the wave-length, and attenuate at the same rate, there is no distortion of the wave form. The only difficulty that hinders even greater achievement is that of obtaining a microphone which will carry larger high-frequency currents.

These then are a few of the achievements which have been lately made in covering greater distances in telephonic communication.

We are yet a long way from telephony across the Atlantic, whether with cables or by wireless, but progress will continue to be made, and it is possible that one day speech transmission from England to San Francisco with one repetition at New York may be an accomplished fact.

In the thirty-eight years which have elapsed since Bell and Edison and Hughes gave us the means of commercial telephony much has been done, but there is still a wide field open for invention in improving a means of communication now so essential to our modern life.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Sheffield.—Mr. Wilfred Jevons has been appointed to the post of junior lecturer and demonstrator in physics, and Mr. A. E. Barnes to the post of lecturer in materia medica, pharmacology, and therapeutics.

Prof. Bergson will begin his Gifford Lectures in Edinburgh on Tuesday, April 21. The subject will be "The Human Personality."

It is announced that Lord Elgin has consented to be nominated for the Chancellorship of Aberdeen University in succession to the late Lord Strathcona.

We learn from *Science* that Prof. Frederick Slocum, who for the past four years has been in charge of the solar observations and stellar parallax work at the Yerkes Observatory, has been elected professor of astronomy at Wesleyan University, Middletown, Connecticut, and will assume his new duties next autumn. A new observatory will be erected immediately as a memorial to the late Prof. Van Vleck, for many years in charge of that department at Wesleyan.

Museums are every day being used more generally in teaching, and a committee to deal with the subject was appointed at the Birmingham meeting of the British Association. The Children's Museum arranged by the secretary of the Selborne Society at the Children's Welfare Exhibition, which opens at Olympia on Saturday, is therefore of interest. The points to be emphasised are, preparation of exhibits especially for young people, introduction of a living side, the use of microscopes, the need especially of changing the specimens at frequent intervals, and the advisability of not having too many things displayed at one time.

The work of the schoolmaster is described in a new light by Mr. E. Boyd Barrett in an article in the current issue of the *British Review*. Early in his essay, to which he gives the title, "How to Complete One's Education," Mr. Barrett lays it down that teaching is worthy of the best minds, and is calculated to repay amply the best minds. He goes on to show that in all the practical effects of school education—character training, intellect training, and the acquisition of knowledge—the schoolmaster benefits more from the teaching he receives from the boys than they do from his. He comes to the conclusion that it would be impossible to devise any educational system of such a nature that the pupil alone would be benefited. To complete his education, every man should devote a few years to teaching; university education, however well it prepares for cultured leisure, does not prepare a man to share his possessions with others—it is too egotistic.

The Yorkshire Summer School of Geography will be held at Whitby on August 3–22. The school was instituted last year by the Universities of Leeds and Sheffield, in cooperation with Armstrong College, Newcastle-on-Tyne, and with the help of the Education Committees of the County Councils of the East, North, and West Ridings, and of certain county boroughs in Yorkshire. Its object is to provide instruction in the methods of geography and to furnish opportunities for the discussion of problems connected with teaching it. The course will consist of lectures and laboratory and field work. There will be excursions in connection with the field work. All the apparatus used will be simple and inexpensive, and methods applicable to school work will be adopted. The special subject this year will be the British Isles, which will be treated as a whole in a general course and in two alternative courses at the choice of each candidate: (i) on the agriculture, rocks and soils, and (ii) on the oceanography, rivers and river development, and the evolution of transport and communication. Prof. Kendall, professor of geology in the University of Leeds, will be the director of the school.

The annual report of the Department of Agriculture of the Union of South Africa for the period 1912–13 has just been issued by the secretary, Mr. F. B. Smith, and is a very interesting document. Necessary as agricultural education and research have proved in other countries, there is probably no part of the world where they are more needed than in South Africa. Agricultural problems are very complex; probably more numerous and virulent diseases of live stock and crops exist there than anywhere else in the world; and, owing to the recent occupation of the greater part of the country and the methods of farming pursued, it is more difficult for young men to acquire a knowledge of up-to-date practical agriculture. A number of institutions have been started, and the object of the department has been to place them on an equality as regards educational and experimental facilities, and at the same time to allow them to specialise in the branches of farming for which they are particularly adapted by virtue of their situation. For instance, Elsenburg, in the Cape Province, is particularly devoted to horticulture, viticulture, and Turkish tobacco; Grootfontein, near Middelburg, also in the Cape Province, to Karoo farming, ostriches, and sheep; Potchefstroom, in the Transvaal, to mealie growing, general agriculture, and cattle; Glen, near Bloomfontein, in the Orange Free State, to live stock and dry-land farming; Cedara, in Natal, to general farming and wattle growing. Provision is made at each institution for the regular in-college courses of instruction, for short courses, extension work, and also for experiments and research and the analysis of soils, manures, and other agricultural commodities. Additional buildings are being erected to meet the needs of the institutions, and their equipment generally is being improved, while the staffs are being strengthened.

SOCIETIES AND ACADEMIES.

Geological Society, March 25.—Dr. A. Smith Woodward, president, in the chair.—Prof. J. W. **Judd**: The geology of Rockall. Rockall is a small isolated rock in mid-Atlantic, lying 184 miles west of St. Kilda, and, except in the calmest weather, is inaccessible. The rock rises from a bank (the "Rockall Bank") upon which there are dangerous reefs. In 1810 Basil Hall, obtained a fragment from this rock, which later found its way into the collection of the Geological Society. More than thirty years afterwards, the specimen was recognised; it was then mislaid for another thirty years, and in 1895 was brought to the author by the late Prof. T. Rupert Jones. He not only studied all the literature connected with Rockall, but was able to trace two other specimens of the rock, the loan of which he obtained and brought to me. They had been procured in 1868 during the survey of the North Atlantic. The microscopic study of these specimens shows that in Rockall there exist rocks of interest, not represented in our islands, but which have analogues in the Christiania district of Norway. These rocks consist essentially of three minerals—quartz, the felspar albite, and the rare soda-pyroxene ægirite, with its dimorphous form acmite. Dredging operations have yielded specimens from the Rockall Bank. The abundance of basalt-fragments among the dredgings suggests the possibility of Rockall belonging to the same petrographical province as St. Kilda, Iceland, the Inner Hebrides, and the north of Ireland. The existence of borolanite and other alkaline rocks in the northern Highlands suggests the possibility of Rockall being the western extension of a much older province. Some months ago Prof. Iddings and Dr. Washington represented to the author the desirability of a detailed analysis of this rock. One of the two fragments available was sent to America, and the following paper gives the result of its study by Dr. Washington.—Dr. Henry S. **Washington**: The composition of Rockallite. A petrographical account is given, with reference to the influence of the constituent minerals upon the bulk-analysis. Rockallite has a fine-grained granitic structure, and is composed of about equal amounts of colourless quartz, alkaline felspar, and soda-pyroxene. The pyroxene is of two kinds: a bright grass-green ægirite and a pale yellowish-brown acmite. Some zircon is present. A chemical analysis has been made, zirconia and the rare earths being especially looked for. Several new points of interest have presented themselves. The outstanding features appear to be the high percentages of silica, ferric oxide, and soda, and the low percentages of alumina, ferrous oxide, magnesia, lime, and potash. The interest of the new analysis, however, lies in the detection of zirconia and cerium oxide in large amounts: the percentage of cerium oxide being larger than that from any known igneous rock, with the exception of the nepheline-syenite from Almunge in Sweden. The norm has been calculated from the old and the new analyses, and the author finds that the rock falls into the subrang rockallose with the general symbol III. 3. 1. 5. These analyses are the only representatives of the subrang rockallose among the 8000 analyses of igneous rocks that the author has now collected. It is proved that the zirconia and cerium oxide enter into the composition of the pyroxenes.

Cambridge.

Philosophical Society, February 23.—Sir J. J. Thomson in the chair.—Dr. **Searle**: (1) Determination of the effective aperture of the stop of a photographic lens; (2) experiments with a prism of small angle.—A. E. **Oxley**: (1) The molecular field in diamagnetic substances (preliminary note); (2) the internal molecular field, which has been shown by the author to exist in diamagnetic substances, is applied to account for the abnormally high values of the specific heat of such substances in the neighbourhood of the fusion point.—Major P. A. **Macmahon**: The superior and inferior indices of permutations.—N. **Wiener**: A simplification of the logic of relations.—R. **Hargreaves**: The domains of steady motion for a liquid ellipsoid, and the oscillations of the Jacobian figure.—J. E. **Purvis** and E. H. **Black**: The oxygen content of the river Cam before and after receiving the Cambridge sewage effluent.

March 9.—Dr. Shipley, president, in the chair.—Prof. **Wood** and G. Udny **Yule**: A statistical study of feeding trials with oxen and sheep. The authors have studied statistically the results of 400 feeding trials with oxen and sheep collected and tabulated by Ingle in the Journal of the Highland and Agricultural Society, 1909–10. They find that as the amount of food is increased above that required for maintenance the successive increases in live weight become smaller until a limiting value is reached.—G. Udny **Yule**: Fluctuations of sampling in Mendelian ratios. The author compares the fluctuations observed, *e.g.* in the proportion of recessives in F_2, in the seeds borne by individual plants, or in individual litters, with the fluctuations to be expected on the theory of random sampling. For the most part the agreement, in the examples taken, is good and in some cases striking.—M. S. **Pease**: Inheritance in Brassicæ.—G. Udny **Yule** and F. L. **Engledow**: The determination of the best value of the coupling ratio from a given set of data.—F. L. **Engledow**: A case of repulsion in wheat. The characters concerned are "roughness" and "blackness" of the chaff. In a cross between "smooth black" and "rough white" the numbers in the second generation indicate a repulsion on the 1 : 3 : 3 : 1 basis.—T. **Rigg**: Soil and crop relations in the Biggleswade market garden area. The author has conducted a soil and crop survey of this district. The soils have been classified and the extent of each soil formation has been determined. Maps were shown illustrating the relationship of the soil formations to the geological formations.—H. A. D. **Neville**: Digestibility of pentosans. Rats were fed on a basal diet, to which was afterwards added a quantity of some pentosan substance, such as (*a*) gum, (*b*) a vegetable mucilage, or (*c*) the pentosan constituent of a cereal straw. The pentosans of (*c*) almost entirely disappeared in the animal, those of (*b*) were almost wholly rejected, while those of (*a*) occupied an intermediate position. The results support the idea that the diverse opinions held on the food value of the pentosans have arisen by reason of the analytical method used yielding furfuraldehyde from differently constituted substances or from substances containing pentose sugar molecules differently united in the parent substance.—W. H. **Parker**: A case of correlation in wheat. A high correlation was found to exist between the total rachis length and the average internode length in ears of wheat. Should the correlation be found to be as high in the case of all varieties of wheat, it seems possible that the relation between these two characters will be found to be the best criterion for classifying wheats according to the density of their ears, as this relation, in this case at least, is much more constant within a variety, than the average internode length.—H. C. **Pocklington**: The factorisation of large numbers.—Dr. **Horton**: The ionisation produced by certain substances when heated on a Nernst filament. Experiments have been made to test (*a*) the negative emission from lime, (*b*) the positive emission from sodium phosphate, when heated upon a Nernst filament, with a view to ascertain whether the effects observed when these substances are heated upon platinum are due, as has been suggested, to contact with the metal. It has been found that this is not the case; an enormous negative discharge can be obtained from lime heated on a Nernst filament, even in a very high vacuum, and sodium phosphate considerably increases the positive discharge, but for the latter test the filament must not be allowed to glow brightly or the salt sublimes away.

Paris.

Academy of Sciences, March 30.—M. P. Appell in the chair.—G. **Lippmann**: A direct photographic method for the determination of differences of longitude. Photographs of the zenith are taken simultaneously at two stations by means of an optical device, and the difference of longitude determined by the position of the zeniths in the star groups. The method is simple, rapid, and accurate.—Armand **Gautier**: The minervites. Analyses of minervites (complex hydrated aluminium phosphates) from different places and a discussion of their constitution.—H. **Parenty**: The freezing of wine, milk, and other alimentary liquids.—Emile **Yung** was elected a correspondant for the section of anatomy and zoology in the place of E. Metchnikoff, elected foreign associate.—J. **Clairin**: Some Bäcklund transformations.—Jules **Drach**: Differential equations of the first order and first degree.—George **Rémoundos**: The series of multiform functions in a domain.—A. **Korn**: The problem of pulsating spheres and the theory of gravitation.—Edouard **Canneval**: A new arrangement of mirrors for lighthouses and other light projectors.—P. **Vaillant**: Tate's law and the variation of the size of the drops with the speed of fall. The weight of a drop from a given tube varies with the number of drops a minute, and there is a discontinuity in the law of variation.—L. **Décombe**: The heat of Joule considered as the heat of Siemens.—Albert **Perrier** and H. Kamerlingh **Onnes**: The magnetisation of liquid mixtures of oxygen and nitrogen and the influence of the mutual distances of the molecules of paramagnetism. The coefficient of specific magnetisation of liquid oxygen increases as the concentration diminishes; the additive law fails for mixtures of liquid oxygen and nitrogen.—Maurice de **Broglie** and F. A. **Lindemann**: A new method for rapidly obtaining spectra of the Röntgen rays.—V. **Auger**: The basic carbonates of copper.—E. **Rengade** and N. **Costeanu**: The heats of formation and some other properties of the alkaline sulphides. The sulphides of the alkali metals can be obtained in the pure state by the action of sulphur vapour upon the metals in a vacuum, separating the excess of metal by distillation. The sulphides of sodium, potassium, and rubidium have been studied in the present paper.—Mlle. H. **Cavaignac**: The precipitation of alumina in presence of fluorides. Aluminium cannot be completely separated from its solutions by the addition of ammonia in the presence of fluorides, and this is very marked at the boiling point.—MM. **Cousin** and **Volmar**: The salicylic nitriles. Of two substances which have been described as nitriles of salicylic acid, one is shown to be disalicylamide and the other trioxytriphenyltriazine. The true nitrile is obtained from salicylaldoxime.—Michel **Longchambon**: The primitive structure of the Pyrenean dolomites.—Edmond **Rosé**: Study of the gaseous exchanges and the variation in the sugars and glucosides in the course of the formation of the anthocyanic pigments in the flowers of *Coboea scandens*. The anthocyanic pigment is not formed at the expense of pre-existing glucosides.—Raoul **Bayeux** and Paul **Chevallier**: Comparative estimations of oxygen and carbon dioxide in arterial and venous blood at Paris, Chamonix, and on Mont Blanc. High altitude determines a variation in the amounts of oxygen and carbon dioxide in the blood, the increase in the carbon dioxide being greater than with the oxygen. Mountain sickness does not appear to cause notable modifications in the amount of carbon dioxide, but this state is accompanied by a marked diminution in the oxygen of the venous blood.—J. **Bergonié**: The variation in the energy expenditure of man during the nycthemeral cycle.—Edm. **Sergent**, H. **Foley**, and Ch. **Vialatte**: The transmission to man and to the ape of exanthematic typhus.—Marcel **Belin**: The action of oxidising substances upon toxins *in vivo*.—Adrien **Lucet**: Researches on the evolution of *Hypoderma bovis*, and the means of destroying it. The injection of tincture of iodine is suggested as a treatment. The larvæ are killed and resorption effected without ill-effects on the animal.—E. **Solland**: Researches on the ontogeny of the Caridea. Relation between the mass of the nutritive vitellus of the egg and the order of appearance of the abdominal appendages.—M. **Warcollier**: Contribution to the study of a disease of cider called "verdissement."—A. **Fernbach** and M. **Schoen**: Some products of the decomposition of dextrose in an alkaline medium. Acetic acid is one product of this decomposition, and there is evidence that pyruvic aldehyde is also formed.—Ch. **Dhéré** and A. **Burdel**: The crystallisation of an oxyhæmocyanine from an arthropod.

"THE GOLDEN BOUGH" COMPLETED.

The Golden Bough. Third Edition. Part vii., "Balder the Beautiful." By Prof. J. G. Frazer. Vol. i. Pp. xx+346. Vol. ii. Pp. xi+389. (London: Macmillan and Co., Ltd., 1913.) Price 20*s*. net.

THE concluding instalment of Prof. Frazer's famous book may be regarded as demonstrating in a vivid manner and at an appropriate juncture the qualities both of itself and of its author. As has been the case with the other editions, this, which, it seems, is final and definitive, contains more than one change of view. It is characteristic of the author's mind that it is receptive of fresh ideas, and grows, instead of hardening into dogmatic attitudes. Prof. Frazer now, for instance, regards the Aryan god, Zeus-Jupiter, as being primarily a god of the sky, as the orthodox view has it, and only secondarily a personification of the oak. The interesting fact, amply proved by statistics, that the oak is more frequently struck by lightning than any other tree is the chief mediating influence between two sets of data. In a similar connection the revised account of the lore of the mistletoe shows cause for supposing that the parasite was believed to be the embodied result of the lightning-flash, "a sort of smouldering thunderbolt," containing within itself the seed of celestial fire.

But it is with a point of extreme importance for history and modern sociology that the most significant change of view is concerned. Prof. Frazer had accepted the explanation of the fire-festivals of Europe, which W. Mannhardt had suggested—namely, that they were in original intention charms to expedite the course and ensure the life-giving operations of the sun. But Dr. Westermarck's researches among the Moors have convinced the author that the fire-festivals are in intention purificatory. This is no mere academic or curious conclusion, as by necessity much of the substance of "The Golden Bough" must be. For "the grand evil which the festivals aimed at combating was witchcraft, and . . . they were conceived to attain their end by actually burning the witches, whether visible or invisible, in the flames." "The wide prevalence and the immense popularity of the fire-festivals provides us with a measure for estimating the extent of the hold which the belief in witchcraft had on the European mind before the rise of Christianity or rather of rationalism; for Christianity, both Catholic and Protestant, accepted the old belief, and enforced it in the old way by the faggot and the stake. It was not until human reason at last awoke after the long slumber of the Middle Ages that this dreadful obsession gradually passed away like a dark cloud from the intellectual horizon of Europe." Here we have the defect of the author's quality, though we gratefully note how well the new theory fits in with modern history, and brings, as few other episodes do, "The Golden Bough" into touch with living humanity. For the fact is that witch-burning and heretic-burning (they are essentially the same thing, as Westermarck has shown) did not become a form of social emotionalism until after the Middle Ages. Nor is the belief in witchcraft dead yet, anywhere in Europe; while its more cultured form, resentment against social abnormality, is one of the strongest forces in modern life.

It is a pleasure to see that Prof. Frazer, as he lays down his pen, promises us yet other works. No man in history has done more for the reasonable soul of the human race and its salvation by sense. Perhaps he may develop "Psyche's Task" into a treatise which shall give us the sociological meaning of religion. In that treatise the study of the modern crowd should be an essential foundation.

A. E. CRAWLEY.

ASSAY OF PRECIOUS METALS.

The Sampling and Assay of the Precious Metals: comprising Gold, Silver, Platinum, and the Platinum Group Metals in Ores, Bullion, and Products. By E. A. Smith. Pp. xv+460. (London: C. Griffin and Co., Ltd., 1913.) Price 15*s*. net.

THE advances in the assay of the precious metals of late years have been directed mainly towards improvement in detail, and have not resulted in any great change in method or in the discovery of new principles. Nevertheless, the minor changes have been numerous, great numbers of useful observations have been made, and it was high time that a new and complete account should be prepared, setting forth the present varied practice, with the considerations on which it is based. The author of this volume is well equipped for such a task, and has produced a valuable treatise which may be taken as authoritative.

Besides gold and silver, Mr. Smith has included the assay of platinum, a course which will be convenient to assayers, on account both of the importance now attached to the ores of platinum and of the increasing use of the metal in jewelry. Moreover, platinum is often associated with gold, and the methods of assaying gold and platinum are so closely allied that they cannot be separately treated. Special attention is devoted to sampling, a subject which is of great interest to assayers, although sometimes neglected by them. Sampling operations being common ground, and by no means peculiar to the treatment of the ores or alloys of any one particular metal, all reference to them is frequently omitted, both in works on metallurgy and in text-books on assaying. There is also a chapter on the laboratory work in a cyanide mill, and a short but adequate account of ore and bullion valuation and sale.

The book compares favourably with its forerunners, both in respect of completeness and accuracy of statement, and the patient care displayed by Mr. Smith in collecting and arranging all the available data might well be envied by his colleagues. There are few changes which can be suggested as desirable in the next edition. It would perhaps be of interest to add to the historical section something as to the evolution of the assay furnaces, balances, and implements generally, say, from the fifteenth century onwards. Another more important addition would be some further discussion on the effects of borax when mixed with a crucible charge. According to many assayers, this influence is always malign, giving low results. Mr. Smith is not precise in his directions as to the proportion of borax to be reserved for a cover to the charge in various cases.

There is also more to be said as to cupel absorption and the use of proofs or checks. Bullion assayers have long recognised that the determination of the absorption of gold and silver by a particular brand or batch of cupels is not enough, and that the variations in the temperature, amount of draught, etc., appreciably affect the loss. Accordingly, they use check assays for every determination. Ore assayers are often too easily satisfied on this head, or in the alternative subject themselves unnecessarily to the inconvenient course of fusing the cupels. If cupel loss were determined by the use of checks for each cupellation or batch of assays, the extra work would, in the opinion of the reviewer, be more than repaid by the increase of accuracy. In any case, the matter should be faced and fully discussed. Lastly, exception may be taken to the statement on p. 201 that it is necessary to remove the cupels immediately after the button has brightened (what exactly does Mr. Smith mean by "brightened"?). Experience generally, and especially the work of Mr. Wilkes (*J. Chem. Met. and Min. Soc.*, 1905, vol. v., p. 237) is not in favour of this contention.

There is, however, little to criticise in this handsome volume. It may safely be placed in the hands of students, and will be of the greatest value to assayers as a book of reference.

T. K. R.

SEISMOLOGICAL PHYSICS.

Modern Seismology. By G. W. Walker, F.R.S. Pp. xii + 88 + 10 plates. (London: Longmans, Green and Co., 1913.) Price 5*s*. net.

THE first thing to strike one, on glancing through this book, is the absence of an index; the second is the absence of footnote references; and the third is an introduction which, purporting to be a history of the progress of modern seismology, contains about as many errors, of misstatement and omission, as can be crowded into five pages of print. But, once the book proper is begun, these unfavourable impressions disappear, and we find an excellent introduction to the study of that modern seismology which is very remote from earthquakes.

The author's qualification to deal with the subject is said to be his experience in having set up at Eskdale Muir, and for a short time taken charge of, a set of modern seismographs of various types, and the book exhibits at once the drawbacks and the advantages of this limited justification. On one hand, the author's acquaintance with the literature of the subject is evidently limited; for instance, he makes several references to Lord Rayleigh's investigation of surface waves in solids, but ignores Prof. Lamb's later and more apposite work, and in more purely seismological work the reader might well leave the book with the entirely erroneous impression that only three names—Wiechert, Zöppritz, and Galitzin—count as really important, and that their importance is in the order of mention. On the other hand, the recentness and brevity of the author's acquaintance with the subject leaves him in close touch with the difficulties and doubts which beset the beginner, and, being a practised observer in other branches of physics, and writing from a first-hand and current experience, he has produced a lucid and sufficient introduction to the subject.

Beginning with the general dynamical theory and principles of construction of modern seismographs, which is a clearly put, concise, but withal sufficient, account of the subject, he goes on to deal with the character of wave motion recorded by them and the interpretation of seismograms, traversing practically the whole of the ground covered by what is known as the modern seismology, and forming an excellent introduction to that branch of the science. The book deserves, and will doubtless run to, a second edition, when the author will be able to revise the references to earlier work on earthquakes proper, which are almost uniformly erroneous in the present issue. In spite of this it may confidently be recommended, not merely to those who approach the subject for the first time, but to the attention of practised workers, who will find both interest and advantage from being brought into contact with those elemental principles and difficulties, which are apt to be lost sight of as they advance along their special lines of research.

PURE MATHEMATICS.

(1) *Plane Geometry.* By Prof. W. B. Ford and C. Ammerman. Edited by E. R. Hedrick. Pp. ix + 213 + xxxi. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 3*s.* 6*d.* net.

(2) *Higher Algebra.* By Dr. W. P. Milne. Pp. xii + 586. (London: Edward Arnold, 1913.) Price 7*s.* 6*d.* net.

(3) *The Twisted Cubic: with Some Account of the Metrical Properties of the Cubical Hyperbola.* By P. W. Wood. Pp. x + 78. (Cambridge: University Press, 1913.) Price 2*s.* 6*d.* net.

(4) *Graphical Methods.* By Prof. Carl Runge. Pp. viii + 148. (London: Oxford University Press; New York: Columbia University Press, 1912.) Price 6*s.* 6*d.* net.

(5) *Einführung in die Mathematik für Biologen und Chemiker.* By Prof. L. Michaelis. Pp. vii + 253. (Berlin: Julius Springer, 1912.) Price 7.80 marks.

(6) *Théorie des Nombres.* By E. Cahen. Tome Premier. Le Premier Degré. Pp. xii + 408. (Paris: A. Hermann et Fils, 1914.)

(1) THIS text-book, written by two American professors, is arranged on lines similar to those of modern English text-books. Fewer theorems, more experimental geometry, and numerous practical applications are its chief characteristics. In placing properties of areas after those of circles and similar figures, the authors have adopted a change of order, which we believe will eventually become general. The idea of similarity is so fundamental and at the same time presents comparatively so little difficulty, that it is in our view regrettable that in many examination syllabuses, and consequently in most school courses, it should be postponed to a late period. In fact, it is probably true to say that many boys leave school without any knowledge of what is one of the most valuable, practical, and important branches of geometry.

(2) There are in this volume distinct merits and a certain originality of treatment such as will appeal to many teachers of the modern school. No attempt has been made to develop the subject in a rigorous and logical fashion from the fundamental axioms of number, and we agree with Dr. Milne's opinion that students at this period of their training are ill-fitted for what is almost a philosophical discussion. But at the same time it is becoming generally recognised that the harm done by inculcating incorrect notions of limits, convergence, etc., is so serious and so difficult to remedy that many teachers have, with little assistance from current text-books, been taking their scholarship candidates through a course of serious analysis. They will undoubtedly welcome the publication of this treatise, which with admirable clearness and with an abundance of detailed explanations and illustrations, sets out the lines upon which accurate investigations of the existence of limits and the convergence of single and double series must proceed. More than half the book is occupied with work of this character.

The scope of treatment is best indicated by an enumeration of the headings of the chapters:—Rational numbers; irrational numbers; summation; binomial theorem; permutations and combinations; exponential and logarithmic series; continued fractions; theory of equations; determinants; miscellaneous theorems. In his selection and arrangement of material, the author has, therefore, departed considerably from the customary plan. What little "Theory of Numbers" there is, comes in the first chapter; the usual account of probability has been considerably curtailed; diophantine problems and inequalities receive very brief treatment; and the chapter on permutations follows, instead of precedes, the binomial theorem. There is a good collection of examples at the end of each chapter; we regard, however, as unfortunate the omission of any intermediate sets. Clearly it is undesirable for a student to read the whole of a chapter before doing any examples, and the result of grouping them at the end is to saddle the teacher with the burden of selection.

The final collection of four hundred miscellaneous problems and a number of questions of an essay type call for special notice. Teachers and pupils alike will probably feel the need of an index. Dr. Milne has produced an essentially scholarly work, and we have no hesitation in classing it with those books which are exercising a wholesome and valuable influence on mathematical teaching.

(3) It is curious that no systematic account should have been hitherto published of the properties of the space curve of the third order, although many mathematicians have given their attention to the subject, the fruit of which is to be found in a number of isolated memoirs and, incidentally, in a few treatises, as, for example,

in Grace and Young's "Algebra of Invariants," where the invariants and covariants of a binary cubic are interpreted in terms of the geometry of the skew cubic. This is now remedied by Mr. Wood's tract, which discusses the subject *ab initio*. The first section deals with the projective properties of the curve, developed analytically with the use of homogeneous coordinates, and the second is specially concerned with the cubical hyperbola (the case in which the curve has three real and distinct points at infinity), and discusses the properties of asymptotes, diameters, vertices, centre, axis, inscribed and circumscribing quadrics, the rectangular cubical hyperbola, etc. No one who is interested in geometry can fail to appreciate the collection of properties which Mr. Wood has made, and many will, no doubt, be encouraged by the way in which the initial stages have been simplified, to pursue the subject beyond the limits which space has here rendered necessary.

(4) The purpose of this book is to supply the theoretical basis upon which graphical methods rest, and to discuss in general terms the manner in which applications may be made to shorten the labour involved in the heavy computation with which the physicist and engineer are so often faced. In many cases special graphical methods have been invented to cope with a particular kind of problem, and in view of the fact that there is little inter-communication between those working in different spheres, the opportunity of making use in one department of a device that has been of value in another is often missed, on account of the failure to recognise the generality of the principle which has been employed. The subject-matter is divided into three sections: the first deals with graphical arithmetic, the evaluation of integral functions, and the treatment of complex quantities; the second with the representation of functions of one or more variables, the principle of the slide rule, and the idea of conformal representation; and the last with the calculus and the solution of differential equations.

(5) This course of pure mathematics is most distinctly a lower limit of the equipment every scientific student should possess. The ideas of the calculus are at last beginning to find their way into the ordinary curriculum, more rapidly on the Continent than in England, and the time cannot be far distant when it will be impossible for boys who specialise in chemistry or physics to leave school ignorant of infinitesimal methods. The book deals with revision of arithmetic, algebra, geometry, and trigonometry; graphs of functions; differential and integral calculus, with special reference to expansion in series; and differential equations. The sections of the calculus make rather dull reading, little indication being given of the nature of the applications that it permits. The systematic treatment of what may be called the grammar of the subject should, however, enable the reader to acquire some degree of facility in performing ordinary operations.

(6) What is the criterion that distinguishes the theory of numbers from other branches of analysis? To this question, M. Cahen makes the following reply:—"The Theory of Numbers is a science in which division is *possible* only in special cases, whereas elsewhere division is *impossible* only in special cases." And this statement gives in brief the limits he has set himself in this treatise. The first eight chapters deal with addition, multiplication, subtraction, and divisions of integers, H.C.F. and L.C.M., and fractions; the next four with systems of diophantine equations of the first degree; then follow chapters on linear substitution and groups, linear and bilinear forms, congruences, matrices, prime numbers.

The treatment is thorough in character, and the work is set out so clearly that no student, however small his previous knowledge may be of the theory of arithmetic, should find it difficult to follow the argument; and if he reads through this volume carefully and tests his progress by working out some of the examples provided, he should obtain a firm grasp of this important modern subject. Text-books such as these form an admirable preparation for the student who wishes to make a more specialised study of the subject, for, by giving him a sound groundwork, they make it possible for him to consult intelligently the original memoirs which mark the growth of the theory, and which no text-book, however comprehensive, can in reality replace.

OUR BOOKSHELF.

Dental Diseases in Relation to Public Health. By Dr. J. Sim Wallace. Pp. viii+90. (London: Office of *The Dental Record*, 1914.) Price 3*s*. net.

This book consists of three chapters. They are addresses given by the author in "response to requests." Chap. i. sets forth in detail the prevalence of dental diseases, the serious effects they exercise on general health—especially during childhood—and the methods by which such diseases may be prevented. There are, however, within its pages statements based on loose figures, which are calculated to mar the effect the writer has in view by causing an impression of exaggeration of unverified inference. On the strength of the statement—itself too wide a generalisation—that 75 per cent. of the total population have irregularities of the teeth, we have presented to us the wild statement that "the number of teeth which are pouring pus into the buccal cavity may be estimated, at least has been estimated, at 200,000,000."

Chap. ii. contains a fairly wide description of the function of mastication, and of the effects of saliva on various foods. Chap. iii., on "Children and Dental Disease," is to a large extent a repetition of parts of chap. i., but clothed in different language.

We do not consider these chapters are a serious contribution to the literature of public health. Careful perusal of them impresses upon us the conclusion that, while condemning physiologists and medical men for their shortcomings in dental hygiene, the author is unduly confident in his own exaggerated and unbalanced opinions. He recommends prevention of dental disease by methods of dieting, which "show beyond all doubt that dental caries is not only preventable, but that it is easily and surely preventable."

The enormous benefit bestowed by early treatment as a method of prevention is not admitted by the author, who asserts that, "compared with modern methods of prevention, however, treatment must be regarded as a failure." He is equally clear that sugar should not be regarded as a wholesome and cheap food for children, but as a large and important factor in the production of dental caries. In these opinions we doubt if many physiologists will join him.

Savants du Jour: Albin Haller, Biographie, Bibliographie Analytique des Ecrits. By Ernest Lebon. Pp. 120. (Paris: Gauthier-Villars; Masson et Cie., 1913.) Price 7 francs.

There is something to be said for the publication of a man's biography during his lifetime. He is at least able to participate in the pleasant things that are said of him. Mr. Ernest Lebon has undertaken the task of writing the lives of the "Savants du Jour," and so far he has completed seven, the latest of the series being the life of Prof. Albin Haller. Son of a joiner and cabinetmaker, of Thaun-St.-Amarin, in the Vosges, Haller was apprenticed to a local apothecary until the outbreak of the Franco-German War, when he served as hospital assistant. At its conclusion in 1871, he left his native town to follow the fortunes of his teacher, M. Gault. When the staff of the Strasburg University was transferred to Nancy, Haller entered as a student of pharmacy, and in 1873 became lecture assistant in chemistry. He quitted the school of pharmacy in 1884 in order to fill the chair of chemistry. He was elected corresponding member of the Academy of Sciences, in 1891, and in 1899 was asked to take the chair vacated by the death of Prof. Friedel as professor of organic chemistry at the Sorbonne. In 1911 he was made commander of the Legion of Honour, and since then he has received widespread recognition by native and foreign scientific bodies.

His principal researches are mainly in the domain of organic chemistry.

In connection with his studies in the camphor group, he not only obtained a great variety of new and interesting derivatives of camphor and borneol, but among them the homologue of camphoric (homocamphoric) acid, which on distillation of its lead salt gives camphor, and in this way he succeeded in effecting a partial synthesis of camphor. The long list of researches which have emanated from his laboratory, in addition to his numerous literary contributions on scientific subjects, give evidence of an unusually active and fruitful career.

J. B. C.

A Course of Practical Work in the Chemistry of the Garden. By D. R. Edwardes-Ker. Pp. 40. (London: John Murray, 1914.) Price 1s. 6d. net.

One of the results of the foundation of a diploma in horticulture by the Horticultural Society is certain to be an improvement in the method of education of horticultural experts. The number of appointments in this direction tends constantly to increase, and now that the Board of Agriculture has established a horticultural branch, the competent expert finds the possibility before him of a highly successful career. In order to meet the demand for text-books that is certain to arise, Mr. Edwardes-Ker has collected a set of experimental lessons to be carried out in a chemical laboratory, and requiring only such limited knowledge of chemistry and of manipulation processes as will be available in the circumstances.

The book is divided into four chapters, headed respectively, "The Chemistry of Plants," "The Chemistry of Soils," "The Chemistry of Manures and Fertilisers," and "The Chemistry of Sprays and Washes." The experiments are simple and well chosen, and should prove of distinct value both to the student and the teacher. They will, of course, require to be supplemented by a suitable series of lectures setting forth the bearing of the facts thus ascertained on the growth of plants, and, in order to bring this out more clearly, we should like to see some pot experiments added. Pot experiments can be made quite simple enough for the purpose, and satisfactorily demonstrate many important phenomena that laboratory exercises alone can never bring out.

A Practical Manual of Autogenous Welding (Oxy-Acetylene). With a chapter on the Cutting of Metals with a Blowpipe. By R. Granjon and P. Rosemberg. Translated by D. Richardson, Pp. xxii+234. (London: C. Griffin and Co., Ltd., 1913.) Price 5s. net.

Autogenous welding consists in uniting metals by fusion without the intervention of solder. Ordinary welds may be effected by heating in a forge, but the local application of heat by an electric current or by the heat of an intense flame is more properly called autogenous welding in contradistinction to the junction of metals made by solder. The work before us treats of welding as done by the oxy-hydrogen and oxy-acetylene blowpipe, the introductory matter on soldering and electric welding being outside the main purpose of the work. The oxy-hydrogen weld was used before oxy-acetylene, but the latter is now the most common. Acetylene burnt with an equal volume of oxygen gives a temperature which is 1000° C. higher than the oxy-hydrogen flame. For successful welding minute attention to the details of construction of the blowpipes is necessary, and the author describes the forms of blowpipes used and the generators for producing acetylene economically.

The enormous extent to which this form of welding is employed in the arts may be gathered from the descriptions of iron and mild steel welds that can be done *in situ* on large pieces of structures and machinery. From repairing a large rudder of a steamer to the delicate junction of rose-petals in ornamental wrought iron work, the usefulness of the oxy-acetylene blowpipe extends, but perhaps the most important application of the blowpipe is in the cutting of metals and removing rivets. The weakest part of the work is in the translation, which in places leaves much to be desired.

Ambidexterity and Mental Culture. By Dr. H. Macnaughton-Jones. Pp. 102. (London: William Heinemann, 1914.) Price 2*s.* 6*d.* net.

THE author's object in this little volume has been to state briefly the conclusions that may be drawn from the authoritative opinions of physiologists, psychologists, and teachers in different parts of the world as to the advantages of ambidexterity and the desirability of teaching it. Recent experience is drawn upon, and accounts of "Eurythmics" and the Montessori system are included.

LETTERS TO THE EDITOR.

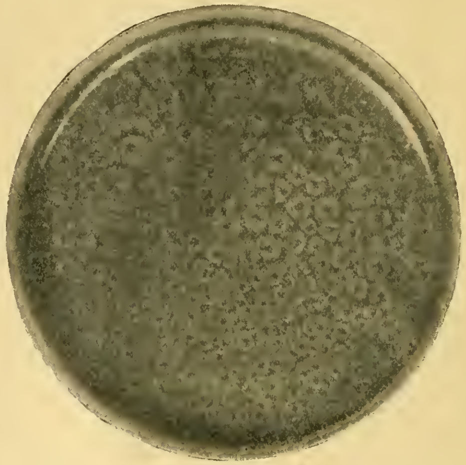
[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Cellular Structure of Emulsions.

WHILE preparing emulsions of radio-active minerals in alcohol for *α* ray examination, my assistant, Mr. E. K. Denton, directed my attention to the mottled appearance of the surface of the emulsion. Closer examination with a lens or low-power microscope shows that the surface is divided into numerous polygonal cells. At the centre of each cell the liquid is flowing vertically upwards, on the surface horizontally outwards, then downwards at the edges of the cell and horizontally inwards along the bottom; such a circulation, in fact, as would be produced by a vertical doublet at the centre of the cell. The hydrodynamical action of these doublets is no doubt responsible for the cellular structure, and the flow is maintained by the evaporation of the alcohol at these centres.

The effect may be obtained with an emulsion of an insoluble powder in any volatile liquid. I have found it, *e.g.* with carborundum, graphite, and lycopodium in ether, alcohol, or molten paraffin. (Certain powders, such as rouge, fail to show it.) The accompanying photograph (graphite in methylated spirits) shows the general appearance of the surface, but does not give an adequate idea of the sharply rectilinear character of the boundaries of the cells.

It seems possible that this effect is related to the formation of flocculi in the solar photosphere, and even to terrestrial cloud formations of flocculent type. I have not been able to find previous reference to it,



and should be obliged to any of your readers who can supply me with such or otherwise comment upon it

KERR GRANT.

The University of Adelaide, March 1.

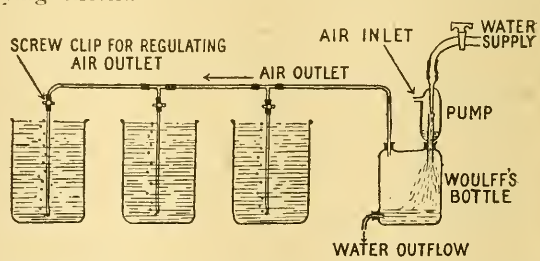
A Simple Method of Aerating Marine and other Aquaria.

THE following method is adapted for aerating aquaria, especially those which contain microscopic organisms, such as Amœba, Vorticella, Hydra, Desmids, Diatoms, and delicate Algæ. Further, the method is admirably suited for marine aquaria, and when once set up the sea-water does not require to be renewed but only maintained at its original level in the aquarium by the addition of distilled water.

The apparatus required is readily obtained and fitted up; and as the cost is only a few shillings, it should appeal to all teachers of nature-study. Apart from the fascination of having several fresh-water and marine aquaria maintained in perfect condition, there is the educational value to be considered.

All that is required is a water pump, a Woulff's bottle, some glass tubing, a short length of rubber tubing, and one or two screw clips.

The apparatus is fitted up as shown in the accompanying sketch.



The pump is connected with the water supply tap, and when the water is turned on it passes through the pump, dragging air with it into the Woulff's bottle; here the air and water separate, and since the water outflow is checked, the air fills the upper part of the bottle, and becomes compressed. The air being under pressure may either blow the water out of the bottle or bubble through the aquaria; the latter being the path of least resistance, produces the desired result, namely, complete aeration of the aquaria.

ELLIS W. GILDERSLEEVES.

Physiological Laboratory, Bedford College, Regent's Park, N.W.

THE RED SEA COAST.[1]

MR. CROSSLAND, as marine biologist to the Sudan Government, has been resident for some years in the neighbourhood of Suakin, and has had ample opportunities to become intimately acquainted, not only with this portion of the Red Sea coast, but also with the inhabitants of this interesting part of Africa. Living in the course of his work in close acquaintance with some fifty or sixty employees, among whom were Arabs from Sinai and Yemen, Negroes from the Upper Nile, and especially Hamites, the descendants of the original inhabitants of north-eastern Africa, he finds that they range in intelligence between much the same limits as the uneducated class of European lands. The social and religious conditions of these three nationalities are well described and illustrated by numerous instances which came under the author's notice, and his descriptions of them provide a valuable addition to our knowledge of these peoples. In the arid region which they inhabit, the life of the Hamitic nomad tribes is a hard one, and the extremely local character of the scanty rainfall and the consequent scarcity of forage for their camels and flocks impose on them the necessity for constantly shifting their encampment. While the Hamites are the camel-owners of the district, the Arabs and their Negro slaves hold almost a monopoly of the sea traffic in their coasting vessels, "Sambuks," in which they cruise up and down the Red Sea, and it is on the coast-belt that they come into contact.

A short chapter on corals introduces us to an account of the building of the reefs. Here a good account is given of the growth of the shore-reefs, with examples from the Red Sea and from other places, and of the erosion and deposition which is going on at various points by the tidal currents where these are sufficiently developed. At Port Sudan the tidal range is extremely small, being rarely more than 30 cm., but at other parts of the Red Sea this is greatly exceeded. The book concludes with a very instructive chapter on the tectonic structure of the Red Sea, which is a welcome addition to Suess's general discussion of it, and to the more detailed work of Hume, Ball, and Blanckenhorn in the northern portion.

Mr. Crossland considers that the sandstone hills of the coastal plain were deposited previous to the extensive faulting of the Red Sea area, which eventually resulted in three parallel fault-blocks. Of these the first and nearest to the Red Sea hill-ranges once formed a barrier reef near the foot of the mountain, and a coastal plain was formed behind it. Further movements produced an outer barrier reef on another fault block, and within this now a coastal plain has been built up. The present barrier itself is being formed on a third and outlying fault-block, and the deep lagoons so typical of this coast lie within it. These descriptions,

An elderly Bishari. From "Deserts and Water Gardens of the Red Sea."

which have largely appeared in the *Journal of the Linnean Society*, show what an interesting field awaits the physiographer and the geologist along these shores of the Red Sea. The descriptions both of the people and of the country are excellently true to life, and furnish an interesting and accurate account of a little-known region, though the discomforts of residence there during the hot season

[1] "Desert and Water Gardens of the Red Sea." Being an Account of the Natives and the Shore Formations of the Coast. By Cyril Crossland. Pp. xv+158+xl plates. (Cambridge University Press, 1913.) Price 10s. 6d. net.

of the year are made light of, and the difficulties which the arid climate offers to the detailed examination of an extensive tract of such country have to be experienced in order that they may be fully appreciated H. G. L.

THE LAWES AND GILBERT CENTENARY FUND.

JUST a hundred years ago was born John Bennett Lawes, followed three years later by his life-long collaborator, John Henry Gilbert; together they carried on their scientific work until the end of the nineteenth century, and now preparations are being made to commemorate the year of Lawes' birth by rebuilding the laboratory in which so much of the pioneer work in agricultural science was done. The issue of the Annual Report on the Rothamsted Experiments reminds us of the historic claims of that institution to all the assistance the public can give it.

Lawes began his agricultural experiments so far back as 1838, but though those early essays led to the invention of superphosphate and so incidentally to the fortune from which he so liberally endowed the Rothamsted Station, the experiments, properly speaking, did not begin until 1842, when Gilbert became associated with them. From that time some of the famous fields began to take shape, and by 1852 had settled down to that scheme of manuring which has never since been changed; in consequence, the plots now supply data as to the effect of fertilisers both upon the crop and upon the soil which are not merely unrivalled in their trustworthiness, but are constantly being re-interpreted as the science of the nutrition of the plant develops. In 1855 the laboratory was built from subscriptions raised as a testimonial to the value of Lawes' work, and it is this laboratory, now out of date and becoming structurally unsound, that the Rothamsted Committee seeks to replace.

Lawes died in 1900, Gilbert in 1901, and that first long and honourable chapter in the history of Rothamsted was closed. With the appointment of a new Director, Mr. A. D. Hall, in 1902, came the desire for a fresh outlook upon the old experiments; new points of view had arisen, particularly the physical and biological aspects of the soil had become important. The first necessity was to get together a body of workers, for one man could no longer cover so complex a field, and to find adequate accommodation for them, because the arrangements of the old laboratory, though equal to the routine determinations which Gilbert needed, were extremely primitive. Unfortunately, the endowment of the Lawes' Trust provided no margin for extension; still the laboratory was reformed, a few voluntary assistants were secured and new ground broken. After a time Mr. J. F. Mason built a new wing for bacteriology and enabled Dr. H. B. Hutchinson to join the staff, and a little later the Goldsmiths' Company added to the endowment so that the services of Dr. E. J. Russell could be secured.

Up to that time no assistance came from Government, but with the creation of the Development Fund in 1910, the Rothamsted Station became recognised as the Institute for the investigation of the soil and the nutrition of the plant, and received an adequate endowment. The first result was that the Committee was able not only to add some experienced workers to the staff, but also to take a long lease of the home farm containing the classic fields and to embark upon the erection of an additional laboratory with all modern conveniences of electric supply, vacuum and air current, etc. At that point Mr. Hall resigned the Directorship, and was succeeded by Dr. Russell, who has no sooner got the new laboratory opened than he has set about the replacement of the old one which, even were it adaptable to modern methods of work, has for years been giving trouble owing to original defects in construction.

Subscriptions have been received from all parts of the world, the farming societies, large and small, in Great Britain, have contributed in a way that shows their increased appreciation of research, but nearly 1000*l.* are still wanted to complete the 6000*l.* that it is necessary to raise from the public. The laboratory is expected to cost 12,000*l.*, towards which there is reason to expect the Development Commissioners will give a sum equal to that raised from other sources, so now is the time for everyone interested in the welfare of this *doyen* of institutions for agricultural research to send along their donations from which the Rothamsted Station will reap a double benefit.

THE LIFE-HISTORY OF THE EEL.[1]

MANY articles in NATURE have dealt, during recent years, with the above subject; but its interest is not exhausted, and we here welcome the appearance of three new contributions to the long-debated question of the eel.

Dr. Grassi's work is the first publication of the Italian Royal Commission on "Thalassography," and in these first-fruits the commission gives promise of a great return from its systematic exploration of the Mediterranean Sea. Mr. Lea's paper is one of the many beautiful and interesting monographs which have already been based on the collections made by Sir John Murray and Dr. Hjort in the deep waters of the Atlantic. Dr. Bowman's paper is a brief but interesting note, based on the work of the Scottish research vessel *Goldseeker*.

In a long and learned introduction Dr. Grassi relates the history of our knowledge of the life-history of the eel; and while this history has been often summarised, it is here told more completely than ever. Dr. Grassi goes back even to Aristotle,

[1] "Metamorphose der Murænoiden: Systematische und Oekologische Untersuchungen "(Text Italienisch). By Dr. Battista Grassi. Pp. x+211 +xv plates. (Jena: Gustav Fischer, 1913.) Price 50 marks.
"Murænoid Larvæ from the *Michael Sars* North Atlantic Expedition, 1910." By Einar Lea. In vol. iii. of the Scientific Reports of the Expedition. Pp. 59+6 plates. (Bergen: John Grieg, 1913.)
"The Distribution of the Larvæ of the Eel in Scottish Waters." By Alexander Bowman, D.Sc. Fishery Board for Scotland, Scientific Investigations, 1912, No. II (December, 1913).

and, telling us that the Sicilians still call the larval eels *casentule,* that is, "earthworms," while the philosopher tells us that the eels spring from "earthworms," γῆς ἔντερα, he inclines to the conclusion that Aristotle knew a deal more about the biology and development of the eel than is actually set forth in his brief recorded references. It was Redi, in the seventeenth century, who showed, with the utmost clearness, that the eels breed out in the open sea, after migrating down the rivers "nel rimpunto della luna," "in the dark of the moon."

Another chapter of the story opens, just 150 years ago to a year, when a certain Mr. William Morris sent to Pennant, from Holyhead, the curious little fish which, in our youth, we used to read of in "Yarrell," under the name of the "Anglesey Morris," or *Leptocephalus morrisii,* as Gronovius had called it. Other similar fishes were from time to time described, until in 1856, Kaup, in a British Museum catalogue, described a number of species, including a certain *L. brevirostris*, from the Straits of Messina. A multitude of naturalists dealt, during the early part of the last century, with these little fishes. Cuvier said that their study was "une des plus intéressantes auxquelles les naturalistes voyageurs puissent se livrer." Johannes Müller, with splendid insight, declared that they were closely allied to the Muraenoids. Carus, in 1861, suspected that they were larval forms of some other fish, perhaps Cepola or Trichiurus, and in 1864 Dr. Theodore Gill asserted that these little Leptocephali were but larval eels, a fine instance of zoological prescience.

A long controversy followed, in which Günther and others maintained that the Leptocephali were not an ordinary necessary stage in the life-history of the eels, but were abnormal larvæ, distorted by an unnatural habitat. At length it was made clear by Dareste, Moreau, and finally and experimentally by Delage, in 1886, that *Leptocephalus morrisii* was the normal larva of the conger. Here begins the series of researches by Grassi and Calandruccio, who between 1892 and 1905 confirmed Delage's account of the metamorphosis of the conger, showed that Kaup's *L. brevirostris* was the larva of the common eel, studied in detail the life-history and metamorphosis of a whole series of other Leptocephalids, and maintained that these little larval fishes were inhabitants of the deep waters, from which sometimes, as in the Straits of Messina, they were brought up to the surface by currents or by whirlpools; just as Yarrell told, long before, of a specimen cast up in the eruption of Graham's Island in the Mediterranean. As was foreseen by Salvatore Lo Bianco, in 1891, the larvæ of the common eel are inhabitants of the deep sea, and three years later Johan Petersen captured the Leptocephalus of the common eel, *L. brevirostris,* out in the Atlantic, south-west of the Faeroe Islands. From that date onwards, together with Prof. Grassi himself, a band of Scandinavian naturalists—Petersen, Hjort, with his pupil Einar Lea, and last but not least, Dr. Johann Schmidt—have carried on the investigation of the metamorphosis and migrations of the eel.[2] Schmidt, Hjort, and Lea have now shown that the main breeding-place of the eel is not only out in the open Atlantic, but is in all probability in the warm and very salt waters of the southern part of the North Atlantic, south and west of the Azores; and an interesting part of Mr. Lea's paper is one in which he discusses the probable duration of the eel's long voyage to its breeding-place, and of the slow return of the young larvæ home. This point is further elucidated by Dr. Bowman, who is able to trace the Leptocephali of the common eel on their way round the west and north of Scotland from about June to August, while by November or December they appear as "elvers" off the coast, and are ready to ascend the rivers in March or April. The Leptocephali of the conger are found off the east coast from December to May.

But there still remain a few points of doubt, and therefore of controversy, on which the learned Italian naturalist and his Scandinavian brethren do not quite agree. These are questions which we would not lightly judge or prejudge, and we may simply say that Dr. Grassi seems to state his case with great fairness, and with a very open mind. Among the points still at issue we may mention two. First, does the eel breed in the Mediterranean? And secondly, are the Leptocephali (at least those of the common eel) inhabitants of the surface-waters, of the bottom, or of intermediate depths? Dr. Schmidt believes that the eel does not propagate at all in the Mediterranean, "conclusione molto sorprendente," as Grassi calls it. He holds that for the Mediterranean eels, as for all those of western and northern Europe, the Atlantic is the one great breeding-ground, and that inwards, through the Straits of Gibraltar, pass the migrating young; while Dr. Grassi still inclines to his old belief that the deeper parts of the Mediterranean are also breeding-grounds. At considerable length Dr. Grassi discusses the other problem, and holds that it is by no means proved, as Dr. Schmidt would have it, that the Leptocephali are dwellers in the upper layers. He refers to the habit, which many species at least of the Leptocephali have, of burrowing in the sand or hiding under stones; he states that he has seen *L. brevirostris* itself actually doing so; and he tells us that in captivity the little Leptocephali avoid the light, and retreat into dark corners of the aquarium. In short, he is unwilling to budge from his old opinion, set forth twenty years ago, that the Leptocephali come only occasionally towards the surface from the great depths which constitute their natural home.

The question is curiously interlinked with the too little-known habits of the sunfish, *Orthagoriscus mola*. Multitudes of Leptocephali are found within the stomach of that fish, and would even seem to constitute its main, though not exclusive, nutriment. Sometimes, and this in itself would seem rather to tell against Prof. Grassi's view, they are still actually living when the fish is

[2] See Dr. Schmidt's article in Nature, August 22, 1912; also Dr. Johann Hjort's communication to Nature of November 24, 1910.

caught and its stomach opened. Now the sunfish is often seen upon the surface, and is harpooned or otherwise captured there; but Prof. Grassi will not admit that this is its normal habitat, but thinks that it only now and then comes up from the greater depths. This is not the usual belief, but it was Lo Bianco's, as Grassi tells us, and Lo Bianco's opinion carries a deal of weight. After all, then, the sunfish may be a denizen of the deep waters, like *Lampris luna*. But, in the few cases where a sunfish has been found to contain other diet than Leptocephali, the stomach was found full of Salpæ, pteropods, and Velellæ, and they had doubtless been fed upon, if not at the surface, at least in the upper layers. If we may at all venture an opinion, Dr. Schmidt seems to have the better of the argument. A minor but curious question is how the sunfish, with its tiny mouth and apparently awkward body, is able to catch, by hundreds and by thousands, these little active, transparent Leptocephali.

D. W. T.

CARTE INTERNATIONALE DU MONDE AU MILLIONIÈME.

The conference of London, which assembled at the Foreign Office in November, 1909, at the invitation of the British Government, drew up an elaborate code of rules for the construction of an international map on the scale of one in a million. In the four years which have passed since that meeting about a dozen sheets in all have been completed, though not so many have been published. It had soon become evident that a second conference was required for two reasons. Certain of the resolutions of London worked badly in practice, and needed modification; while several of the Governments which would be called upon to undertake a considerable share of the work had not been represented in London, and desired to be heard before committing themselves to the scheme.

The second international conference met in Paris, at the invitation of the French Government, in December last, and thirty-three countries were represented by delegates officially nominated, whose resolutions will be submitted to their respective Governments for formal ratification. This official character of the meeting has much practical importance. The scheme had been discussed at successive meetings of the International Geographical Congress for twenty years; it remained inoperative until the first official conference of 1909.

The first business of the Paris meeting was to decide what parts of the London resolutions should stand unchanged, and what was open to discussion. A prompt decision to leave as much as possible untouched cleared the way for the real business of the meeting, which resolved itself into three parts—the revision of the conventional signs; the improvement of the colour scale for the layers, and other details of the representation of relief; and the distribution of the sheets which covered the territory of several Powers. The three commissions which were nominated to deal with these questions chose as their presidents Prof. Penck, Colonel Thiébaut, of the *Service géographique de l'armée*, and Colonel Close, respectively. General Bourgeois, chief of the *Service géographique*, presided over the full conference with admirable firmness and lucidity.

The work of the first commission involved long meetings and animated discussion on the classification of towns and the spelling of place names, which affect different countries in very different ways. A system of town classification which is good for Europe is hopeless for Africa, while the relative claims of population and administrative importance lead to difficulties on a single sheet. The spelling of place names in Eastern Europe is fiercely contestable; the transliteration of African names into European equivalents produces endless trouble on boundary sheets. On these matters no hard and fast agreement was possible; much must be left to the discretion of the establishment that makes the sheet. Minor difficulties in the classification of railways, navigable rivers, and roads were amicably adjusted, and the resulting conventional signs sheet is in many respects a great improvement on that adopted four years ago.

The work of the second commission was very much simplified by the production of experimental variants of the Istambul sheet, which had been prepared by Colonel Hedley in the Geographical Section of the General Staff. Fine black contours, instead of brown, were accepted without difficulty. The ugly and unsatisfactory upper tones of the London colour scale for layer tints found few defenders, and it was not difficult to substitute a scale running into orange and red in place of the old brown and magenta. Above the snow line the layer tint is to be omitted; glaciers are to be distinguished by blue form lines or hachures, and there is liberty to use shading when the contours are not sufficient to bring up the form of the snow peaks. In principle the contour interval is, as before, 100 metres throughout; but this is not always feasible, while the suppression of contours at discretion leads to unnecessary diversity. The remedy was to declare certain contours obligatory (*courbes maitresses*), the others being discretionary.

The third commission laid down the principle that the right to produce a sheet belonged to the country which owned most territory within its limits, and refused to make any pronouncement as to sheets lying wholly in territories which have no cartographical establishments. The significance of the latter decision was lessened by the announcement of the Chinese delegate that topographical establishments were now in active operation in all the provinces of the Republic. The delegates of the South American States came to an important agreement among themselves in regard to the representation of doubtful boundaries.

In the full sessions the decisions of the commissions were ratified without excessive rediscussion, and there was happily no need to settle the awkward question whether delegates of countries which had not produced, and never would produce, a sheet of the map should have an equal voice with others more deeply interested.

In an enterprise needing so much cooperation and exchange of information a central office is necessary. The British delegates had the satisfaction of being authorised by their Government to propose that a central office should be established in England, of which the small expenses should be borne by contributions from the consenting Powers in equal shares. The conference did England the honour of accepting this proposal unanimously, and if the agreement is ratified it is probable that the office will be at the Ordnance Survey, Southampton, with an auxiliary office in London where all information will be available for reference.

It was decided that the official name of the map shall be the French name—"Carte internationale du monde au millionième." A strict adherence to this rule is desirable, especially in indexing and cataloguing the literature which will grow up, in notices, reviews, and lists of published sheets.

The labours of the conference were lightened by the excellent arrangements made for its reception in the Salle d'honneur at the Invalides, and in the rooms of the *Service géographique;* by the cordial attentions of the hosts; and by the splendid hospitality, public and private, extended to the delegates.

The British delegates were Colonel Close (Ordnance Survey), Colonel Hedley and Captain Cox (Geographical Section, General Staff), and Mr. Hinks (Royal Geographical Society), representing Great Britain; Major Tandy (Survey of India) representing India; and Major Richardson, representing New Zealand.

INTERNATIONAL CONVENTION ON PLANT DISEASES.

SHORTLY after the final sitting of the International Phytopathological Conference, which was held at Rome last month, an official statement was issued, and extracts from it were given in our issue for March 26 (p. 90). The text of the draft convention which was prepared at this conference has now been issued by the International Agricultural Institute at Rome, and the Governments which were represented on that occasion will be invited to consider whether they will signify their formal acceptance of the proposed agreement. Their decision will depend on political and administrative reasons with which we are not here concerned, but the suggestions contained in the document mark an advance in public opinion on the subject of plant diseases of great interest to men of science, which cannot be entirely overlooked. The delegates of thirty independent States have decided that it is desirable that a uniform procedure should be adopted to control the spread of those diseases which have in the past done so much injury to agricultural and horticultural crops, and, indeed, are still doing so, and that this procedure should include both the scientific study of the insect and fungus pests at one or more Government phytopathological stations in each country, and the application of remedial measures by administrative order where these pests exist.

The official acceptance of this policy would in any case give a great stimulus to the study of applied biology, and would tend to concentrate the attention of entomologists and mycologists on economic problems. But the scheme contemplated by some of the articles of the convention is likely to be productive of even more important results. It was evidently felt impossible to prepare a list of dangerous diseases applicable to all countries, and while, on one hand, it was decided not to legislate for those diseases which attack agricultural crops, such as seeds, grain, potatoes, and other "articles de grande culture," each Government is invited to prepare a list of those diseases against which it wishes to be protected. The preparation of such a list is bound to be difficult, since many of the diseases which are comparatively harmless in a country where they have been established for many years are apt to assume a virulent character when introduced into a country where they are unknown. The ravages caused by the Brown Tail Moth (*Euproctis chrysorrhoea*) and the Cotton Boll Weevil (*Anthonomus grandis*) in America, by the Vine Louse (*Phylloxera vastatrix*) and the American Gooseberry mildew (*Sphaerotheca mors-Uvae*) in Europe, are familiar examples. The attention of official plant pathologists will have, therefore, to be directed not only to the study of the pests of their own country, but also to those of other countries the character of which is such that they might prove dangerous if introduced.

The field for this kind of research is, of course, very wide; but lest an opening should be given to unreasonable and alarmist measures likely to cause a serious disturbance of trade, it is laid down in a very important article what are the conditions on which the list must be prepared. It is wisely declared that the list must be as restricted as possible, and must not include any of those common pests which are widely distributed in almost every country, and are well established there. (Les espèces banales, dont la dispersion déjà ancienne s'étend à presque tous les pays.) Moreover, the pest must be epidemic in character, and destructive, or at least very injurious, in action, as well as be easily capable of being conveyed on living plants, or parts of plants.

In those cases where the pest is already known to be of such a character in its native home or in some country into which it has already been introduced, its inclusion in the list is a foregone conclusion, and there will be little hesitation about including the San José Scale (*Aspidiotus perniciosus*) or the Mediterranean Fruit Fly (*Ceratitis capitata*), the Black Knot (*Plowrightia morbosa*) or the Chestnut disease (*Endothia parasitica*).

But in other cases a difficulty will arise. Where experience cannot speak with certainty, a scientific reason must be urged, and it will be necessary to formulate a series of deductions from the life-history of the insect or fungus which would justify a presumption that in different surroundings the pest might prove epidemic as well as destructive to plant life, or at least injurious to the crop. No doubt it will be possible, in the course of time, to declare with more accuracy than at present what are the circumstances in which such conditions might arise; but it will require a long and careful study, not only of plant hygiene, but also of the limits of the powers of adaptation to environment possessed by parasitic organisms, under the stimulus of altered climatic and cultural conditions, as well as freedom from injurious influences. This article in the proposed convention will, if adopted, have a marked influence on the trend of economic biology and plant pathology.

NOTES.

A collection of rock specimens of considerable historic interest has just been presented to the Department of Minerals of the Natural History Museum. The specimens in question were collected in Arctic North America by Sir John Richardson, who accompanied Sir John Franklin's Arctic Expeditions of 1819–1827. They have since that time been kept in the museum of the Royal Naval Hospital at Haslar, but inasmuch as the fossils collected in the same Arctic expeditions are in the National Museum at South Kensington, it was felt to be in the fitness of things that the rocks should be also preserved there. An application was accordingly made to the Lords of the Admiralty to sanction the transfer of the specimens from Haslar to Cromwell Road, with the result that, as we have stated, they are now in the Department of Minerals.

On Tuesday next, April 21, Dr. Walter Wahl will deliver the first of two lectures at the Royal Institution on problems of physical chemistry: (1) study of matter at high pressures, (2) study of matter at low temperatures; on Thursday, April 30, Dean Inge will begin a course of three lectures on the last chapter of Greek philosophy: Plotinus as philosopher, religious teacher, and mystic; and on Saturday, April 25, Dr. T. E. Stanton will commence a course of two lectures on similarity of motion in fluids: (1) the theory of similarity of motion in fluids and the experimental proof of its existence, (2) the general law of surface friction in fluid motion. The Friday evening discourse on April 24 will be delivered by Dr. F. W. Dyson, the Astronomer Royal, on the stars around the north pole.

Prof. E. Heyn, of Berlin, is this year to deliver the annual May lecture before the Institute of Metals, upon the subject of "Internal Strains in Cold Wrought Metals, and Some Troubles Caused Thereby." The last May lecture, by Sir J. Alfred Ewing, was on the subject of "The Inner Structure of Simple Metals," and previously Dr. G. T. Beilby had lectured on an allied subject, "The Hard and Soft States in Metals." Prof. Heyn's discourse will be given in the building of the Institution of Mechanical Engineers, Storey's Gate, Westminster, S.W., under the chairmanship of Admiral Sir Henry Oram, president of the Institute of Metals, on Tuesday, May 12, at 8.30 p.m. The secretary of the Institute, Mr. G. Shaw Scott, of Caxton House, Westminster, S.W., will be glad to forward tickets to any readers who may desire to be present at the lecture.

Prince Galitzin will preside over the fifth meeting of the International Seismological Association, to be held early next September, in St. Petersburg. The exact date of the meeting is not yet fixed, but the provisional programme has just been issued. Reports will be presented by the committees on microseisms, on tides in the earth's crust, the bibliography of seismology, the catalogues of earthquakes prepared by the permanent committee, and the uniformity in the arrangement of seismological bulletins. It will be proposed that a new station shall be founded at Bergen, that a reserve supply of seismographs should be kept for occasional or temporary use, and it will be urged that all seismographs should be provided with suitable "damping" arrangements, and that correct time should be supplied by telegraphic signals to all earthquake observatories. Among the papers promised may be mentioned those of the president on the analysis of seismograms, the comparative study of seismograms from different stations, and on observations of the angle of emergence, and of Prof. Omori on the tromometric observations made during the recent eruptions on the flanks of the Asama-yama.

News has just reached us of the death on February 18, in his forty-sixth year, of Dr. J. Huber, director of the Museu Goeldi, Pará, Brazil.

Mr. G. H. Martyn, writing from Biarritz, says that on March 30, at the end of a bright day with light winds, the sun appeared to pass through a clear sky and set in the sea, from which it seemed immediately to start rising again. "The reflecting layer of air was not wide enough to reflect the whole disc of the sun, but a band having a width of a third of the sun's diameter, so that the appearance was of the sun rising and passing behind a bank of invisible clouds."

In the *Irish Naturalist* for March Mr. N. Colgan contributes an article entitled "Field Notes on the Folk-lore of Irish Plants and Animals." He shows the current traditional knowledge of the transmogrification of species, and that of sexes in plants. Thus, the royal fern is believed to be the wild rannyock or common bracken, and the spargantium or bur-reed the wild shellistring or flagger. The people identify a he- and she-bulkishawn or ragweed, the latter turning out to be the common tansy. On the Irish coasts the common limpet or *patella* is firmly believed to develop out of the acorn-shell or *balanus* which covers the rocks. The grimmest belief about the elder is thus stated by a car-driver: "That's the elder tuff. It's a bad thing to give a man a scelp of that. If you do, his hand 'ill grow out of his grave."

A considerable portion of the second number of vol. v. of the Journal of the Federated Malay States

Museums is devoted to various groups of Malay aboriginal tribes, Mr. C. B. Kloss communicating a number of measurements and photographs of Biduanda (Mantra) of the Ulu Kenaboi, Jelebu, while Mr. J. H. Evans furnishes notes on the same tribe, as well as others relating to the natives of Lenggong, Upper Perak, and yet others on those of the Ulu Langat, Selangor. The Lenggong aborigines, although derived from a Negrito stock, speak a Sakai dialect, like the pure (Negrito) Semang of Grit, from which, however, they differ by their lighter colour. Like many of the other native tribes, they object, however, to be called either Semang or Sakai, the reason for this being that both these names are commonly used by the Malays as terms of reproach. The people of the Ulu Langat and Ulu Kenaboi, who are all of one race, are more or less pure-bred Sakai.

In the issue of *L'Anthropologie* for November-December, 1913, Mr. O. G. S. Crawford discusses the question of prehistoric trade between England and France. He directs attention to the discovery in southern England of certain stone celts, vases, and bronze palstaves of Continental types. These seem to have reached this country from the Cotentin peninsula, in which prehistoric remains, especially hoards, are abundant. In support of these views he further considers the position of sites in this country sacred to the worship of St. Catherine. These lie in the western half of our south coast, but are wanting in the eastern half. He suggests that her wheel is a symbol of light connected with a Gaulish divinity, known as Lhud in Britain, and Nuada in Ireland. The cult of St. Catherine, not known in England before the Norman Conquest, is believed to have arisen in sites sacred to her predecessor, the olden Gaulish deity.

At a recent meeting of the Prehistoric Society of East Anglia, Mr. J. Reid Moir announced the discovery of a flint workshop floor in Ivry Street, St. Albans. An excavation for building purposes disclosed one foot of surface soil and two feet of fine stoneless sand. Then came the prehistoric stratum, containing flint cores and flakes, calcined flints, fragments of pottery, quartzite pebbles used as hammer-stones, and animal bones, some of which had been cut through, and, for some purpose, incised. Under this stratum lay fine sand to an unknown depth. Most of the flints were in the form of long flakes, patinated of a light blue colour. One had been trimmed for use as a scraper, and though it is difficult to attribute these specimens to any particular culture, Mr. Moir, judging from the length of the flakes, is inclined to assign them to the Magdalenian period. The bones found were those of a small sheep, teeth of an ox, and a tibia, probably that of a red deer. It is curious that another "find" of flints recently discovered at Ipswich is assigned to the Aurignacian period. If this attribution be accepted, we find remains of two Palæolithic periods within the confines of this town.

In *Meddelelser fra Kommissionen for Havundersogelser, Fiskeri*, Bd. iv., we have two papers dealing with the biology of the plaice. The first of these is by Dr. A. C. Johansen, on the immigration of plaice to the coastal grounds and fiords on the west coast of Jutland, and contains some interesting data on the changes in frequency of young plaice from one year to another in the shore zone. The second paper is by B. Saemundsson, on marking experiments carried out in the neighbourhood of Iceland. These experiments yield some results of interest, though they are not altogether satisfactory on account of the small numbers of fish dealt with. It is interesting to note that by far the largest number of recaptures were made by English trawlers from Grimsby and Hull. In the same volume there is a useful report by P. L. Kramp on fish-eggs and larvæ collected in 1909 in the Langelands Belt.

In the March number of the *Journal of Economic Biology* (of which we notice that Mr. W. E. Collinge is now sole editor) Mr. A. A. Girault, of the University of Illinois, completes his "Preliminary Studies on the Biology of the Bed-bug (*Cimex lectularius*)," giving details of successive pairings and generations with statistics as to the periods of feeding and the numbers of eggs laid by the females under observation. In summarising the reactions of bed-bugs to various stimuli, Mr. Girault states that the insect's usual behaviour of shunning light may be abandoned under the stronger stimulus of hunger. "Bed-bugs will visit a host in daylight or in bright artificial lights when hungry . . . as soon as the food-stimulus is neutralised by engorgement, however, the negativeness to light becomes dominant again, and the insect runs off to hide itself."

The February issue of the *Bulletin of Entomological Research* contains, as usual, systematic papers of considerable interest. Mr. F. V. Theobald writes on African Aphididæ, and is able to record "only thirty-five species for the whole African continent, about the number one can collect in a single afternoon in one's own garden in England," and several of these have clearly been introduced with nursery stock from Europe. Prof. R. Newstead describes new Coccidæ, and Mr. E. E. Austen new Tabanidæ, both papers being well illustrated. Of considerable interest is Mr. R. B. Woosnam's report on a search for Glossina (Tsetse-flies) on the Amala River in the southern Masai Reserve, of which he is game-warden. In a definitely restricted area along the river and its tributaries at more than 5000 ft. altitude he found a Western species, *G. fusca*, hitherto unknown in the East African Protectorate. The cattle, sheep, and goats of the Masai suffer very little from tsetse-borne disease, either because the people manage to avoid the fly-belt when moving their stock, or because only a very small proportion of the flies are infective.

By publishing reports for two successive years in a single cover, the Felsted School Scientific Society is enabled to reproduce some of the prize photographs taken by its members, the report for 1912–13 consequently presenting a more than usually attractive appearance. Particular interest attaches to the photographs of a young cuckoo and its foster-parent, a whitethroat.

In the newly issued vol. xxxiv. of "Botanisk Tidsskrift," Copenhagen, Ø. Winge gives an account of some new Sagasso Sea investigations. During 1911–13, the Danish Commission for the Study of the Sea organised a collection of plankton samples by Danish Transatlantic vessels. This material is now to be worked up, and Winge, who is studying the distribution and frequency of the Sargasso, finds the Gulf-weed consists chiefly of two species (*S. bacciferum* and *S. vulgare*), besides other less common forms (*Sargassum* species and *Ascophyllum nodosum*). The great quantity of Sargasso was met with between lat. 37° and 23° N., and long. 35° to 60° W., within an oval area about 600 miles broad. As was the case with the earlier "Sargasso-frequencies" of Krümmel and Antze, all the samples show an autumnal simultaneous increase of the quantity of the Sargasso. This suggests that the floating Gulf-weed has a long-lasting drift and a yearly growth-period in the late summer. Sexual reproduction of the drifting Sargasso is still unknown.

P. D. Quensel adds very greatly to our knowledge of the geology of western Patagonia in his "Geologisch-petrographische Studien in der patagonischen Cordillera" (Bull. Geol. Inst. Univ. of Upsala, vol. xi., p. 1). The great group of laccolitic intrusions, varying from granite to gabbro, is younger than the Cretaceous period, and even cuts the folded structure of the chain. As the photographs of scenery show, frost-action produces superb crags and pinnacles in these young and well-jointed granitoid rocks.

British geologists may be both surprised and gratified to find an elaborate paper in English on the geological structure and history of the Falkland Islands, by Thore G. Halle, in the Bulletin of the Geological Institution of the University of Upsala (vol. xi., pp. 115–226), accompanied by numerous illustrations and a coloured map. The feature of cardinal importance is the discovery of Permo-Carboniferous strata, with Glossopteris, and a glacial boulder-bed ("tillite") at the base. For this series the author proposes the local name Lafonian. The Permo-Carboniferous glaciation is thus seen to have a very wide extension, and it is interestingly pointed out that a laminated clay, and the occurrence of annual rings in the Dadoxyla of the local Gondwana flora, indicate a solar control of the climate during cold conditions. The laminated clay is figured, and bears a remarkable resemblance to those associated with the pre-Cambrian glacial beds in Ontario and with post-Pliocene glacial beds in Sweden.

A full report of the recent Sakura-jima eruption has been issued in Japanese by the Kagoshima Meteorological Station; it is especially interesting as giving accurate records of the events which preceded and followed the great eruption. The actual eruption commenced on the morning of January 12, but earthquakes, gradually increasing in intensity and frequency, were felt from early morning on January 11. The general features of the eruption have been already described, but we have now further particulars concerning the lava-flow. On January 14, at 7 a.m., a lava-stream was seen issuing from the mountain, but, encountering high ground, it spread out to a width of a mile and a half, with a thickness of "some scores of feet"; the flow of lava was resumed on the following day, several small craters being opened along its course, and on January 16 the lava-current reached the sea, pushing its way out to one of the small islands in the bay. The activity of the volcano gradually diminished from this time, but did not entirely cease until January 27. The earthquake shocks, which became less violent during the eruption, increased in number and intensity as the volcanic action declined, and then gradually died away. The seismometer recorded no fewer than 418 shocks on the day before the eruption, but during the eruption the seismometer having been broken, it was difficult to distinguish between earth-vibrations and the volcanic rumblings.

The Royal Meteorological Institute of the Netherlands has published the third quarter (December-February) of a new edition of its very laborious work, "Oceanographic and Meteorological Observations in the Indian Ocean." It consists of two parts: (1) tabular results for the years 1856–1910, and (2) charts constructed therefrom. This issue is much more complete than that for the previous quarter, owing to the inclusion (1) of observations for a longer period, and (2) of a large amount of data received from other meteorological services. In this latter respect special thanks are accorded to our own Meteorological Office. These additions, referring partly to routes not usually taken by Dutch vessels, have allowed certain areas to be more fully represented. The charts, twenty-five in number, show the frequency of direction and mean velocity of currents and winds, together with the general circulation of air and water for each of the months in question, isobars, isotherms, etc. On the backs of some of the charts details likely to be of use to seamen, and based upon all available data, have been carefully prepared. Taking into account the possible establishment of a direct service between the Netherlands' East Indies and South Africa routes are laid down for vessels between those parts, in addition to the tracks recommended for other places on either side of the Indian Ocean.

The shape of a nearly spherical drop falling in a viscous liquid of different density forms the subject of a paper by Shizumi Saito in the Science Reports of the Tokyo Imperial University, vol. ii., No. 5. The solution is obtained by harmonic analysis, though the method could be shortened by employing the ordinary polar equations of motion or Stokes's stream function. The paper leads to the conclusion that the drop may be deformed into a prolate or oblate spheroid, the distinguishing criterion being in the form of a relation connecting the densities and viscosities of the inner and outer liquids.

A valuable report on the effect of ice on the flow of streams in the United States has been drawn up by Mr. W. G. Hoyt, and forms Water Supply Paper 337 of the U.S. Geological Survey. The first report on the subject was issued in 1907, and dealt mainly with the field operations necessary for the estimation of the rate of flow. The present paper goes much further, owing to the work which has been done in the interval, and includes a discussion of the factors which influence the flow during the low-temperature period, and the calculation of the flow from the observations taken.

The Journal of the Washington Academy of Sciences for March 19 contains a *résumé* of a paper on the brightness of optical images by Mr. P. G. Nutting, which is to be published *in extenso* elsewhere. The results obtained deal principally with the transmitting power of various types of photographic lenses. The method adopted consists in exposing a white magnesia block to a luminous source of 1500 candle-power enclosed in opal glass, and comparing the brightness of the magnesia when illuminated direct, with the brightness of the image of the source when thrown on the same surface by the lens system under test. The observed transmissions vary from 57 per cent. for a Zeiss-Krauss tessar to 92 per cent. for a Fuess telescope objective. For several process lenses the transmission is 76–78 per cent., showing that for the six glass-air surfaces of which they consist the transmission is quite up to that theoretically obtainable.

It is interesting to read in the *Revue Générale des Sciences* (March 15) an elementary discussion of the principle of relativity by Prof. H. A. Lorentz, to whom, more than to any other, the hypothesis owes its origin. After a very clear exposition of some simple ideal experiments which illustrate the relative nature of the measures of space and time, he dismisses in a single paragraph what is to most physicists the greatest objection to the principle, the apparent denial of the existence of the æther as they had come to think of it. "That is, as it seems to me, a question towards which each physicist may take the attitude which best agrees with the way of thinking to which he is best accustomed." ". . . he must recognise that it is impossible for him to know the direction and the velocity of the æther (relative to his apparatus), and, if he feels the need of not concerning himself with his ignorance, he will take the side of M. Einstein." It is interesting to speculate how far it is possible to use these words and at the same time to feel convinced of the objective existence of a unique æther, which is something more than a convenient way of correlating phenomena, but may be described in Prof. Lorentz's own words as "always remaining at rest," and "endowed with a certain degree of substantiality."

In the *Monist* (vol. xxiv., No 1) Mr. Leonard T. Troland, under the title "The Chemical Origin and Regulation of Life," combats recent views on vitalism, that "cult of incompetence" in biology. The position taken up is that "a single physico-chemical conception may be employed in the rational explanation of the very life phenomena which the neo-vitalists regard as inexplicable on any but mystical grounds. This conception is that of the enzyme or organic catalyst." The thesis is developed along five distinct lines, the author maintaining that this conception will ultimately prove adequate to resolve such fundamental mysteries as the origin of living matter, the origin of organic variation, the problems of heredity, the mechanism of individual development, and the nature of physiological regulation in the mature organism.

An important method for the rapid estimation of zinc in coinage bronze and similar alloys is described by Dr. T. K. Rose, Assayer to the Mint, in a paper read before the Society of Chemical Industry (vol. xxxiii., No. 4). In this method the zinc is volatilised away by heating one gram of the alloy in a carbon crucible for two hours at a temperature of about 1375° C. Strictly speaking, this is not an entirely new method in principle, having been described many years back, but it is a process that has never come into general use. Dr. Rose has now made the method a perfectly practical one by accurately defining the conditions which are necessary for success. The main advantage of the method lies in the great saving of time and the avoidance of troublesome chemical manipulations.

The use of catalysis in organic syntheses has come into increasing use in recent years. In the current number of the *Comptes rendus* (No. 14, April 6) additional details are given by MM. Paul Sabatier and A. Mailhe on the advantages of manganous oxide as a catalytic agent in the synthesis of aldehydes and ketones. A fatty acid mixed with an excess of formic acid passed over a column of manganous oxide at a temperature of 300° C. to 360° C. gives the aldehyde corresponding to the acid, the yields being from 50–70 per cent. of the theoretical. The authors describe the preparation by this method of six aldehydes. With the same reagent adipic acid gives *cyclo*pentanone in 80 per cent. yield, and β-methyladipic acid gives β-methyl*cyclo*pentanone. Manganous oxide is cheap, and preserves its catalytic properties over a long period.

Oil-seeds, oils, fats, and waxes are the subjects dealt with in a recently issued collection of "Selected Reports" from the Scientific and Technical Department of the Imperial Institute (No. 88, Colonial Reports—Miscellaneous, Cd. 7260). The publication includes all the more important reports on the above-mentioned products made to the Colonial, Indian, and other Governments during the years 1903 to 1912. A large number of seeds and oils have been analysed and otherwise tested by the department, the object in view being to give information as to the yield and nature of the oil obtainable from the seeds, and the possibility of utilising the products commercially. The reports proper are preceded by a short introduction explaining the classification of the oils into groups, and the meaning of the analytical terms employed in the descriptions. Among the more interesting memoirs is one on the utilisation of para rubber seed, which contains a drying oil possessing properties very similar to those of linseed oil; it is concluded that the kernel is a valuable economic product. One of the longest reports treats of the palm-oil industry in British West Africa. Large areas of oil-palm forest still exist almost untouched, and though the native processes for extracting the oil are crude and wasteful, it is considered that no failure of supply is likely to occur in the immediate future.

The April issue of Mr. C. Baker's list of "Second-hand Instruments for Sale or Hire" is now available, and can be obtained post free on application to 244 High Holborn, London. The catalogue contains descriptions of nearly 2000 pieces of scientific apparatus, amongst which modern microscopes and objectives, telescopes and spectroscopes, take a prominent place. The preface to the catalogue points out that every instrument is guaranteed to be in adjustment, and that customers may in certain circumstances have instruments for three days on approval.

Messrs. Dulau and Co., Ltd., 37 Soho Square, London, W., have just issued their Catalogue 65 dealing with works on recent and fossil ichthyology which they are offering for sale. The list contains 1740 entries, and includes periodicals as well as books on every branch of the science concerned.

OUR ASTRONOMICAL COLUMN.

April Shooting Stars.—Mr. W. F. Denning writes:—On Tuesday night, April 21, there may occur a rich return of the April meteoric shower. It is uncertain, however, what this year's aspect of the display will be, as the periodic time is not known. There were brilliant returns in 1803 and 1851, and there is indication that the brighter and more abundant exhibitions of this stream occur at intervals of sixteen years. If so, it ought to be well seen in 1915, but in view of the doubts remaining, the phenomenon should be watched every year, for negative evidence is sometimes useful. The Lyrids probably form a moving radiant like the Perseids, the motion being to the eastward one degree a day. This feature should be attentively looked for, but the shower is usually a very brief one, and meteors directed from it are rarely seen before April 19 or after April 22. This year the moonlight will be almost absent from the sky at the time of the maximum, so that with a clear atmosphere the circumstances will be highly favourable for its observation.

Nova Geminorum No. 2.—A number of observations has recently come to enrich the general store of data regarding this nova, and some of these later contributions possess a high degree of importance. This applies especially to a memoir appearing in Bulletin No. 3 of the Imperial Academy of Sciences, St. Petersburg, communicated by M. N. V. Vojtkevič-Poliakova, of the Pulkova Observatory. Unfortunately for English students this memoir is printed in Russian, but it contains an excellent plate giving reproductions of eight spectrograms of the new star. It is at once apparent that evidence has been obtained regarding the transient proemial phase during which the nova exhibited a dark-line spectrum showing characteristics resembling that of Procyon. Although the Harvard spectrograms had established beyond any possibility of doubt that this nova had indeed passed through this so much questioned stage, the value of independent confirmatory evidence need not be insisted on. The series of thirty-six spectrograms discussed in the paper extends from March 15, 1912, to October 8, 1913, and includes two excellent plates taken on the first date, and others for March 16, 17, and 18. The wholly dark-line stage so happily caught at the Harvard College Observatory was missed at Pulkova, but the leading Procyonian features are still predominant in the first two spectra, although the bright-line spectrum is making its appearance, and on March 16 predominates, but the H and K lines may still be seen quite plainly.

Another spectroscopic paper comes from the Catania Observatory, and is the work of Dr. Vittorio Fontana. It appeared in the Memoirs of the Società Spettroscopisti Italiani, vol. ii., series 2, pp. 201–10.

Additional observations of the light changes of this nova are given in two papers published in No. 4720, *Astronomische Nachrichten.* In the first of these von J. Kasansky, Moscow Observatory, presents fifty-seven determinations, ranging from the time of the discovery (March 14, 1912) to March 27, 1913. The observed magnitudes range from 3·58 (H.R.) on the former to 8·76 on the latter date. By March 16 the brightness of the nova had fallen nearly two magnitudes to 5·54. The magnitudes for the greater part of the series are also stated in terms of the Potsdam scale, and can thus be at once compared with the values given in the other paper, which is by Sig. Eugeni Guerrieri, Capodimento Observatory. This series includes 139 determinations of magnitude between March 28, 1912, and April 29, 1913. The light curve exhibits the typical characteristics of nova variability. For the few common dates the two series show good agreement.

Diurnal Variations of Latitude.—During last year M. Jean Boccardi, in discussing the results of his observations for latitude made by the method of Struve, drew the conclusion that an effect of lunar attraction was suggested by displacements from the vertical. As these displacements were considerably greater than those which he could calculate by theory he was led to conclude that these latitude variations were caused by geological conditions special to the place of observation. Having subsequently become acquainted with M. Schumann's researches on latitude variations in which he could trace undulatory curves showing diurnal variations of latitude, M. Boccardi has completed some diagrams showing the march of the latitude values. These diagrams are not published in the communication which he sends to the *Comptes rendus* of the Paris Academy of Sciences (February 9, 1914, No. 6); tables only are given, but he states that the maxima and minima values of the latitude obtained with the four stars which he has observed follow one another at intervals which correspond to the movement made by the moon in right ascension during the corresponding intervals of right ascensions between the stars. Thus the action of the moon seems to be demonstrated.

A Perpetual Calendar.—We have received a neat perpetual calendar, "Alle Jahreskalender auf einem Blatt," by "Dr. Doliarius," of Leipzig (B. G. Teubner). It is of postcard size, and seems well adapted to the requirements of clergymen and others. Three tables are given: (1) the dates of Easter according to the Gregorian calendar, 1582–2000; (2) the corresponding Julian dates, 1470–2004; and (3) a double enumeration of the days of the year arranged in thirteen columns in such a way that any seven consecutive columns are complete in themselves. A separate card frame is supplied having a slit which fits over the width of seven columns, and as the top of the slit is marked with the seven days of the week an annual calendar is displayed when the frame is placed over table (3). The correct position of the frame is determined by a marked space which is adjusted to the date of Easter for the year required according to the indication of table (1) or (2). The manipulation of the calendar is quite simple, and furnishes the dates of the principal church festivals very readily.

PRIMARY EDUCATION AND BEYOND.

THE national system of education adumbrated by Lord Haldane and other responsible authorities about a year ago has not yet taken shape, but meanwhile a measure embodying some of the prospective reforms in the domain of elementary education has passed its second reading in the House of Commons. We refer to the Children (Employment and School Attendance) Bill introduced by the Hon. R. D. Denman, member for Carlisle. The principal changes in the law proposed by this Bill are the grant of optional powers to local education authorities to extend the age of leaving school from fourteen years to fifteen; no exception from school attendance to be allowed for children under thirteen years; the abolition of the existing half-time system; the grant to local education authorities of power to require attendance at continuation classes; and the prohibition of street trading by boys under fifteen and girls under eighteen.

While we await the complete scheme of national education promised by the Government, it may be worth while to state the present position as regards those points of primary education for which provision is made in Mr. Denman's Bill, particularly in the matter of continuation classes, which is likely to be given much attention in the near future. Mr. Pease, the President of the Board of Education, has recently made a personal examination of the continuation-school systems in France and Germany; and we may expect to hear something of his impressions and conclusions when he makes his next statement to Parliament upon the work and outlook of his Board.

As the law stands in England at present, a child can leave school immediately it reaches the age of fourteen years, whatever its position in the school may be. Partial exemption from school in order to enter employment during certain hours of the day can be obtained at the age of twelve years, or at eleven in agricultural districts, if the standard of exemption fixed by the local education authority has been passed. This is the "half-time system"; and since the year 1907–8 there has been a continued decrease in the number of children who have taken advantage of it; or rather of whom parents and employers have taken advantage by exploiting their labour. The latest report of the Board of Education (Cd. 6707) shows that there are about 70,000 half-timers, and that nearly 59,000 of these belong to the districts of Lancashire and Yorkshire engaged in textile industries. As about half a million children normally leave the elementary school every year, it is surely not much to insist that the seventy thousand partial exemption pupils should be compelled to remain like the rest until they have reached at least the age of thirteen years. If the age of compulsory attendance at school of all children were raised to fourteen years, the nation would benefit by the enaction of such a law.

But whatever may be the leaving age of the elementary-school career, the work and influence of the school are rendered largely nugatory unless the pupil passes at once into a system of continuation classes. In the "unguarded years" which follow elementary-school life, almost all that has been learnt is forgotten, and when later the thoughtful youth awakes to a sense of his deficiencies, he has to pick up in evening classes the threads carelessly thrown down a few years before. The voluntary attendance at evening classes in technical and other schools is a measure of the desire for further education among youths and girls who are arriving at years of discretion. The adult who, after a day's work in the workshop or office, devotes several hours a week to classes and preparation throughout a session shows by this very act that he has the spirit of perseverance and industry which leads to success. The number of such students is large—about 700,000—but when it is critically examined and compared with what it might be, the result is disappointing. After the first month or so of a session, when the novelty has worn off, there is a steady fall in the attendance at evening classes; and about 18 per cent. of the 700,000 students at the beginning fail to complete the small minimum of attendances—not more than fourteen hours—required in order to enable State grants to be paid toward their instruction. The average number of hours of instruction received by all enrolled evening students in the English county boroughs (including London) is fifty-eight, this number being about the same as that of the working periods in two weeks of ordinary school life. It is evident, therefore, that very many of the students who enter evening classes are not likely to receive instruction of any substantial value.

The great bulk of the work done in evening classes is of the continuation-school type; and it is with the juvenile students attending such classes that we are now particularly concerned. Nearly one-half of the students are under seventeen years of age, and this number—roughly 300,000—represents the position of continuation classes in England. The Board of Education estimates that the juvenile students attending evening classes do not make up more than 13 per cent. of the population between the ages of fourteen and seventeen, after making allowance for those still at elementary and secondary schools. The failure of the classes to attract anything like a sufficient proportion of the possible students is regretfully recognised by the Board as "one of the weakest links in the educational system of the country."

The voluntary system of continuation classes breaks down just when it is most needed. It is essential that children should attend such classes immediately upon leaving the day school, and not after several years' interval, as is usually the case at present. On account of this break of continuity, many evening classes are for adults who have forgotten their early schooling, and have to begin again with elementary subjects at a time when they want to take up technical studies with the view of advancement or of increased efficiency in their respective vocations. If most of the 223,000 students above twenty-one years of age attending evening classes had received suitable continuation education after leaving the elementary school, they would be capable of much higher work than is possible at present. The commonest complaint of teachers in technical institutes is that the students lack the basis of elementary knowledge upon which advanced technical instruction can be built; and the defect is largely due to the absence of a system of compulsory attendance at continuation classes. A few years ago the City and Guilds of London Institute, in conjunction with the Board of Education, took active steps to encourage the attendance of young persons engaged in different trades at evening continuation classes, with the view of their acquiring a competent knowledge of English, arithmetic, drawing, and elementary science before entering upon their first year's course of training in technology. Notwithstanding the establishment of group courses, and an increased grant for the attendance of students at evening continuation classes, it has not been found possible to insist upon evidence of attendance at such classes prior to the admission of students to a technical school. We have well-equipped technical institutes and colleges with teachers capable of giving instruction in the highest branches of specialised education, but most of the adult evening students, though familiar with the practice of their particular trades, are unable to take advantage of the instruction offered because they have forgotten what they learnt at school.

Advance in technical education properly so called is thus connected very closely with the problem of continuation classes; and the only satisfactory way of solving the problem is by a system of compulsory attendance at such classes from the time a boy or girl leaves the elementary school up to seventeen or eighteen years of age. The main difficulties are to decide when the classes should be attended, and to devise the means of enforcing attendance. Ought the hours of attendance to be in the day and within the number of hours of employment of young persons, or ought they to be taken out of the juvenile's own leisure time after the day's work is done? Some large firms make it a condition of employment of their apprentices that continuation classes should be attended for a specified number of hours weekly, but unless facilities are given for such attendance the objection can be made that the firms are increasing the number of working hours sanctioned by Acts of Parliament. It is not surprising, therefore, that trades unions have come into conflict with this system. Assembled representatives of labour, and of teachers, have on several occasions expressed their conviction that attendance at continuation classes should be counted as working hours under the Acts of Parliament limiting the hours of juvenile labour weekly. Only the most enlightened employers will be prepared to accept these conditions of continuation classes for the young persons in their employ, so that even when the principle of compulsory attendance is accepted the actual establishment of it in practice presents real difficulties.

Probably the most adaptable plan will be found in a modification of the system which has worked successfully in H.M. Dockyard Schools for many years. Apprentices in the dockyards have to attend school for twelve hours a week (two afternoons and three evenings). The Admiralty gives the apprentices seven and a half of these hours, and pays for this time as if it were spent in the workshop; the remaining periods have to be taken from the boys' own free time. Both employer and apprentice have thus to make some sacrifice; and the plan may well be taken as a model upon which a compulsory continuation-school system could be constructed.

This principle is embodied in the recommendations as to continuation schools drawn up by the education committee of the British Science Guild, and adopted at the last annual meeting of the guild. The recommendations represent the most practical scheme with which we are acquainted, and they are, therefore, here given in full:—

(1) Local education authorities should be required to make provision for the attendance up to seventeen years of age at suitably equipped continuation schools of all young persons above the age of fourteen years within their respective areas who are not otherwise receiving suitable education. In these schools, particular attention should be given to the continuance of manual and physical training commenced in the elementary schools, together with instruction having some relation to the occupations of the pupils.

(2) Employers should cooperate with local education authorities with the view of securing the attendance at continuation schools for at least six hours weekly during forty weeks a year of all young persons in their regular employment under seventeen years of age. As a practicable means of ensuring such attendance, it is suggested that the following conditions should be observed:—

(i) It should be illegal to employ any young person under seventeen years of age who is not in regular attendance at continuation classes for at least six hours weekly unless reasonable cause for absence be assigned.

(ii) In order to avoid undue strain upon young persons, after working the usual hours during the day, employers should grant them at least three hours a week out of the ordinary working hours for the purpose of attendance at continuation classes. It would, however, be most desirable where possible for employers to grant the whole six hours during the working day. Many young people would undoubtedly add evening hours of attendance, actuated by the desire for self-improvement.

(iii) The education authority should notify employers of any young persons in their employment who are not attending day or evening continuation classes for at least six hours weekly, in order that the employers may take the necessary steps to ensure attendance at such classes.

This scheme may not satisfy all the demands of extreme advocates of compulsory continuation schools, but it has the merit of reasonableness on its side, and its enforcement is well within the range of practical politics. It approaches the standard of requirement of continuation schools in many parts of Germany, where laws have been passed, and are in active operation, for the compulsory attendance for about 240 hours per annum, or six to eight hours a week, of all children who have left school, and until they are seventeen years of age, chiefly in day continuation schools, and within the hours normally devoted to labour; and its adoption would help to bring us in line with progressive educational movements abroad.

The most complete system of continuation schools on the Continent is at Munich, where every boy not attending a secondary or other day school is compelled to attend continuation classes for eight or nine hours weekly, in the daytime, for three or four years following the termination of the elementary-school course at fourteen years of age. Munich has an average of 330 hours annually for the pupils under instruction in the continuation schools, under a system of compulsory attendance. In the county boroughs of England the average number of hours of instruction in the evening schools is only fifty-eight, and in the administrative counties forty-nine, while, as we have seen, 18 per cent. of the students receive less than fourteen hours' instruction in the year, and not more than 13 per cent. of the young people between the ages of fourteen and seventeen are in attendance at continuation classes. In county boroughs (including London) the attendance at continuation classes is about 18 per cent. of the available juvenile population, and in administrative counties not quite 10 per cent.; but the ratio varies greatly, being only 5 per cent. or less in seventy-one county boroughs and forty-nine county areas.

The success attained at Munich is due to the intimate connection between the teaching and the trade of the pupils; and the provision of workshops and laboratories for practical work as the centre of the entire organisation. The continuation schools are of two types—a highly organised kind for youths between the ages of fourteen and eighteen years during their apprenticeship, at which they receive instruction in specific relation to their trades, and a central school for girls at which three years' attendance is compulsory after the close of the primary-school career. For every trade in which there are thirty apprentices to attend continuation schools, special classes are provided; and there are at present fifty-six of these trade schools, as well as twelve general schools. It is in this direction, namely, that of close relation between the occupation of the pupil and the work of the continuation school, that advocates of compulsory continued education in England may hope to obtain the cooperation of employers. Our trade preparatory schools, which are attended by boys from twelve to fifteen years of age, who will afterwards be engaged in trade, represent roughly the type of school in which continuation classes can best be carried on.

It is useless to make continued education of primary-school pupils compulsory without the provision and adequate equipment of schools for practical instruction in close relationship with the occupations of the pupils. The schools should thus do something to relieve the monotony and extend the outlook of the young workman who, on account of the minute subdivision of manual labour, may spend his life upon one small detail of some product or process, and learn nothing beyond it. Industrial advance demands the production of intelligent and adaptable types of workmen; and practical continuation classes offer a means of training them which is impossible under modern conditions of manual work. Mr. J. C. Smail, organiser of trades schools for boys under the London County Council Education Committee, has recently studied in Germany the compulsory system of continued education for boys from fourteen to eighteen years of age; and we may appropriately give here a statement of the conclusions arrived at by him with regard to such schools, as they have a direct bearing upon the foregoing remarks, which were written before the report was published:—

(1) There has been, broadly speaking, a difference in ideals between Germany and Britain in the organisation of technical courses. Germany is aiming at benefiting the nation by training properly all the workers through definitely specialised courses. Britain has organised so that individuals may secure what they think best for their own advancement.

(2) The fundamental basis of any course of study for technical students must be their trade or employment. If this is recognised and acted on in the preliminary years from fourteen to eighteen there is little danger of work at more advanced stages, even if irregularly organised, being ineffective.

(3) Germany is aiming at making good citizens and has realised that a good citizen must be a good workman.

(4) Germany has come to believe that workshop training alone is insufficient to make a sound industrial nation; that it must be reinforced by adequate education specialised to trades.

(5) This specialised education must include specialised calculations, technology, drawing, and citizenship. Munich also believes in trade work in the compulsory schools, Berlin does not.

(6) Citizenship must be taught to enable the worker to recognise his individual position in the State, his position with respect to his employer and his fellow-workmen, his family and social duties, the relative position of his trade in his own country, and in the world's commerce and industry.

R. A. Gregory.

CYTOLOGICAL ASPECTS OF HEREDITY.

THE current number of the *Quarterly Journal of Microscopical Science* (vol. lix., part 4) will be of exceptional interest to students of heredity from the cytological point of view. Dr. L. Doncaster contributes a very useful review of the present state of the evidence with regard to the material basis of hereditary transmission and sex-determination, under the title, "Chromosomes, Heredity and Sex." He concludes that the arguments in favour of the view that Mendelian characters are determined by chromosomes, though very strong indirectly, are lacking in direct evidence. The direct evidence of a relation between chromosomes and sex-determination is much stronger, and various cases are discussed. The phenomena of sex-limited inheritance, now known to occur in various groups of the animal kingdom, taken in conjunction with this relation, afford strong support to the view that the chromosomes play a very important part in the transmission of Mendelian characters, although the part played by the cytoplasm must also be taken into account. With regard to sex-determination difficulties arise in connection with the fact that this has been shown in certain cases to be modifiable by environmental conditions, and it therefore seems probable that the sex chromosome is associated with a particular type of cell-metabolism, which in turn is responsible for sex-determination.

A very important contribution to the discussion is made by Dr. R. R. Gates and Miss Nesta Thomas in "A Cytological Study of Œnothera mut. lata and Œ. mut. semilata in Relation to Mutation." These authors find that in the "mutants" of the evening primrose known as "lata" and "semilata," fifteen chromosomes always occur instead of the normal fourteen. The peculiar characters of these mutants are thus shown to be associated with the presence of an extra chromosome, which they are believed to have acquired by the abnormal distribution of both chromosomes of one pair to the same daughter-nucleus in the reduction division, the actual occurrence of such abnormal distribution having previously been demonstrated by Dr. Gates. The authors maintain that mutations and Mendelian hybrids are not of the same nature but must be contrasted with one another, the former owing their origin to germinal changes (*e.g.* the presence of an extra chromosome), and the latter to recombinations of the parental characters. Dr. Gates adds a useful note on the meaning of the term "mutation," and the difference between "mutations" and "fluctuations."

THE CURRENTS IN BELLE ISLE STRAIT.[1]

THE behaviour of tidal streams and currents in Belle Isle Strait, described by Dr. Dawson, Superintendent of Tidal Surveys to the Canadian Government, in a number of reports, the latest of which are before us, affords an example of the manner in which the various elements in a complex current may be distinguished one from the other. As the same may apply to other straits where the conditions are similar it should, therefore, be of more than local interest. The current in the strait is primarily tidal in character, and under normal conditions it will turn regularly; the flood running westward, and the ebb eastward with equal velocity. When, however, the moon is in high declination the resulting diurnal inequality causes one flood and one ebb in the day to be twice as strong as the other; the difference being much greater than that between ordinary or average springs and neaps.

In addition to the tidal fluctuations, the water has a tendency to make through the strait in one direction more than the other, thus causing a continuous gain to eastward or westward, as the case may be. The overbalance in one direction which is superimposed upon the usual tide elements to which the term element of *dominant flow* is given, introduces complications, because larger in relation to the strength of the tidal streams, especially at neaps when weak. It may, in fact, be so strong as to reverse the ordinary tidal streams or prevent them from turning, although the fluctuation in velocity be well marked.

The dominant flow, it is stated, cannot be attributed to local wind, because wind would produce merely a surface drift, whereas the dominant flow is that of the whole body of the water. It is, however, apparently

[1] The Currents in the Gulf of St. Lawrence. By Dr. W. Bell Dawson. (Ottawa: Government Printing Bureau, 1913.)

due to meteorological causes affecting, it is suggested, changes in the Labrador current or in the volume of water passing into the Gulf of St. Lawrence, occasioned by the distribution of barometrical pressure. The highest tides have been found to occur with winds from between north-east or north-west, and the lowest with winds from west or south-west.

The probable direction of the dominant flow may be inferred from the general weather conditions of the region, and from the presence or absence of floating icebergs in the strait; there being, as a rule, icebergs in the offing of the strait. With a dominant westward flow, bergs afloat in the offing will drift into the strait, whereas with a dominant eastward flow the strait is free from floating bergs; for the icebergs near either shore are certain to be aground and are therefore no guide; they may have been there for weeks. Even in the middle of the strait a berg, if large enough, may ground.

Briefly, the best indications are as follow:—The strait being clear of floating bergs, the barometer moderately high and rising or high and steady, a dominant flow to eastward is probable. There being floating bergs in the strait, and a barometric depression passing southward, indicated by broken weather, a dominant flow to westward is probable; and after a gale from north or north-west certain. The temperature of the water as an indication cannot be relied on.

On the whole the westward flow probably predominates in May and June; and, although less pronounced, the eastward flow is the more frequent in summer; while from September onwards the flow is more to the westward than to the eastward.

As regards the velocity of the current, when the moon is at its maximum declination and there is no dominant flow; at spring tides the strong flood and ebb velocity is 2·27 nautical miles; the weak flood and ebb 0·72 mile. At neaps, strong flood and ebb, 1·04 miles; weak flood and ebb, 0·32 mile. The greatest rates of dominant flow, observed during two seasons, considered separately, were:—Westward average, 1·69 nautical miles running continuously, but fluctuating from 2·65 miles to 0·64 with flood and ebb; eastward average, 1·30 miles to 0·50 mile with ebb and flood.

Under combined conditions the highest velocities observed were:—Westward during flood period, 3·45 nautical miles; eastward during ebb, 2·83 miles.

SUPERSTITIONS RELATING TO WEATHER.

IN an interesting article in the February number of *Himmel und Erde*, Prof. G. Hellmann, director of the Berlin Meteorological Institute, discusses some of the widespread notions generally included in the above heading. At the same time, he points out that some theories long believed in, although afterwards proved to be false, cannot be classed among superstitions.

The subject is divided into three parts, but we can here only refer to a very few typical cases. (1) That relating to the character and causes of meteorological phenomena. This takes us back to mythological times when all the forces of nature were personified; even to-day Jupiter Pluvius is frequently spoken of. Many of the present-day ideas still savour of superstition, *e.g.* the occurrence of thunderbolts, the *return* of a thunderstorm at a later time of the same day, and the belief in equinoctial gales. With regard to the latter, the author refers the idea to Greek and Roman origin, as such storms are prevalent in the Mediterranean regions.

(2) The possibility of predicting weather for any period. Many old sayings have been handed down from father to son; while most of them are based on unsound conclusions, some of them are good, *e.g.* the strengthening cold with lengthening days, the coloration of morning and evening sky, etc. Of modern sayings, that relating to the "ice-saints" (May 11–13) has been attributed both to cosmical and terrestrial sources. Investigations have shown that cold periods in May may occur in any of the three decades (especially the second), but cannot be referred to any special days. The moon's influence is still believed in by millions of people, notwithstanding the proofs given to the contrary.

(3) The possibility of influencing the weather and of making any special kind. This idea extends back to earliest times, and is still prevalent in some parts. One of the principal objects was the warding off of hail- and thunder-storms. Modern hail-shooting has proved to be ineffectual, but it will in all probability return later on in another form. The practice of bell-ringing for the prevention of thunderstorms was at one time much favoured, and is still in vogue in a few alpine districts. The belief in the possibility of making weather is very old, but its origin cannot be exactly fixed. Unsuccessful attempts at rain-making have frequently been made in recent times, but Europe appears to have been practically free from this superstition.

Prof. Hellmann's researches relating to the early history of meteorological questions are always very instructive; in this article he points out that at times it is not easy to draw a sharp boundary line between knowledge, belief, and superstition.

THEORIES OF ORE-GENESIS.[1]

THE subject of ore-genesis is of the greatest importance to the mining engineer, for it is evident that every forecast of the continuity of an ore-body beyond the limits of the ore in sight must, if it is not to be entirely empirical, rest on some hypothesis as to origin. This field of inquiry has since the beginning of this, and during the latter half of the past century, riveted the attention of the best mining geologists in all parts of the world. In a comparatively small interval of time, our knowledge has advanced by leaps and bounds, and many important principles governing ore-deposition have been firmly established.

It was, however, preceded by a long period, which, although fertile in suggestion and hypothesis, was not one of real progress because, contrary to the Baconian principle, "Non fingendum aut cogitandum sed inveniendum quid natura faciat aut ferat," the theories advanced were not founded on ascertained facts.

Prior to the sixteenth century the metallic contents of ore-veins were supposed to have been determined by their orientation in regard to the planets; and Agricola (1494–1555) was the first to formulate a reasonable genetic theory. Reduced to its simplest terms, Agricola's view was that ore-channels (*canales*), formed by erosion, had been filled by metallic minerals deposited from solution. These solutions, or juices (*succi*), as Agricola terms them, were waters of meteoric origin which, under the influence of heat, had taken mineral matter into solution.

From the time of Agricola to the end of the eighteenth century the mines of Saxony produced nearly all the writers on vein-formation. Such were Rösler, Becher, Henckel, Hoffmann, Zimmermann, von Oppel, von Charpentier, and von Treba.

Becher and Henckel, who wrote in the beginning

[1] From the presidential address delivered at the Annual Meeting of the Institution of Mining and Metallurgy, on March 26, by Dr. F. H. Hatch.

of the eighteenth century, supposed the metallic constituents of veins to have been produced by the action on pre-existing stony and earthy matters of subterranean vapours arising from certain processes of "fermentation" in the bowels of the earth.

In 1749 Zimmermann put forward a hypothesis which clearly had in it the germ of the modern theory of metasomatism. He ascribed the origin of veins to a transformation of the rocks into metallic minerals and their accompanying vein-stones, along certain directions now marked by the course of the veins, the solvents that effected the alteration finding a path through innumerable small rents and other openings in the rocks.

But Zimmermann applied his theory indiscriminately to explain the origin of all veins, including those that, by common agreement, are now considered to have been formed by the filling of fissures without replacement. Von Treba, in supporting Zimmermann's view, insisted particularly on the far-reaching changes effected in rocks by circulating waters, especially when aided by heat. "I am persuaded," he wrote in 1785, "that there is constantly going on in our mountains a variety of transformations, compositions, and decompositions, which not only take place at present, but will continue to the end of time."

According to Gerhard, who wrote in 1781, waters circulating through the rocks adjacent to a vein become charged with certain of the metallic and earthy substances contained in them. Passing through the crevices and interstices of the rocks to the larger rents and fractures, they deposit their mineral burden in cavities which, when filled, become veins. It will be seen that Gerhard's hypothesis must be regarded as a precursor of the more modern theory of *lateral secretion.*

To von Oppel belongs the credit of having shown that mineral veins were largely the filling of fault-fissures, a principle which up to that time does not appear to have been clearly recognised.

At the end of the eighteenth century the mining world was dominated in all matters relating to ore-genesis by the famous Freiberg professor, Abraham Gottlieb Werner, who insisted that all veins, including those that we now term "intrusive dykes," had resulted from the filling of contraction-fissures open above and connected with the primeval universal ocean, which according to the Wernerian doctrine covered the globe and contained in solution all the necessary materials for the formation of its crust. These waters, descending into the fissures from above, deposited the vein minerals by chemical precipitation.

This Neptunist view was in the beginning of the nineteenth century attacked and finally overcome by Hutton and his Plutonist or Vulcanist school. Unfortunately, however, the Plutonists went to the other extreme, and would not allow even ore-veins to have any other than an igneous origin: "The materials," wrote Playfair, "which fill the mineral veins were melted by heat and forcibly injected into the clefts and fissures of the strata."

But Hutton's broad generalisation, even with the important modifications of Elie de Beaumont, Daubrée, and Durocher to the effect that many of the metallic ores had been deposited from vapours and solutions emanating from cooling igneous magmas, was soon discarded in favour of the deposition from waters of meteoric origin; and an animated discussion was maintained for half a century on the respective merits of the *descensionist, ascensionist* and *lateral secretionist* theories; or, in other words, whether the mineral burden of the circulating waters instrumental in vein-formation was derived from superficial rocks, from deep-seated sources, or from the wall-rocks of the veins themselves.

The chief supporters of the modified form of the ascension theory here alluded to, which must, of course, be distinguished from De Beaumont's *ascension by emanation,* were Stelzner and Posepný. They argued that the ground-water (originating by precipitation from the atmosphere) descends by capillarity through the interstices of the rocks to deep-seated regions, and thus acquires a high temperature and pressure, and, consequently, a vastly increased solvent power, whereby in its passage through the rocks it is enabled to take up certain of the mineral substances there disseminated in a minute form. At a certain depth the water moves laterally towards open conduits, on reaching which it ascends towards the surface, depositing its mineral burden in proportion to the decrease of temperature and pressure.

It has been seen that the theory of lateral secretion, or the derivation of the mineral contents of veins by an aqueous leaching of the country rock, was advanced in a crude form as early as 1781 by Gerhard; but it remained a mere hypothesis without the support of ascertained facts until the middle of the nineteenth century, when the chemical work of Bischof, Forchhammer, and Sandberger definitely established two important facts in support of the theory, namely:—(1) That the gangue of ore-veins varies in correspondence with the wall-rock; and (2) that the heavy metals occur in minute traces in certain of the igneous and sedimentary rocks constituting the "country" of ore-veins.

Sandberger's researches were specially directed to prove that the heavy metals (gold, silver, copper, lead, etc.) are contained in the common ferro-magnesian silicates (namely, the micas, hornblendes, and augites) of the igneous rocks; and having satisfied himself on this point he was led to extend his investigations to the sedimentary rocks, with the result that small quantities of the heavy metals were found in the sediments of all ages, and especially in the slates of the older systems. Whether, however, they are there present as constituents of sporadic fragments of ferro-magnesian silicates derived from igneous rocks, or as sulphides that were introduced during the secondary mineralisation connected with ore-deposition, was not satisfactorily settled by Sandberger's researches. The more recent work of Don, carried out on a great variety of material, tends to show that the ferro-magnesian silicates do not carry gold or silver in amounts determinable by chemical analysis. Where the rocks examined by him were found to contain these metals they were present as a constituent of sulphides, such as iron pyrites, pyrrhotite, mispickel, chalcopyrite, and galena, which in most cases are secondary introductions.

But long before this the inapplicability of lateral secretion as Sandberger conceived it had become apparent; and the theory became the subject of vigorous attack on the part of Stelzner and Posepný.

Lateral secretion, in a much more extended sense and in combination with the ascension theory, is advocated by Van Hise. Van Hise's view may be briefly summarised thus: the meteoric waters, after penetrating the surface, are widely scattered through the rocks in innumerable small openings as they travel downward to great depths in the earth's crust. With steadily increasing temperature and pressure they take up mineral matter. The downward movement ultimately develops a lateral component, by which the waters are carried to the larger openings. During this process, also, the waters continue to take material into solution. In the larger openings the waters ascend with decreasing temperature and pressure, and there the ores are deposited.

It will be seen that this view is a combination of the ascension and the lateral secretion theories, and presupposes the existence of a continuous sheet of water in circulation between the ground-water level and the lower limit of the "zone of fracture," no circulation being admittedly possible in the underlying "zone of flowage." The weak point in Van Hise's assumption of a "sea of underground water" lies in the fact that deep mines are usually found to be dry, the drainage being confined to the upper levels. This, for instance, is the experience in the copper mines of Lake Superior, in the gold mines of the Rand, and in those of Bendigo. Van Hise, in reply to this criticism, attributes this dry zone to the closing of the passages by cementation; but the restriction of the ground-water circulation is equally fatal to the meteoric derivation of deep-seated thermal springs and other phenomena connected with vulcanicity.

In recent years there has been a partial reaction to igneous views. Thus certain classes of ore-deposits are now held to have been formed by a *differentiation of igneous magmas* prior to consolidation. Such, for instance, is the origin ascribed to certain titaniferous iron-ores in basic eruptives, chromite in peridotites, nickeliferous pyrrhotite in norite, and primary platinum in ultra-basic rocks. Similarly pegmatites, and even some quartz-veins, are considered to have originated by the consolidation of the aqueo-siliceous residuum of a slowly cooling granite magma.

But more important in its application to ore-deposition than *magmatic differentiation* is the theory which Vogt has founded on the metalliferous emanation hypothesis, by which Elie de Beaumont and Daubrée sought to explain the origin of tin-ore deposits. According to the *pneumatolytic* theory, certain *agents minéralisateurs*, such as fluorine, chlorine, sulphur, phosphorus, silicon, and boron, have the property of forming with the metals volatile compounds, which escape from the granite-magma as gases with low critical temperatures (the *aura granitica* of Elie de Beaumont). These compounds ascend through already formed fissures in the overlying rocks, or force their own passage by attacking the minerals that compose them. In this manner, for instance, cassiterite, wolfram, tourmaline, fluorspar, topaz, beryl, axinite, datolite, apatite, etc., are deposited either in the granite itself, or in the sediments comprised within its metamorphic aureole.

Closely connected with pneumatolysis in the rôle ascribed in ore-deposition to the so-called *magmatic waters*, a term that has come into use for water not of atmospheric origin, but dissolved or occluded in some way in molten magmas, from which it separates by liquation and distillation on the fall of temperature and pressure. In it are concentrated the substances that (at the existing temperature) are more soluble in water than in the silicate magma.

Suess, in an address on the Karlsbad springs, delivered in 1902, directed attention to the connection existing between thermal springs, vulcanicity, and ore-deposition. He applied the term *hypogene* or *juvenile* to thermal springs (like those of Karlsbad) which, originating in the depths of the earth's crust, bring water to the surface for the first time. Such hot springs are, in fact, the last survivors of vulcanicity, being the relics of a late stage of fumarole activity. Their mineral content comprises readily soluble compounds of the alkalies and alkaline earths, together with, and partly in combination with, sulphur, chlorine, and carbon dioxide, the less soluble metallic compounds having already been deposited as ores at lower depths in the earth's crust. According to Suess the after-products of eruption vary with the temperature; in the earlier (pneumatolytic) *phases of emanation* the gases are dry and their deposits (such as tin-ore and its accompanying boron, fluorine, tungsten, and uranium minerals) are the products of sublimation. At a later period, strongly alkaline magmatic waters are given off, and to these are attributable the *sulphide* and *arsenide phases* of vein-formation, *e.g.* the deposition of iron pyrites, chalcopyrite, primary bornite and chalcocite, enargite, galena, blende, etc.

But although, as we have seen, waters of meteoric origin have been displaced from their pride of place as agents of deposition for what we must term the primary sulphide ores, they are undoubtedly the formative agents for a considerable number of ore-deposits, including the products of oxidation, chlorination, and reduction above the permanent water level, and the secondarily enriched ores usually found immediately below the junction of the zone of oxidation with the zone of primary sulphides. So important are the functions of the vadose waters (to use Posepný's term for the shallow water circulation) in dissolving and redepositing at a lower level the ores of copper in a concentrated form, that it has been confidently stated that the bulk of the copper production of the world, not alone in the past, but also at the present time, is drawn from the zone of secondary enrichment. This view will, perhaps, appear exaggerated in the light of the results recently obtained by Sales at Butte; but for the majority of the great copper deposits of the world it may still pass unchallenged.

In the same way, vast deposits of high-grade iron-ore have been formed as the result of secondary enrichment, but under entirely different conditions from those that determine copper-ore enrichment. Thus the hæmatite ores of Lake Superior are believed by Van Hise to have been derived by the oxidising and concentrating action of vadose waers, from a low-grade cherty iron carbonate originally deposited under water as a chemical sediment; and he draws the important conclusion that "the ore-bodies cannot be expected to extend beyond the depth to which the descending waters may bear oxygen and precipitate iron oxide." He has "no doubt that vastly more high-grade iron-ore will be taken out in the Lake Superior region above the 1000-foot level than below it." If this be true, the iron-ores of that district, with more than 60 per cent. of metallic iron, are not inexhaustible.

The enrichment of gold-ores also takes place in the zone of oxidation; but in their case the action of the vadose waters results in an abstraction of the more soluble and less valuable metals, leaving behind a smaller quantity but a relatively richer material; in other words a diminution of the specific gravity of the whole material raises the gold tenor. Furthermore, there is also an increase in the fineness of the gold, due to the removal of a portion of the silver with which it is alloyed. The Mount Morgan mine in Queensland is a good instance of a gold-ore enrichment brought about by the vadose circulation; here the oxidation of a pyritic copper lode with subordinate gold has, by the removal of the sulphides of iron and copper, led to the formation of an upper zone of cellular quartz, in which the increased ratio of gold to vein-stuff was the *vera causa* of the richness of one of the premier gold mines of the world. But, as with increasing depth the mine-workings are extended below the oxidation-zone, the copper production is becoming more important than the gold yield.

The Witwatersrand Banket is another example. In this case the primary ore is auriferous iron pyrites disseminated in a quartz-conglomerate on which intense silicification during cementation has impressed the character of a quartz vein. The removal of the pyrites from the zone of oxidation, which extends to 200–300 ft. below the surface, left an enriched free-milling ore that gave marvellous returns on the amalgamation plates of the first Rand mills. Since the exhaustion of this high-grate, free-milling ore early in the history of gold mining on the Rand, the mines have been worked in low-grade unoxidised pyritic ore; and this has shown a gradual but steady impoverishment with increasing depth—a fact which supports the view that the gold of this deposit was precipitated by ascending thermal waters in proportion to their loss of temperature and pressure.

One of the most remarkable advances in the science of ore-genesis during the period under review is the recognition of the important rôle played by metasomatism in the formation of ore-bodies. The fact that the rocks adjacent to vein-fillings often contain small quantities of metallic ores similar to those composing the veins themselves, or are altered for some distance away from them, was observed at an early date; but its significance was very differently interpreted. The lateral secretionists pointed on one hand to ore-disseminations in the wall-rocks as indicating the source of the vein-filling, and on the other, to the

Classification of Ore-Deposits.

Nature of Deposit	Vehicle or Agent of Ore-Deposition					
	a. Molten Magmas	*b.* Gases and Vapours above their critical temperatures	*c.* Deep-seated waters, whether of magmatic or meteoric origin	*d.* Vadose Waters	*e.* Mechanical Agents such as moving water and wind	*f.* Chemical and Bacterial Agents in seas, lakes and swamps
1. IGNEOUS DIFFERENTIATES.	*Certain Massive Iron and Nickel Ores associated with basic igneous intrusions* (*e.g.* those of Sudbury in Ontario).					
2. CAVITY-FILLINGS.	*Injected Tin-Ores* (*e.g.* tin-pegmatites and tin-elvans on the margin of granite intrusions.	*Pneumatolytic Cavity-fillings* (*e.g.* tin quartz veins).	*Hydato-genetic Cavity-fillings* (many fissure veins).	*Superficial Fracture-fillings*, such as gash-veins in limestones and cavity-fillings (*e.g.* the hæmatite-ores of Cumberland).		
3. META-SOMATIC REPLACEMENTS.		*Pneumatolytic Replacements* (*e.g.* tin-greisens and many contact-deposits).	*Hydato-genetic Replacements.* (Many veins and massive deposits, also the Rand Banket).	*Some Lead and Zinc Ores* in *limestones. Iron-ores replacing limestones* (*e.g.* Cleveland). Some *lateritic iron* and *manganese deposits. Secondary enrichments of copper ores.*		
4. STRATIFIED DEPOSITS.			*Possibly some Sedimentary Deposits in which the cementing materials are ores of the metals.*	*Some Lead and Copper Ores interstitial in sandstones and shales.*	*Mechanical Concentrates in bedded deposits* (*e.g.* gold and platinum placers, stream-tin, iron-sands, detrital laterites and other metalliferous gravels and sands).	*Chemical and Bacterial Sediments* (*e.g.* lake- and bog-iron ores; clay-iron-stone and other sedimentary siderites; bog-manganese-ore and other sedimenttary manganese ores).
5. RESIDUAL DEPOSITS.				*Mantle-deposits* *e.g.* pisolitic and nodular ores of iron (Bilbao and Appalachian hæmatites and limonites of manganese (psilomelane) and of aluminium (bauxite).	*Eluvial Gravels formed near the outcrop of veins* (*e.g.* those of gold, cassiterite and wolfram, galena and zinc-ores).	

alteration of these rocks as a concomitant of the leaching that collected the filling material. But the ascensionists, whether belonging to the school of Elie de Beaumont and Durocher or to that of Stelzner and Posepný, recognised that the solutions from which the materials of the lode were precipitated, whether gaseous or liquid, also penetrated the walls and there caused certain deposits in the rock itself—metallic ores taking the place of some other mineral dissolved, as, for example, when cassiterite forms pseudomorphs after feldspar in the granite country of tin-veins. Much evidence favouring the latter view has since been accumulated. Thus Posepný described in 1873 the replacement of carbonate of calcium by carbonate of zinc in the Raibl deposits; and Pumpelly in the same year attributed the origin of the native copper of the famous Michigan deposits to metasomatic processes.

In 1881 Emmons showed that the Leadville silver-lead deposits had been formed by the replacement of limestone by galena, blende and pyrites, an alteration which, although chemically complete, left untouched the granular texture, joints, and other structural features of the original limestone. He pointed out that the resemblance of the altered rock to limestone was so perfect that, when the faces of the drifts were covered with dust, the observer was often completely deceived until the breaking of a fresh fragment with the hammer revealed the metallic gleam of galena beneath.

In a later paper he showed that many so-called fissure veins were not true cavity-fillings, but owed their origin to the metasomatic replacement of the rock material by substances brought in by solutions circulating along fault-fissures, through crush-zones or in sheeted zones. In such cases a vein may be formed by the replacement of the material enclosed between adjacent parallel fractures, true cavity-filling being only of a restricted character. Owing to the difference in character between replaced sheets of country rock and the filling of the fissures that divide them, deposits formed in this way sometimes possess a banded structure, which, however, is distinguishable from the normal "crustification" of vein-fillings. The whole subject has been admirably reviewed by Lindgren and by J. D. Irving in their well-known papers, in which will be found many illustrations of the potency of metasomatic processes in vein-formation.

Modern views on ore-genesis may be reduced to two principal lines of inquiry, one dealing with the agent or vehicle by which the metals have been collected, conveyed to, and deposited in the places where they are now found, and the other with the nature of the concentrates formed in the course of these processes.

Considering the latter first, ore-deposits are found to be either:—(1) Igneous differentiates; (2) cavity-fillings; (3) metasomatic replacements; (4) stratified or sedimentary deposits; (5) residual deposits. Of these, the sedimentary deposits comprise marine, lacustrine, and fluviatile accumulations, including placers.

Coming now to the agents or vehicles of ore-concentration, these are found to be:—(*a*) Molten magmas; (*b*) gases and vapours above their critical temperature; (*c*) deep-seated waters, whether of magmatic or of meteoric origin; (*d*) vadose waters; (*e*) chemical and bacterial agents in lakes and seas; (*f*) mechanical agents, such as moving water and wind.

It is possible, by combining the facts elicited by these two lines of inquiry, to formulate a genetic scheme of classification. For example, cavity-filling may be due to igneous injection, to gases and vapours above their critical temperatures, to deep-seated waters, or to vadose waters; again, metasomatic replacement may be brought about by gases and vapours, by deep-seated waters, or by vadose waters. By arranging these two series of relationships in vertical and horizontal columns respectively, all the various types of ore-deposits are obtained at their intersections; and in this way the classification shown in the table on p. 179 is obtained.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

It is announced in *Science* that provisions for the creation of a trust fund, said to be approximately 100,000*l.*, for the maintenance of male graduates of the Williamsport, Pa., high school at Cornell University are made by the will of Mr. A. D. Hermance. From the same source we learn that Mr. E. Palmer, a Princeton graduate, has offered to build and present to Princeton University a stadium costing 60,000*l.* Mr. Palmer is a son of the late Mr. Stephen S. Palmer, who was for many years a trustee of Princeton University, and gave large sums to the University, including the Palmer Physical Laboratory.

Many important recommendations are made in the report of the Royal Commission on the Civil Service just issued as a Blue-book (Cd. 7338). It is proposed to abolish the grades known as the Second Division, the Intermediate Class, the Assistant Clerks, and the Boy Clerks, and to substitute for them a new class, to be known as the Junior Clerical Class, to be recruited at the age of sixteen, at which many boys leave the public secondary schools. Another new class recommended is the Senior Clerical Class, to be recruited at the age of eighteen. In both cases the examinations for appointments in these grades are to be brought into close relation with the work of the schools. Other recommendations are:—(1) Greater facilities should be provided, especially in England and Ireland, for the progress from the primary to the secondary schools, and thence to the universities, of pupils capable of benefiting by secondary and university training respectively. (2) There should be closer coordination between the educational systems of the country and the Civil Service Examinations, and to this end the Treasury and the Civil Service Commissioners should consult more freely and systematically than hitherto with the Departments of Education before framing examination schemes. (3) The principle of open competition should be adhered to, and whenever it is applicable, extended. (4) The competitive examinations for recruiting each class of officer, administrative and clerical, should be adjusted in respect of the age of competitors and the subjects of competition to the stages of the educational system actually existing in the country. (5) The examinations should be directed to testing the natural ability of candidates, and the results of their education both with respect to acquirement of knowledge and the formation of mind and character. It should not be directed to testing proficiency in particular subjects which lie outside the normal scope of education.

SOCIETIES AND ACADEMIES.

London.

Linnean Society, April 2.—Dr. A. Smith Woodward, vice-president, in the chair.—W. **Rushton**: Structure of the wood of Himalayan Junipers.—W. B. **Turrill**: A contribution to the flora of Fiji.—Prof. C. **Chilton**: A new Amphipodan genus and species (family Dexaminidæ) from New Zealand.—Prof. E. B. **Poulton**: Mr. W. A. Lambourn's breeding experiments upon *Acraea encedon* (Linn.), Poulton, in the Lagos district of West Africa, 1910–12.

DUBLIN.

Royal Dublin Society, March 24.—Dr. J. H. Pollok in the chair.—Prof. John **Joly**: The local application of radium in therapeutics. The method now very often adopted in treating malignant growths with radium or its emanation is to introduce the radio-active substance, heavily screened with lead, into the tumour. This is a wasteful method, as the lead screen causes a loss by absorption of from 25–30 per cent. of the rays. The use of the screen is, however, necessary in order to cut off the more easily absorbed rays which otherwise would produce injurious effects close to the tube. If tubes containing much smaller quantities are used, screening need not be resorted to. One strongly charged tube may be replaced by a number of small ones, if the latter are in the convenient form of ordinary exploring needles. In conjunction with Dr. W. C. Stevenson the author has worked out a system enabling such needles to be charged with any required quantity of the emanation sealed into capillary glass tubes. By the use of these radio-active needles local injury is avoided, and a more controllable and uniform radiation is attainable. They can be made of any required length to reach more deep-seated tumours. An apparatus was exhibited permitting any desired number of capillary tubes to be sealed off at once, each containing a known charge.

PARIS.

Academy of Sciences, April 6.—M. P. Appell in the chair.—Paul **Sabatier** and A. **Mailhe**: The use of manganous oxide for the catalysis of acids. The preparation of aldehydes and pentamethylene ketones. Formation of the *cyclo*pentylamines (see p. 171).—R. de **Forcrand**: Potassium trioxide and the stability of the alkaline peroxides. Pure potassium trioxide can be obtained by heating the tetroxide to 580° C., the pressure being maintained at about 1 mm. The heats of solution and formation of the trioxide were determined.—G. **Charpy** and S. **Bonnerot**: Iron nitride. Iron in very thin foil, heated in a current of ammonia at 650–700° C., can be completely converted into the nitride Fe_2N. At higher temperatures the nitride dissociates, and it does not appear possible that this nitride could exist in the steel or iron of commerce.—A. **Schaumasse**: Observations of Kritzinger's comet (1914*a*) made at the Observatory of Nice. Positions are given for March 30, 31, and April 4.—Paul **Bruck**: The elements of comet 1914*a* (Kritzinger).—P. **Chofardet**: Observations and calculation of the parabolic elements of Kritzinger's comet (1914*a*) made at the Observatory of Besançon. Positions are given for March 31 and April 4.—J. **Guillaume**: Observations of Kritzinger's comet made at the Observatory of Lyons. Positions given for March 31 and April 4.—M. **Esmiol**: Observations of Kritzinger's comet made at the Observatory of Marseilles. Observation on April 4.—M. **Coggia**: Observations made at the Observatory of Marseilles on the same.—P. **Salet** and M. **Millochau**: The spectra of the chromosphere. The Stark effect due to the possible influence of the solar electric field is either absent or very small in the sun.—B. **Fessenkoff**: The distribution of the cosmic dust in the invariable plane of the solar system.—Arnaud **Denjoy**: Examples of derived functions.—A. **Buhl**: The integral form of the equations of Monge-Ampère.—A. **Hurwitz**: The critical forms of the inverse functions of integral functions.—Paul **Lévy**: The functions of Green and Neumann.—M. **Hadamard**: Remarks on the preceding paper.—G. H. **Hardy**: The zeros of the Riemann function $\zeta(s)$.—M. **Moulin**: The terminal curves of spirals: influence of the terms of the second order.—H. **Bourget**, Ch. **Fabry**, and H. **Buisson**: The atomic weight of nebulium and the temperature of the nebula of Orion. The strong double ultra-violet line $\lambda\lambda$ 3726, 3729, is attributable to no known gas. From a spectroscopic study by interference methods the atomic weight of the element, named nebulium, is found to be about 3. The temperature of the nebula is of the order of 15,000° C.—Maurice **Drecq**: The determination of the emissive power in the infra-red. Details of the construction of a very sensitive silver-bismuth thermocouple and of a new form of furnace for giving high black-body temperatures are given.—Jean **Bielecki** and Victor **Henri**: Contribution to the study of tautomerism. A quantitative study of the absorption of the ultra-violet rays by fatty diketones. The constitution admitted for the second tautomeric form of acetylacetone, $CH_3.CO.CH:C(OH).CH_3$, is incompatible with the absorption spectra. A more probable constitution is $CH_3.CO.CH_2.C(OH):CH_2$.—A. **Portevin**: The carbon equilibrium of steels in fused mixtures of potassium chloride and cyanide.—R. **Devisé**: The microsporocytes of Larix.—L. **Massol**: The effects of snake poisons on the coagulation of the serum of the horse by heating. Differentiation of the poisons of Viperideæ and Colubrideæ. The effects of cobra poison are consistent with the view that it contains two diastases with contrary actions, one retarding and the other accelerating the coagulation.—Mme. Victor **Henri**: Study of the metabiotic action of the ultra-violet rays. The production of forms of mutation of the anthrax bacillus. The exposure of spore-bearing anthrax bacilli to ultra-violet light causes profound changes in the organism. The surviving bacilli are transformed into new forms distinguished from normal anthrax bacilli by their morphological, biochemical, and biological characters.—Louis and Charles **Fortineau**: The treatment of anthrax by injections of sterilised pyocyanic cultures. An account of the treatment of nine cases of malignant œdema and forty-one of malignant pustule by subcutaneous injection of sterilised pyocyanic cultures: the mortality was reduced to 10 per cent.—Em. **Bourquelot** and Alexandru **Ludwig**: The biochemical synthesis of β-*ortho*methoxybenzylglucoside and of β-*meta*nitrobenzylglucoside. These syntheses were effected with the aid of emulsin in aqueous acetone solutions.—Adrien **Guébhard**: The tectonic in the neighbourhood of Castellane (Basses Alpes).—Sabba **Stefanescu**: The origin of the cuneiform sheets of the molars of elephants.—Henri **Bresson**: Eight hydrographical maps of the Normandy region.

A TREATISE ON IGNEOUS ROCKS.

Igneous Rocks. Composition, Texture and Classification, Description and Occurrence. By Joseph P. Iddings. In Two Volumes. Vol. i. Pp. xi+464+3 plates. (1909.) Price 21*s.* net. Vol. ii. Pp. ix+685. (London: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1913.) Price 25*s.* 6*d.* net.

UNIFORM with the "Rock Minerals" of the same author, now in its second edition, the work which Prof. Iddings has now completed will take an assured place as the fullest and most comprehensive treatment of the subject in our language. Nor is it of the nature of a compilation, but presents numerous features of originality. There are novelties which will be cordially welcomed, and others which will probably meet a more doubtful reception. The author has not shrunk from introducing many debatable questions, and has pronounced on them in no uncertain tone. Although the spirit is that of the missionary rather than the controversialist, this somewhat impairs the utility of the work as a hand-book for students.

The first volume, which has been for some time in the hands of petrologists, deals with the composition, texture, and classification of igneous rocks. It includes a good account of the chemical composition of the rocks and of their component minerals, a discussion of the chemistry and physics of rock-magmas, an admirable and well-illustrated chapter on rock-textures, and a statement of the problem of magmatic differentiation. The last three chapters are concerned with the thorny subject of nomenclature and classification. Here we have first a historical sketch, then an arrangement of the principal igneous rocks in a "qualitative" mineralogical scheme, and finally an exposition of the "Quantitative Classification," of which our author is one of the creators.

The second volume, recently issued, deals with the description and occurrence of the rocks, and is divided into two equal parts. The final test of any classificatory scheme is its applicability in practice; and doubtless many petrologists have waited with curiosity to see how the author would develop a systematic treatment of igneous rocks on the lines of the Quantitative Classification. It seems that we may now congratulate him on recognising the impossibility of the task, for the system actually adopted does not differ in general plan from others in current use. The rocks are first divided into those characterised by (1) preponderance of quartz, (2) quartz and felspar, (3) felspar, (4) felspar and felspathoids, (5) felspathoids, and (6) ferro-magnesian minerals. Under each head "phanerites" and "aphanites" are separated, while the subdivisions are again based on mineralogical characters. To introduce the quantitative element, the author has often redefined terms already in use (a practice which he deprecates in others); but he has succeeded in producing a working scheme with less disturbance of accepted usage than we had expected. The principal relic of the specific "Quantitative Classification" is the use of an ideal mineral composition (the "norm") instead of the actual composition.

Nevertheless, there are many signs that the author is reluctant to abandon the conception of a classification laid down *a priori*. The precise boundaries which he demands are to be fixed by arithmetic, not by chemistry. He counts it a defect of the current systems that special importance is attached to the presence of even very small amounts of certain minerals, such as nepheline and leucite; but, as he has himself pointed out (prior to the birth of the Quantitative Classification), the mere appearance of one of these minerals shows that we have crossed a significant boundary-line in respect of chemical composition. Surely it is he, not his critic, who has lost appreciation of "the mathematical precision of stochiometric chemistry" (p. 7).

The second part of the volume we can praise without reserve. It is an account, such as has never been attempted before, of the geographical distribution of igneous rocks over the globe, with special reference to their chemical composition. This has not been merely compiled in the library, but represents the results of much travel and study in many lands. It is illustrated by maps of the several continents, and by more than 1200 analyses. We hope that in another edition some attempt will be made to distinguish on the maps igneous rocks of different geological ages.

A. H.

MATHEMATICS FOR FRENCH FRESHMEN.

Les Principes de l'Analyse Mathématique: Exposé Historique et Critique. By Prof. P. Boutroux. Tome Premier. Pp. xi+547. (Paris: A. Hermann et Fils, 1914.) Price 14 francs.

PROF. BOUTROUX appears to belong to the school of the laughing philosophers; for, like many of his distinguished compatriots, he has composed a work which is amusing as well as learned. His six chapters range from elementary arithmetic to differential equations, and touch upon such things as friendly numbers, magic squares, the transcendency of π, Tartaglia's rhymed rule for solving a cubic, and so on. Altogether, the book is written in a light and elegant style, reminding us of Lucas; it is neither so technical, nor so critical, as its title might suggest.

Sometimes we are inclined to think that the author is poking fun; for instance (p. 50), he suggests that o (zero) is the initial letter of *οὐδέν*! It is scarcely necessary to say that the Greeks adopted the decimal notation, including zero and the nine other digits, after it had been invented by Eastern (probably Indian) mathematicians; and that our zero is almost certainly an enlargement of the dot which is still used by Oriental printers (unless the dot is a contraction for an older circle).

"Bernouilli," instead of Bernoulli, occurs so often that it can scarcely be condoned as a misprint; "Neper" we let pass, as a traditional misspelling; otherwise the names of authors seem to be correct. This is a small matter; a much more important fact is that the author, besides being interested in the discoveries of the ancients, is fully awake to the merits of the moderns. For instance, we have the modern definition of "function"; references to the modern theories of irrational numbers, of functional equations, and the like.

It is interesting to see from the preface that this book is intended to be a "repertorium" for "débutants en mathématiques." As a repertorium it is certainly not one of formulæ; so it must be judged as one of ideas, and since it begins with a quotation from Plato's "Republic," we may suppose that this is what the author means.

From this point of view, the author may be congratulated, because the ideas which he suggests are eternal, though the forms under which he presents them are merely those which seem for the present the most convenient and suitable. One great advantage of the historical treatment of the subject is that it shows how what we may call the machinery of the subject has been improved and simplified.

Prof. Boutroux promises us another volume dealing mainly with analytical geometry, mathematical logic, and infinitesimal calculus; it will also deal with complex quantities and series. Teachers will note that the range of the whole work approximately covers the course of general mathematics in the science faculties of the higher educational bodies in France.

G. B. M.

ANALYTICAL AND SYNTHETICAL CHEMISTRY.

(1) *Industrial Organic Analysis: for the Use of Technical and Analytical Chemists and Students.* By Paul S. Arup. With a foreword by Prof. J. C. Irvine. Pp. xii + 340. (London: J. and A. Churchill, 1913.) Price 7*s.* 6*d.* net.

(2) *A Text-book of Quantitative Chemical Analysis.* By Dr. A. C. Cumming and Dr. S. A. Kay. Pp. xi + 382. (London: Gurney and Jackson; Edinburgh: Oliver and Boyd, 1913.) Price 7*s.* 6*d.* net.

(3) *The Sugars and their Simple Derivatives.* By Dr. J. E. Mackenzie. Pp. xvi + 242. (London: Gurney and Jackson; Edinburgh: Oliver and Boyd, 1913.) Price 7*s.* 6*d.* net.

(4) *The Silicates in Chemistry and Commerce: including the Exposition of a Hexite and Pentite Theory and of a Stereo-chemical Theory of General Application.* By Dr. W. Asch and Dr. D. Asch. Translated, with critical notes and some additions, by Alfred B. Searle. Pp. xx + 456. (London: Constable and Co., Ltd., 1913.) Price 21*s.* net.

(5) *Die Elemente der siebenten Gruppe des periodischen Systems: aus Abegg's der anorganischen Chemie.* Vierter Band. Zweite Abteilung. Herausgegeben von Dr. Fr. Auerbach. Pp. x + 904. (Leipzig: S. Hirzel, 1913.) Price 26 marks.

(1) THIS volume is intended for the use of students who, having received a grounding in theoretical and practical chemistry, are desirous of gaining an insight into the methods of industrial organic analysis. Eight typical series of commercial organic products have been selected, and detailed instructions are given of the analytical processes employed in determining the industrial value of the materials under consideration. The subjects chosen include coal and coke, coal tar and its distillation products, the petroleums, the fatty oils and fats, soap, milk, butter, starch and its degradation products, flour, barley, malt, and the preservatives and colouring matters introduced into foods. One very valuable feature of the book is the references to the larger manuals and special monographs given at the end of each chapter.

In the foreword Prof. Irvine deals with the controversial topic of the college training of industrial chemists. The subject was not new thirty years ago, and although the discussion is unending there is really no general problem to be faced; still less is there any general solution to be provided. Experts differ, and the weighty opinions of Prof. Martin (*sic*) Bogert, President of the Society of Chemical Industry, should be balanced against those of Dr. Messel, his predecessor in this office. The workings of the latter's mind in this connection are adumbrated in the recent creation of two additional Chairs of "pure" chemistry in the Imperial College of Science and Technology. However, if some degree of technical proficiency is insisted on, the student cannot do better than to work through a selection of Mr. Arup's thoroughly practical exercises in industrial analysis.

(2) The authors have arranged this manual so that some knowledge of the principles of quantitative analysis may be acquired by a practical study of the three introductory sections, which include general principles, volumetric analysis, and gravimetric analysis, including electrolytic methods. Owing to its educative value, a thorough training in volumetric analysis is recommended when time permits of little or no gravimetric work. The exercises included in the volumetric section form a very instructive and comprehensive series, involving the use of all the ordinary standard solutions. In view of the great importance attached by the authors to this side of analysis, it is perhaps allowable to suggest that a short description of the chemical nature of the organic indicators (methyl-orange, methyl-red, phenolphthalein) would have made the volumetric section more self-contained. The preliminary chapters are followed by sections devoted to colorimetric methods, systematic quantitative analysis, and the analysis of simple ores and alloys. Modern methods have been selected, among which may be indicated the estimation of potassium as perchlorate and the separation of iron from allied metals in acid solution by the use of "cupferron," the ammonium salt of nitrosophenylhydroxylamine. The appendix contains details of the preparation of this useful organic reagent. The section on gas analysis refers to the use of the simpler forms of apparatus, such as the Lunge nitrometer and the apparatus devised by Hempel and by Orsat. Water analysis is included as an introduction to the estimation of substances present only in traces. The short section on ultimate organic analysis would have been rendered more complete by a brief reference to the Carius method for the halogens and sulphur. The determination of molecular weights includes details of the vapour density, cryoscopic and ebullioscopic methods.

(3) This treatise is a very readable monograph on the sugars and their immediate derivatives, based on a course of lectures given at the Birkbeck College and in the University of Edinburgh. Rightly on account of their intrinsic importance three chapters each are devoted to cane sugar and glucose, these sections being a mine of information in regard to these well-studied sugars. Among the many researches summarised may be mentioned those on the methyl glucoses, the methyl glucosides, and their acetyl derivatives. One very interesting chapter is that relating to the configuration of the sugars, in which the stereochemical relationships of these compounds are fully discussed. Succeeding chapters deal with dioses, trioses, tetroses, pentoses, together with the naturally occurring mannose, *d*-fructose (lævulose), and raffinose. The less important synthetic sugars are also reviewed. A synopsis is furnished of the glucosides found in plants, and the concluding sections deal with fermentation and with the metabolic changes attending the use of sugars and allied carbohydrates as foodstuffs. References are given throughout to original sources of information, and the work is provided with complete author and subject indexes.

(4) It is impossible within the space available to discuss in detail the hexite–pentite theory devised by the authors, in the first instance, to explain the constitution of the naturally occurring aluminosilicates, and subsequently employed to elucidate the chemical structure of clays, ultramarines, glasses, glazes, porcelains, dental cements, hydraulic cements, and especially Portland cements. It is assumed that five or six molecules of hydrated silica, $Si(OH)_4$, unite with partial elimination of water to form cyclic systems containing five or six silica residues, these complexes being termed respectively silicon pentite and hexite. Aluminium pentite and hexite arise in a similar way by the condensation of five and six molecules of hydrated alumina, $Al(OH)_3$. The mineral aluminosilicates are regarded either as complex acids composed essentially of combinations of these silicon and aluminium pentite and hexite rings, or as salts of these acids when the hydroxylic hydrogens are more or less replaced by metallic elements. The felspars, micas, scapolites, etc., need no longer be regarded as molecular compounds belonging to different mineral groups; they can all be represented as unitary atomic compounds of the same class with definite structural formulæ. A similar hexite–pentite hypothesis is employed to explain the constitution of vanadic, molybdic, and tungstic complexes.

The translator, who has added several instructive and critical notes, doubts whether the authors are justified in extending their views to explain the plasticity of clays. The authors' theory has already been criticised by several writers, and the present volume contains many polemical replies, notably in connection with the constitution and hardening of Portland cements. These hydraulic cements are considered to be basic lime salts of complex aluminosilicic acids containing coalesced hexite and pentite rings with calcium oxide side-chains replacing the hydroxyls of the hydrated silicon complexes, and occasionally containing alkali metals similarly attached to the aluminium hexite rings.

It is highly probable that the refractory oxides, silica, alumina, and their allies exist in highly complex molecules, and since among both inorganic and organic compounds there exists a certain tendency for the formation of five- and six-membered rings, it would probably be accepted by most chemists as a working hypothesis that such cyclic systems occur in the natural and artificial aluminosilicates and their derivatives, but it is open to doubt whether the authors do not greatly prejudice their case by attempting to extend this hypothesis to the explanation of the facts of coordination, radioactivity, and the constitution of organic substances, such as benzene, the artificial colouring matters, and the proteins.

(5) The appearance of this volume is a welcome indication that this monumental treatise on inorganic chemistry will be brought to completion in spite of the untimely death of its originator, the late Prof. Richard Abegg. There still remain for consideration, however, several important groups of elements, and the remaining volumes of the work are eagerly awaited by all interested in the systematic study of the chemical elements. A praiseworthy feature of the treatise so far as it has yet appeared is the thoroughness with which the compilers have accepted the periodic classification of the elements; this insures uniformity of arrangement, and renders the task of reference a very easy one. It is rarely necessary to turn to the indexes. The present volume is devoted to the halogens and manganese, the elements of the seventh periodic group. In the case of each element the opening section deals with the determination of its atomic weight. The descriptions of the physical and chemical properties of the elements and their compounds are very complete, and include, in addition, the mathematical treatment of many important examples of chemical equilibria, such as the Deacon's chlorine process, the variations in the vapour density of the halogens and their partition coefficients in various solvents. Special sections deal with the colloidal chemistry of the halogens and manganese.

The bibliography is remarkably full, there being more than fifteen hundred references for iodine and its derivatives alone. Manganese varies considerably in its habit of combination, and its compounds are arranged whenever possible under the headings of the various valencies of the metal, but reference is also made to its alloys, and to compounds in which the valency of the metal is undetermined.

G. T. M.

TEXTILES.

Textiles: a Handbook for the Student and the Consumer. By Mary S. Woolman and Ellen B. McGowan. Pp. xi+428. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1913.) Price 8*s*. 6*d*. net.

THIS book strikes a new note from an educational point of view, and represents a serious attempt to present a course of instruction to students who intend to make some branch of textile work their future business, or who are, or will be, the buyers of textiles for personal or household purposes. Whilst its strongest appeal is to students of the type mentioned, the matter is so arranged that it offers a mass of information to a wide range of readers who are out of touch with technical methods, and yet are seriously concerned and interested about the character of the textile materials they sell, purchase, or use. It fills the wide gap at present existing in the domestic economy course of instruction in our colleges and schools, and as it deals with practically all kinds of fibres and the textiles into which they are made, it presents in a most interesting manner a remarkably concise and exact description of the methods and machinery used for producing the various materials.

Unusually full details are given for distinguishing the constituents of any textile material, to detect frauds and to estimate value. The character of the various types of dyes and their use, together with notes on finishing and laundry work, add materially to the value of the book. The last three chapters deal with the hygiene of clothing, economic and social aspects, and a series of clothing budgets, these latter being unusually complete and valuable as guides in the laying out of money the clothing of families and individuals of various degrees of economic status.

The book represents a well-defined arrangement of accurate information gathered from a multitude of sources, chiefly of a highly technical nature, and rewritten in a simple and interesting manner with a very clear view to their utilisation by those who are, after all, the consumers of all that is produced by the vast number of our textile factories and workshops, and on whom these innumerable industries depend for their existence. In addition to its value as a text-book on domestic economy, it is well worthy of a place in every textile-worker's library, and can be recommended as a reference book in the household.

WM. SCOTT TAGGART.

OUR BOOKSHELF.

The Reform of the Calendar. By Alexander Philip, Pp. xiii + 127. (London: Kegan Paul, Trench, Trübner and Co., Ltd., 1914.) Price 4*s.* 6*d.* net.

MR. PHILIP reminds us that, apart from minor notes, we have discussed different aspects of calendar reform already in these columns (April 27 and October 26, 1911). The reader who looks for enthusiastic advocacy of some change and an account of the various proposals which have been put forward in recent years may be referred to this little book on the subject.

We wish to speak of Mr. Philip with some respect. Not that we regard calendar-making as a high order of achievement, although Mr. Philip's original scheme was probably as good as any other of its class, and certainly a great deal better than some. But he has also the broad mind which appreciates objections and prejudices, and he has been led to reduce his first proposal to a minimum adjustment of the days of the months. The week is left undisturbed, and his present scheme may be represented thus:—

Jan. 31	Feb. 30	Mar. 30	April 31	May 30	June 30 (31)
July 31	Aug. 30	Sept. 30	Oct. 31	Nov. 30	Dec. 31

Perhaps something might be said in favour of interchanging the second and fourth quarters so as to bring leap day (when it occurs) to the end of the year. But little can be seriously urged against a change which makes the months and quarters more equal and introduces an approximately rhythmic (? dactylic) arrangement. What is to be feared rather is that so slight an adjustment offers so small an advantage, in spite of Mr. Philip's glowing optimism, as to lack the necessary driving force for its adoption. Does there indeed exist a practical middle course between the Scylla of traditional prejudice and the Charybdis of triviality?

H. C. P.

Les Zoocécidies des Plantes d'Europe et du Bassin de la Méditeranée. By C. Houard. Tome Troisième. Supplément: 1909–1912. Pp. 1249–1560. (Paris: A. Hermann et Fils, 1913.) Price 10 francs.

THE rapid progress of cecidology has led Prof. C. Houard to publish a supplement to his two indispensable volumes on the Animal Galls of Europe. This third volume deals with what has been done between 1909 and 1912, and it is astonishing to find a registration of 1,300 new galls, bringing up the total to 7,556! The author has exercised discretion in what he has included, and he makes an appeal to those interested in galls—and what naturalist is not?—to refrain from rushing into print with new discoveries until they have studied them for, say, two successive years! Everything has been done in the way of double entry and bibliography to make the catalogue serviceable, and both pagination and enumeration are in continuity with the previous volumes. There are 201 illustrations, and there is an appropriate frontispiece with photographs of Rübsaamen, Kieffer, Massalongo, and the late Prof. Giard.

The Principle of Relativity in the Light of the Philosophy of Science. By Paul Carus. Pp. 105. (London and Chicago: The Open Court Publishing Co., 1913.) Price 4*s.* net.

THE author of this work has made up his mind in advance that the question of relativity is a philosophical problem. It is therefore necessary for him to dismiss contemptuously all the history of the purely physical principle technically known as "the principle of relativity." To say as he does that the Michelson-Morley experiment "assuredly has nothing to do with the principle of relativity" is simply to say that the principle is not what it is. The author refuses to call the principle a hypothesis, and asserts "that it is an *a priori* proposition, a postulate of pure thought which either holds good universally or has no validity whatever."

Whatever opinion may be held on this point, it is impossible to say that to the student of dynamics there is no difference in status between rotation and translation. If relativity is a requirement of pure thought, why cannot Newton's laws of motion be used equally well for two frames of reference, of which one is in rotational motion relative to the other? Are those laws wrong, or is pure thought irrelevant to dynamics? One aspect of the principle of relativity is that we do know whether it is convenient to think of a system as having no rotation. This is a matter of common experience. If pure thought denies it, it is clear that it is thinking about something other than the facts with which experiment deals.

Nature and the Idealist. Essays and Poems. By H. D. Shawcross. Pp. xii + 186. (London: Sampson Low, Marston and Co., Ltd. n.d.) Price 5*s.* net.

THE late Mr. Shawcross died last year at the early age of twenty-nine. He was a newspaper journalist whose work had to be done in a busy Lancashire town, though all his instincts and his love for nature would have taken him into the country. His essays and poems reveal much of the struggle he continually had and their merit suggests that had he lived longer he would have become known as a poet and essayist to a wide circle of lovers of nature.

LETTERS TO THE EDITOR.

The Sand-Blast.

AMONG the many remarkable anticipations contained in T. Young's lectures on natural philosophy (1807) is that in which he explains the effect of what is now commonly known as the sand-blast. On p. 144 he writes :—"There is, however, a limit beyond which the velocity of a body striking another cannot be increased without overcoming its resilience, and breaking it, however small the bulk of the first body may be, and this limit depends on the inertia of the parts of the second body, which must not be disregarded when they are impelled with a considerable velocity. For it is demonstrable that there is a certain velocity, dependent on the nature of a substance, with which the effect of any impulse or pressure is transmitted through it; a certain portion of time, which is shorter accordingly as the body is more elastic, being required for the propagation of the force through any part of it; and if the actual velocity of any impulse be in a greater proportion to this velocity than the extension or compression, of which the substance is capable, is to its whole length, it is obvious that a separation must be produced, since no parts can be extended or compressed which are not yet affected by the impulse, and the length of the portion affected at any instant is not sufficient to allow the required extension or compression. Thus if the velocity with which an impression is transmitted by a certain kind of sound be 15,000 ft. in a second, and it be susceptible of compression to the extent of 1/200 of its length, the greatest velocity that it can resist will be 75 ft. in a second, which is equal to that of a body falling from a height of about 90 ft."

Doubtless this passage was unknown to O. Reynolds when, with customary penetration, in his paper on the sand-blast (*Phil. Mag.*, vol. xlvi., p. 337, 1873) he emphasises that "the intensity of the pressure between bodies on first impact is independent of the size of the bodies."

After his manner, Young was over-concise, and it is not clear precisely what circumstances he had in contemplation. Probably it was the longitudinal impact of bars, and at any rate this affords a convenient example. We may begin by supposing the bars to be of the same length, material, and section, and before impact to be moving with equal and opposite velocities v. At impact the impinging faces are reduced to rest, and remain at rest so long as the bars are in contact at all. This condition of rest is propagated in each bar as a wave moving with a velocity a, characteristic of the material. In such a progressive wave there is a general relation between the particle-velocity (estimated relatively to the parts outside the wave) and the compression (e), viz., that the velocity is equal to ae. In the present case the relative particle-velocity is v, so that $v=ae$. The limit of the strength of the material is reached when e has a certain value, and from this the greatest value of v (*half* the original relative velocity) which the bars can bear is immediately inferred.

But the importance of the conclusion depends upon an extension now to be considered. It will be seen that the length of the bars does not enter into the question. Neither does the equality of the lengths. However short one of them may be, we may contemplate an interval after first impact so short that the wave will not have reached the further end, and then the argument remains unaffected. However short one of the impinging bars, the above calculated relative velocity is the highest which the material can bear without undergoing disruption.

As more closely related to practice, the case of two spheres of radii r, r', impinging directly with relative velocity v, is worthy of consideration. According to ordinary elastic theory the only remaining data of the problem are the densities ρ, ρ', and the elasticities. The latter may be taken to be the Young's moduli q, q', and the Poisson's ratios, σ, σ', of which the two last are purely numerical. The same may be said of the ratios q'/q, ρ'/ρ, and r'/r. So far as dimensional quantities are concerned, any maximum strain e may be regarded as a function of r, v, q, and ρ. The two last can occur only in the combination q/ρ, since strain is of no dimensions. Moreover, $q/\rho=a^2$, where a is a velocity. Regarding e as a function of r, v, and a, we see that v and a can occur only as the ratio v/a, and that r cannot appear at all. The maximum strain then is independent of the linear scale; and if the rupture depends only on the maximum strain, it is as likely to occur with small spheres as with large ones. The most interesting case occurs when one sphere is very large relatively to the other, as when a grain of sand impinges upon a glass surface. If the velocity of impact be given, the glass is as likely to be broken by a small grain as by a much larger one. It may be remarked that this conclusion would be upset if rupture depends upon the *duration* of a strain as well as upon its *magnitude*.

The general argument from dynamical similarity that the maximum strain during impact is independent of linear scale, is, of course, not limited to the case of spheres, which has been chosen merely for convenience of statement.

RAYLEIGH.

The Earth's Contraction.

THE conclusion of the Rev. Osmond Fisher (NATURE, February 26) that if the moon originated as a detached portion of the earth, the earth's radius at the time (even allowing for the much more rapid rate of rotation indicated by Sir G. H. Darwin's researches) must have been about three times its present one, leads to a very interesting speculation, namely, as to whether the earth's radius may not have contracted very considerably *within the time represented by the known geological formations*. There is, I think, observational evidence which warrants us in believing this to have been the case.

Prof. Heim estimated the linear compression required to produce the Alps at seventy-four miles, which means a reduction of the earth's radius by twelve miles, or 0·3 per cent. Taking the whole of the existing mountain ranges, we may roughly estimate a total reduction of ten times this amount, or 3 per cent., as being indicated since the middle of the Tertiary epoch. Yielding of the earth's crust by intense folding has probably always taken place in particular areas, but it is a fact that as a whole the rocks show more and more folding, faulting, and overthrusting the farther back we go into the geological record, and the mountains formed in the older epochs have long since been removed by denudation, which was naturally most active where the plication was most intense. Taking the rock-structures alone into consideration, would any geologist who has worked extensively amongst the oldest fossiliferous rocks affirm that the evidences are against a contraction of the earth's radius of the order of 20 per cent. since they were deposited? A contraction of this magnitude would be accommodated by a continuous folding of the crust into anticlines and synclines at angles of 37° with the horizontal, and most accounts of the tectonics of the earlier Palæozoic rocks describe folding and shearing which approach this average, though, of course, there are some extensive areas where the disturbance has been much less. When we come to the Archæan rocks the case is even stronger.

A very simple calculation shows that the amount of contraction suggested above implies only a rate of shrinkage so slow that if going on at present it would fail to be detected by the most refined geodetic measurements repeated after a century. A contraction of the earth's radius of only three inches a year, which would cause a 20 per cent. diminution of the radius in about twenty million years (and this is probably a low estimate for the age of the Cambrian strata) would only change the absolute length of geodetic lines by less than one part in a million in a hundred years. Observations of the lunar parallax, which afford another theoretical means of detecting changes of the earth's radius, would have to be repeated at intervals of twenty-five thousand years in order to detect a single second of diminution, even if we could assume the moon's mean distance to be constant throughout this period.

If the hypothesis of a continuous contraction of the earth's radius at an average rate of somewhere about three inches a year throughout geological time is entertained, it not only furnishes a plausible explanation of the prevalent folding of the ancient rocks, but also tempts one to indulge in a number of other speculations, such as, for instance, how far the flying-powers of the great Mesozoic reptiles may have been influenced by the lesser value of gravity at the earth's surface with a larger terrestrial radius and a greater speed of rotation. But collateral issues may well rest until the main point has been argued, and as to this I should like the opinion of geologists whose experience of the older formations has been greater than my own. I am at present surveying in a disturbed country where I should certainly have had to correct my base-line very considerably for dislevelment if I had measured it along the planes of stratification of the rocks, and this circumstance has suggested the question to my mind on reading Mr. Fisher's letter.

Zoological Classification.

The complaint, thus entitled, of Mr. H. C. Williamson in Nature for April 9, p. 135, is a fairly common one just now, and his way of putting it suggests some remarks from the other side.

The zoological classification of this or any other day is "satisfactory" in proportion, first, as the principles of that classification commend themselves to the general intelligence of zoologists; secondly, as the classification is in agreement with those principles. The multiplication of the units to be classified, whether subspecies, species, or genera, can have no bearing on the validity of the classification.

The object of classification is the arrangement, but not the nomenclature, of the units.

The older genera have been subdivided, not merely because the number of species has proved unwieldy (indeed, if the necessary bases be absent, such genera cannot be split, however much it be desired), nor merely because it has proved possible to group the species (for in this case subgeneric divisions are adequate), but because study has shown that the species formerly included in a genus have not really the close interrelationship which such inclusion implies, but are of very diverse descent. In nomenclature as affected by classification most of the serious difficulties which happen to have come under my own notice are due to our increased, but still imperfect, knowledge of origins.

The real trouble and source of disagreement between zoologists is that some (and especially the "applied" workers) look at taxonomy with the eyes of the old school, which regarded only the amount of resemblance in structure, while others follow the new school which seeks to express history and relationship. In a word, there are two sets of principles, and our classification is, if not halting between the two, at least passing rather lamely from one to the other. And as for nomenclature, the trouble is that the Linnean system was devised for a classification on the old principles, and one often doubts how far it is applicable to the new method.

When the nature of our difficulties is clearly understood, nobody will propose to effect progress by such retracing of our steps as "the extinction of half at least of the genera." In ordinary writing one practical way of getting round the difficulty is half hinted at in Mr. Williamson's last sentence; it is to use the family name. Thus we can speak of a Cidarid, a Terebratulid, a Phacopid, a Pentacrinid. Or the transition may be eased by using the old name with some such *caveat* as *sensu lato*, *e.g.* Rhynchonella (s. l.), Antedon (s. l.). In writing the "Guide to the Fossil Invertebrate Animals in the British Museum" the conflict between accuracy and intelligibility was settled by adding the older better-known name within square brackets after the correct or modern generic name, *e.g. Dalmanites* [*Phacops*] *caudatus*.

Electric Emissivity at High Temperatures.

We have recently conducted at the National Physical Laboratory some experiments on the emission of electricity from a number of substances at very high temperatures—between 2000° C. and 2500° C. The experiments were carried out in a carbon-tube resistance furnace at atmospheric pressure. Among the substances tried were the alkaline earths and a number of metals. In every instance the temperature was sufficient to vaporise rapidly the substance under test, and, under these conditions, very large amounts of electricity were emitted. For example, barium oxide emitted negative currents of the order of 4 amperes per sq. cm., while boiling tin gave currents of about 2 amperes per sq. cm. No external potential was applied in any of the experiments.

We hope to publish very shortly a full discussion of the results.

An Optical Illusion.

Some days ago I was reading, the sunrays falling aslant on my forehead, it being about five o'clock p.m. After having read awhile, the letters showed a vivid red, the paper itself retaining its white colour. The rays did not fall on either of the two sides of the page.

When I used my hand to shade the eyes, the letters *immediately* became black again. On removing my hand, it took them some seconds to change from black through dark red to bright red. I may add that I am short-sighted, but was reading without spectacles.

I should feel obliged if some reader of Nature would give me an explanation of this.

Delft, Holland, April 11.

THE NATIONAL BOTANIC GARDENS OF SOUTH AFRICA.

It is perhaps difficult to appreciate in their due proportion the various factors that have been instrumental in founding these National Botanic Gardens. At the same time it is necessary to make the attempt; for their future development must be influenced, if not controlled, by the ideals entertained by those who for many years have been working for what has at length been achieved.

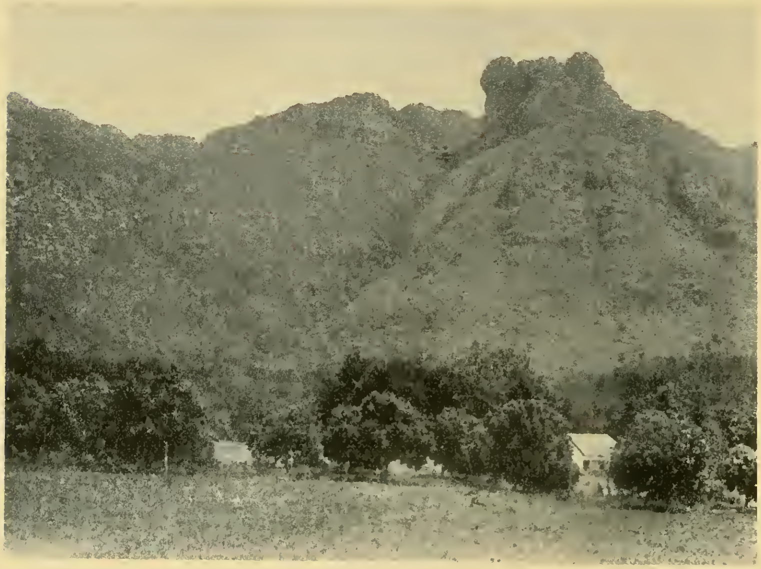

FIG. 1.—National Botanic Gardens. Looking westwards from within the eastern boundary. Curator's house on the right; in front of it, part of the Camphor Avenue running obliquely across the picture. The western boundary runs immediately beneath the steep rocks about 1200 ft. above the curator's house.

Among these factors a very important place must be assigned to the keen interest displayed by almost the whole white population in the remarkable vegetation of the country. The manifestation of this interest has in many cases endangered the existence of ornamental species. Most districts furnish examples of the disastrous effects of reckless wood-cutting or ill-judged burning. Public opinion has awakened somewhat tardily to the necessity for conservative action. Recent legislation has given a measure of protection to certain of the threatened forms. But it is now generally realised that the problem is too big to be solved by the protection of a few favourites. That the reservation of areas is more adequate to the circumstances than the protection of individual species is recognised. And further, there has gradually been developed a tendency to adopt the positive measure of introducing native plants into cultivation in South African gardens.

There can be no doubt that the movement to establish a national botanic garden has received great impetus from the widely felt desire to see this tendency accelerated. Its first mission is to lead the way in the preservation and cultivation of South African plants, and in the improvement of those of them that, for various reasons, are worthy of improvement.

Kirstenbosch possesses exceptional facilities for dealing with these problems. Of its total area of about 600 acres,[1] approximately two-thirds is well-stocked with native species, representing all the more important plant associations of the region. Half this area is clothed with indigenous forest, the rest mainly with low bush in which proteas, heaths, orchids, restiaceæ, and many striking compositæ and leguminosæ are conspicuous. This area is admirably suited for development into a most instructive miniature of what would be called in America a "national park."

During the six months ending on December 31 last, about 1500 species, the vast majority not indigenous to Kirstenbosch, have been sent in by correspondents from various parts of the coast-region between Damaraland and Zululand, the Karoo and Upper Region, Swaziland, Transvaal, Bechuanaland, Rhodesia, and British East Africa.

FIG. 2.—National Botanic Gardens. Looking westwards near the southern boundary. A silver tree forest (*Leucadendron argenteum*).

Among these contributions a large proportion are succulents. Probably a greater variety of South

[1] Since the establishment of the gardens an additional area of about 200 acres has been added at the southern end of the original Kirstenbosch estate.

African bulbs and ground orchids than has yet been brought together in one place is already established in the nursery. Most of these were introduced here during the winter rains, which have been followed by an exceptionally wet summer. The results are such that any doubt that may have been entertained as to the possibility of establishing here a representative collection of South African—one may almost say African—plants is set at rest.

Most of those who have taken an active part in the foundation of these gardens will not be satisfied merely with the collection and cultivation of South African plants. The educational effect of such a collection will nevertheless not be small. The great extent of the country and the sharpness of its physical divisions militate against the slowly growing sense of national unity. The presentation, even on a small scale, of typical representatives of its regional floras to the view of many who of necessity are acquainted with but little of its area, must do something towards the obliteration of hard dividing lines.

Fig. 3.—National Botanic Gardens. Group of *Aloe succotrina*. This is part of a very remarkable plant association about five acres in extent, on a steep slope strewn with large blocks of Table-mountain sandstone, 1500 ft. s.m. Associated with the aloes are lichen-covered trees of *Olea verrucosa*, *Cunonia capensis*, *Maurocenia frangularia*, *Plectronia* sp., etc., and a number of moisture-loving annuals, ferns and mosses.

From a purely scientific point of view, the importance of the National Botanic Gardens depends upon the use that is made of them for purposes of investigation. It is clearly realised that they will fall short of justifying their existence if they fail to make adequate provision for the proper study of the material they contain. Whether this provision will come through the much-needed university, or partly or entirely by private benefaction, or through some other channel, remains to be seen. The work at present in progress is ordered on the assumption that such provision will be made in the near future.

Since the publication of Pappe's "Floræ capensis Medicæ Prodromus" (1850), it has been known that a very large number of native species are, or have been, in use locally for medicinal or other domestic purposes. Plants yielding essential oils and other products of probable or possible economic value are numerous. While much of the work of acclimatisation, which in tropical countries has been done by the Botanic Garden, is here receiving adequate attention in the departments of agriculture and forestry, there are yet very many exotic plants worthy of attention, the possibilities of which await investigation. Among these the drug- and perfume-yielding species of the Mediterranean region are conspicuous. The economic garden, for which some twenty to thirty acres have been reserved, should therefore become an important part of the establishment.

The functions assigned to the National Botanic Gardens cover a wide range. At present much of the equipment which will make it possible to fulfil them is to seek. But the gardens exist in response to a popular demand, and popular support to make their future secure will not be wanting.

WAVES IN SAND AND SNOW.[1]

Dr. Vaughan Cornish has written a charming book, full of interesting observations. He starts with descriptions of waves and ripples in blown sand, and passes later to the similar forms produced under water, giving many good photographs to illustrate their various characteristics. Whether the waves are large or small, or whether formed by wind or water, it is obvious that the same causes are at work, and the author rightly distinguishes these waves from drifts and sand banks, the latter having their lengths parallel to the direction of the average stream, while the ridges of the waves are at right angles to it. The origin of the lateral drift which gives rise to sand-banks was first explained by W. Froude and independently by Prof. James Thomson about the same time.

Snow waves and snow drifts, and other forms of accumulations of snow, are described in chapters iii. and iv., and these also are well shown by photographs. The phenomena of snow are much more complex than those of sand, both on account of the variable size of the snow-flakes and particles and of the varying conditions as to moisture and temperature in which they are deposited. In some states snow particles cohere on contact; in others when the temperature is low they behave more like a dry powder, and it re-

[1] "Waves of Sand and Snow and the Eddies which Make Them." By Dr. Vaughan Cornish. Pp. 383+plates. (London: T. Fisher Unwin, n.d.) Price 10*s*. net.

quires a pressure applied for some time to make them stick together. The resulting forms taken by accumulations near obstacles differ considerably in consequence.

One of the most interesting observations in the book relates to the natural sifting which sand undergoes whilst being blown hither and thither by the wind. One sample of desert sand was passed by the author through a series of wire gauze sieves of graduated mesh; a single sieve with a 1/48 in. mesh retained 94 per cent. of the total, the sieve above with a 1/24 in. mesh stopping 2 per cent. and the one below with a 1/96 in. mesh stopping 4 per cent. Practically, therefore, 94 per cent. of the sand grains had linear dimensions of between 0·02 and 0·01 in.

It would have been of interest if this sorting test had been carried further, for several phenomena of sand, notably "singing sand," and also the extraordinary roar which is sometimes heard when a slip occurs in a slope of blown sand, must depend on the uniformity of the size of the grains. Darwin in his voyage of the *Beagle* refers in chapter xvi. to a hill in Chile known as "El Bramante," on account of the roaring sound produced by the slipping of sand, and also states that the same circumstances are described in detail by Leetzen and Ehrenberg as the cause of the sounds which have been heard by many travellers on Mount Sinai. I have had a description from a friend who, with a party, was descending a slope of blown sand drifted against a cliff in the Nile valley. So far as could be seen, only a small surface flow of sand started by their footsteps appeared to be in motion, but the noise gradually increased to a loud roar, and the whole mass of the drift seemed to vibrate. This implies that each grain was doing the same thing at the same time for a considerable depth, which could scarcely happen were there not a fairly close uniformity in their size.

How the sorting is carried out by the wind does not clearly appear. Dr. Cornish's explanation is that the predominant size of grain is reached when mutual attrition ceases. If this is correct, it might be possible to determine the size in terms of the hardness of the material and the $\sqrt{}$mean square velocity of impact. There is no doubt a definite size for which the whole work of impact could be taken up by elasticity and without rupture. The whole question, however, of the way in which dust is raised by the wind is rather obscure. Presumably the wind in contact with the ground must move parallel to its surface, and it seems probable that particles drifting along the surface can only be raised above it by impact more or less oblique with others which are stationary or moving with a different velocity. Once they are lifted into the eddying current their further distribution does not present the same sort of difficulty.

FIG. 1.—A nine-foot snow-mushroom seen from below. From "Waves of Sand and Snow."

Any structure which shows a "period" always presents interesting problems, but the periods and wave-lengths which Dr. Cornish deals with must not be confused with those belonging to stable systems, such as water waves, etc. The latter are definite in the same way and for the same reason as the period of a pendulum.

The sand waves are products of instability, and in all quasi-periodic structures which originate in this way the amplitude and wave-length are independent. In this they differ from stable systems which are isochronous. In the unstable systems a change, however small, tends to increase until a limit is reached at which a breakdown of some sort occurs. Instances might be given in great variety in which instability leads to a quasi-periodic motion or arrangement. Geysers which boil over at fairly constant intervals, the whistling of the wind (here the period is the rate of production of eddies round small obstacles), and the ladder-like shavings taken off various materials by cutting tools, are all cases in point, although drawn from such different quarters.

FIG. 2.—Aeolian sand-ripples at Southbourne. From "Waves of Sand and Snow."

Notice of many of the matters of which the author treats, such as snow mushrooms, and the ridges trodden out by cattle, must be omitted for want of space, and although it must be said that the explanations are not as good as the descriptions, the book is to be recommended as the most interesting collection of observations concerning the whole subject which has yet appeared.

A. MALLOCK.

MUTATIONS OF BACTERIA.

VARIOUS alterations in the morphology and in physiological characters of certain bacteria have been obtained by many observers. Thus *Bacillus coli*, the plague bacillus, and other organisms show considerable variation in the size of the cells on different culture media; the *Bacillus prodigiosus*, which forms a brilliant red pigment when grown at ordinary temperatures, completely loses the power of pigment production after cultivation at blood heat, at which temperature (98° F.) it grows as luxuriantly as at 65° F. Twort and Penfold have "educated" the typhoid bacillus to ferment sugars which ordinarily it does not attack, and Revis has obtained marked varieties of *Bacillus coli*, morphological and physiological, by prolonged culture in various media. Minchin holds that if there be no syngamy (sexual reproduction, *e.g.* conjugation) among bacteria, as seems to be the case, the so-called species of bacteria are to be regarded as mere races or strains, capable of modification in any direction.

A marked instance of the artificial production of mutations of *Bacillus anthracis*, a particularly well-defined and stable bacterial species (Fig. 1), is described by Mme. Victor Henri (*Compt. rend. Acad. Sci.*, vol. clviii., No. 14, 1914, p. 1032). The method employed was to expose an aqueous suspension of sporing anthrax in a quartz tube to ultra-violet radiations for times varying from one to forty minutes, and afterwards subculturing.

Whereas the majority of the organisms was killed by this treatment, the ultra-violet rays being markedly bactericidal, a few survived. Of the

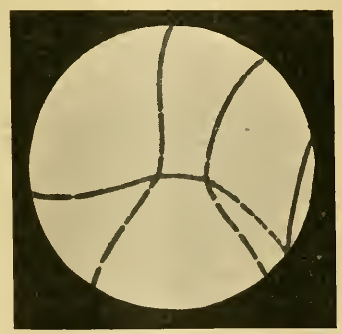

FIG. 1.

FIG. 2.

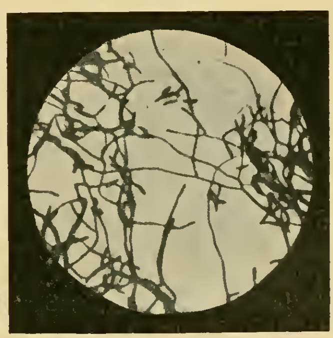

FIG. 3.

latter, while most presented a normal aspect, a few showed characters decidedly different from the typical anthrax bacillus. The principal of these were (*a*) coccoid forms (Fig. 2) which remained stable during a period of two months; (*b*) thin filamentous forms (Fig. 3), not taking Gram's stain, not liquefying gelatin, nor curdling milk, and producing an infection different from anthrax on inoculation. This form remained absolutely fixed after daily subculture for more than eighty days; but, though stable *in vitro, in vivo,* after passage through an animal, Gram-positive coccoid forms made their appearance, and subsequently, after subculture in broth, a certain number of bacillary forms, approximating to typical anthrax, were obtained. These experiments open up wide possibilities in the transformation of micro-organisms. R. T. Hewlett.

NOTES.

The first of the two annual soirees of the Royal Society will be held in the rooms of the society at Burlington House on Wednesday, May 13.

The twenty-second James Forrest lecture of the Institution of Civil Engineers will be delivered on Tuesday, May 5, by Mr. F. W. Lanchester, upon the subject of "The Flying Machine from an Engineering Standpoint."

Prof. C. S. Sherrington, Waynflete professor of physiology in the University of Oxford, has been elected a member of the Royal Danish Academy of Sciences, in the class of natural sciences.

The death is announced, at fifty-eight years of age, of Prof. Adolf Fischer, director of the Museum for Asiatic art, founded last October at Cologne, and consisting almost entirely of collections made by Prof. Fischer himself during repeated journey to the Far East.

The death on March 19 is announced of Prof. G. Mercalli, one of the leading Italian seismologists. Mercalli, who was born at Milan in 1850, is known chiefly for his researches on regional seismology, for his observations on Vesuvian phenomena, and for his scale of seismic intensity, which, in Italy, has displaced the widely used Rossi-Forel scale. In conjunction with Prof. T. Taramelli, he issued the principal reports on the Andalusian earthquake of 1884 and the Riviera earthquake of 1887. In 1897, were published his valuable monographs on the earthquakes of Liguria and Piedmont, and of southern Calabria and the Messinese district. At the time of his death he was director of the Vesuvius Observatory and professor of seismology in the University of Naples.

Two articles on the work of the late Prof. Milne have appeared this month, one by Dr. C. Davison, in *Science Progress*, the other by Comte de Montessus de Ballore, in the Bulletin of the Seismological Society of America (vol. iv., pp. 1–24). The former contains a brief account of his life and a summary of the principal work accomplished by him. The latter is more bibliographical in form. Milne's papers are classified and briefly described under fourteen headings, such as earthquake-catalogues, earth tremors and pulsations, aseismic buildings and practical seismology, relations between earthquakes and variations of the vertical and changes of latitude, etc. Both writers claim for Milne the chief share in the growth of seismology.

The twelfth annual meeting of the South African Association for the Advancement of Science will be held at Kimberley from Monday, July 6, to Saturday, July 11, inclusive, under the presidency of Prof. R. Marloth. The sections and their presidents will be as follows:—A, Astronomy, Mathematics, Physics, Meteorology, Geodesy, Surveying, Engineering, Architecture, and Irrigation, Prof. A. Ogg; B, Chemistry, Geology, Metallurgy, Mineralogy, and Geography, Prof. G. H. Stanley; C, Bacteriology, Botany, Zoology, Agriculture, Forestry, Physiology, Hygiene, and Sanitary Science, Prof. G. Potts; D, Anthropology, Ethnology, Education, History, Mental Science, Philology, Political Economy, Sociology, and Statistics, Prof. W. Ritchie.

The precise physical cause which has brought the publicity of newspaper paragraphs to the shrinkage of the Caspian Sea must be, pending the official investigation by Prof. Shokalski, a matter for conjecture. That the surface of the sea stood formerly, and at no remote geological date, at a much higher level, and that its extent was much greater, is well known. Again, the level is subject to recognised fluctuations, both annually and over longer periods. The discharge of the several great rivers into the sea strives constantly but often unsuccessfully to keep up with the loss by evaporation. The level usually stands highest in the middle of the year, and lowest at the beginning. As to the fluctuations of longer period, observations extending from 1851 to 1885 showed maxima of height in 1868–69, in 1882, and in 1885, and minima in 1853 and 1873; these oscillations appear to have had an extreme range of some 42 in. The present fall may be associated with this phenomenon; a scientific investigation towards the close of last century led to the conclusion that no perceptible permanent shrinkage was in progress.

A summary of the weather for the first three months of the year has been given by the Meteorological Office in its Weekly Weather Report for the period ending April 4. The mean temperature for the whole period is shown to be in excess of the average in every district of the United Kingdom. In the east and north-east of England the excess of temperature amounted to 3°, and in the midland counties and in the south-east, north-west, and south-west of England the excess was 2°. In all other districts which comprise Scotland, Ireland, and the Channel Islands, the excess of temperature was only 1°. There was an excess of rainfall over the entire kingdom except in the north-east of England, where the fall was only 95 per cent. of the average. In the south-east of England the rainfall for the three months was 160 per cent. of the average, in the east of England 145 per cent., in the Channel Islands 143 per cent., in the south-west of England 142 per cent., in Ireland, north and south, 140 per cent., and in the east and west of Scotland 122 and 123 per cent. respectively. In the midland counties the fall was only 107 per cent. of the average. There was a slight deficiency of sunshine over the whole kingdom, except in the north of Scotland, where there was a slight excess. At Greenwich the mean temperature for the three months to the end of March was $42 \cdot 5^{\circ}$, which is $2 \cdot 5^{\circ}$ in excess of the average, and the temperature was above the normal on fifty-seven days out of the ninety. The aggregate rainfall was 6·92 in., which is 142 per cent. of the average, and is 2·05 in. above the normal. The duration of sunshine was 216 hours, which is an excess of 29 hours.

The first course of a series of lectures arranged by the National Academy of Sciences, Washington, under the William Ellery Hale foundation, is being delivered by Sir Ernest Rutherford, at the National Museum, Washington, on April 21 and 23. The series of lectures is to cover several years on the general subject of evolution, the intention being to present a clear outline of the broad features of inorganic and organic evolution in the light of recent research. The subjects of Sir Ernest Rutherford's lectures are the constitution of matter and the evolution of the elements. The second course in the evolution series will be given at the autumn meeting of the academy by Dr. W. W. Campbell, director of the Lick Observatory; and a distinguished European geologist will be invited to give the third course at the annual meeting of the academy next year. Taking the earth from the hands of the astronomer, he will show how its surface features have been altered in the process of time. Later lectures, preserving the continuity of the series, will then enter the field of organic evolution and illustrate the bearing of recent investigations in palæontology, zoology, and botany on the evolution of plant and animal life. The evolution of man will form the subject of another course, and the series will close with an account of the rise of the earliest civilisations, coming into touch with the modern times in the life of the Nile Valley. In all cases the lectures will be given by leading European and American investigators, whose personal researches have contributed largely towards the development of the fields of science which they represent.

The second reading of a Bill to prohibit experiments on dogs was carried in the House of Commons on Friday last, April 17, by a majority of forty-two, the voting being 122 for the second reading and 80 against. It was stated on behalf of the Government that an amendment will be moved in Committee to abolish the proposed prohibition and to allow experiments only in cases where no other animal but a dog is available for the purpose. The Bill was brought in by Sir F. Banbury, one of the members for the City of London. The motion for the second reading was seconded by Colonel Lockwood, member for the Epping Division of Essex. Mr. Rawlinson, Cambridge University, moved the rejection of the Bill; and the amendment was seconded by Sir P. Magnus, London University, and supported by Sir H. Craik, Glasgow, and Aberdeen Universities. Before the second reading was taken, a memorial signed by more than three hundred eminent physicians, surgeons, and other scientific investigators, protesting against the measure, was addressed to the Home Secretary. The memorial is in the following terms:—"We desire to express to you our strong conviction that the Dogs Protection Bill, which is put down for second reading on Friday, 17th inst., would inflict very severe injury, not only on medicine and surgery, but also on the study of the diseases of animals. We think that we have some right to ask you to oppose this attack on the advancement of medical science and practice; especially as the Final Report of the Royal Commission on Vivisection does not advise the prohibition of experiments on dogs. We are absolutely certain that such experiments are necessary for the complete study of many problems of physiology, pharmacology, and pathology."

The discovery of a prehistoric workshop floor, with flints, and other fragments, was incorrectly said in a note last week (p. 169) to have been made at St. Albans, instead of Ipswich, though the latter place was mentioned later in the paragraph.

In the *Times* of April 11 Mr. H. St. George Gray gives his final report of the results of excavations at Maumbury Rings, Dorchester. The great earthwork has now been investigated. In prehistoric times there existed an immense circular ditch, having a medial diameter of 169 ft. This was adapted by later Roman settlers for use as an amphitheatre. In some respects Maumbury resembles Avebury, and the fosse in both cases may have been intended to prevent animals and the ordinary public from trespassing on a spot reserved for ceremonies conducted by the privileged. The excavations now in progress at Avebury may result in strengthening a comparison between these two important prehistoric enclosures.

In part i., vol. xxxvi., of the Transactions of the Bristol and Gloucestershire Archæological Society for 1913, Miss I. M. Roper discusses the delineation of flowers in stone in Bristol Church architecture. Such carvings appear only sporadically in Anglo-Saxon work, as at Britford, near Salisbury, and on Acca's Cross at Hexham. But they become numerous at the close of the Norman period, from A.D. 1175 to A.D. 1200. The designs are naturally conventional, but display much appreciation of botanical forms. It is possible in some churches to recognise the campanula, trefoil, and vine-leaf. The magical use of the holy herb, now known as yellow avens or herb bennet, constantly appears. Such flower ornamentation appears on the tower of St. Mary Redcliffe, A.D. 1292, and in the choir of Bristol Cathedral, A.D. 1298–1332. In the latter the oak-leaf is a common subject, and we also find the maple, beech, ivy, and hawthorn. Among herbaceous plants may be recognised the yellow water-lily, white bryony, and the buttercup. Miss Roper identifies the familiar ball-flower type of ornament with the ripe fruit of the juniper. Excellent as most of the carving is, its best efforts naturally bear no more than a coarse resemblance of nature's handiwork.

We have received the first progress report of the Thompson-McFadden Pellagra Commission. It includes a study of the epidemiology of pellagra by Capt. Siler and Surgeon Garrison, in which it is stated that observations on the habitual use of the more common foodstuffs failed to discover any points of difference between pellagrins and non-pellagrins.

The Journal of the Royal Society of Arts for March, 1914 (vol. lxii., No. 3199) contains a paper by Prof. Bottomley on the bacterial treatment of peat. The raw peat is treated in three stages—first, the raw peat is moistened with a culture solution of the special "humating" bacteria, and the mass is kept at a constant temperature for a week or ten days; during this time the bacteria act on certain organic constituents of the peat, and gradually convert a large amount of the humic acid present into soluble humates; secondly, the "humating" bacteria having done their work are destroyed by sterilising the peat by live steam; thirdly, the sterilised peat is treated with a mixed culture of nitrogen-fixing organisms—*Azotobacter chroococcum* and *Bacillus radicicola*—and after a few days' incubation at 26° C. is ready for use. The material so obtained possesses astonishing fertilising properties, and extensive trials with satisfactory results have been carried out at Kew.

Bulletins No. 10A and 10B of the Eugenics Record Office contain a report of "the committee to study and to report on the best practical means of cutting off the defective germ plasm in the American population." The former of these discusses the scope of the committee's work, which indeed covers the whole of "negative" eugenics and extends beyond it. The first problem is, of course, to decide what is defective germ plasm and how it manifests itself in the life and character of the individual who bears it. The committee has gathered little fresh knowledge in this field, and their treatment of the questions involved is rather unsatisfactory. For example, the most conspicuous feature of their discussion on criminality is an elaborate classification of crimes, which has not the merit of being logical, since qualities such as "incorrigibility" and conditions such as "prostitution" are included in it, whereas a crime must necessarily be an act. Bulletin 10B is a more useful work, as it contains an account of the American Sterilisation Laws, and of Bills which have been brought forward in State legislatures for this end without reaching the statute-books. An excellent summary of the laws was communicated to the last Eugenics Congress by Mr. Van Wagenen, in the form of a preliminary report of the committee, but the report now under notice is much fuller, and contains, in addition to the items mentioned, a record of the legal proceedings which have arisen out of the laws.

The *Psychological Review* for March contains an interesting paper by E. K. Strong, illustrating the application of psychological experiment to problems of commercial interest. The special problem under investigation was the relative efficacy of the one-page advertisement in four months compared with two half-page advertisements every two months, and with four quarter-page advertisements every month. This problem involved the consideration of two distinct points: the effect of increase in the size of an advertisement and the effect of continued repetition of an advertisement on the reader's memory. The advertisements for the experiment were carefully chosen so that they were not likely to be seen save in the test; other suitable precautions were also taken. The 288 advertisements selected were divided by the experimenter into four sets corresponding to the four monthly issues of a magazine. The four sets were shown to the subjects at intervals of a month. One month later the subjects were tested, by their ability to select from an equal number of advertisements previously seen and unseen, as to their remembrance of what had been shown them. The writer concludes (1) that the value of space in advertising as affecting permanent impressions increases approximately as the square-root of the increase in area, (2) that when the interval of time between successive presentations is very long (a month), space used in advertising is more effective when used in a large advertisement than if presented in small advertisements repeated with greater frequency.

The twenty-seventh annual report of the Marine Biological Station at Port Erin records that the number of workers in 1913 was seventy-two, and that all the available work-places were fully utilised during the Easter vacation. Though some relief was obtained by converting part of a large apparatus-room into a laboratory for bio-chemistry, extension of the laboratory accommodation will evidently be required in the near future. Besides the usual work in the laboratory and the shore-collecting, the students attending the course during the Easter vacation had the advantage of demonstrations of oceanographic work on Prof. Herdman's S.Y. *Runa*. The work of the fish hatchery has proceeded as in previous years; more than seven and a half millions of plaice larvæ were hatched, taken out to sea, and liberated, and the difficult work of rearing young lobsters has been carried on with some success. The report records the captures (many of which have already been noticed in the columns of Nature) made during the cruise of the *Runa* in the Hebridean Sea in 1913; these include 259 species of Foraminifera, several new to Great Britain, a preliminary list of which is given by Messrs. Heron-Allen and Earland.

We have received the report of the Rugby School Natural History Society for 1913, in which the secretary takes a thoroughly optimistic view of the present position and future prospects of that body. An article on the architectural works of Robert Adam and the "Adelphi" affords much interesting reading.

According to a statement issued by the Smithsonian Institution, the nearly complete skeleton of a dwarf horned dinosaur (Ceratopsia) has been discovered recently in the Montana Cretaceous. The skull measures only 22 in. in length, against from 6 to 8, or even 9 ft., in the larger members of the group, the whole size of the new form being only about one-fourth that of the latter.

The most interesting item in vol. x., part 1, of the Records of the Indian Museum is the description by Dr. W. M. Tattersall, in an article on Indian brackish-water crustaceans of the family Mysidæ, of a new genus and species from Bombay, for which the name *Indomysis annandalei* is suggested. So distinct is the genus that its inclusion in the subfamily to which it is most nearly related involves a modification in the definition of that group. It is "distinguished by the combination of characters afforded by the unjointed antennal scale, the short entire quadrangular telson, and the form of the pleopods in the male."

AN important contribution to our knowledge of the zoology of the Austro-Malay Archipelago is made by the appearance in vol. xix. of *Bijdragen Tot de Dierkunde* of the full scientific results of Dr. L. F. de Beaufort's journey in that region during the years 1909 and 1910. As we learn from the introduction, by Dr. de Beaufort, the main object of the expedition was to collect the fresh-water fauna of Buru, Ceram, Waigeu, and other islands, and thus complete, so far as possible, the work initiated by Prof. Max Weber, who was the first to collect systematically the fishes and other members of the fresh-water fauna of Sumatra, Java, Celebes, and other Sunda islands. But collecting, although not indiscriminate, was by no means restricted to the rivers and lakes, as may be seen by reference to the list of contents, which comprises ten articles by specialists, including one, with a coloured plate, on the fishes by Dr. de Beaufort, with remarks on the zoogeography of the region.

THE aforesaid article by Dr. de Beaufort on the fishes of the eastern islands of the Austro-Malay Archipelago is supplemented by one in the same fasciculus on those of Celebes by Prof. Max Weber. This issue also contains the results of Dr. C. Kerbert's study of the various local forms of long-beaked echidnas of the genus Zaglossus (Proëchidna), to which reference has been made previously in NATURE. It is illustrated by a plate showing the marvellous similarity between the walking pose of these strange beasts and that of a giant land-tortoise.

AT the price of one penny, the London County Council has issued "A Handbook to the Collections Illustrating a Survey of the Animal Kingdom," in the Horniman Museum and Library, Forest Hill. Although the text conveys a large amount of information, it would have been better suited to its purpose if a larger use had been made of the vernacular and fewer technicalities employed. It would also have been well to avoid the misstatement (p. 58) that the lower teeth of a dog are equal in number to the upper; whilst the merest tyro in natural history ought to be aware that Sibbald's fin-whale (p. 71) does not belong to the same genus as the Greenland whale. It is, moreover, unnecessary to add to the brain-worry of students by introducing so-called orders, like Ancylopoda (p. 65), which have long since been abolished.

THE *Bulletin Hydrographique* of the International Council for the Study of the Sea for the year July, 1911, to June, 1912, records the hydrographical observations carried out in the North Sea and adjacent waters during the period named. The observations do not appear to have been carried out upon as extensive a scale as in former years, and a chart of surface salinities for the North Sea is only provided for one month, viz., May, 1912. The mean surface temperatures are more fully shown in a series of charts which give the surface isotherms for periods of ten days, three charts being given for each month. A number of sections showing the conditions in the North Sea below the surface are also provided, based chiefly on Scottish and English work. The Finnish and Danish investigators contribute the results of numerous gas analyses of sea-water, the measurements given referring to the amounts of oxygen present at different depths at certain stations in the Gulf of Finland, in the Belts and Kattegat, and at the Faroes.

THE fauna of the great Ringk bing Fjord, on the west coast of Jutland, in the neighbourhood of Holmsland, forms the subject of an elaborate memoir by Dr. A. C. Johansen, published at Copenhagen in the volume entitled "Mindeskrift for Japetus Steenstrup," 1913. The subject has been treated by several previous writers, notably by Rambusch, in his "Studier over Ringkøbing Fjord," published in 1900, while a large amount of literature relating to the fisheries has appeared. Of all these sources of information the author has availed himself to the full, especial interest attaching to the physical changes recorded as having taken place between the middle of the seventeenth and the middle of the nineteenth century.

AN important study in European geography was contributed to the *Bulletin international de l'Académie des Sciences de Cracovie* during 1912 by L. Sawicki, entitled "Beiträge zur Morphologie Siebenbürgens." The explanatory method is followed, and a broad view may be gained of the changes that have taken place in the eastern Carpathian mass since the coastal plain of the Pontian sea was uplifted and a consequent system of westward-running rivers was established on its slope. This system was greatly interfered with by volcanic outpourings and cone-building in the Hargitta region, and the present young gorges of the Maros and the Alt are due to the escape of water that was ponded back in a series of lakes, and thus kept for a time from flowing westward. The same author describes glacial landscapes in the Westbeskiden, where the somewhat feeble local ice has left more evidence in the way of cirques and moraine-barriers than has previously been observed.

THE ninth paper by Dr. E. van Rijckevorsel on the periodicity of secondary maxima and minima in meteorological phenomena appears in No. 16 of the *Mededeelingen en Verhandelingen* of the Royal Meteorological Institute of the Netherlands. As any subsequent papers on this subject will be continued in the same publication, a brief statement of some of the results hitherto arrived at is given in the present number. In the yearly march of temperature certain small maxima were found about every ten or eleven days, which were constant in time and space. These zigzag curves ("Zacken") were also shown to exist for air-pressure, rainfall, etc., with important modifications relating to the occurrence of maxima and minima in different seasons. The author assumes that these zigzags are only special cases in a whole series of small periodical variations, and he has undertaken the laborious task of investigating these variations in detail.

IN a recent number of the *Annalen der Physik* there appears an important paper by Prof. Quincke on "Electrische Schaumwände der Materie." The subject-matter is a continuation of the work which has been done on the structure of "foam" walls and chambers, but in particular he points out an analogy between these and the electrical "dust" figures, which he regards as being due to the formation of foam chambers by electrical emanations of positively or negatively charged particles. Ordinary foam chambers made by precipitation or other methods he regards as being of two kinds: (1) those formed quickly in viscous fluids, and which may take a variety of forms, (2) those formed slowly in less viscous fluids, and which consist of globular cells connected by tubes. When the charged knob of a Leyden jar is presented to a cake of resin, he supposes that an electrical emanation of charged particles is emitted, and these particles are attracted to the plate of resin. By their impact they melt the resin locally to form an oil-like substance which solidifies around the charged particle, and thus produces a "foam" chamber with electrified walls. These chambers are rendered visible by dusting with the usual mixture of red lead and sulphur. He regards those upon which the sulphur is deposited as being similar to type (1), and those upon which the red lead settles as being similar to type (2).

NEARLY all the optically-active carbon compounds that have been prepared hitherto have been substances of relatively complex composition. The two simplest, lactic acid, $CH_3.\mathbf{C}H(OH).CO_2H$, and *sec.*-butyl alcohol, $CH_3.\mathbf{C}H(OH).C_2H_5$, contain three and four carbon atoms respectively; in each case also three of the four radicles attached to the asymmetric carbon atom **C** are compound radicles, and only one (the hydrogen atom) is simple. Special interest attaches therefore to the two simple substances, ammonium *d*- and *l*-chloroiodomethanesulphonates,

$$\mathbf{C}HClI.SO_3.ONH_4,$$

which have been prepared and separated in an optically-active form by Prof. Pope and Mr. Read (Trans. Chem. Soc., 1914, vol. cv., p. 811). In these substances three of the radicles are simple, and only one is compound; none of the four radicles contains a carbon atom, and the percentage of carbon amounts to less than 5 per cent. The two acids were separated by fractional precipitation from the ammonium salts by the addition of brucine; after reconverting into the ammonium salt the dextro-acid gave the molecular rotation $[M]_{5461}+43^\circ$. The active material is remarkably stable; the optical activity is not changed by boiling alone or with acids or alkalis, or by heating with water in a sealed tube to 130–150°.

Engineering and the *Engineer* for April 17 contain articles dealing with electric power supply in London. Messrs. Merz and McLellan have investigated this subject recently, and have presented a report to the London County Council. Apart from traction stations there are seventy generating stations at present in London, containing 585 engines. The report states that there are practically only two ways of effecting important economies in electricity generation in London; first, to allow the extension of eight or ten of the best existing stations, and gradually to abandon all the others; secondly, to abandon all sites in or near the metropolitan area, and to concentrate the production of electricity for all purposes well outside. The primary distribution system throughout London should be standardised. Assuming all existing stations for the supply of light and power to be in the hands of one authority, the final conclusions are that it would pay to shut them all down, sell most of the plant, and generate all energy on sites down the river. Considering only the central area, it is estimated that the saving in working costs with this scheme would be about 18 per cent., or 170,000*l.* a year.

THE editor of the new quarterly, *Isis*, devoted to the history and organisation of science, asks us to say that the annual subscription is 30 francs per annum, and not 24 francs as stated in a note in NATURE of April 9 (p. 143).

A COPY has been received of the second supplement, 1911–13, to the catalogue of Lewis's Medical and Scientific Circulating Library, 136 Gower Street, London, W.C. A classified index of subjects, with the names of those authors who have written upon them, is included.

OUR ASTRONOMICAL COLUMN.

COMET 1914*a* (KRITZINGER). — The following ephemeris of comet 1914*a* (Kritzinger) is published by Prof. Kobold in *Astronomische Nachrichten*, No. 4727:—

12h. Berlin M.T.

THE VARIABLE 081041, −41° 3911, H.V. 3372.—Prof. E. C. Pickering communicates some interesting facts relative to the spectrum and magnitude of the star C. DM. −41° 3911, this star having previously been found by Mrs. Fleming to be peculiar, and also later independently by Miss Cannon. In identifying this object Miss Mackie has found that it is a variable, and in this paper the magnitudes are given for the period 1890 to 1912. The nature of the variation is indicated by a curve. Prof. Pickering describes the object as a very curious one. At first sight it might appear to be a variable star with a period of about twenty years, and varying from the eleventh to the fourteenth magnitude. He points out that ordinary variables of long period have a very different spectrum and undergo all their changes in less than two years. In this case the variations may prove to be irregular and to resemble those of the three stars of the class of R. Coronæ. The position of the star for 1900 is R.A. 8h. 10·8m., and declination −41° 24′, and additional observations of both its magnitude and spectrum are required to settle the peculiarity above mentioned.

THE SOLAR CONSTANT OF RADIATION.—No one interested in this subject should fail to read an address delivered before the Philosophical Society of Washington by Prof. C. G. Abbot, the retiring president, and reported at length in *Science* of March 6. The address forms a valuable aperçu of the subject from Herschel's pioneer actinometric observations down to the experiments made late last summer under the joint auspices of the Smithsonian Institution and the U.S. Weather Bureau on the employment of *ballons-sondes* in pyrheliometric investigation. With regard to the solar constant, the mean value of 690 measurements made in connection with the Astrophysical Observatory of the Smithsonian Institution during the period 1902–13 is stated to be 1·933 calories per sq. cm. a minute, a value which is probably accurate to 1 per cent. It will be noted that this period covers one sun-spot cycle, and it is also stated that the Mount Wilson measures indicate that the solar radiation is more intense at spot maximum than at minimum, the sun thus showing affinity with variable stars of the *o*-Ceti type.

THE ACTION OF GRAVITY ON GASEOUS MIXTURES.—M. G. Gouy, in a recent communication to the Paris Academy of Sciences (*Comptes rendus*, vol. clviii., pp. 664–8) extends to the terrestrial atmosphere his researches on gaseous mixtures which during 1912 led him to the conclusion that pressure could not be the cause of the general displacement of the Fraunhofer lines towards the red. We may direct attention to the fact that the suggestion he then made that perhaps the explanation of this phenomenon would be found in the Doppler effect has received striking confirmation on purely spectroscopic grounds very recently in the work of Mr. Evershed (NATURE, March 19, p. 69). The present paper affords a mathematical demonstration of the impossibility of stratification according to density by the action of gravity on the gases in the earth's atmosphere where the pressure exceeds that of a Crookes tube as the final result indicates that under these conditions the effect of gravity on the composition of the air is too slow to produce sensible effects.

GROWTH AND CULTIVATION OF HOPS.[1]

THE close attention which is being given in many foreign countries to the scientific study of plants of economic importance is evidenced in the two reports on the hop lately published by Dr. J. Schmidt. Although the cultivation of hops in Denmark is at present restricted to about 100 acres, Dr. Schmidt, of the Carlsberg Laboratory, Copenhagen, was recently commissioned to visit this and other countries with the object of collecting information on the most modern methods of cultivation, and also to collect data and material likely to prove of value in the work of breeding improved varieties of hops for cultivation in Denmark. In 1910 the physiological department of the Carlsberg Laboratory began a series of investigations on the hop plant (*Humulus lupulus*, L.), with a view of obtaining information of theoretical and practical interest regarding this plant. These reports by Dr. Schmidt are the first-fruits of this work.

In the first report, the growth in length of the stem and its diurnal periodicity is dealt with. One of the first problems for investigation that presented itself was to ascertain if the foreign varieties of hops obtained from southern regions which are being grown in the experimental garden attached to the Carlsberg Laboratory have a different rate of growth in the northern climate of Denmark from the wild-growing plant of that country. In the course of making these investigations, which are not yet concluded, the experiments detailed in this first report were made.

Dr. Schmidt was at the outset inclined to the belief—a belief, by the way, which is firmly held by the practical hop-growers of Kent—that the growth of the hop stem, or "bine," would be strongest during the night. Observations on a number of plants soon showed, however, that the reverse is the case. The least growth took place during the six hours 9 p.m. to 3 a.m., which proved that darkness was not the dominant factor of growth. It might have been expected that the growth-promoting factor of darkness would first show itself as an "after-influence," and that consequently the greatest growth would be during the following morning period, 3 a.m. to 9 a.m. It was found, however, that the strongest growth occurred during the period 3 p.m. to 9 p.m., immediately preceding the darkest period, the value for the rate of growth increasing evenly from the minimum of the latter period to the maximum of the afternoon period.

In the two main series of experiments, which were carried out in 1911 from the end of April, to the end of June, and in 1912 during July, the plants, growing in an unheated glasshouse, were kept as far as possible under natural conditions. The measurements were made continuously at 6 o'clock in the morning, 12 o'clock noon, 6 o'clock in the afternoon, and at 12 o'clock at night. The diurnal oscillations of temperature were followed by means of a thermograph.

Further experiments made seemed to show conclusively that the influence of the temperature on the rate of growth under natural conditions predominates over the influence of humidity; as the author remarks, "the growth-promoting power, which high humidity is known to have under natural conditions, is 'covered' by the influence of the temperature, so that it appears as if only the temperature was of any importance for the rate of growth of hop-stems."

The results of the investigations are summed up as follows:—"The growth in length of hop-stems under natural conditions has a very distinct diurnal period, the rate of growth being smallest during the night, greatest during the day. This periodicity is determined by outer factors, among which the temperature has such a predominant influence that under natural conditions it determines the rate of growth."

The second report deals with investigations into the rotational movement of the hop-stem. In experiments with vigorous three-year-old hop-plants, in an unheated glasshouse, the stems were found to show, during May and June, a rotational movement amounting on an average for one to two weeks' observations to about 120° an hour, or one-third of the rate of the minute hand of the clock. The following table records the facts observed with two hop-plants, one (No. 14) obtained from Germany, the other (No. 36) from England:—

	No. of whole days under observation	Total rotation in degrees	No. of turns	No. of turns in 24 hours (Average)	No. of degrees an hour (Average)
Plant No. 14		°			°
Shoot *a* ...	9 ...	24865 ...	69 ...	7·7 ...	115
,, *b* ...	9 ...	25875 ...	72 ...	8·0 ...	120
,, *c* ...	11 ...	29810 ...	83 ...	7·5 ...	113
Plant No. 36	13 ...	37600 ...	104 ...	8·0 ...	120

The rotational movement proved to have a very distinct daily periodicity, the rate being greatest during the day, least at night. This daily periodicity is determined by external factors, among which the temperature is of such dominating importance that

[1] Johs. Schmidt: (1) "The Growth in Length of Hop-stems and its Diurnal Periodicity" (*Comptes rendus des travaux du Laboratoire de Carlsberg*, 10me vol., 2me livraison, 1913).
Idem. (2) "The Rotational Movement of Hop-stems and its Diurnal Periodicity" (*l.c.*, 3me livraison, 1913).

its variation under natural conditions is determinative for the rate of rotation.

A graphic comparison of the fluctuations in the rate of rotation and degree of humidity showed that there was no connection between them under the (natural) conditions prevailing when the observations were carried out.

From some laboratory experiments with pot-plants it appeared that the rotational movement is not different, or at any rate not essentially different, in the dark and in scattered daylight.

An endeavour was made, with the minimum temperature (which "lies in the neighbourhood of 4°") as starting point, to obtain an expression of the relative quantities of heat, which were of importance for the rate of rotation. The numbers obtained, which are called "active quantities of heat," show that there is a very complete agreement between fluctuations in these and in the rate of rotation, the fluctuations showing a perfect synchronisation under the conditions observed.

Comparative experiments with twining bean-plants, and with *Lonicera periclymenum*, L., showed that a similar daily periodicity in the growth in length and rate of rotation of the stem occurred and that temperature is here also the determining factor. The author concludes by remarking:—"It is probable that the growth movements in many plants living under climatic conditions such as ours, where great temperature fluctuations occur in a diurnal period, have a diurnal periodicity which follows that of the temperature." E. S. S.

EDUCATION IN INDIA.[1]

IN the two substantial volumes before us Mr. Sharp gives an exceedingly able and comprehensive summary of the educational work done in India in the period 1907–12. The value of this record is enhanced by the inclusion of a Resolution of the Government of India dated February 21, 1913, summarising its educational policy, and forming a masterly exposition of its aims. A member of the Council of the Government of India has now been appointed with special charge of education, and the first incumbent of the post is Sir Harcourt Butler, who is to be congratulated on this very able summary.

The impression gained from the volumes is that education in India has now entered on a new and hopeful page of its history, for the progress made in the past five or ten years has been very great. Every effort is being made not only to widen the area of education, but also greatly to improve its methods, while in the forefront the formation of the character of the pupils is rightly insisted on. There are also clear signs that in the future efforts will be made to raise the status of those engaged in education, and to make their position such that the post of a teacher will be much sought after, and not taken as a last resource, as is largely the case at the present time.

India is sometimes pictured as a single country, but it really shows far greater complexities in education than Europe itself. It is computed that there are about thirty-eight million children of school-going age in the area dealt with in this report, while there are only 176,225 educational institutions of all classes, and in these six and three-quarter million pupils are under instruction. Almost all of these are boys, and the most trustworthy figures show that in 1911–12 for every mille of population of school-going age there were 268 boys and 47 girls under education. Five years previously these figures were 227 and 32 respectively. This really represents rather rapid progress, though compared with civilised Europe, India is still very far behind in the education of its masses.

Until recent years more attention was paid to the development of higher education than to that of the masses, but this has been largely changed during the past ten years, and now primary education is being largely fostered.

The type of higher education at first introduced was unpractical, largely literary, and tended to superficial knowledge, and in a large proportion of the students it did not fit them for their work in after life. Various efforts at reform were made, but the first effective movement came from Lord Curzon when Viceroy of India, who in 1901 summoned a representative conference which dealt with the whole subject of education from the university down to the primary stage. Numerous far-reaching reforms were formulated, and the history of many of the reforms is illustrated in the work under review.

One of the results of the conference was the Universities Act of 1904, under which regulations were framed, which came into force about the beginning of the period which is dealt with in Mr. Sharp's volumes. This Act was most bitterly opposed, but it is now admitted that it has produced a general and most important improvement in both university and secondary education, for some of the universities in India have large powers over the secondary schools which prepare candidates for university education, as they regulate the courses of study and even have powers of inspection, etc. It is probably true to say more progress has been made during these five years in improving and consolidating secondary and university education than in any previous quinquennium, for institutions which were working inefficiently have ceased to be recognised and have disappeared, while others have been helped and made more efficient. Indeed, the report indicates there have been great improvements in the courses of instruction in colleges and schools, also in thoroughness of study, in the more practical requirements in the study of, and examination in, science subjects, and finally in considerable improvements in discipline and in the formation of character, due to the students being compelled to live in recognised hostels (on which much money has been spent) or in messes under proper supervision.

The reforms due to the Educational Congress of 1901 included a large extension and improvement in primary education and its more efficient inspection, and a recommendation that greater attention should be paid to the teaching in and through the vernaculars. Both these reforms have made large progress during the past five years, and are undoubtedly leading to sounder education. Attention is now also being paid to manual training and nature-study. An endeavour to obtain more trained teachers in all stages of education is occupying considerable thought, and efforts are being made to effect this, but when it is stated that there are 215,518 teachers in India, who all ought to be trained, the magnitude of the problem is seen to be almost overwhelming.

Increased attention has also been given to female education, which, owing to the peculiar difficulties arising from the customs of the people themselves, has always been, and still is, in a very backward condition. As the result of this increased attention during the five years, the number of girls at school has increased by 47·7 per cent., but even this large increase only brings up the percentage of girls at school to the population of girls of school-going age to 5·1 per cent. Strenuous efforts are being made to

[1] Progress of Education in India in 1907–12. Sixth Quinquennial Review, by H. Sharp. Vol. i., pp. xvii+284+index; vol. ii., pp. 292. (Calcutta: Superintendent Government Printing, India, 1914.) Prices, vol. i., 6*s.*; vol. ii., 3*s.*

render female education more popular and effective, and on their success the future progress of India in a large measure depends.

It is remarked that during the five years a very great change has taken place in the feeling of the population of India towards education, and it is now much more popular than it was. Indeed there was a proposal to make primary education compulsory in India generally, but this has been negatived, though it is being adopted in Baroda.

Much more money is now being spent on education. In 1907 the cost of education was said to be 559 lakhs of rupees, and in 1912 it had risen to 786 lakhs, of which the Government contributed a very large proportion. With this liberal policy there is no doubt very rapid progress will be made, for the cost of educating individual pupils in India is still small. Thus the annual cost of a primary-school pupil is about six shillings, of a secondary-school pupil about *1l. 12s.*, and of a pupil reading for a university degree about *11l. 5s.*, and yet with these small individual sums a fair training is being given in the case of university and secondary education, though the primary education is still very defective.

THE MOUNT WILSON SOLAR OBSERVATORY.

IT is always difficult to condense in a few lines the essence of the work accomplished during a year at the Mount Wilson Solar Observatory. The report for the past year, just issued by the director, is a concentrated essence by itself, and as it covers forty-five pages the difficulty of the task will at once be grasped. The director commences the report by summarising the principal results obtained during the year, and the brief paragraphs which compose this summary, each of which is practically restricted to an important piece of research work, number no fewer than *seventy-two*. Space does not permit one to refer even to the more important of these, but many have already received notice from time to time in our astronomical column, and are therefore familiar to our astronomical readers. Perhaps the most important result is that concerning the magnetism of the sun. Observations of the Zeeman effect at various solar latitudes have indicated that the sun is a magnet, and that the magnetic poles are at or near the poles of rotation. Further, the polarity of the sun corresponds with that of the earth, a conclusion, as the director, Prof. Hale, remarks, which may prove to have an important bearing on theories of terrestrial magnetism. The first approximate value for the vertical intensity of the sun's general field at the poles is given as 50 gausses, which is about one-hundredth of the intensity of the most powerful sun-spot fields, and about eighty times that of the earth's field.

One of the most interesting items usually associated with these reports is the work of construction in hand, and this report shows an astonishing amount of work in progress. The fact that the 100-in. disc has been proved to be serviceable for a reflecting telescope has given rise to a great increase of activity. The grinding of the mirror and the 60-in. plane mirror for testing it have been pressed forward, and the requirement for larger shop tools necessitated by the construction of many parts of the 100-in. telescope mounting and the auxiliary instruments to be used with it have even demanded an increase in the already large shop floor-space. The work involved in the preparation of the foundations for this telescope and of the building and the eventual transport of the instrument to the mountain-top has necessitated the adoption of especially powerful motor trucks in place of the mule teams.

Other important work in hand is the construction of a large ruling-machine, embodying the general principles of Rowland's successful ruling-machines. An idea of the accuracy attained after the grinding and polishing of the screw will be gathered from the statement that no periodic errors were found greater than 0·000001 in., and no appreciable error of run could be detected. The maximum error in the teeth of the wormgear did not exceed 0·001 in., a quantity too small to produce appreciable ghosts.

To gain a more complete insight into the contents of the report the reader must be referred to the report itself. The fact that such rapid advances are being made in both solar and stellar physics is due to the happy combination of an energetic and able director, a keen and active staff, a good observing site, and an annual grant (for 1913) of 33,126*l.* for construction, investigations and maintenance.

MARINE INVESTIGATIONS.

THE report on the Danish Oceanographical Expeditions, 1908–10, to the Mediterranean and Adjacent Seas, under the superintendence of Johs. Schmidt, No. 2, contains two memoirs, one by Dr. Kyle, on flat fishes, and one by Dr. Schmidt, on experiments with drift-bottles. Dr. Kyle's paper is an important contribution, and deals with the following genera in a very comprehensive way :—Arnoglossus, Bothus, Solea, and Symphurus. The much disputed question as to the number of species of Arnoglossus occurring in European seas is very elaborately discussed, and Dr. Kyle's conclusions differ in several respects from those of previous authors. He recognises five species, the specific names being used, however, in a different sense from that which has been adopted by recent writers on the subject. The species are *Arnoglossus grohmanni*, Bonap., non auctorum, *A. thori*, nov. nom., *A. laterna*, Will., *A. imperialis*, Raf., and *A. rüppelli*, Cocco. Of these *A. thori* is the species which has generally been called in this country *A. grohmanni*. Dr. Kyle discusses not only the adult characters, but also the larval and post-larval stages of this genus and of the other genera of which he treats. The paper is well illustrated with text figures and plates, and will be of the greatest value to future workers. An excellent bibliography of the subject is added. Dr. Schmidt's experiments with drift-bottles show that there is an easterly drift of the surface water from the entrance of the Mediterranean, especially along the north coast of Africa, so that water from the Atlantic is being constantly carried into the Mediterranean. The velocity of this drift may reach eighteen to twenty miles a day.

The Central Bureau of the International Council for the Study of the Sea has issued vol. xvii. A of the "Rapports et Procès-verbaux des Réunions" (English edition), which contains the first part of Prof. Heincke's long-delayed general report upon the investigations on the plaice. This part of the report is confined almost exclusively to a discussion of the statistics obtained from commercial fishing vessels, and is further limited in scope by the fact that the English statistics are alone considered. The report is, in fact, little more than a renewed attempt to discuss the conclusions to be derived from these English statistics, matters which had already been dealt with by the officers of the Board of Agriculture and Fisheries. It is doubtful whether Prof. Heincke's methods of dealing with the statistics are in any way an improvement upon those followed in this country, and, probably from want of adequate trained assistance, it seems clear that the work has not been carried out with that accuracy of detail which is, we believe, attained by the statistical department of the English Board. In this connection Prof. Heincke states (p. 66):—"The appendix to this report contains a number of these tables drawn up by me from the English measurements. Close inspection will show, that here and there inaccuracies and errors have crept in during the preparation of the tables. Thus, in the case of large numbers which are the sum of many measurements, smaller or larger differences may be present between the English data and my tables. These small discrepancies will perhaps be excused, when the enormous amount of calculating work is considered; I do not believe that any essential error is present, which might lead to erroneous conclusions." In the opinion of the writer of this note there can be no excuse for a slovenly and inaccurate treatment of statistical data, and figures should not be published until errors such as those alluded to by Prof. Heincke have been eliminated.

SURFACE COMBUSTION.[1]

During his researches upon flame,[2] Sir Humphry Davy discovered, in 1817, that the constituents of a combustible mixture will combine slowly below the ignition temperature; this led him to inquire whether, seeing that the temperatures of flames far exceed those at which solids become incandescent, a metallic wire can be maintained at incandescence by the combination of gases at its surface, without actual flame. He thereupon tried the effect of introducing a warm platinum wire into a jar containing a mixture of coal-gas and air rendered non-explosive by an excess of the combustible constituents; the wire immediately became red hot, and continued so until nearly the whole of the oxygen had disappeared.

During the twenty years which followed Davy's discovery, several distinguished chemists (William Henry and Thomas Graham in this country, but more particularly Dulong and Thénard, and independently Döbereiner in France) experimented upon the slow combination of gases at temperatures below the ignition point, in contact with hot solids, whereby it was established (1) that hot solids, and pre-eminently metals of the platinum group, have the power of inducing gaseous combustion at relatively low temperatures; and (2) that hydrogen is, of all combustible gases, the most susceptible to this action.

The mechanism of this induced slow surface combustion formed the subject of a celebrated controversy between Faraday and De la Rive in 1834–5. De la Rive held the view that it consists essentially in a series of rapidly alternating oxidations and reductions of the surface; Faraday, on the other hand, contended that the function of the surface is to condense both the oxygen and the combustible gas, thus producing in the surface layers a condition comparable to that of high pressure. But, owing to lack of crucial experiments, no satisfactory theory of the phenomenon could be evolved, nor, with the exception of the famous "Döbereiner lamp," was there any practical outcome of this early work. In 1836 interest in the subject suddenly dropped, and was not revived for half a century.

Meanwhile, the researches of Deville upon the dissociation of steam and carbon dioxide at high temperatures led to the notion, which was strongly upheld by the late Frederick Siemens, that inasmuch as incandescent surfaces promote dissociation, they must necessarily hinder combustion. This, of course, is fallacious; we now recognise that if, as Deville proved, an incandescent surface accelerates the dissociation of steam, it must, according to a principle enunciated by Ostwald, of necessity accelerate the combination of oxygen and hydrogen in like degree, provided always that the surface remains chemically unaltered.

A notable demonstration of the possibility of realising a flameless incandescent surface combustion in contact with metals other than those of the platinum group was given by Thomas Fletcher in a lecture at the Manchester Technical School so far back as 1887.[3] He injected a mixture of gas and air on to a large ball of iron wire, flame being used at first in order to heat the wire to the temperature necessary to induce a continuous surface combustion; on extinguishing the flame, by momentarily stopping the gaseous mixture, the combustion continued without any flame, but with an enormous increase of temperature. Fletcher grasped three important points, namely, (1) that "this invisible flameless combustion is only possible under certain conditions"; (2) "that the combustible mixture shall come into absolute contact with a substance at high temperature . . ."; and (3) that "in the absence of a solid substance at a high temperature, it is impossible to cause combustion without flame"; but, so far as I am aware, he did not follow up the matter beyond this point, either in its theoretical aspects or practical applications, and his work had but little influence upon contemporary opinion or practice.

My own investigations upon surface combustion began in 1902 with a systematic attempt to elucidate the factors operative in the slow combination of hydrogen and of carbon monoxide in contact with various hot surfaces (*e.g.* porcelain, fire-clay, magnesia, platinum, gold, silver, copper, and nickel oxides, etc.) at temperatures below 500°.[4] Into the details of these earlier experiments, which preceded and led up to the technical developments about which I shall speak later, I do not propose to enter; it will be sufficient for my present purpose if I say that it was proved beyond all question:—(1) That the power of accelerating gaseous combustion is possessed by *all* surfaces at temperatures below the ignition point in varying degrees, dependent upon their chemical characters and physical texture; (2) that such an accelerated surface combustion is dependent upon an absorption of the combustible gas, and probably also of the oxygen, by the surface, whereby it becomes "activated" (probably ionised) by association with the surface; and (3) that the surface itself becomes electrically charged during the process. Finally, certain important differences between homogeneous combustion in ordinary flames and heterogeneous combustion in contact with a hot surface from a chemical point of view were established, so that there can be no longer any doubt as to the reality of the phenomenon.[4]

If hot surfaces possess the power of accelerating gaseous combustion at temperatures below, or in the neighbourhood of, the ignition point, the same power must also be manifested in even a greater degree at higher temperatures, and especially so when the surface itself becomes incandescent. Indeed, there are experimental grounds for the belief that not only does the accelerating influence of the surface rapidly increase with the temperature, but also that the differences between the catalysing powers of various surfaces, which at low temperatures are often considerable, diminish with ascending temperatures until at bright incandescence they practically disappear.

Such considerations as I have thus briefly explained

[1] From a discourse delivered at the Royal Institution on Friday, February 27, by Prof. W. A. Bone, F.R.S.

[2] Collected Works, vol. vi., p. 8.

[3] Journal of Gas Lighting, 1887, i, p. 168.

[4] Bone and Wheeler, Phil. Trans. Roy. Soc., 1906 (A. 206, pp. 1–67), also further (unpublished) results (1905–12) in collaboration with Messrs. G. W. Andrew, A. Forshaw, and H. Hartley, which are summarised in *Berichte der Deutschen Chem. Ges.*, 1913.

convinced me some years ago that if an explosive gaseous mixture be either injected on to or forced through the interstices of a porous refractory incandescent solid under certain conditions, which will be hereafter explained, a greatly accelerated combustion would take place within the interstices or pores, or, in other words, within the boundary layers between the gaseous and solid phases wherever these may be in contact—and the heat developed by this intensified combustion would maintain the surface in a state of incandescence *without any development of flame*, thus realising the conception of *flameless incandescent surface combustion*, as a means of greatly increasing the general efficiency of heating operations wherever it can be conveniently applied.

There are critics who, whilst admitting the accelerating influence of an incandescent surface upon gaseous combustion, are sceptical about the process being really flameless. The force of such objections largely disappear when we get into close quarters with the phenomenon, and realise how extremely slow a transaction flame combustion really is when considered in terms of molecular time. Take, for example, the case of such a quick-burning mixture as electrolytic gas ($2H_2+O_2$). When this is ignited at atmospheric pressure, the flame is initially propagated by conduction with a uniform slow velocity of 20 metres a second, and during this initial period of "*inflammation*," the total duration of chemical change in each successive layer is something like the order of 1/50 second, an interval of at least one hundred million times as long as the average interval between successive molecular collisions in the gas. Even after "*detonation*" has been set up in the mixture, when the combustion is propagated from layer to layer as a wave of adiabatic compression, at a velocity of 2820 metres a second, the total duration of chemical change is still of the order of 1/5000 or 1/10,000 second, or about a million times as long as the interval between successive molecular collisions.

The New Processes of Incandescent Surface Combustion.

Leaving the theoretical aspects of the subject, I will now describe some of the more important features of two processes of incandescent surface combustion evolved at the works of Messrs. Wilsons and Mathiesons, Ltd., in Leeds, under my direction, with the assistance of Mr. C. D. McCourt, in which a homogeneous explosive mixture of gas and air, in the proper proportions for complete combustion (or with air in slight excess thereof), is caused to burn without flame in contact with a granular incandescent solid, whereby a large proportion of the potential energy of the gas is immediately converted into radiant form. The advantages claimed for the new system, now known as the "Bonecourt" system, are:—(1) The combustion is greatly accelerated by the incandescent surface, and, if so desired, may be concentrated just where the heat is required; (2) the combustion is perfect with a minimum excess of air; (3) the attainment of very high temperatures is possible without the aid of elaborate regenerative devices; and (4) owing to the large amount of radiant energy developed, transmission of heat from the seat of combustion to the object to be heated is very rapid. These advantages are (as I believe) so uniquely combined in the new system that the resultant heating effect is, for many important purposes not only pre-eminently economical, but also easy of control.

Diaphragm Heating and its Applications.

In the first process the homogeneous mixture of gas and air is allowed to flow under slight pressure through a porous diaphragm of refractory material from a suitable feeding chamber, and is caused to burn without flame at the surface of exit, which is thereby maintained in a state of red-hot incandescence. The diaphragm is composed of granules of firebrick, or other material, bound together into a coherent block by suitable means; the porosity of the diaphragm is graded to suit the particular kind of gas for which it is to be used. The diaphragm is mounted in a suitable casing, the space enclosed between the back of the casing and the diaphragm constituting a convenient feeding-chamber for the gaseous mixture which is introduced at the back. Such a mixture may be obtained in either of two ways, namely, (1) by means of suitable connections through a Y-piece with separate supplies of low pressure gas and air (2 or 3 in. W.G. is sufficient), or (2) by means of an "injector" arrangement connected with a supply of gas at a pressure of 1 to 2 lb. per sq. in.; the gas in this case draws in its own air from the atmosphere in sufficient quantity for complete combustion, the proportions of gas and air being easily regulated by a simple device.

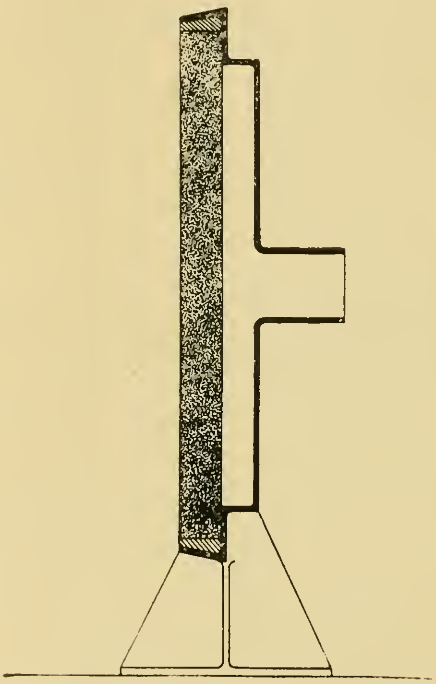

FIG. 1.—Diaphragm.

We will now start up a diaphragm (Fig. 1). Gas is first of all turned on and ignited as it issues at the surface; air is then gradually added until a fully aerated mixture is obtained. The flame soon becomes non-luminous, and diminishes in size; a moment later, it retreats on to the surface of the diaphragm, which at once assumes a bluish appearance; soon, however, the granules at the surface attain an incipient red heat, producing a curious mottled effect; finally, the whole of the surface layer of granules becomes red-hot, and an accelerated "surface combustion" comes into play. All signs of flame disappear, and there remains an intensely glowing surface throwing out a genial radiant heat which can be steadily maintained for as long as required.

Whilst the diaphragm is in operation before you, I may point out some of the more striking features of the phenomenon which it presents. First, the actual combustion is confined within a very thin layer—⅛ to

$\frac{1}{4}$ in. only—immediately below the surface, and no heat is developed in any other part of the apparatus. Kindly observe that while the front of the diaphragm is intensely hot, the back of the apparatus is so cold that I can lay my hand on it. Secondly, the combustion of the gas, although confined within such narrow limits, is perfect, for when once the relative proportions of gas and air have been properly adjusted, no trace of unburnt gas escapes from the surface. Thirdly, the temperature at the surface of the diaphragm can be instantly varied at will by merely altering the rate of feeding of the gaseous mixture; there is practically no lag in the temperature response, a circumstance of great importance in operations where a fine regulation of heat is required. Fourthly, a plane diaphragm such as this may be used in any position, *i.e.* at any desired angle between the horizontal and vertical planes. Fifthly, the diaphragm method is amenable to a variety of combustible gases —coal or coke oven gas (either undiluted or admixed with water gas), natural gas, petrol-air gas, carburetted water gas are all well suited in cases where unimpeded radiation is required. Finally, the incandescence in no way depends upon the external atmosphere. When once the diaphragm has become incandescent, and the proportions of air and gas supplied in the mixing chamber at the back have been properly adjusted, the surface will maintain its incandescence unimpaired, even in an atmosphere of carbon dioxide.

I need scarcely point out to you the many obvious purposes, domestic and industrial, to which "diaphragm heating"[2] may be applied. In the domestic line the boiling of water, grilling, roasting, and toasting are at once suggested, and although the best existing types of gas fires are thoroughly hygienic and efficient, I think that the diaphragm may come in for the heating of apartments; at any rate experiments are being carried out in that direction.

Incandescent Surface Combustion in a Bed of Refractory Granular Material.

The second process is applicable to all kinds of gaseous or vapourised fuels; it consists essentially in injecting, through a suitable orifice at a speed greater than the velocity of back-firing, an explosive mixture of gas (or vapour) and air in their combining proportions into a bed of incandescent granular refractory material which is disposed around or in proximity to the body to be heated (Fig. 2).

This process is capable of adaptation to all kinds of furnace operations, as, for example, to the heating of crucibles, muffles, retorts, and to annealing and forging furnaces generally. Moreover, it is not essential that the bed of refractory material should be very deep; indeed a quite shallow bed suffices to complete the combustion. Neither is it necessary that the bed shall be disposed *around* the vessel or chamber to be heated; for if contact with the burnt products is not objectionable, a shallow bed may be arranged *within* the heating chamber itself; or the refractory material may be equally well packed into tubes, or the like, traversing the substance or medium to be heated. The last-named modification is, as we shall see later, specially important in relation to steam-raising in multitubular boilers.

By means of this process much higher temperatures are attainable with a given gas than by the ordinary methods of flame combustion without a regenerative system, and, as a matter of fact, we have found that with any gas of high calorific intensity (such as coal gas, water gas, or natural gas) the upper practicable temperature limit is determined by the refractoriness of the material composing the chamber to be heated (*i.e.* the muffle or crucible) rather than by the possibilities of the actual combustion itself. When I tell you that in a crucible fired by coal gas on this system we have melted Seger-cone No. 39, which according to the latest determination of the German Reichsanstahlt melts at 1880° C. (3416° F.), and also that we can easily melt platinum, you will appreciate the possibilities of the method in regard to high temperatures with gas-fired furnaces.

Surface Combustion as Applied to Steam Raising.

I now come to an important application of the new process to the raising of steam in multitubular boilers; not that the application of surface combustion is limited to boilers of the multitubular type, but because our investigations have so far been principally made with these.

Our first experiments in Leeds were made with a single steel tube 3 ft. in length and 3 in. in diameter, packed with fragments of granular refractory material, meshed to a proper size, and fitted at one end with a fire-clay plug, through which was bored a circular hole, $\frac{3}{4}$ in. in diameter, for the admission of the explosive mixture of gas and air at a speed greater than that of back-firing. The tube was fitted into an open trough, in which water could be evaporated at atmospheric pressure.

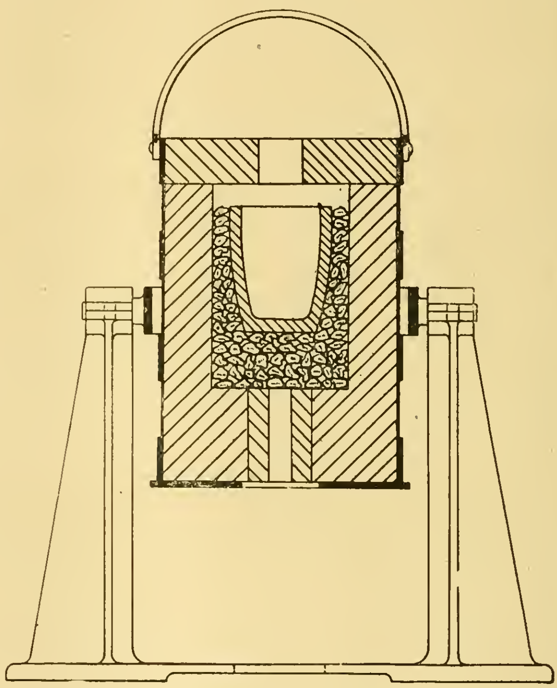

FIG. 2.—Crucible furnace.

Such a tube may be appropriately termed the fundamental unit of our boiler system, because boilers of almost any size may be constructed merely by multiplying the single tube, and as each tube is, so to speak, an independent fire or unit, the efficiency of the whole is that of the single tube, or, in other words, the efficiency of the whole boiler is independent of the number of tubes fired.

Experimenting with such a tube, it was found possible to turn completely a mixture of 100 cu. ft. of coal gas plus 550 cu. ft. of air an hour, and to evaporate about 100 lb. of water from and at 100° C. (212° F.) an hour (20 to 22 lb. per sq. ft. of heating surface), the products leaving the further end of the tube at practically 200° C. This meant the transmission to the water of 88 per cent. of the net heat developed by the combustion, and an evaporation per sq. ft. of heating surface nearly twice that of an express locomotive boiler. The combustion of the gas was completed within 4 or 5 in. of the point where it entered the tube, whilst the temperature of the products leaving the tube was about 200° C. Of the total evaporation, no less than 70 per cent. occurred over the first linear foot of the tube, 22 per cent. over the second foot, and only 8 per cent. over the last foot. This points to a very effective "radiation" transmission from the incandescent granular material in the first third of the tube, where the zone of active combustion is located, although it should be remarked that the *loci* of actual contact between the incandescent material and the walls of the tube are so rapidly cooled by the transmission of heat to the water on the other side that they never attain a temperature even approaching red heat. The granular material in the remaining two-thirds of the tube serves to baffle the hot products of combustion, and to make them repeatedly impinge with high velocity against the walls of the tube, thus materially accelerating their cooling, and either preventing or minimising the formation of the feebly-conducting stationary film of relatively cold gases which in ordinary boiler practice clings to the tube walls, seriously impairing the heat transmission.

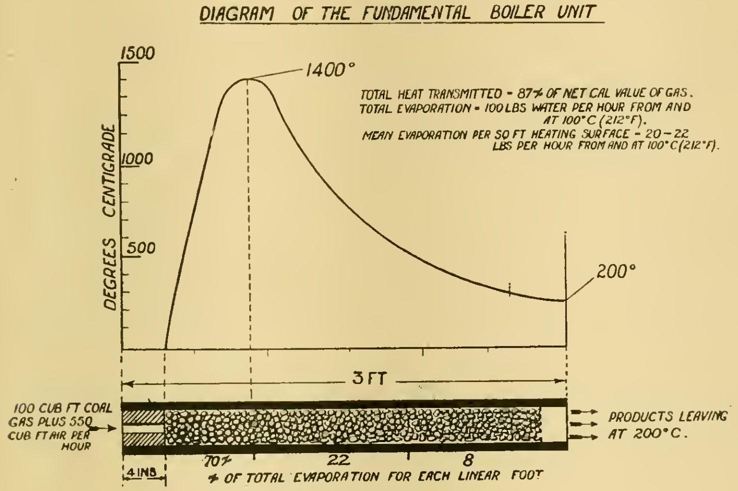

Fig. 3.—Fundamental boiler unit.

Having thus satisfied ourselves of the efficiency of the fundamental unit as an evaporator, we proceeded to construct our first experimental boiler, made up of ten tubes, each 3 ft. long and 3 in. in diameter, fixed horizontally in a cylindrical steel shell capable of withstanding a pressure of more than 200 lb. per sq. in. The gaseous mixture was forced through the tubes under pressure from a special feeding chamber attached to the front plate of the boiler; the products of combustion, after leaving the boiler, passed through a small feed-water heater containing nine tubes, each 1 ft. long and 3 in. in diameter, filled with granular material to facilitate the exchange of heat.

This combination of boiler and feed-water heater proved remarkably successful in every way; its thermal efficiency was 94 per cent., with an evaporation of from 21 to 33 lb. per sq. ft. of heating surface per hour.

The 110-Tube Boiler at the Skinningrove Ironworks.

Six months' continuous experience with our first experimental unit gave us great confidence in its trustworthiness, so that when in the early months of 1911 we received an inquiry from the Skinningrove Iron Co., Ltd., for a boiler of about ten times the capacity of the experimental unit, to be fired by means of the surplus gas from their new Otto by-product coking-plant, we had no hesitation in accepting a commission to install our first large boiler there, under a strict guarantee as to its output and efficiency.

The plant was successfully started up on November 7, 1911, for a month's trial run—day and night continuously—after which it was opened up for an official inspection by the representative of a Boiler Insurance Company. Everything worked without a hitch during this trial; steam was generated at 100 lb. gauge pressure, from a feed-water of about 4° of hardness, whilst the average temperature of the waste gases leaving the feed-water heater was reduced to 80° C. (say 175° F.), a sure indication of the high thermal efficiency of the plant. When, at the conclusion of the month's trial, the boiler was opened up for inspection, the combustion tubes were found to be in good condition and free from scale; indeed, owing to the extremely high rate of evaporation, the scaling troubles experienced with other types of multitubular boilers appear to be completely obviated, the scale being automatically and continuously shed from the tube in thin films (about 1/30 in. thick) as fast as it is formed; a very important advantage, as anyone who is plagued by scaling troubles will appreciate. An independent trial of the plant on July 29, 1912, gave a thermal efficiency of 92.7 per cent.

Within the last few months the firm of Krupps have put down a boiler in connection with one of their coking plants in the Ruhr district of Westphalia, from the plans of the Skinningrove plant. This boiler has been running successfully since October last, and about three weeks ago underwent its official steam trials, which were carried out by the Bergbauliche Verein. Pending the official publication of the results in the German technical Press, I am precluded from giving any details now, but, I am informed, that they have entirely confirmed the Skinningrove trial.

I have perhaps said enough already about the boiler and its working to convince you that it combines high thermal efficiency and concentration of power, in a unique degree, and perhaps I may be permitted to summarise the other important advantages which may be claimed for it. First, from the constructional point of view, nothing could be simpler or more compact than a cylindrical shell only 4 ft. long by 10 ft. in diameter, traversed by straight tubes, supported on a casting, and requiring neither elaborate brickwork setting nor expensive chimney flues and stack. Secondly, it has a further advantage over all multitubular boilers in that the front plate can never be heated beyond the temperature of the water, however much the firing may be forced, a circumstance which, coupled with the extremely short length of the tubes, implies an absence of strain and greatly reduces the risk of leaky joints. Thirdly, the high rate of mean evaporation obviates scaling troubles, and the very steep evaporation gradient along each tube causes a considerable natural circulation of water in the boiler, a factor of great importance from the point of view of good and efficient working; in this connection I may remind you that under normal working conditions we obtain a *mean evaporation* of 20 lb. per sq ft. of heating surface an hour, and can, if need be, force this up to 35 lb.; of this total evaporation, 70 per cent. occurs over the first *third* length of the tube, 22 per cent over the *second* third, and only 8 per cent. over the last third. Fourthly, inasmuch as each tube of the boiler is, so to speak, an independent combustion unit, capable of being shut off or lit up without affecting the others, and as it only takes five minutes after lighting up a cold tube to attain its maximum steam output, it is obvious that not only is such a boiler highly responsive to rapid variations in the load, but also it works with equal efficiency at both small and big loads; indeed, within very wide limits, its efficiency is practically independent of the load.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Aberdeen.—Lord Elgin has been elected Chancellor of the University in succession to Lord Strathcona.

London.—The following courses of advanced lectures, addressed to students of the University and to others interested in the respective subjects, to which admission is free without ticket, are announced in the issue of the *London University Gazette* of April 8:—Five lectures on the earlier Palæozoic land plants at University College, by Dr. D. H. Scott, on Wednesdays, May 6 to June 3; two lectures on plant pigments at University College, by Prof. R. Willstätter, professor of chemistry in the University of Berlin, on Monday, May 4, and Tuesday, May 5; two lectures, in French, entitled "La Catalyse, et mes divers travaux sur la Catalyse," at King's College, by Prof. Paul Sabatier, of the University of Toulouse, on Thursday, May 14, and Friday, May 15; eight lectures on the rate of the blood-flow in man in health and disease, in the Physiological Laboratory of the University, South Kensington, by Prof. G. N. Stewart, professor of experimental medicine, Western Reserve University, Cleveland, U.S.A., on Tuesdays, May 5–23; eight lectures on oxidation in the tissues, at University College, by Dr. C. Lovatt Evans, on Fridays, May 8 to June 26; four lectures on the regulation of the composition and volume of the blood, in the Physiological Laboratory of Guy's Hospital, by Dr. J. S. Haldane, on Thursdays, May 7–28; four lectures on the gaseous exchanges of the body, in the Physiological Laboratory of King's College, by Prof. T. G. Brodie, professor of physiology in the University of Toronto, on Monday, June 8, Wednesday, June 10, Monday, June 15, and Wednesday, June 17; three lectures on the morphology of the cranial muscles in vertebrates, in the Zoological Department, University College, by Prof. F. H. Edgeworth, professor of medicine in the University of Bristol, on Monday, May 4, Tuesday, May 5, and Wednesday, May 6; five lectures on the measurement of social phenomena, at the London School of Economics and Political Science, by Dr. A. L. Bowley, University reader in statistics, on Mondays, April 27 to May 25.

Among the public lectures, to which admission is free without ticket, announced to be delivered at University College during the third term of the present academic year, the following may be mentioned:—Four lectures on the ethnology and pathology of the ancient Egyptians, by Dr. D. E. Derry, beginning on May 5, at 5 p.m.; a lecture on Ptolemy's map of Germany and the Cimbric Chersonese, by Prof. Gudmudd Schütte, on May 11, at 5 p.m.; an introductory lecture on recent discoveries in Egypt, by Prof. Flinders Petrie, on May 21, at 2.30 p.m.

Glasgow.—The following doctorates were among the degrees conferred on April 20:—Doctor of Philosophy (D.Phil.): L. J. Russell; thesis, "The Development of the Philosophy of Leibniz, 1666–86." Doctors of Science (D.Sc.): Margaret B. Moir; thesis, "The Influence of Temperature on the Magnetic Properties of Carbon Steels; Sensitive Magnetic State induced by Thermal Treatment and by Strain; Magnetic Properties of Chrome Steels at Ordinary and Low Temperatures: Permanent Magnetism of Chrome Steels; with other papers." F. Mort; thesis, "North Arran: a Physiographic Study; with others papers." Maggie M. J. Sutherland; thesis, "Camphenanic Acid, its Isomers and Derivatives; with other papers."

Science states that a contribution of 10,000*l*. from Mrs. E. H. Harriman to the endowment fund of Barnard College, Columbia University, is announced toward the million dollar fund now being raised for the twenty-fifth anniversary of the institution. The amount now promised is 110,000*l*.

Mr. H. Norman Edge has been appointed honorary lecturer on meteorology to the Lancashire (Navy League) and National Sea Training Homes. As increased attention is now being given to the subject of marine meteorology, and a number of vessels keep a four-hourly log, the instruction in the keeping of the meteorological log to boys being prepared for a seafaring life is of real practical value.

It is announced in the *Times* that the late Mr. H. B. Noble, of Douglas, Isle of Man, left practically all his large estate for educational and charitable purposes in the island. The trustees of his will have decided to devote 20,000*l*. for the fostering of agriculture in the island. In connection with this gift a Bill has been introduced into the Manx Legislature constituting a Board of Agriculture for the island. The Board will administer the income arising from the gift, and will, in addition, have a fund placed at its disposal by the Government of the island.

A comprehensive resolution dealing with the age of exemption from attendance at school, continuation classes, and child labour, was passed by the National Union of Teachers at the Lowestoft conference on April 15. The resolution, which was moved by Mr. G. Sharples, was as follows:—That all regulations recognising the half-time system, labour examinations, and other forms of early exemption from attendance at school should be abolished; that no child should be exempt from attending under the age of fourteen; that local authorities should be empowered to make by-laws requiring the attendance of children up to the age of fifteen; that all wage-earning work, and particularly all street trading, should be prohibited for all children under fourteen, both in urban and rural districts; and that a system of compulsory attendance at continuation classes should be established for children between the ages of fourteen and eighteen who are not otherwise receiving a suitable education, such a system to be accompanied by a statutory limitation of the hours of child labour.

A weak point in most of the Continental educational systems is that there is no easy bridge by which the public elementary and trade continuation class pupil can pass into the higher ranks of his vocation and complete his studies in the polytechnic or university. The avenue to these higher institutions is almost solely through the gymnasial secondary schools. In the facilities offered by scholarships for the transference of gifted pupils from primary schools to secondary schools and through these to universities and like places of advanced learning, we have nothing to learn from Continental methods. The scholarship systems of the education authorities of English counties and county boroughs provide the means by which any elementary-school pupil of little more than average ability can obtain a free-place in a secondary school; and the brilliant pupil can proceed from this stage to a higher by means of senior scholarships. We are reminded of the efficiency of this educational ladder by a return just made to the Somerset County Council by the County Education Committee. It appears from this report that twenty-five out of the thirty senior county scholars referred to in it were enabled by the Education Committee's system of scholarships to pass from a public elementary school to a university or a university college. Many of the senior scholars have had remarkably successful careers since their university courses, and some have reached exceptional distinction. The return as a whole is very gratifying, and the result is due in part at least to the committee's policy of awarding scholarships of any grade only when candidates of really satisfactory merit present themselves.

Mr. J. A. Pease, Minister of Education, last week received at the offices of the Board in Whitehall, an influential deputation representing the civic, commercial, and educational life of Nottingham, and headed by the Duke of Portland, on the subject of granting the status of a university to University College, Nottingham. His Grace gave a *résumé* of the history of the college, emphasising the fact that its work would bear favourable comparison with that of the majority of the modern universities in the country. The time had now come when steps should be taken to broaden the constitution of the college, to place it in the same position as other similar institutions, and to establish it definitely as the university centre of the east midlands, spreading the responsibility for its government and maintenance over the area which it serves. Principal Heaton dwelt upon the educational work in the college itself, especially its honours, post-graduate, and research work, upon the home the college afforded to local branches of various national associations (such as Classical, Historical, English, Workers' Educational, Chemical Industry), and on the increased facilities it now offered for social intercourse among the students. The patriotic side of its work was well represented by its efficient Officers Training Corps, and the fact that it was the first college in England to form for women students a voluntary-aid detachment of the Red Cross Association. In his reply, Mr. Pease said :—"I appreciate, and the Board of Education appreciates, the desires of the people of Nottingham, their ambition, their aspiration, in connection with the formation of what one might call a full-blown university. There are schools of thought which think provincial universities have already been established in enough centres up and down our land. I am not one of those who take this view; I believe that there is work for additional universities, and I for one would be very glad to see a provincial university which would meet all requirements in connection with the wants of the people in the east midland area."

SOCIETIES AND ACADEMIES.

Edinburgh.

Royal Society, March 16.—Prof. James Geikie, president, in the chair.—Rev. T. R. R. **Stebbing** : Stalk-eyed Crustacea Malacostraca of the Scottish National Antarctic Expedition. Most of the fifty specimens described were collected by the *Scotia* at various stations during its voyage out and home, so that not more than ten could claim to be Antarctic or sub-Antarctic in their place of capture. Six new species were described, viz., *Coryrhynchus algicola*, *Eupagurus modicellus*, *Gennadas kempi*, *Nauticarus brucei*, *Phye scotiae*, *P. rathbunae*.—D. W. **Steuart** and Ingvar **Jörgensen** : Note on the atmospheric electrical potential gradient in industrial districts. The experiments were carried out in the neighbourhood of Leeds. The chief feature was the magnitude of the potential gradient under certain conditions.—J. B. **Robertson** : A chemical examination of the organic matter in oil-shales. Thirteen samples had been analysed. The carbon hydrogen ratio varied from 6 to 8, the lower ratio belonging to the shale yielding the larger amount of oil produced from a definite percentage of organic matter. The ratios were lower than that of ordinary bituminous coal. The organic matter, the main bulk of which was insoluble in organic solvents, was the product of the decomposition of vegetable substance (algæ, spores, etc.), similar in nature to what was found in peat and cannel coal.

Paris.

Academy of Sciences, April 14.—M. P. Appell in the chair.—L. E. **Bertin** : Calculation of the increase of load or of velocity obtainable by increasing the dimensions of ships. A development of some consequences of a formula given in an earlier communication.—G. **Gouy** : The absorbing power of the electric arc for its own radiations. Confirming results previously obtained with flame spectra, a complete opacity of the vapour for the line it produces is never observed. The absorptive power is between 0·5 and 0·7 for the very strong lines, and less for the weaker lines.—A. **Laveran** : New facts tending to demonstrate that Mediterranean kala-azar is identical with the Indian kala-azar. Comparative inoculation experiments were carried out on monkeys, dogs, and mice. *Macacus cynomolgus* rendered immune to the Mediterranean kala-azar is refractory to the Indian virus, whilst another animal of the same species, inoculated under the same conditions as the first, and serving as a control, rapidly contracted a fatal infection. From this it is concluded that the diseases are identical.—A. **Bilimovitch** : The canonical transformations of the equations of motion of a non-holonomial system.—L. **Dunoyer** and R. W. **Wood** : Photometry of the superficial resonance of sodium vapour under the stimulation of the D lines. Fineness of the resonance lines. The magnitude of the resonance lines was of the order of 0·03 Ångström.—Félix **Ehrenhaft** : Minimum quantities of electricity and the existence of quantities (quanta) smaller than the charge of an electron. The electrical charges of particles of mercury and gold in the colloidal state were determined, the spherical shape of the particles under examination being previously proved by the microscope. The minimum charge is not the charge of the electron.—Albert **Perrier** and H Kamerlingh **Onnes** : The interpretation of the magnetic properties of mixtures of oxygen and nitrogen. The molecular field varies inversely as the third power of the mean distance of the oxygen molecules.—R. **Fosse** : The gravimetric quantitative analysis of urea. The urea is precipitated from an acetic acid solution with xanthydrol, and the compound weighed. Its composition is definite, and can be controlled by analysis.—J. **Bergonié** : The rational distribution of meals in man in the nycthemeral cycle. The best times are shown to be 7.30 a.m. for principal meal, 4.30 p.m., and 8 p.m.

BOOKS RECEIVED.

Echinoderma of the Indian Museum. Part viii. Echinoidea (1). By Prof. R. Koehler. Pp. 258+xx plates. (Calcutta: Indian Museum.) 20 rupees.

Gibt es denkende Tiere? By Dr. S. v. Máday. Pp. xiv+461. (Leipzig and Berlin: W. Engelmann). 9.60 marks.

Die wichtigsten Lagerstätten der "Nicht-Erze." By Dr. O. Stutzer. Zweiter Teil. Kohle (Allgemeine

Kohlengeologie). Pp. xvi+345+xxix plates. (Berlin: Gebrüder Borntraeger.) 16 marks.

Ministry of Public Works, Egypt. Zoological Service. Report on a Zoological Mission to India in 1913. By Capt. S. S. Flower. Pp. viii+100+xii plates. (Cairo: Government Press.) 5*s*.

Mysore Geological Department. Report of the Chief Inspector of Mines for the Year 1912–13. With Statistics for the Calendar Year 1912. Pp. 59+tables. (Bangalore: Government Press.) 2 rupees.

Nedboriagttagelser i Norge. Utgit av det Norske Meteorologiske Institut, Middelværdier, Maksima og Minima. Pp. xxii+79+79+iv plates+maps. (Kristiania: H. Aschehoug and Co.) 3 kroners.

The Foundations of Character. By A. F. Shand. Pp. xxxi+532. (London: Macmillan and Co., Ltd.) 12*s*. net.

Marriage Ceremonies in Morocco. By Prof. E. Westermarck. Pp. xxi+422. (London: Macmillan and Co., Ltd.) 12*s*. net.

Icones of the Plants of Formosa, and Materials for a Flora of the Island. By B. Hayata. Vol. iii. Pp. iv+222+xxxv plates. (Taihoku: Bureau of Productive Industries.)

La Cémentation de l'Acier. By Prof. F. Giolitti. French translation by M. A. Portevin. Pp. 548. (Paris: A. Hermann et Fils.) 16 francs.

Traité de Physique. By Prof. O. D. Chwolson. Translated by E. Davaux. Tome Cinquième. Premier Fascicule. Champ magnétique variable. Pp. vi+266. (Paris: A. Hermann et Fils.) 9 francs.

Publications de la Société de Chimie-Physique. vii., Le Paramagnétisme appliqué a l'Etude des sels Métalliques. By Mlle. E. Feytis. Pp. 27. viii., Relations entre la constitution Chimique et la Coloration des Corps Organiques. By M. A. Meyer. Pp. 48. (Paris: A. Hermann et Fils.) 1 franc and 2 francs respectively.

Encyclopédie de Science Chimique Appliquée. Tome v. Principes d'Analyse et de Synthèse en Chimie Organique. By M. Hanriot, Prof. P. Carré, A Seyewetz, Prof. E. Charabot, and Dr. A. Hébert. Pp. 795. (Paris and Liége: Ch. Béranger.) 30 francs.

DIARY OF SOCIETIES.

THURSDAY, April 23.

Royal Geographical Society, at 5.—The East African Trough: J. Parkinson.

Child Study Society, at 7.30.—Raising the Standard of Child Upbringing Rev. I C. Pringle.

Concrete Institute, at 7.30.—The Architect and Structural Engineering: W. E A. Brown.

Institution of Electrical Engineers, at 8.—Electrification of Railways as affected by Traffic Considerations: H. W. Firth.

Royal Society of Arts, at 4.30.—The Port and City of Rangoon: G. C. Buchanan.

FRIDAY, April 24.

Royal Institution, at 9.—The Stars around the North Pole: Dr. F. W. Dyson.

Junior Institution of Engineers, at 8.—A Visit to the Iron Districts of French Alsace: G. Evetts

Institution of Mechanical Engineers, at 8.—Application of Electrical Driving to Existing Rolling Mills: L. Rothera.

SATURDAY, April 25.

Royal Institution, at 3.—Similarity of Motion in Fluids. I. The Theory of Similarity of Motion in Fluids and the Experimental Proof of its Existence: Dr. T. E. Stanton.

MONDAY, April 27.

Royal Society of Arts, at 8.—Some Recent Developments in the Ceramic Industry: W. Burton.

Royal Geographical Society, at 8.30.—The Land of the Ibibios (Southern Nigeria): P. A. Talbot.

Institute of Actuaries, at 5.—Section 72 of the National Insurance Act. Some other Features of Friendly Societies and National Insurance, including a Note on the Proposed Belgian National Insurance Act: E. B. Nathan.

TUESDAY, April 28.

Royal Institution, at 3.—Problems of Physical Chemistry. 2. Structure of Matter at low Temperatures: Dr. W. Wahl.

Royal Society of Arts, at 4 30—The Administration of Imperial Telegraphs: C. Bright.

Royal Anthropological Institute, at 8.15.—Some Hopi Textiles from the Pueblo of Hano: Miss B. Freire Marreco.

Eugenics Education Society, at 8.30.—Le Mesure de l'Intelligence: Dr. Simon.

WEDNESDAY, April 29.

Royal Society of Arts, at 8.—The Need for a Better Organization of Economic and Industrial Resources: C. R. Enock.

Geological Society, at 8.—On the Lower Jaw of an Anthropoid Ape (Dryopithecus) from the Upper Miocene of Lérida (Spain): Dr. A. Smith Woodward.—The Structure of ihe Carlisle—Solway Basin and the Sequence of its Permian and Triassic Rocks: Prof. J. W. Gregory.

THURSDAY, April 30.

Royal Society, at 4.30.—*Probable Papers*: The lack of Adaptation in the Tristichaceae and Podostemaceae: Dr. J. C. Willis.—The Genetics of Tetraploid Plants in *Primula sinensis*: R. P. Gregory.—The Action of certain Drugs on the isolated Human Uterus: J. A. Gunn.—The Presence of Inorganic Iron Compounds in the Chloroplasts of the Green Cells of Plants, considered in Relationship to Natural Photo-synthesis and the Origin of Life: Prof. B. Moore.—The Influence of Osmotic Pressure upon the Regeneration of *Gunda ulvae*: D. J. Lloyd.—(1) *Glossina brevipalpis* as a Carrier of Trypanosome Disease in Nyasaland. (2) Trypanosome Diseases of Domestic Animals in Nyasaland. *Trypanosoma pecorum*. Part III. Development in *Glossina morsitans*: Sir D. Bruce, Major A. E. Hamerton, Capt. D. P. Watson and Lady Bruce.

Royal Institution, at 3.—The Last Chapter of Greek Philosophy: Plotinus as Philosopher, Religious Teacher and Mystic; The very Rev. W. R. Inge.

FRIDAY, May 1.

Royal Institution, at 9.—A Criticism on Critics: E. F. Benson.

Junior Institution of Engineers, at 8.—The Control and Organisation of the Engineering Profession: S. T. Robson.

Geologists' Association, at 8.—A Geological Excursion in Matabeleland: F. P. Mennell.

SATURDAY, May 2.

Royal Institution, at 3.—Similarity of Motion in Fluids. (2) The General Law of Surface Friction in Fluid Motion: Dr. T. E. Stanton.

British Psychological Society.—The Psychology of Play with special reference to the value of Group Games in Education: Miss M. J. Reaney. —Corresponding points: Prof. C. Spearman.—An attempt at an exact Estimation of Character: E. Webb.

NEW YORK WATER SUPPLY.

The Catskill Water Supply of New York City: History, Location, Sub-surface Investigations, and Construction. By Lazarus White. Pp. xxxii+755. (New York: John Wiley and Sons; London: Chapman and Hall, Ltd., 1913.) Price 25*s.* 6*d.* net.

TECHNICAL records of important engineering undertakings, so far as their accessibility to the public is concerned, are apt to be scattered and fragmentary. A paper will usually be read before one or other of the leading professional societies, giving in condensed form so much of the history of the work as is deemed suitable for publication. In addition, articles will have appeared from time to time in the technical and daily Press, authoritative in varying degree, giving descriptions in general terms of the progress made. But these, while admirable in themselves, scarcely exhaust the desire for information on the part of the general body of the profession, who would often wish to be furnished with certain specific details omitted from the condensed official accounts. A marked reticence, for instance, is observed, as a rule, on the subject of cost. There seems to be a fear lest the disclosure of more than a few figures of comprehensive significance should give rise to criticism of an adverse and inconvenient nature. And such details, accordingly, are almost invariably withheld, or, at best, are obtainable with difficulty.

These remarks are prompted by the consideration that the volume before us is quite exceptional in its scope and treatment to the experience described above. It is a commendably full, clear, and complete account of an undertaking of considerable magnitude, in which a great wealth of information germane to the subject is set out in much detail.

The author, a division engineer engaged on the work, has been fortunate in a chief who encouraged him in his task of compilation, and "gave him a helping hand throughout." He was also favoured with the cooperation of his colleagues. The long list of names mentioned in the preface demonstrates a very generous and loyal effort on the part of all concerned to produce a trustworthy and comprehensive account of the experience gained, the difficulties encountered and overcome, and the carrying through to a successful conclusion of a notable engineering feat.

The water supply of New York City has long been the subject of contention and conflicting opinion. It has been derived from many and varied sources. In the early days of Dutch colonisation it was mainly drawn from public and private wells. One well in particular, we are told, known as the Tea Water Pump, was so frequented that its neighbourhood became congested with water carts, and the spout of the pump had to be raised and lengthened to permit pedestrians to pass under it. Wells, however, are not a very trustworthy source of supply, and with the growth of the town they became tainted and inadequate. Spurred on by the ravages of epidemics which visited them, the inhabitants initiated a variety of schemes for obtaining a better and purer service; but it was not until 1830 that the first public waterworks were inaugurated. These consisted of a shaft, 16 ft. in diameter, sunk 112 ft. deep into the solid rock at a point situated at the junction of 13th Street and Broadway, with two horizontal galleries near the bottom of the shaft. The daily yield obtained by pumping was 21,000 gallons—an utterly inadequate provision for the needs of a rapidly-developing town.

The first really effective undertaking was the old Croton overflow weir or dam and aqueduct, constructed between 1837 and 1842, the former being located about six miles above the mouth of the Croton River. The capacity of the aqueduct was estimated at from 72 to 95 million gallons a day, and the population at this time was about 300,000. As time went on, it became necessary to increase the number and capacity of the storage reservoirs, and in spite of efforts made in that direction, the city experienced serious shortages of water in the years 1869, 1876, 1880, and 1881. By this last-named date, the population had increased to a million and a quarter, while the supply, augmented by a connection with the Bronx River, did not come to more than 102 million gallons a day. It was estimated that the demand was for 45 million gallons in excess of this. And here it may be remarked, in passing, that the daily consumption of water per head is curiously very much higher in the United States than it is in this country. For six of the largest cities in the United Kingdom, the quantity averages 35 gallons per head, as compared with more than 100 gallons in New York, 139 gallons in Chicago, and 187 gallons in Philadelphia.

The new Croton aqueduct from Croton Lake was built between 1885 and 1890, and the daily consumption of the population of 1,720,000 in 1890 immediately mounted to 170 million gallons —about one-half of the maximum capacity of the supply. The new Croton dam, commenced in 1892, was completed as recently as 1907.

As, owing to the growth of the city, the capacity of the Croton watershed showed signs of becoming exhausted at an early date, a commission was appointed, in 1903, to report on the whole question of future policy, and after due inquiry they recommended the impounding of the Catskill watershed, including the Esopus, Rondout, Schoharie, and Catskill creeks. Following this report, in 1905, the Board of Water Supply was organised, and the necessary sanction having been obtained, the field was open for operations to be commenced.

The basins from which the new supply is taken lie due north of New York, within a range of about one hundred miles from the centre of the city. It is calculated that the available yield of the total area is about 660 million gallons daily, but from this, for the present, at any rate, must be deducted the Schoharie watershed (136 million gallons), for which powers of incorporation have not been granted.

At this point we must leave the reader who wishes to pursue his researches further to do so in the volume itself. It will be found replete with data and particulars relating to the various contracts entered into for the execution of the project which has just recently been completed, and the author must be complimented on the result of his painstaking efforts to produce an account worthy of the achievement, which, with its 120 miles of dams, aqueducts, and tunnels, he proudly describes as "hardly second to the Panama Canal."

B. C.

ROMANCE IN ARCHÆOLOGY.

Egyptian Art. Studies by Sir Gaston Maspero. Translated by Elizabeth Lee. Pp. 223+plates. (London and Leipzig: T. Fisher Unwin, 1913.) Price 21*s*. net.

"AT two o'clock in the afternoon of February 12, 1906, while Naville was finishing his lunch, a workman came running up to tell him that the top of a vault was beginning to emerge from the earth." This is the opening sentence of the eleventh section or chapter in Sir Gaston Maspero's latest work, and it may serve as an indication of the book's quality. We here have no carefully reasoned presentation of the various aspects and problems presented by Egyptian Art. Such a work, by the same author, we already possess in "Art in Egypt," which has appeared within the year in the *Ars una: species mille* Series. "Egyptian Art" falls into quite a different category, and will prove an admirable foil or supplement to the more formal treatise.

It consists, in fact, as a sub-title warns us, of a collection of "Studies," written during a period of more than thirty years, which have been rescued from the pages of old periodicals, and are here presented together in an attractive English dress. Each is a separate essay, complete in itself; in some a single piece of Egyptian sculpture is described; others deal with an allied group of pieces, or of goldsmiths' work. But one characteristic is common to them all: the subject is used as a peg on which the author displays some idea or principle, generally of wider application than the particular example he selects. So any reader who already possesses "Art in Egypt" will here find Sir Gaston's views applied in a number of specific instances. The relation of the two books is very much that of a treatise on algebra to a series of worked-out problems.

The papers are here translated direct from the journals in which they made their first appearance, and have been subjected to no subsequent re-writing. Consequently, describing, as several of them do, masterpieces of Egyptian art within a day or two of their discovery, they still reflect the author's first enthusiasm, unblunted by later familiarity. The reader is transported from the atmosphere of a museum to the clear air of the Egyptian desert. He watches the diggers at their work, and shares something of their excitement. If he continues the chapter from which we quoted the opening words, he will soon see the head of the wonderful Hathor Cow standing out from the black recesses of the rock-hewn vault at Deir-el-Bahari as the *débris* of centuries is removed. Or turning to chapter xvii. he may, if he will, stand with Sir Gaston's *ghafirs* as they watch the workmen who are making a railway embankment on the site of ancient Bubastis. It has been reported that jewelry has been found; the police have searched the workmen's houses, and have recovered some of the pieces, but the fellahs have kept their secret. Suddenly a workman with his pick lays bare several fragments of silver. He tries to conceal them, but the *ghafirs* are too quick for him; and soon the Treasure of Zagazig, exquisite jewelry and vases of the XIXth Dynasty, is uncovered in the sunlight, a heap of gold between two layers of silver.

We have purposely laid stress on the vivid character of Sir Gaston's pages, for they serve to restore the element of romance which of late years archæology has run some risk of losing, at least for the general reader. But in doing so, we have left no space to touch on the general principles which the essays are intended to drive home, such as the utilitarian character of Egyptian art and the influence of a fixed purpose on its forms and conventions. Nor can we follow the author in his discrimination of the local schools of sculpture, each with its own traditions and technique. It may suffice to say that in "Art in Egypt" the reader will find these subjects treated systematically. In the work before us he will see Sir Gaston Maspero evolving the principles he there explains. A special word of praise must be given to the illustrations, the great majority of which are admirable reproductions of photographs on a large scale. L. W. K.

ASTRONOMY.

Astronomy: a Popular Handbook. By Prof. Harold Jacoby. Pp. xiii+435+32 plates. (New York: The Macmillan Company; London: Macmillan and Co., Ltd., 1913.) Price 10*s.* 6*d.* net.

IN the arrangement of the subject-matter in this book the author has attempted to serve a double purpose, namely, to provide material to satisfy the requirements of the ordinary reader who wishes to make himself acquainted with the present state of astronomy and also to produce a text-book for use in high schools and colleges. To attain this end the book consists of two parts, the former being a series of chatty discourses on astronomical matters devoid of all mathematics, the latter, called an appendix, which contains a series of notes involving the occasional use of elementary algebra, geometry and trigonometry so far as the solution of plane right angle triangles. The first part covers 361 pages and the second 58 pages.

As an introduction the author gives the reader a good general idea of the whole universe, at the same time pointing out the practical use of astronomy and its value as a culture study. In the subsequent twenty chapters he deals with the subject more in detail. The general reader will find that the author has been very clear and precise in all his statements and presents the matter in an easy, readable form. The thirty-two plates and numerous figures in the text enhance the value of the book considerably, the reproductions being principally from the fine negatives secured by Barnard and by the astronomers at the Lick Observatory.

In reading the book a few points have come to the reviewer's notice which rather invite criticism. In the chapter on solar parallax a good account is given of Gill's determinations, but while reference is made to the Eros value, the name of Mr. Hinks is omitted. In describing the solar features the reader is shown a fine photograph of the solar disc taken in calcium light by Fox; while the bright portions shown in the reproduction are referred to as faculæ, the usual term "flocculi" is not mentioned.

Of recent years fine photographs of the spectra of comets have been secured, but the reference to a comet's spectrum here given is decidedly brief, and occupies two lines as follows: ". . . existence of hydrocarbon gas in a luminous state as well as a dim continuous spectrum containing Frauenhofer lines. . ." Stellar spectra classification is also curtly dismissed, being restricted to that given by Secchi, the fact that other classifications have been suggested and are in use receiving no mention whatever.

It may be said, however, that in spite of the above minor deficiencies, the book is one that will serve a very useful purpose, and should appeal to a large circle of readers.

TEXTILE FIBRES.

(1) *Chemische Technologie der Gespinstfasern.* By Dr. Karl Stirm. Pp. xvi+410. (Berlin: Gebrüder Borntraeger, 1913.) Price 12 marks.

(2) *The Textile Fibres: their Physical, Microscopical, and Chemical Properties.* By Dr. J. Merritt Matthews. Third edition. Pp. xi+630. (New York: John Wiley and Sons; London: Chapman and Hall, 1913.) Price 17*s.* net.

(1) IT cannot be said that the contents of this work quite correspond to its title, for if the chemical parts of the subject were left out altogether, a very substantial volume would still remain. The actual chemical technology of the fibres is inadequately represented, though the author may be said to err rather on the side of omissions than on that of mis-statements. In this latter respect, however, attention should be directed to the statement (p. 6) that the temperature at which cotton begins to decompose is 160° C., no mention being made of the time factor used in arriving at this result. It is well known that by prolonged heating cellulose begins to decompose at much lower temperatures than that stated. A further statement that caustic potash is much less energetic in its action on cellulose than caustic soda might well have been qualified, for in equivalent strengths there is no difference in the mercerising action of the two alkalies. Again, the descriptions of the processes of bleaching cotton and linen are of the nature of generalisations, and are more likely to confuse than to enlighten the student. It might have been expected that the work of Haller, Lester, Knecht and Allan, Hoff-

meister, and others on the natural impurities contained in these fibres would at least have been mentioned, but such is not the case. On p. 37 reference is made to the presence in raw cotton of resins which withstand the action of alkalies, but no mention is made of the source of the information nor does the author appear to have published any original communication on this subject.

Wool and silk are more adequately dealt with from the chemical point of view, though here we miss a very important property of the former, viz., its behaviour on steaming which Breinl has shown to account for "ending" in the dyeing of piece goods (by which is meant that one end of the piece comes out deeper in shade than the other). A fairly good account is also given of the artificial fibres.

The rest of the work (pp. 261–378) contains what can scarcely be called more than a rudimentary account of dyeing and printing, in which the chemistry of the products employed and of the processes plays a very subordinate part.

The figures in the work are generally good, but it appears strange that in a special work of this kind the author has not recognised the importance of giving the appearance of cross-sections of the fibres described. A very large proportion of the text is taken up by matter which is quite irrelevant to the subject. Thus, in the case of wool no fewer than five pages are taken up by a description of the spinning process, while five more are devoted to trade statistics. Altogether the work is disappointing. It must, however, be said in its favour that the author generally acknowledges the source of his information, which has been largely taken from other German works. His copious references to current literature will act as a good guide to students and others who make use of the book.

(2) Since the textile fibres constitute the raw materials for some of our most important industries, a well-planned and conscientiously compiled monograph on the subject, in which all the facts concerning them are systematised and lucidly discussed, should form a welcome addition to our technical literature. It has been the endeavour of the author, in writing the present volume, to carry out this ideal, and though he does not claim to have attained it, we have no hesitation in saying that he has produced a most useful monograph. The subject-matter is well arranged, and is brought up to date, chiefly in the copious footnotes which give epitomes of the more recent researches and patent specifications. The figures representing the textile fibres are mostly micrographs by the author, and although they are somewhat rough, they bring out the essential features more prominently than many of the photographic reproductions that have been published. The figure on p. 230 seems to be out of place.

The last, and not the least, useful part of the work (pp. 461–592) gives an account of the various methods available for the analysis of textile materials. In his classification of the fibres (especially bast fibres) and the enumeration of the numerous species of the genus Gossypium (cotton), the author is rather too profuse. No mention appears to be made of the important effect of drying mercerised cotton in decreasing its affinity for dyestuffs. While admitting in the footnote on p. 283 that cotton begins to decompose above 120° C., the author seems to place the temperature at which decomposition begins at 160° C. (p. 282), but both are too high. No mention is made of that excellent reagent paranitroaniline for lignocellulose. The chlorination of wool, which is now a most important large-scale operation in connection with the production of unshrinkable fabrics, might with advantage have been more fully gone into. In spite of these shortcomings, the work must be regarded as one of considerable merit. That it has supplied a want is shown by the fact that within a comparatively short period it has gone through two editions.

OUR BOOKSHELF.

Pflanzenphysiologie. Versuche und Beobachtungen an höheren und niederen Pflanzen einschliesslich Bakteriologie und Hydrobiologie mit Planktonkunde. By R. Kolkwitz. Pp. v + 258 + xii plates. (Jena: Gustav Fischer, 1914.) Price 9 marks.

Prof. Kolkwitz tells us that his book has grown out of courses of practical instruction in plant physiology for university and agricultural classes. It is a little difficult to see exactly for whom it is designed—students would probably find it a difficult book to use, still the teacher of ordinary plant physiology will discover many hints that he can utilise with advantage.

A number of experiments are described, illustrative of the physiology of the higher plants, but the greater part of the volume is devoted to the lower forms of life. This later portion is an odd mixture of systematic description of illustrative species, but the accounts given are often so meagre as to be practically worthless. Directions are given for the culture of some forms, and the distribution of certain plankton species is briefly discussed. Incidentally, the chief sources of information are usefully given, but the whole volume suggests that it is a reproduction of the private notes of a teacher who has explored a fairly wide field himself, and wants the notes to refresh his recollection while conducting a course for students. But it is perhaps not often that short notes of this kind are of very much service to anyone except the man who put them together.

Lessons in Elementary Tropical Hygiene. By Henry Strachan. Pp. xi+116+vi plates. (London: Constable and Co., Ltd., 1913.) Price 1*s.* net.

We heartily recommend this little book. It is, of course, quite simple and very elementary; that is what it was intended for. Still, London school-teachers will find many useful hints in it. But it is written chiefly for the help of school-teachers in the tropics, both in Africa and in the West Indies. The author has been Principal Medical Officer of Lagos and of Southern Nigeria, and for two years he was acting as Colonial Secretary in Lagos. If he does not know the feel of the white man's burden, who does? And he knows well that the way to put things right in this world is to get at the children. It is they who will hold the ground which our men of science have won in the tropics. The victories of protective medicine and of sanitary administration over tropical diseases in Africa are, to us older people, still new, still wonderful; to the children, before many years are past, they will be old stories retold, facts taken for granted.

Anaesthetics: their Uses and Administration. By Dr. D. W. Buxton. Fifth edition. Pp. xiv+477. (London: H. K. Lewis, 1914.) Price 10*s.* 6*d.* net.

The advances in the knowledge of anæsthesia and analgesia made it necessary for Dr. Buxton to rewrite most of the sections in the previous edition of his useful work, to delete obsolete apparatus and theories, and to add much new matter. Among other new features are the procedures involved in giving nitrous oxide and oxygen in major surgery; of ether by the open method, by intra-vascular infusion, by intra-tracheal and pharyngeal insufflation, and by colonic absorption; the methods of local regional and spinal analgesia, and the employment of alkaloids in analgesia and anæsthesia.

Defensive Ferments of the Animal Organism. By Emil Abderhalden. Third enlarged edition. English translation by Dr. J. O. Gavronsky and W. F. Lanchester. Pp. xx+242. (London: John Bale, Sons and Danielsson, Ltd., 1914.) Price 7*s.* 6*d.* net.

The first German edition of this work by the director of the Physiological Institute of the University at Halle a/S. was reviewed in the issue of Nature for September 19, 1912 (vol. xc., p. 66). That two further editions were published in Germany in the following year is good evidence of the increasing interest being shown in Abderhalden's methods. The English edition will serve to bring these researches within the range of English students to whom the German text has been inaccessible.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

Cellular Structure of Emulsions.

On Prof. Kerr Grant's letter (p. 162) see for previous observations of this striking phenomenon Prof. James Thomson, Proc. Glasgow Phil. Soc., February 15, 1882, reprinted in his collected Papers (p. 136); also by reference given in a footnote to the reprint, to more detailed and independent investigations by Prof. Bénard, of Bordeaux, in *Annales de Chimie,* 1901, and more recent papers, including a recent lecture to the Société de Physique, and to their discussion in connection with the solar phenomena referred to by Prof. Grant, by H. Deslandres, in the Annals of the Observatory of Meudon (vol. iv., 1910).

Joseph Larmor.

The cellular arrangement of convection currents in emulsions, described by Prof. Kerr Grant in Nature of April 16, was first recorded by E. H. Weber in 1855, with gamboge suspended in a mixture of alcohol and water. It is discussed in O. Lehmann's "Molekularphysik." The structure is most conveniently seen in molten wax or spermaceti, and in this form was discovered by H. Bénard. Many papers by Bénard, Dauzère, and others have appeared on the subject in the *Comptes rendus* and *Journal de Physique* since 1901, and the possible bearing of the phenomenon on geological and astronomical problems has been discussed. A paper by James Thomson on cellular structure due to convection, originally published in 1882, is included in his collected works. In this case soapy water was the liquid used. An account of the phenomenon, with references, is given in the present writer's report to the Beilby Prize Committee, read at the March meeting of the Institute of Metals.

The Origin of the Moon and the Earth's Contraction.

In my letter to Nature of February 26, I said that, with the earth's radius and gravity at their present values, and with the speed of rotation assumed to be one revolution in five hours, gravitation would exceed the centrifugal force until a distance from the surface was reached of more than double the earth's radius. Dr. Ball upon this writes that I "concluded" that when the moon was detached from the earth, "the earth's radius must have been about three times its present one." I did not mean to imply this.

The whole subject of the moon's origin is highly speculative, as Sir G. H. Darwin himself admitted. There are two causes that might be invoked to account for the separation of her mass from the earth, viz., centrifugal force, and the sun's tidal action. These require different speeds of rotation. In Pratt's "Figure of the Earth," 4th ed., art. 102, he shows that with a homogeneous earth the time of rotation which would render the centrifugal force equal to gravity would be one revolution in two hours and twenty-four minutes. I think that if the central parts were the more dense the speed would be rather greater. It seems impossible that a solid crust could have formed at this early period, when the spheroid could only just hold together. The eccentricity would then have been about 0·22.

The other possible cause of separation would be that the times of the tide produced by the sun's attraction coincided with the period of gravitational oscillation of the mass of the spheroid; that is, that the period of free oscillation would be the same as that of the forced oscillation due to the solar tide. After this had gone on for some while, the tidal protuberances would become so large that, in the opinion of Sir G. H. Darwin, one (or both) might break away. He considered that the rate of rotation in this case would have been about one revolution in five hours. And it was this rate that I assumed in my letter to NATURE. By the time the earth's rotation had been reduced so far as this, it does not seem impossible that a crust might have been formed.

If the material which now constitutes the moon was in any way detached from the earth, the matter so detached cannot have coalesced into a single sphere until Roche's limit was passed, which would be 2·44 of the earth's radii from its centre. During this initial stage of the moon's existence the nearest analogy seems to be found in Saturn's rings. But the difficulty remains why the matter detached should not have fallen back again.

As regards the formation of mountains by the contraction of the earth, I have discussed the question to the best of my ability in my "Physics of the Earth's Crust," and have come to the conclusion that the theory is untenable. O. FISHER.

Graveley, Huntingdon, April 4.

Movements on Water Surfaces.

I HAVE often wondered what is the real explanation of the following observation. If on a bath of soapy water a skin is allowed to collect on the surface, and then lumps of soapy lather be allowed to drop from one's hands on to it, the skin will crack in all directions, radiating from the point where the skin was first pierced, and this will continue for some time after the initial cause of the disturbance has ceased. The phenomenon is very striking, and can be repeated several times, after which the effect cannot be produced. Also if a cake of wet soap be placed on a wet level surface, the moisture is repelled from the cake, until the latter becomes surrounded by a dry patch. These seem to suggest repulsion of similarly electrified bodies. EDWARD A. MARTIN.

MR. MARTIN's second question is more easily answered than his first. The surface tension of clean water is about three times as great as that of water containing soap, so when the soap touches the wet surface the surrounding wet being no longer pulled towards the soap as strongly as it is pulled away, obeys the latter force as fast as it can.

I am inclined to think that his first observation may relate to a similar phenomenon, but of this I am not sure. With oleate of soda a very small quantity reduces the tension to the lower limit at once, and with this I do not think the experiment would succeed. I can only suppose, but I do not know it as a fact, that with the soap used first a scum is formed, and then when fresh lather breaks this at a point there is rather less surface tension at this point than there is in the surrounding surface. If so, the result observed would naturally follow. I should not, however, have expected to find this difference in the surface tensions. Or, possibly, the lather from the hand is warmer and for this reason has somewhat less surface tension. I have often shown in a striking way the diminution of surface tension with rise of temperature by holding the hand steadily against one side of the rainbow cup when the film upon it is already thin and highly coloured. Almost immediately a circulation is set up and a stream leaves the part warmed by the hand, and crossing the film diametrically, curls round on either side, producing a tree-like pattern in other colours. The film is very sensitive to temperature changes. C. V. BOYS.

66 Victoria Street, London, S.W., April 24.

X-Ray Spectra.

J. HERWEG (*Berichte der Deutschen Physikalischen Gesellschaft*, Heft 1, 1914) using a crystal of gypsum, obtains by means of the photographic method the result that the α and β lines of the tungsten X-ray spectrum coincide with the α and β lines of the platinum X-ray spectrum, the values of the glancing angles being $4^\circ\ 56'$ and $4^\circ\ 16'$ for the α and β lines respectively. But there is reason to suppose that the wave-length of X-rays characteristic of an element varies inversely as the square of the atomic weight of that element. If this is so, we can calculate from the experimental results for a platinum antikathode obtained by Herweg the glancing angles for the tungsten X-ray spectrum and we obtain :—

Tungsten Antikathode (Calculated).

Spectrum line	α	β	γ	δ	ϵ
Glancing angle	$5^\circ\ 34'$	$4^\circ\ 48'$	$4^\circ\ 43'$	$4^\circ\ 6'$	$3^\circ\ 51'$

We thus see that the calculated values of the β and δ lines are nearly the same as the experimental values found by Herweg for what he calls the α and β lines of the tungsten spectrum. G. E. M. JAUNCEY.

Physical Laboratory, University of Toronto, March 30.

An Optical Illusion.

I HAVE often noticed the phenomenon mentioned by Mr. J. W. Giltay in NATURE of April 23 (p. 189). In the position in which he was reading the sunlight passed through his eyelids and the coats of his eyes, and on account of having to pass through a layer of blood which acted as a red screen his retinas become flooded with red light. The red is not noticed where it is diluted with white, but the print appears red because red light is falling on the portions of the retina which receive the images of the printed letters. F. W. EDRIDGE-GREEN.

SOME LIFE-HISTORIES AND HABITS OF INSECTS.[1]

(1) IN his "Insect Biographies," Mr. J. J. Ward has written a pleasant and popular account of the life-history of several of our best-known insects. He has contrived to show how full of interest are the facts concerning the growth, development, and general mode of life of the subjects of his pen and camera, without overburdening his pages with technicalities, or, on the other hand, being guilty of inaccuracy or looseness of statement. The photographs with which the book is plentifully illustrated have been in almost every instance taken directly from living specimens in their natural attitudes and surroundings, and their execution must have involved the

[1] (1) "Insect Biographies with Pen and Camera." By John J. Ward. Pp. 206+plates. (London: Jarrold and Sons. 1913.) Price 6*s*. net.
(2) "Lebensgewohnheiten und Instinkte der Insekten bis zum Erwachen der sozialen Instinkte." Geschildert von O. M Reuter. Vom Verfasser revidierte Uebersetzung nach dem schwedischen Manuskript besorgt von A. u. M. Buch. Pp. xvi+448. (Berlin: R. Friedlander und Sohn, 1913.) Price 16 marks.

expenditure of much time and patience. They form an important feature of the work, and are in most cases excellent examples of their kind; some of them, however, are too much reduced in size for perfect clearness. One of the best illustrations shows the extraordinarily indented outline of the "Comma" butterfly (*Vanessa C-album*) in its attitude of rest with closed wings. The eggs and larvæ of the common lace-wing fly (Chrysopa), valuable for its destructive activity among the aphides, form the material of a series of figures some of which are here reproduced, while the life-history of another foe to the aphid pest, the wasp-like hover-fly or syrphid, is also well illustrated on Mr. Ward's photographic plates. One of the best chapters in the book is that devoted to the subject of the tree- and ground-wasps; the construction of the nests is clearly explained and well figured. Another interesting section is that which deals with the hornet-like clear-wing moth (*Aegeria crabroniformis*), remarkable in its larval stage for its powers of burrowing in the trunks and branches of various species of willow. Much stress is laid throughout the book on the protective value of the forms and colours adopted by many of the subjects of illustration, and the author has ingenious explanations to offer of the meaning of several curious instincts, such as the wholesale destruction of wasp larvæ by the workers towards the end of the season. Mr. Ward's bionomic conclusions are for the most part well grounded, but he seems in some passages somewhat too ready to admit without question the interpretation of instinct as inherited habit.

5. Larva of the lace-wing fly attacking an aphis. 6. Head of the larva. 7. Cocoons formed by the larvæ. 8. Lace-wing fly depositing eggs on a lilac leaf. 9. Another view of the lace-wing fly and eggs. 5 and 6 are enlarged, and 7, 8, 9, are actual size. From "Insect Biogaphies with Pen and Camera."

(2) The name and reputation of the late Dr. Odo Reuter were a sufficient ground for the anticipation that his work on the habits and instincts of insects would be a contribution to entomological science of high value. Such expectations are fully borne out by the work before us, which has been translated into German by A. and M. Buch from the original Swedish. The various heads of the subject are treated with great care and thoroughness, and the importance of the book as a work of reference is enhanced by the useful list of recent literature which concludes the volume. Among the topics dealt with are the various manifestations of activity and rest, including sleep and hibernation, the instincts concerned in feeding, in parasitism, commensalism, and mutualism. A chapter is devoted to the subject of migration; and the various methods of protection, active and passive, against unfavourable natural conditions, and the attacks of insectivorous foes, receive extended treatment. Instincts associated with metamorphosis, with pairing, with oviposition, and provision for the future needs of the offspring, are also fully discussed; and much space is given to the nesting and feeding habits of the solitary bees and wasps. The treatise concludes with a consideration of the transition from the solitary to the social habit in insects.

Dr. Reuter brought together for this work a great quantity of information gathered from the recorded observations of many naturalists in different countries. The treatment can scarcely be called exhaustive, and it is almost inevitable that some parts of so wide a subject should be dealt with in greater detail than others of equal importance. But the book is a useful storehouse of facts, selected with discretion, arranged with judgment, and pleasantly recounted.

F. A. D.

THE MINERAL INDUSTRY OF CANADA.[1]

THE Department of Mines of Canada is doing excellent work in distributing information concerning the mineral wealth of the Dominion by means of publications that appeal both to the trained expert and to the seeker after general information. A good example of the latter form may be found in a pamphlet of some seventy-seven pages entitled "Economic Minerals and Mining Industries of Canada," written by the "Staff of the Mines Branch," which gives in clear and convenient form a brief review of the occurrences and distribution of all the economic mineral products of the Dominion of Canada, together with indications of the legislative enactments that control the tenure of mineral property, the latter being especially important, seeing that each province has its own mining laws. This popular description, which, though brief, is clear and easily intelligible to anyone interested in mining matters, should prove of the utmost value to prospectors or others who may be going to Canada and are anxious to acquire some general knowledge of the more important economic minerals that are found in Canada, of the districts in which they chiefly occur, and the conditions under which their occurrence may be looked for with the greatest probability of success.

No better example of the opposite extreme, that is to say, of publications written essentially for the trained mining or metallurgical engineer, can be quoted than the monograph on the nickel industry of Sudbury by Dr. A. P. Coleman, a work of some 200 pages, in which a full account is given of these important mineral deposits. The general geology of the region is first described in much detail, then descriptions of the various minerals met with and of typical forms of the ore deposits themselves, all of these being very careful and apparently very accurate. Dr. Coleman discusses the mode of formation of the deposits, and seems inclined to adopt the magmatic segregation theory in its simplest and most definite form; he certainly mentions the researches of Dr. Campbell and others which have shown that there is very much to be said in favour of the aqueous origin of the ores, but Dr. Coleman apparently lays but little stress on these. He does not appear to have considered the possibility that these conflicting views might be reconciled on the hypothesis that the ores might have been formed by some form of hydrothermal process, in which separation from a cooling magma in the presence of water in some form or other under conditions of intense pressure may have produced the phenomena that characterise these ore deposits. Detailed descriptions of the various mines are given, together with some account of the method of mining and an outline of the smelting processes in use. The value of the monograph is enhanced by a comparison of the nickel occurrences at Sudbury with the remaining most important sources of nickel in the world.

The Annual Report on the Mineral Production of Canada is a volume that interests both the specialist and the seeker after general information, though it must be admitted that it appears to cater for the latter rather than for the former class of reader, there being throughout evidence of a desire to make the figures, especially the value of the mineral production of Canada, look as large as possible. No doubt the pernicious example of its neighbour, the United States, has much to do with this striving after inflated figures. The unfortunate result is that the figures given in the report are not the real value of the mineral production of the Dominion, as several items appear more than once. Thus in the report on the mineral production for 1911 the grand total of the value of the mineral production is given as 103,220,994 dollars; this is made up of metallic products, 46,105,423 dollars, non-metallic products (in which are included such items as arsenious oxide, chromite, manganese, ochres, pyrites!), 34,405,960 dollars, and structural materials and clay products, 22,709,611 dollars. Amongst the so-called non-metallic mineral products, by far the most important is coal, the value of which is given as 26,467,646 dollars, or about 77 per cent. of the whole; a very large proportion of this coal is, however, used in smelting the metals which are included in the first-named group and in burning the Portland cement, bricks, tiles, and other ceramic goods, and the lime included in the last-named group. As the value of all these products depends in part, often in quite considerable part, upon the fuel used in their production, the value of the coal appears twice over in the above grand total. Furthermore, very large quantities of coal and coke are imported into Canada, their value in 1911 exceeding 41,000,000 dollars, and it is certain that a very large proportion of this imported fuel is also used in manufacturing the metallic and other products above referred to, so that the value assigned to these includes in no small part the value of the imports of coal, etc. In spite of these facts, which show that the value of the mineral products of

[1] "The Nickel Industry: with Special Reference to the Sudbury Region, Ontario." By Dr. O. P. Coleman. (Ottawa: Government Printing Bureau, 1913.)
"Annual Report on the Mineral Production of Canada during the Calendar Year 1911." By John McLeish, Chief of the Division of Mineral Resources and Statistics. (Ottawa: Government Printing Bureau, 1913.)
"Economic Minerals and Mining Industries of Canada." By the Staff of the Mines Branch. (Ottawa: Government Printing Bureau, 1913.)
"A General Summary of the Mineral Production of Canada during the Calendar Year 1912." By John McLeish. (Ottawa: Government Printing Bureau, 1913.)
"The Production of Copper, Gold, Lead, Nickel, Silver, Zinc, and other Metals in Canada during the Calendar Year 1912." By Cosmo T. Cartwright. (Ottawa: Government Printing Bureau, 1913.)
"Summary Report of the Mines Branch of the Department of Mines for the Calendar Year ending December 31, 1912." (Ottawa, 1913.)

Canada cannot be compared with the mineral statistics of other countries unless these causes of inflation are taken into account, it is obvious that the Canadian mining industry is flourishing, and forms an important item in the wealth-producing power of the Dominion.

Important as was the mineral production in 1911, it appears to have been quite eclipsed by that of 1912, for it may be taken for granted that the figures contained in the General Summary, just issued, are not likely to be greatly modified in the final report. This gives the grand total of the entire mineral output, made up as it was in 1911, as 135,048,296 dollars, equal to an increase of 30·8 per cent. There is no new feature of any importance, except perhaps that the gold production shows an increase of about 40 per cent., due to the Porcupine district of Ontario. The silver output has fallen off slightly in Cobalt, but all other metals show an increased production. By far the most important mineral product is still coal, and as its output has increased by 28 per cent., this alone would cause the year to compare favourably with its predecessor. All that can fairly be said is that the 1912 report shows clearly that the mineral production of Canada is steadily growing in importance.

It is to be regretted that the scheme of Canadian mineral statistics takes no account of the labour conditions of the industry, and that no information is given concerning the number of men engaged in the industry, the wages earned by them, and of the accidents, fatal or non-fatal, that have befallen them during the year. Statistics on these points ought to be forthcoming in order to enable students of the subject to form a clearer picture of the course of development of the mineral industry of the Dominion.

The Report upon the production of the various metals in Canada may be taken as a final report, whilst it at the same time goes into somewhat greater detail than is possible in the General Summary, and also devotes more especial attention to the economic side of the subject. It can only be said fully to confirm the impression given by the General Summary as to the flourishing condition of the Canadian mineral industry.

The Summary Report of the work performed by the Mines Branch of the Department of Mines forms most interesting reading, and indicates that the Mines Branch is carrying out a vast amount of research work for the benefit of the mineral industry of the Dominion. A report upon the metallurgy of cobalt and its alloys, and another upon recent progress in the electrical manufacture of iron and steel may be named as indicating the nature of the work being carried on; it is most satisfactory to find evidence of the existence of a Government Department equipped for conducting such researches upon modern scientific lines, and to have such proof that the Canadian Government is far-seeing enough to give such excellent assistance to an important industry. It may fairly be said that if Canadian mineral industries are flourishing, the result is due not only to the great resources of the Dominion, but to the enlightened policy of a Government which devotes its energies to turning these resources to the best possible account.

IMPROVEMENTS IN THE BINOCULAR MICROSCOPE.

Microscopists long ago appreciated the advantages that might accrue could *both* eyes be employed to view the object by means of a "binocular" microscope—the natural method of viewing objects with both eyes would be preserved and eye-strain lessened, and stereoscopic vision may be attained.

The viewing of an object with both eyes not only lessens eye-strain, but there is a summation of stimuli in binocular vision, and, even without a stereoscopic effect, a better appreciation of the object viewed is probably obtained—there is greater "vividity" about the image.

Three principles have now been applied in the construction of the binocular microscope. The first of these is the use of two complete microscopes pointed obliquely at the same object, as in the Greenough binocular. This form has but a limited application as it is adapted for low-power work only. In the second form, best represented by the "Wenham" binocular and its modifications, the light coming from a single objective

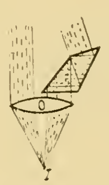

Fig. 1.

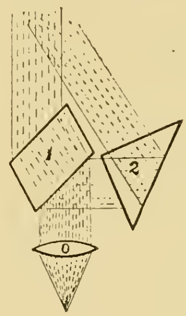

Fig. 2.

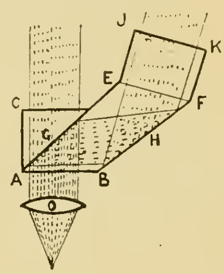

Fig. 3.

is "geometrically" divided, *i.e.*, the beam is bisected and half is directed into each eye. This is accomplished by interposing one or more prisms in the path of the beam as shown in Fig. 1.

This type of instrument involves the use of long tubes and is consequently bulky, resolution is diminished by reducing the size of the beam of light, and it cannot be used with high powers as the dividing prism cannot be placed sufficiently close to the back lens of the objective properly to bisect the beam before the rays have intermingled.

The third form alone embodies correct principles. In this, of which the Powell and Lealand and Abbé are the best examples, the beam of light is not bisected, but is physically sifted or filtered, so that a portion of every part of it goes to each eye. This "sifting" or "filtering" is accomplished in the forms mentioned by interposing in the path of the beam a glass plate or prism which transmits part and reflects part, as shown in Fig. 2 (the Powell and Lealand type) where 1 represents the glass plate, and 2 is a reflecting prism.

In this form resolution is unimpaired, but the instrument is bulky, and there may be a good deal of difference in the amount of light which reaches the two eyes.

A great advance has recently been made in the last-named form by Messrs. Beck, in this country, and Messrs. Leitz, in Germany, by the use of a half-silvered film cemented between two prisms. The silvered film is semi-transparent and allows part of the light to pass through and part to be reflected by the surface of the prism into the second tube.

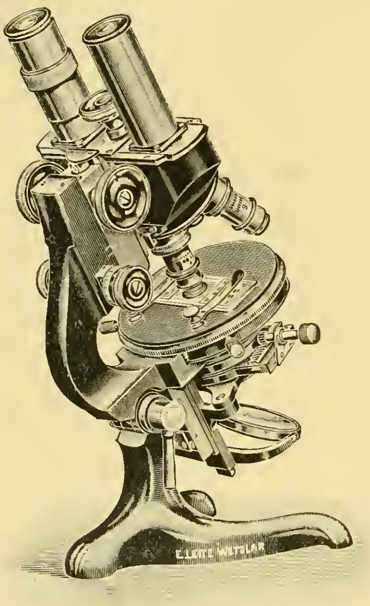

FIG. 4.—The Leitz binocular microscope.

Fig. 3 represents the construction in the Beck model, where EA represents the silvered film between the two prisms.

In both the Beck and the Leitz model, resolution is unimpaired, the illumination in both eye-pieces is the same, the instrument is much less bulky than the old forms, and short tube-lengths can be retained.

There can be no doubt of the superiority of this binocular form over the ordinary monocular microscope. Eye-strain is lessened, and there is an increased "vividity" about the image, even though a true stereoscopic effect is not attained. It is particularly valuable in the examination of objects with dark-ground illumination; more seems to be visible than with the ordinary monocular microscope.

There is an important difference between the Beck and Leitz models in the adjustment of the distance between the two eye-pieces to compensate for the varying distance between the two eyes in different individuals. In the Leitz model (Fig. 4) the tubes carrying the eye-pieces are parallel, in the Beck model they diverge (see Fig. 3). The inter-ocular distance in the former is adjusted by an arrangement which alters the distance between the two tubes; in the latter the inter-ocular distance is varied by lengthening or shortening the diverging tubes. Now the former method entails much less alteration of tube length than the latter, and inasmuch as the best lenses are corrected for a particular tube-length, for critical work we cannot help thinking that the Leitz adjustment is decidedly superior to that which obtains in the Beck model.[1]

R. T. HEWLETT.

THE SCOTTISH ANTARCTIC EXPEDITION.

BRITISH men of science will notice with keen regret the unpromising answer given by the Government to the application for 3,800*l.* to complete the publications of the Scientific Reports of the Scottish National Antarctic Expedition of 1902–1904. The application has been supported by a very influential body of Scottish scientific opinion. The expedition was entirely equipped by money privately raised in Scotland, and was mostly due to the generosity of Messrs. J. and A. Coats. The discovery by the *Scotia* of Coats Land is generally recognised as the most important addition to our knowledge of the boundaries of the Antarctic continent that has been made by the Antarctic expeditions of this century. It added half a million square miles to the previous estimates of the area of the continent and settled the position of the coast in the one part where there was no clue to its situation.

The *Scotia* made a series of voyages in the least known of the Antarctic seas and, as the whole of the energies of the expedition were devoted to scientific work, it made collections and oceanographic observations of the highest importance. Five volumes of its scientific results have been published and three others have been arranged owing to a grant previously made by the Government. Four further volumes are required to complete the series. The remaining volumes would be mainly devoted to description of the biological collections, and the memoirs have been already prepared by many distinguished British and foreign naturalists. The work of these men of science has been entirely gratuitous and it is peculiarly ungracious to the foreign contributors that it should be wasted owing to the lack of the comparatively small sum required to complete the publication. 17,500*l.* has been set apart to defray the cost of preparing the reports on the scientific work of the *Terra Nova* expedition, which excludes the reports on natural history which are being published at Government expense by the British Museum; hence the expenditure on the *Scotia* publications has not been excessive. Much confusion in biological nomenclature may be produced if the publication of these reports be delayed, so that they appear simultaneously with those prepared from the collections of later expeditions.

The application to the Treasury for a grant for the publication of the results has received very influential support; it is accompanied by letters from all the leading scientific societies and authorities in Scotland, and by the past and present

[1] In the preparation of this summary, free use has been made of the articles by Dr. Jentzsch and Mr. Conrad Beck in the Journal of the Royal Microscopical Society, 1914, part 1, pp. 1 and 17. For the loan of the blocks from which the illustrations are reproduced, we are indebted to Messrs. R. and J. Beck and Messrs. E. Leitz.

Presidents of the Royal Society. There certainly seems good grounds for the complaint that the Scottish expedition has not received its fair share of support from the Treasury. It will be lamentable if scientific results of such importance be still further delayed in publication, and it is to be hoped that the Government will give favourable consideration to this reasonable appeal.

NOTES.

We record with deep regret the death in Vienna, on April 25, at eighty-three years of age, of Prof. E. Suess, foreign member of the Royal Society, and emeritus professor of geology in the University of Vienna.

Mr. Herbert Samuel stated in the House of Commons on Tuesday that he is about to appoint a Committee to consider the question of smoke abatement. The names of the members will be announced in a few days.

The April number of *Science Progress* contains an editorial article of nine pages, entitled "Sweating the Scientist." During the past year an inquiry has been conducted by our contemporary as to the emoluments of scientific workers, and the article referred to is a provisional report on the results of this inquiry. As might, perhaps, have been anticipated, the replies received suffice to prove the "low scale of payment given throughout the British Empire for such work." This result is no doubt due to the law of supply and demand, and an interesting sketch is given of the conditions which give rise to such a state of affairs. Other grievances are also dealt with. "Besides the low rate of pay, there are, in this country at least, many small abuses attached to high intellectual work. Large portions of the income of many institutions are given to the maintenance of more or less useless pursuits. Originality and success in research do not receive their due place in selection for appointments. The best-paid posts are seldom given for the best work done, but rather for qualities which are of little account—popularity, eloquence, text-book knowledge, private influence, and skill in the arts of time service. We appear to judge men, not by the work which they have done, but by the work which we may imagine, from their appearance, that they may do." The lack of financial support afforded by the Government to the higher forms of intellectual effort and to higher education is also criticised. The article is a timely one, and deserves the careful attention of all scientific workers, as the question of remuneration is one of paramount importance to the future welfare of science in this country. Particular reference is made to the unpaid services of men of science upon Government Committees, and to the custom of Government departments going to learned societies for expert advice for which no payment is made. "In other words, the State exploits the man of science on account of his enthusiasm for his work and his patriotism." The whole subject is one which the British Science Guild could take up appropriately and refer to a committee.

Dr. Basil T. Parsons-Smith has been awarded the Hunterian Society's medal for his essay, "The Intermittent Pulse."

We learn from the *British Medical Journal* that sufficient funds have now been collected for the erection at Verona of a memorial to Prof. Cesare Lombroso. It is hoped that the monument (which will be the work of Leonardo Bistolfi) will be unveiled in 1915 at the time of the International Congress on Pellagra, which is to be held at Verona.

On Tuesday next, May 5, Prof. W. Bateson will deliver the first of two lectures at the Royal Institution on (1) double flowers, (2) the present state of evolutionary theory, and on Saturday, May 9, Prof. C. J. Patten, of Sheffield University, will begin a course of two lectures on bird migration. The Friday evening discourse on May 8 will be delivered by Prof. Karl Pearson on albinism in men and dogs, and on May 15 by Prof. F. Keeble on plant animals: a study in symbiosis.

The council of the Institution of Civil Engineers has made the following awards for papers read and discussed during the session 1913–14:—A Telford gold medal to Mr. F. W. Cowie (Montreal); a George Stephenson gold medal to Mr. F. E. Wentworth-Sheilds (Southampton); Watt gold medals to Mr. Thos. Clarkson (Chelmsford), and Mr. Henry Fowler (Derby); and Telford premiums to Prof. E. G. Coker (London), Mr. W. A. Scoble (London), Mr. Wm. Willox (London), and Mr. S. P. W. D'Alte Sellon (London).

In the House of Commons on April 22, Mr. Astor directed attention to the unsatisfactory state of legislation and administration with reference to the supply and sale of milk and cream in the United Kingdom; and moved "That fresh legislation is needed to control the supply and sale of milk and cream in the United Kingdom, and that the existing laws should be more thoroughly administered." Mr. Herbert Samuel, in reply, stated that the Board of Agriculture is about to issue a new Order granting more generous compensation to the farmers for the cows slaughtered for the purpose of checking the spread of tuberculosis, and that local authorities are to be assisted in the administration of the law. He further stated that he hopes shortly to introduce a Milk and Dairies Bill, more restricted than its predecessors, which will substitute for various codes now administered by local authorities the uniform provisions of a general statute. He is anxious not to disturb the dairying industry, or to raise the price of milk, and the Bill will be framed in that spirit.

Final arrangements are now being made for the International Congress of Tropical Agriculture, which is to be held in London at the Imperial Institute in June next, under the presidency of Dr. Wyndham Dunstan. Invitations to take part in the congress have been issued to foreign countries by H.M. Secretary of State for Foreign Affairs, and already many foreign Governments have nominated delegates to represent them at the congress. The cooperation of many planters' associations, commercial museums, chambers of commerce, Colonial societies, and similar bodies in this country and abroad has also been secured, and it is already known that at least forty countries will be represented at the congress, ranging from our nearest neighbour France, to such remote places as Formosa, Hawaii, and Papua. A notable feature of the congress will be the organised discussions on certain questions of outstanding importance to tropical agriculture. Four of these have been arranged, viz., technical education in tropical agriculture; the organisation of tropical agricultural departments in relation to research work; the defects of plantation rubber and the means of avoiding them; and problems of cotton cultivation. The fact that the British Cotton Growing Association, the International Federation of Cotton Spinners, the Egyptian, Indian, Nyasaland, Uganda, and Nigerian Government Departments of Agriculture, and the German Colonial Economic Committee have each deputed officials to contribute papers in the discussion on problems of cotton cultivation, indicates the success attained by the organising committee for the congress in securing competent exponents of different points of view on these questions. Full particulars of these and other arrangements for the congress are given in the preliminary general circular and the members' circular, copies of which can be obtained on application to the congress secretaries (Dr. T. A. Henry and Mr. Harold Brown) at the Imperial Institute, London, S.W.

In the second part of *Ancient Egypt* Prof. Flinders Petrie, the editor, discusses the question of so-called "mummy wheat." At Hawara in the Fayum he discovered a large store of corn of the Roman period, some of which was sown, but failed to germinate. The "mummy wheat" legend is based on various accidents: some dealers in Thebes sell little pots of ordinary corn to tourists; Sir Joseph Hooker noticed accidental admixture of fresh raspberry seeds with some found in the Laurion Mine; there is, lastly, the desire of the gardener to make the experiment successful. Doubtless from time to time the story of the germination of "mummy wheat" will be told, and only credulous people will continue to believe it.

In the Museum Journal of the University of Pennsylvania for December last Dr. Edith H. Hall describes a fine collection of ancient glass, recently increased by numerous specimens from graves in Palestine and Italy. It includes fine examples of the primitive type, in which the decoration was achieved by laying threads of variously coloured glass over the surface of the vase while it was still hot, and then rolling the whole upon a smooth stone until the threads were pressed in. Besides these there is a good series of Roman mosaic glass, of which the best are the *millifiori* bowls, so called by the Venetians who valued them highly. The rapid increase of the art collections in this museum, due to the wise expenditure of its income and the munificence of American citizens, is noteworthy.

A large portion of the April number of the *Irish Naturalist* is devoted to a memoir, with portrait, of the late Major G. E. H. Barrett-Hamilton, by Mr. C. B. Moffat.

To the first part of vol. xxxvi. of Notes from the Leyden Museum, Dr. J. H. Vernhout contributes an article on the land and fresh-water molluscs of Surinam, or Dutch Guiana, a subject which has hitherto received but scant attention at the hands of naturalists, the only complete list being one published by van Martens in 1873. Many new species are described in the part now issued.

At the conclusion of an article in the April number of the *American Naturalist*, by Dr. A. F. Shull, on the biology of the Thysanoptera (thrips, etc.), it is stated that *Anaphothrips striatus*, hitherto known almost exclusively by females, recently produced about 25 per cent. of males at Douglas Lake. This suggests that the theory of an alternating life-cycle in this and certain other members of the group, which was at one time formulated but subsequently rejected, may have some measure of justification.

In the February number of the *American Museum Journal* Dr. F. A. Lucas concludes his account of groups of animals in museums, with reproductions from photographs of a large number of the most striking examples selected from various American museums. Among these, the great albatross colony on Laysan Island in the State University of Iowa and the scene illustrating North American mammalian life in the museum of Kansas University are perhaps the most wonderful. Nothing approaching them is to be seen in any English museum.

The thorough and exhaustive manner in which the German Government explores its colonial possessions in Africa is well exemplified by *Ergänzungsheft*, No. 9*a*, of *Mitteilungen aus den Deutschen Schutzgebieten*, which is devoted to the topographical results of several exploring expeditions in the southern and eastern Cameruns, as well as of one in Togo. Members of the various exploring parties have contributed their own notes, well illustrated with photographs of scenery, these notes including remarks on the anthropology, zoology, and botany of the districts traversed.

With the view of improving the Zoological Gardens under his care at Giza, Egypt, Captain Stanley Flower made a tour of inspection of the establishments of a similar or kindred nature in India during 1913, the results of which are published, with a number of interesting illustrations, in a Report on a Zoological Mission to India, issued by the Ministry of Public Works, Egypt, as No. 26 of the Zoological Service Publications. The author observes that in every zoological garden visited in India there were features of interest, and in each there were new facts of menagerie-technique to be learnt. The gardens at Calcutta were notable for the extent of the collection, those at Trivandrum for the scientific method on which they are arranged, and those at Peshawar for the splendid condition of the animals.

Optimism pervades the report of the council of the Zoological Society for 1913, the total number of fellows and the income from their subscriptions continuing to show a steady increase, while the receipts for admission at the gates of the gardens were the highest on record. The year will be notable for the commencement of the "Mappin Terraces" in the gardens, now nearing completion, and also for the preparation and acceptance of a general plan, made under expert advice, for improvements in the arrangement of the gardens as a whole. These alterations, which have become imperative owing to the increasing popularity of the gardens, will involve the abolition of the old bear-terrace, which, although one of the landmarks of the gardens, is now hopelessly antiquated and out of date. It is satisfactory to learn that plans for new and up-to-date salt- and fresh-water aquaria are under consideration. Neither has the scientific side of the society's work been neglected, special attention being directed in the report to the society's share in the new mammal survey of British India, which has already resulted in the discovery of one new genus and several new species of rodents.

In the twenty-seventh annual report of the Marine Biological Station at Port Erin, Prof. B. Moore and his co-workers have summarised important observations on the hydrogen-ion concentration of sea-water, determining its degree of alkalinity or acidity, which does not remain constant throughout the year but varies with the relative activities of vegetable and animal organisms, and acts as an index to these activities. There are two maxima of alkalinity corresponding to the two seasonal outbursts of diatoms. The change observed indicates a synthesis, at these seasons, of some tons per acre of sea-water of organic vegetable matter for the nutrition of the animals. The green plants or diatoms break up the bicarbonates present in sea-water and form organic compounds, the amount of the removal of the carbon dioxide being shown by the increase in alkalinity in the water. It is noteworthy that the spring increase in alkalinity is just of the grade formerly found to be most favourable to the rapidity of cleavage in the initial stages of development of the eggs of the sea-urchin (Echinus).

A recent issue of the *Naturwissenschaftliche Wochenschrift* (March 15, 1914) contains an article by Dr. F. Stellwaag, of Erlangen, in which he directs attention to the apparently contradictory results obtained by various observers who have experimented on the colour-sense of bees. Following the methods of Lord Avebury and of Forel, von Dobkiewicz came to the conclusion that bees are able to distinguish between colours, but are only attracted by them when they have learnt by experience to associate a given colour with the presence of honey. This he considers to accord with the fact remarked by Plateau that many colourless and inconspicuous flowers are eagerly sought after by bees, while many brightly-coloured flowers are unvisited by them. These results were to some extent confirmed by von Frisch, who concluded further that the colour-vision of bees must resemble that of "red-blind" men. Hess, however, disputes the conclusions of both preceding experimenters, and considers that bees show no indication of being otherwise than totally colour-blind. Stellwaag himself is of opinion that in all these experiments an important factor has been overlooked, viz. the condition of the bees with regard to the general supply of provender. When this is deficient, bees will seek it anywhere.

An interesting paper has been issued by W. E. Castle and J. C. Phillips in Publication No. 195 of the Carnegie Institution of Washington (1914), on the effects of selection in modifying the pattern of piebald rats. The piebald or "hooded" pattern behaves as a Mendelian recessive to the self-coloured condition, but within the hooded class there is considerable variation in the extent of the coloured areas. The authors have made continuous selection experiments, both in the direction of greater and of less pigmentation, extending over thirteen generations and involving the breeding of some 25,000 rats. Although the hooded pattern behaves as a Mendelian unit, selection of either plus or minus variation brought about permanent changes extending far beyond the original variation of the race. In each generation the offspring of selected parents tended to regress towards the mean of the preceding generation, with the result that when, after several generations of selection, the selection was reversed, the regression was *away* from the original mean. But by continued reversed selection from a race which had become very divergent, the mean was brought back nearly to the original starting point. Results are described of crosses between extreme plus and minus strains, and between such strains and self-coloured types. An account is also given of an extreme variant which appeared as a mutation. The paper should be compared with the recent work of Hagedoorn (*Zeitsch. indukt. Abstam.*, xi., 1914, p. 145).

A detailed account of the twelve months' poultry laying competition at the Harper Adams Agricultural College is given in the report of the college for 1913. Upwards of six hundred birds were tested, the average egg production being 152 for the twelve months period. A comparison of the returns obtainable from one acre of grass land when stocked entirely with poultry and the same area used for milk production, shows that a much greater return per acre can be produced in the former case, these being respectively 41*l.* 13*s.* 4*d.* and 4*l.* 3*s.* 2½*d.* It must be borne in mind that, although the gross return per acre in the case of the poultry is so much greater than for cattle, the expenses, capital and depreciation of stock, would be correspondingly high. Unfortunately, there seem to be no available figures which might be utilised for purposes of comparison. That the possibilities of egg production on commercial lines are great cannot be denied, and the actual determination of these, and the factors which govern such production, should prove an interesting and profitable field for further investigation.

A report on sugar cane experiments in the Leeward Islands which has just been published, contains a summary of the varietal trials and work on manuring conducted during the last few years. Of the varieties which have been under cultivation for some considerable time, and of which the relative merits and suita bility to various conditions are well appreciated and recognised, Sealy seedling and B 147 have attained considerable popularity, while the more recently introduced varieties, B 4,596 and B 1,528, are more prominent. The importance of incorporating with the soil a sufficiency of organic matter, either as pen-manure or green crops, is becoming more and more recognised, and the various bacterial changes concerned in the breakdown of these manures are discussed in this report in the light of recent investigations. The extreme rapidity with which such changes proceed in tropical climates is indicated by the fact that under favourable conditions the humus content of the soil may be decreased by as much as 25 per cent. in the space of six months.

SOME interesting observations on the action of thunderstorms in giving rise to seiches have recently been made by Messrs. Okada, Fujiwhara, and Maeda (Proc. Tokyo Math. Phys. Soc., vol. vii., 1914, pp. 210–221). The measurements of the seiches were made with a Honda limnimeter on the shores of Lake Biwa in central Japan. The authors indicate as important causes of seiches during thunderstorms the accumulation of rain-water over a portion of the lake, the impulsive action of winds on the surface, and sudden changes of barometric pressure; and as subsidiary causes the impact of falling raindrops on the surface of the lake and the attraction of the electrified mass of thunderclouds. They examine in detail the effects of a heavy thunderstorm that swept over Lake Biwa on April 19, 1912, and estimate that the change of barometric pressure (2·7 mm.) would account for an amplitude of 6·6 cm. in the seiches, the rainfall (32 mm. in twenty minutes) for an amplitude of 6·1 cm., while the impulsive action of the wind may have contributed an amplitude of 4·5 cm. The sum of these amplitudes is 17·2 cm., which is very close to the total amplitude observed

THE two last contributions to the geology of the Antarctic Expedition of the *Belgica* ("Expédition Antarctique Belge: Résultats du Voyage du s.y. *Belgica* en 1897, 1898, 1899; Zoologie, Tuniciers, Caducichordata," by Ed. van Beneden and Marc de Selys-Longchamps, 1913; and "Géologie, Petrographische untersuchungen der Gesteinsproben," part ii., by Dragomir Sistek, 1912) include the account of the tunicates and a further contribution to the description of the rocks collected. The memoir on the tunicates was begun by E. van Beneden, and after his death was continued and completed by M. Marc de Selys-Longchamps. The expedition obtained eight species, of which five are new and another is represented by a new variety. All the species collected have been described in elaborate detail; the memoir comprises 120 pages, and is illustrated by seventeen plates and some figures in the text. The classification adopted is that by Hartmeyer. The new contribution on the petrography of the expedition is a description by D. Sistek of the rocks collected in the Straits of Magellan and the Beagle Channel, which is on the southern side of Tierra del Fuego. The rocks are all igneous or metamorphic. The most varied collection, including granite, diorites, quartz-porphyries, andesite, diabase, basalt, gneiss, schists, and clay slate, was made at Cape Gregory in the Straits of Magellan. The crystalline schists include a varied series. The chief rocks are illustrated by a plate of microphotographs of unusual clearness.

AN important by-product of the adjustment of the primary triangulation of the United States was the discussion of the deflections of the vertical and anomalies of gravity, by Mr. J. E. Hayford, on the hypothesis of isostatic compensation of inequalities of the earth's surface. In this way the discrepancies between the observed and the anticipated values of each was very largely reduced, but, whatever the precise form of hypothesis used, there still remained an average anomaly of gravity of not less than 0·020 dyne, which was attributed by Mr. Hayford to an imperfection of isostatic adjustment. Prof. G. K. Gilbert has taken up the subject in Professional Paper 85–C of the U.S. Geological Survey, and shows that the distribution of the anomalies of gravity does not indicate any relation to the leading features of geological structure, as would be expected if they were due to variation in the distribution of density, or imperfect isostatic adjustment, within the earth's crust. From this he concludes that they are due, at least in part, to variations in the nuclear portions of the earth, below the limits within which isostatic adjustment, and compensation of elevated tracts of the earth's surface, take place.

PROF. G. A. GIBSON, of Glasgow, has issued in separate pamphlet form the address he recently gave before the Royal Philosophical Society of Glasgow on Napier and the invention of logarithms. The pamphlet contains a clear picture of the career and personality of the great Scottish mathematician, bringing together within the compass of twenty-four pages the salient facts of his life. The interest for the mathematical student is the account given of the way in which Napier originally defined the logarithm. This does not correspond exactly with what is known as the Napierian logarithm, although it is closely related to it. There is a passing reference to Bürgi, whose "Progress Tabulen" has probably been seen by very few mathematicians in this country. The evidence that Napier was in possession of his method at least twenty years before he published his tables is also referred to; and Napier's other mathematical and arithmetical discoveries have as adequate a notice as is possible in such a brief statement. Prof. Gibson's sketch comes at an opportune time when mathematicians are preparing to celebrate the tercentenary of the publication of the "Canon mirificus logarithmorum."

A PAPER by Messrs. K. M. Faye-Hansen and J. S. Peck, published in the last issue of the Journal of the Institution of Electrical Engineers, deals with some interesting uses of inductance coils or "reactances" in heavy electrical engineering. These are being used to an increasing extent on large power supply systems of the order of 100,000 kilowatts for the purpose of limiting the current that may flow in various parts of the circuits in cases of accidental short circuits with the view of localising the damage that can be done. For example, it is possible by placing reactances in the conductors between the generators and the switchboard, to limit the current under conditions of short circuit on the switchboard or feeders to, say eight times, the normal working current, and thus to protect the machines from enormously greater rushes of current that would be destructive. The paper discusses the relative utility of such reactances in the generator leads, in the feeders, and between different sections of the main "bus-bars," and suggests various combined arrangements. These reactances generally take the form of large coils without iron in their magnetic circuit, but a partial iron circuit is sometimes employed. An appendix discusses the effect of bus-bar reactance on the parallel operation of alternators.

IN twelve pages of the March number of the Journal of the Franklin Institute Mr. W. P. Davey, of the X-ray laboratory, Cornell University, succeeds in giving a most valuable summary of the present state of our knowledge of Röntgen, or X-rays. After explaining the production of Röntgen rays by the impact of kathode rays on the target of a vacuum tube, he shows that they produce fluorescence in certain bodies on which they impinge, they affect photographic plates and ionise the air through which they pass. In each case the laws which have been found to hold are stated. When the rays fall on metals or on metallic salts they produce in certain cases secondary radiations which differ in properties from the original rays, and by analogy have been called fluorescent Röntgen or X-radiations. The methods adopted for the measurement of the quality or penetrating power of the radiations, and the quantity of radiation which falls on a given surface in a given time, are also described. The article will prove of great value to those who wish to make themselves acquainted with the principal facts of the subject without entering into details.

THE Société de Chimie-Physique has issued two more numbers of its series of monographs. These are vii., "Paramagnetism Applied to the Study of Metallic Salts," by Mlle. E. Feytis; viii., "Relations between Chemical Constitution and the Coloration of Organic Substances," by M. André Meyer. The latter contains, in addition to a review of the chief types of coloured compounds, a bibliography of the subject extending over ten pages, and containing more than two hundred references to original papers.

AN interesting illustrated article on charcoal burning in the Weald, by Mr. W. R. Butterfield, is contained in the April number of the *Selborne Magazine*. This primitive industry is still carried on in the Weald, although it has declined considerably during the last thirty years, owing to the decreased quantity of home-grown hops, for the drying of which the charcoal is mainly used. All the charcoal that is required is made during the few weeks before hop-picking, and the "collier," as the burner is called, and his mate move from farm to farm as required, and cover a wide area each season. The burners depend wholly upon empirical knowledge, either acquired by their own experience or handed on to them by their predecessors, and the operation is one requiring considerable skill and unremitting vigilance day and night.

THERE is an interesting illustrated article in the *Engineering Magazine* for April, giving an account of the workshops and methods of the Ford Motor Company. This company turns out 1000 automobiles a day at its Highland Park Works in Detroit. The other two factories belonging to the company, one at Ford, Ontario, Canada, and one at Manchester, England, bring the total Ford car-producing capacity to at least 1200 cars a day. The company produces one article only, viz., the Ford motor-car, and employs rather more than 15,000 hands.

OUR ASTRONOMICAL COLUMN.

ASTRONOMICAL OCCURRENCES FOR MAY:—

May 1. 11h. 24m. Neptune in conjunction with the Moon (Neptune 4° 17′ S.).
,, 20h. 43m. Mars in conjunction with the Moon (Mars 1° 37′ S.).
15. 7h. 4m. Uranus in conjunction with the Moon (Uranus 2° 3′ N.).
16. 1h. 50m. Jupiter in conjunction with the Moon (Jupiter 1° 13′ N.).
,, 2h. 7m. Venus in conjunction with Saturn (Venus 2° 10′ N.).
,, 20h. 0m. Uranus stationary.
,, 23h. 0m. Mercury in superior conjunction with the Sun.
25. 23h. 5m. Saturn in conjunction with the Moon (Saturn 6° 9′ S.).
26. 21h. 2m. Venus in conjunction with the Moon (Venus 3° 21′ S.).
28. 17h. 57m. Neptune in conjunction with the Moon (Neptune 4° 1′ S.).
30. 5h. 16m. Mars in conjunction with the Moon (Mars 0° 42′ S.).
,, 10h. 0m. Mercury at greatest heliocentric latitude N.

COMET 1914A (KRITZINGER).—Recent observed positions of comet 1914*a* (Kritzinger) have enabled Prof. Kobold (*Astronomische Nachrichten*, No. 4729) to improve the elements of this comet, and consequently the ephemeris. The new positions for the current week are now as follows:—

12*h*. *Berlin M.T.*

	R.A. (h. m. s.)	Decl. (° ′)	Mag.
April 30	18 13 21	+16 30·7	8·6
May 1	17 56	17 31·9	
2	22 34	18 32·8	
3	27 14	19 33·3	
4	31 55	20 33·3	
5	36 39	21 32·6	
6	41 23	22 31·2	
7	18 46 9	+23 29·0	8·5

The comet is situated in that portion of the constellation of Hercules lying to the south of Vega, and it will be noticed that the present calculation makes the object brighter by more than half a magnitude than that previously given.

THE APRIL METEORIC SHOWER.—Mr. W. F. Denning writes:—More favourable weather for meteoric observations could scarcely have occurred at the period of the Lyrid meteors. At Bristol the fourteen successive nights from April 10 to 23 were clear or generally clear throughout. The expected shower of meteors, however, failed to display itself in a prominent manner. There were a few bright Lyrids seen between April 19 and April 22, but the return of this year must certainly be classed among the failures. A number of other streams showed themselves in the absence of the major shower, but meteors were rather scarce generally, with a great exception on one night, April 22, when they were quite abundant, though the Lyrid display was scarcely visible. On April 14 there was a remarkable dearth of meteors before midnight, though the firmament was splendidly clear.

Mr. Denning has computed the real paths of several interesting meteors recently observed at two stations:—

1914 April	G.M.T. h. m.	Mag.	Height at first. Miles.	Height at end. Miles.	Path. Miles.	Velocity per sec. Miles.	Radiant Point. ° °
12	10 5	2–1	64	44	21	18	167+31
15	9 46	4–2	88	64	49	35	309+61
,,	10 22	2–1	71	55	18	36	180+77
,,	10 44	1	73	57	29	29	312+61
20	11 7	>1	62	48	57	29	319+40
22	10 51	2	76	44	76	24	238–2

The chief radiant points have been:—

° °			° °
142+27	...	...	220+13
199+ 7	...	...	239± 0
204+55	...	...	272+33
209–10	...	...	312+61

The Aquarid meteoric shower, supposed to be connected with Halley's comet, is due to reappear on the mornings of May 1–6. The radiant point is at about $337^\circ-2^\circ$.

THE PRESSURE IN THE REVERSING LAYER OF THE SUN.—In an early number of a Bulletin of the Kodaikanal Observatory (No. 18) Mr. Evershed attempted to make a rough estimate of the pressure in the reversing layer of the sun based on the assumption that those lines which were most and least affected by pressure in the laboratory were similarly affected in the sun. In a more recent Bulletin (No. 36) he suggests a new interpretation of the general displacement of the lines in the solar spectrum towards the red. He shows that taking into consideration probable differences of level, the absolute and relative shifts can be quite easily explained as due to motion in the line of sight, and have very little relation to pressure shifts. While the quantities measured are exceedingly small, and, as he says, subject to considerable errors, yet he is so convinced that pressure is not the main factor involved that he publishes his results, even although all the work of measurement is not yet completed, and exact values cannot be submitted. Many interesting points are mentioned in the paper, one being that a small pressure effect is traceable in the relative positions of the solar and arc lines, but that it is a minus effect, thus indicating a decidedly smaller pressure in the sun than in the arc in air. With such a small pressure effect he finds the shifts closely related to the intensities of the lines, the strong lines showing larger shifts than the weak. He arrives also at the conclusion that in the higher levels of the sun there is a movement of descent which is retarded in the lower levels.

THE NEW UNIVERSITY OF ZÜRICH.

ON the four days from Friday, April 17, to Monday, April 20, Zürich celebrated in a very interesting fashion the inauguration of the new University which for six years she has been engaged in building at a total cost of 5,600,000 francs (224,000*l.*). As is usual on such occasions, the guests were welcomed at a reception in their honour on the Friday evening. The *Weiheakt* of Saturday morning was held in the central court of the new University, which is covered with a roof of tinted glass carried on light iron girders. Thither the University authorities and their guests marched two and two from the Kunsthalle, the procession rendered picturesque by the robes of the foreign delegates, for the republican simplicity of Switzerland does not admit of academic dress. Many speeches were delivered, those of the local officials naturally dwelling upon the efforts required to complete the task. Amongst those of foreign delegates that of Dr. Macan, master of University College, Oxford, was distinguished by its wit and humour, and by the obvious pleasure which it gave to the people of Zürich where he had been a student thirty-nine years before.

The speeches were followed by a cantata written by Prof. Alfred Frey, and set to music by the director of the Conservatorium, Dr. Hegar. Both words and music were well adapted to the occasion, most parts of the libretto attaining a high poetic level. A banquet lasting nearly four hours followed, and for those who wished for more festivity still there was a students' *kommers* in the evening. Sunday was no less full, with a special service in the Fraumünsterkirche, a luncheon given by the Guild of Smiths, a trip on the lake, and an admirable performance of Gluck's "Orpheus," in the Stadt-Theater in the evening. Monday was the annual festival of the *Sechseläuten*, where, as of old, the departure of winter was betokened by the burning of a huge puppet filled with fireworks at the end of a procession through the town which lasted the whole afternoon. This year the procession was developed into a gorgeous pageant of the history of learning from its beginnings in Egypt and Babylon, through Greece and Rome, troubadours and goliards, monks and reformers, to the present day. In the evening the trade guilds had their separate banquets, to which visitors were invited. The entertainment was followed by visits from the younger members of one guild to each of the others in turn. As they came in with their band and banner, with lanterns hanging from long poles, and the emblems of their craft, while their leader exchanged loving-cups with the master of the guild visited, and the two made, and in turn listened to, speeches at one another's expense, one felt that one had here a custom which had known no change since at least the fifteenth century.

Nothing could exceed the hospitality and kindness with which the foreign visitors were welcomed. As a means of identification the guests were asked to wear in the buttonhole a stud with the colours of Zürich (light blue and white), which proved a most useful "open sesame" everywhere.

This is the third time that the University of Zürich has been furnished with buildings since its revival in 1833. The intermediate edifice was built in 1864. For some time back the University has shared in the building occupied by the Polytechnic, but by 1907 it was felt that the difficulties of accommodation must be otherwise provided for. In 1908 architects were invited to compete, and ultimately the plan of the firm of Curjel and Moser, of St. Gallen and Karlsruhe, was adopted. The site on the Zürichberg was not easy, because the slope is very considerable, and from parts of it various other institutions had to be removed. The buildings, which, of gray stone and many windowed, resembles many Germany university buildings, consists of two wings with a great tower between. The northern and lower wing is the biological institute, the southern is the University proper, in the sense that it contains the lecture-rooms, reading-rooms, *seminars*, libraries for the theological and arts faculties, and accommodation for the administration. To it also have been moved the archæological and ethnological collections. Natural science and medicine are provided for in the biological institute and in other buildings adjacent.

Apart from the tower, the building is in three storeys at present, though in the University proper it will be possible, as the numbers increase, to provide more accommodation for classes in the attics. With an imposing façade on two sides, the rooms are admirably lighted. Round the central court runs a wide passage on each storey, thus giving easy access from room to room, and also providing in these passages, which can be seated, excellent galleries for such occasions as that of April 18. The parapet towards the court is broken by openings, the superincumbent mass being on the first storey supported in each case by two Moorish pillars. In the storeys above are romanesque arches, so that the appearance towards the inner court is more like that of some southern palazzo than could be guessed from its external aspect. The effect is heightened by the insertion in the walls of small artistic figures. The rooms for the administration are well furnished; the desks and seats in the lecture-rooms are substantial but simple.

On the walls of the galleries are frescoes which the spectator was asked by notices to believe were not yet finished, and which seemed, truth to tell, to represent an early stage of art. But the general effect of lightness and airiness was excellent, and the people of Zürich and their architect, Mr. Moser, are to be congratulated on the way in which they have secured an admirable result at what, for the accommodation provided, seems a minimum of cost. It is to be remembered that the whole of this is paid for out of the rates of the Canton of Zürich, which not unnaturally are very high. But as the inscription above the entrance tells us, all has been done "by the will of the people," which, when the first credit was insufficient, voted a second. The people of Zürich are convinced of the value of good and cheap education, and nothing in the whole celebration perhaps was more interesting than to mix with the crowd on Monday morning, when the building was thrown open to the public, and to hear the approving remarks of tradesmen and labourers as they examined the new building which they were proud to call their own. G.

RADIUM AND QUACK MEDICINES.

IN view of the fact that a large number of drugs, earths, and waters, said to be radio-active, are being offered for sale to the general public for the treatment of certain diseases, the medical committee of the British Science Guild recently instituted an inquiry into the question of radium and its therapeutic uses.

The result of the inquiry indicates the urgent necessity for legislation in order to safeguard the interests of the community in the sale of these substances, by compelling a written guarantee to be given as to the quantity of radium present in the substances offered for sale.

The use of radium in cases of cancer is now widely known, but it is necessary to warn the public that no definite evidence that cancer is permanently curable by radium is yet forthcoming. The immediate effect of the treatment of cancer by radium is often highly satisfactory, but it must not be forgotten that agents other than radium are known to give equally good results. It is only by keeping under observation for at least five years patients who have been so treated that a definite decision can be come to as to the place radium-therapy shall take in the treatment of malignant diseases.

The great strides that have been made in recent years in the use of radium for the treatment of disease, and the results obtained, encourage the medical profession to persevere with this therapeutic agent. However, radium in its application to disease is still but little understood, and until more experimental, pathological and clinical data have been collected to show the effect of this agent upon, not only the diseased but also the healthy tissues of the body, dogmatic statements as to its therapeutic value cannot be made.

In these circumstances of uncertainty the public is warned that there is danger that the claims which have been advanced for radium as a curative agent may lead to frauds on the credulous section of the public, which may be imposed upon by the sale of substances or waters in which radium does not exist, or may be harmfully treated by persons with no medical qualifications.

The inclusion of radium in the Pharmacopœia would be of material benefit to the public, and it is proposed to take the steps necessary to secure this end. It has also been suggested that radium should be scheduled as a poison under the Foods and Drugs Act, which would be an additional safeguard against the victimisation of the public.

The report of the medical committee of the British Science Guild contains further valuable and important information concerning the sources, etc., of radioactive substances, the price of radium, and diseases which are treated with radium, and this will be published in full in the annual report of the guild, to be issued in May next.

JAPANESE FISHES AND NOMENCLATURE.

THE latest part of the Journal of the College of Science in the Imperial University of Japan (vol. xxxiii., article 1, March, 1913) is a catalogue of the fishes of Japan, by David Starr Jordan, Shigeho Tanaka, and John Otterbein Snyder. It consists of 497 pages, and has 396 figures in the text. There is a very excellent index, and the volume is one which is likely to be of considerable assistance to ichthyologists. The list is based on the work of Temminck and Schlegel (1848 to 1850), on the collections made by David Starr Jordan in 1900. the collections of Snyder (1906), and the collections in the Imperial University of Japan, and the Imperial Museum at Tokyo. It includes all records of Japanese fishes made up to February 1, 1913.

The fish fauna of Japan appears to be an extraordinarily rich one, for the present list deals with 1230 species, while it is pointed out that many additional species from the tropics may yet be found in the Kuroshiwo (that is, the Japan current corresponding to the Atlantic Gulf Stream); the deep-sea species are yet imperfectly known; and large accessions to the lists may be expected when Hokkaido is explored. Japanese names are given for all the species, but full synonymies are not given, and this is occasionally rather troublesome to the worker unaccustomed to the light-hearted manner in which the American systematists play fast and loose with generic names, and their uncompromising insistence on the rules of priority with regard to specific names.

One example from this catalogue may be given—it is not the only one that might be quoted in illustration of our complaint; the Japanese sardine called "Iwashi," was described by Schlegel in 1846 as *Clupea melanosticta*, and this name was adopted by Günther. Richardson also described the same fish in

1846, calling it *Clupea caeruleovittata*, but Schlegel's description appeared on p. 237 of his book, while Richardson's appeared on p. 305 of *his* book. Therefore Schlegel's name has "page priority." But in 1901 Jordan and Snyder changed the generic name from Clupea to Clupanodon; and then in 1906 Jordan (the same worker) and Herre changed it from Clupanodon to Sardinella. In the present paper Jordan, Tanaka, and Snyder discard Sardinella and go back to an old generic name Amblygaster, used by Bleeker in 1849. So it remains for the immediate present.

Of course, irritating as all this is, one cannot but feel that a rigid adherence to the rules of priority (provided that systematists can agree about these) is the only way by which we can approach finality in matters of nomenclature. The case is different, however, with regard to generic and family names, and one may reasonably urge that so long as large tracts of the earth are imperfectly explored, and so long as accessions to specific lists may be expected, the older generic names should be retained. Even should the genus attain "unwieldy" dimensions, it may be broken up into divisions of a provisional nature, but the temptation to make new genera might be resisted, for as a rule these generic changes only burden the synonymies. When the same author places a species in three genera, almost within the same decade, one does not feel confident that the state of our knowledge justifies the adoption of the rather fine distinctions on which these groupings depend. J. J.

THE CANADIAN ENTOMOLOGICAL SERVICE.

THIRTY years ago, in 1884, the Canadian Government appointed a Dominion Entomologist to advise agriculturists and others regarding the control of insect pests. Two years later, on the establishment of the experimental farms system, Dr. James Fletcher, who occupied the position, was attached to the new branch of the Department of Agriculture in the joint capacity of entomologist and botanist, which position he occupied with conspicuous success until his death in 1908. The growth in importance of the subjects necessitated their separation, and accordingly divisions of entomology and botany were created. Dr. C. Gordon Hewitt was appointed Dominion entomologist in 1909, and entrusted with the work of organising the new division of entomology of the Experimental Farms Branch of the Department of Agriculture, with offices and laboratory at the Central Experimental Farm, Ottawa.

The urgent need of legislation in order to permit action to be taken to prevent the introduction into Canada and spread within the country of serious insect pests and plant diseases was responsible for the passage of the Destructive Insect and Pest Act in 1910. The still greater need of investigations on the insect pests affecting agriculture, forestry, and other branches of human activity has led to the establishment of field or regional laboratories in different parts of Canada, with trained entomologists in charge to study local problems.

Owing to the consequent expansion of the entomological work along investigatory and administrative lines, and the fact that such work did not constitute a necessary part of the work of the experimental farms system, and executively was virtually distinct, the Entomological Service has now been separated from the Experimental Farms Branch, and has been constituted an independent branch of the Department of Agriculture under the direction of the Dominion Entomologist. It is proposed to erect a building to provide offices and laboratories for the new entomological branch. Correspondents are requested to note that all official communications and publications should be addressed to "The Dominion Entomologist, Department of Agriculture, Ottawa"

This reorganisation, which will also include the establishment of a national collection of the insects of Canada in the Canadian National Museum (the Victoria Memorial Museum) at Ottawa, under the care of the Dominion Entomologist, marks an important step in Canadian entomology. It will result in a still greater development of the study of Canadian insects along scientific and practical lines.

DISEASES OF PLANTS.

DR. G. H. PETHYBRIDGE, economic botanist to the Department of Agriculture and Technical Instruction for Ireland, has recently published two papers, of considerable scientific as well as economic interest, on species of the genus Phytophthora, and the diseases which these fungi cause in the potato. In the first paper (Sci. Proc. Royal Dublin Soc., vol. xiii., No. 35) he describes the rotting of potato tubers by a species of Phytophthora having a method of sexual reproduction hitherto undescribed, and gives in the introductory portion of the paper a useful summary of the literature dealing with the chief forms of rot previously known to occur in the potato tuber. The new form of rot ("pink rot") is caused by the new fungus *Phytophthora erythroseptica*, the most peculiar feature of which is the fact that the oogonium rudiment enters the antheridium at or near its base, the female organ then growing up through the male and out at the top, expanding there to form the oogonium proper in which the oosphere develops. The "pink rot" disease is prevalent in the west of Ireland, and the losses caused by it, which are considerable, and in some cases being greater than those due to *P. infestans*, are greatest in crops grown continuously on the same land (infection taking place from the soil), and can be avoided by a proper rotation; it is probably transmitted to some extent by oospores which adhere to the seed tubers.

In the second paper (*ibid.*, No. 36) Dr. Pethybridge, in conjunction with Mr. P. A. Murphy, describes the results of investigations on the common potato blight fungus, *Phytophthora infestans*, and points out that much remains to be discovered regarding the life-history and modes of transmission of this well-known parasite. Thick-walled spores were found in the tissues of various parts of the potato plant that had been destroyed by *P. infestans*, and these are probably the oospores of this fungus. The two papers are illustrated by beautiful figures, including two plates of very fine photomicrographs.

In connection with the foregoing paragraphs, mention may be made of a paper received simultaneously, dealing with the same group of fungi, entitled "Studies in Peronosporaceæ," by Mr. E. J. Butler, Imperial Mycologist, and Mr. G. S. Kulkarni, Mycological Assistant, Bombay Department of Agriculture (Memoirs of the Department of Agriculture in India, Botanical Series, vol. v., No. 5, 1913). The forms described in detail by the authors are *P. colocasiae* (parasitic on *Colocasia esculenta*), the ubiquitous *Pythium debaryanum*, *Sclerospora graminicola* (parasitic on three Indian cereals and a fodder grass), and *S. maydis* (a very destructive parasite on maize, which has apparently reached India recently from Java). The four papers included in these careful studies are illustrated by fine plates, in some cases coloured, and directions are given for treatment of the disease in question. F. C.

EASTER VACATION WORK AT PORT ERIN.

THE Easter vacation party at the Port Erin Biological Station has this year been larger than ever before, and has carried out a longer programme of work—both in the laboratory and on the seashore. During the last few weeks (March and April) the number of researchers and senior students enrolled in the books of the station has reached the record total of eighty-five, including half a dozen professors and a dozen university lecturers and demonstrators, while nearly half of the total number were post-graduate researchers. Altogether twelve universities or university colleges have been represented. Practically all the senior students and post-graduate workers of the botanical and zoological departments of the University of Liverpool, under Profs. Harvey Gibson and Herdman, migrated to the Port Erin laboratory for the vacation. Prof. Cole brought a considerable contingent from the University College of Reading, and Dr. Stuart Thomson a number from Manchester; Mr. Holden came with some students from University College, Nottingham, and smaller groups came from Birmingham, Cambridge, Oxford, Bristol, Bangor, Cardiff, London, and Melbourne. In addition to the laboratory work of the students and their collecting expeditions on the seashore, the activities of the biological station at this time of year are threefold: first, the flat-fish hatching (seen at its best during March and April); secondly, the plankton investigation going on at sea from the s.y. *Runa*; and thirdly, the special investigations of the post-graduate researchers.

The spawning of the mature plaice in the open-air fish-ponds started at the beginning of February this year, at least a fortnight earlier than usual, and it is by no means finished yet. Already more than eight millions of eggs have been skimmed from the ponds, and about seven millions of young fish have been set free in the sea round the south end of the Isle of Man.

Work at sea was much hampered by bad weather during the earlier part of the time, and it was sometimes difficult to get the periodic plankton hauls taken. This is now the eighth year of Prof. Herdman's scheme of intensive study of the nature and distribution of the plankton, of which it is hoped to complete ten years' statistics before winding up the investigation. Up to the present the phytoplankton this spring has been characterised by the prevalence of Coscinodiscus.

In addition to the collecting and recording of rare species, both of animals and sea-weeds, which has gone on very much as in former years, there has been a large amount of special investigation both at sea and in the laboratory on the part of those who are engaged in the preparation of L.M.B.C. Memoirs, and also of others who are at various researches. For example, Mr. R. D. Laurie has been making observations on the movements of Amphidinium in the sand, Mr. S. T. Burfield has been working at Sagitta, Miss Gleave at Archidoris, Mr. H. G. Jackson on Decapod larvæ in the plankton, and Prof. B. Moore and Mr. E. Whitley on the nutrition of marine animals and the variations in the alkalinity of the sea-water. The memoir on Echinoderm larvæ which Mr. Chadwick has been engaged on for some years is now in the printer's hands, and will be published at an early date. The pressure on the laboratory accommodation has been very great during this vacation, and the need of further extension of the building is urgent.

W. A. H.

RELATIONS BETWEEN THE SPECTRA AND OTHER CHARACTERISTICS OF THE STARS. *

I.

Historical.

INVESTIGATIONS into the nature of the stars must necessarily be very largely based upon the average characteristics of groups of stars selected in various ways—as by brightness, proper motion, and the like. The publication within the last few years of a great wealth of accumulated observational material makes the compilation of such data an easy process; but some methods of grouping appear to bring out much more definite and interesting relations than others, and, of all the principles of division, that which separates the stars according to their spectral types has revealed the most remarkable differences, and those which most stimulate attempts at a theoretical explanation.

In the present discussion, I shall attempt to review very rapidly the principal results reached by other investigators, and shall then ask your indulgence for an account of certain researches in which I have been engaged during the past few years.

Thanks to the possibility of obtaining with the objective prism photographs of the spectra of hundreds of stars on a single plate, the number of stars the spectra of which have been observed and classified now exceeds one hundred thousand, and probably as many more are within the reach of existing instruments. The vast majority of these spectra show only dark lines, indicating that absorption in the outer and least dense layers of the stellar atmospheres is the main cause of their production. Even if we could not identify a single line as arising from some known constituent of these atmospheres, we could nevertheless draw from a study of the spectra, considered merely as line-patterns, a conclusion of fundamental importance.

The spectra of the stars show remarkably few radical differences in type. More than 99 per cent. of them fall into one or other of the six great groups which, during the classic work of the Harvard College Observatory, were recognised as of fundamental importance, and received as designations, by the process of "survival of the fittest," the rather arbitrary series of letters B, A, F, G, K, and M. That there should be so few types is noteworthy; but much more remarkable is the fact that they form a continuous series. Every degree of gradation, for example, between the typical spectra denoted by B and A may be found in different stars, and the same is true to the end of the series, a fact recognised in the familiar decimal classification, in which B5, for example, denotes a spectrum half-way between the typical examples of B and A. This series is not merely continuous; it is *linear.* There exist indeed slight differences between the spectra of different stars of the same spectral class, such as AO; but these relate to minor details, which usually require a trained eye for their detection, while the difference between successive classes, such as A and F, are conspicuous to the novice. Almost all the stars of the small outstanding minority fall into three other classes, denoted by the letters O, N, and R. Of these O undoubtedly precedes B at the head of the series, while R and N, which grade into one another, come probably at its other end, though in this case the transition stages, if they exist, are not yet clearly worked out.

From these facts it may be concluded that the prin-

* An address delivered before a joint meeting of the Astronomical and Astrophysical Society of America and Section A of the American Association for the Advancement of Science, at Atlanta, Georgia, December 30, 1913, with a few additions, by Prof. H. N. Russell.

cipal differences in stellar spectra, however they may originate, arise in the main from variations in a single physical condition in the stellar atmospheres. This follows at once from the linearity of the series. If the spectra depended, to a comparable degree, on two independently variable conditions, we should expect that we would be obliged to represent their relations, not by points on a line, but by points scattered over an area. The minor differences which are usually described as "peculiarities" may well represent the effects of other physical conditions than the controlling one.

The first great problem of stellar spectroscopy is the identification of this predominant cause of the spectral differences. The hypothesis which suggested itself immediately upon the first studies of stellar spectra was that the differences arose from variations in the chemical composition of the stars. Our knowledge of this composition is now very extensive. Almost every line in the spectra of all the principal classes can be produced in the laboratory, and the evidence so secured regarding the uniformity of nature is probably the most impressive in existence. The lines of certain elements are indeed characteristic of particular spectral classes; those of helium, for instance, appear only in Class B, and form its most distinctive characteristic. But negative conclusions are proverbially unsafe. The integrated spectrum of the sun shows no evidence whatever of helium, but in that of the chromosphere it is exceedingly conspicuous. Were it not for the fact that we are near this one star of Class G, and can study it in detail, we might have erroneously concluded that helium was confined to the "helium stars." There are other cogent arguments against this hypothesis. For example, the members of a star-cluster, which are all moving together, and presumably have a common origin, and even the physically connected components of many double stars, may have spectra of very different types, and it is very hard to see how, in such a case, all the helium and most of the hydrogen could have collected in one star, and practically all the metals in the other. A further argument—and to the speaker a very convincing one—is that it is almost unbelievable that differences of chemical composition should reduce to a function of a single variable, and give rise to the observed linear series of spectral types.

I need not detain you with the recital of the steps by which astrophysicists have become generally convinced that the main cause of the differences of the spectral classes is difference of temperature of the stellar atmospheres. There is time only to review some of the most important evidence which, converging from several quarters, affords apparently a secure basis for this belief.

The first argument is based upon the behaviour of the spectral lines themselves. To appreciate its full force, one must familiarise himself with a multitude of details. A typical instance is that of the heavy bands in the region of longer wave-length, which are the most characteristic feature of spectra of Class M, appear faintly in Class K5, and are absent in Class K and all those higher in the series. Fowler has shown[1] that these bands are perfectly reproduced in the spectrum of the outer flame of an electric arc charged with some compound of titanium, while the spectrum of the core of the arc, though showing conspicuously the bright lines of titanium, does not contain the bands. Here we are evidently dealing with some compound—perhaps titanium oxide—the vapour of which is present in the relatively cool flame of the arc, and emits a spectrum of the banded type, characteristic of compounds, while in the hotter core it is dissociated, and only the lines of the metal are seen. There seems then to be no escape from the conclusion that the atmospheres of stars of Class M are cool enough to permit the existence of this compound, and hence cooler than the core of the arc, and that the temperature of its dissociation is approached in Class K5, and surpassed in Class K. In general, those metallic lines which are relatively strong in the spectra produced in the oxyhydrogen flame or the electric furnace are also strong in spectra of Classes M and K; the lines most prominent in Class G are the typical arc lines; and the relatively few metallic lines which persist into Classes A and B are those which appear exclusively, or with greatly enhanced intensity, in the spark spectra of the laboratory.

[1] Proc. Roy. Soc., vol. lxxii., pp. 219–225, 1904.

The second line of evidence is afforded by the distribution of intensity in the continuous background of the spectra, the differences of which from type to type are obvious to the eye as differences in the colour of the stars. This characteristic is fortunately capable of accurate measurement. For the brighter stars, spectro-photometric comparisons may be made with a terrestrial light-source the energy curve of which is known, as has been done visually by Wilsing and Scheiner,[2] and photographically by Rosenberg.[3] Much fainter stars may be reached by the comparison of their brightness as measured visually (or on isochromatic plates with a suitable colour-screen), and photographically on ordinary plates. The "colour-index" so obtained, which expresses, in stellar magnitudes, the relative photographic brightness of stars of equal visual brightness, is found to be very intimately related to the spectral type, the differences within each spectral class being scarcely greater than the errors of observation. The results of King,[4] Parkhurst,[5] and Schwarzschild,[6] working with different instruments and on stars of very different brightness, are in excellent agreement, as is shown in Table I. The near approach to equality among the differences in colour-index from class to class is very remarkable, when it is considered that these types were picked out somewhat arbitrarily according to the general appearance of the photographic spectra. The judgment of the Harvard observers in selecting the really important points of difference was evidently very good.

Table I.

Spectrum	Colour-index King	Colour-index Parkhurst	Colour-index Schwarzschild	Temperature °
B0	−0·32			20,000
B5	−0·17	−0·21	−0·20	14,000
A0	0·00	0·00	0·00	11,000
A5	0·19	0·23	0·20	9,000
F0	0·30	0·43	0·40	7,500
F5	0·42	0·65	0·60	6,000
G0	0·72	0·86	0·84	5,000
G5	0·98	1·07	1·10	4,500
K0	1·10	1·30	1·35	4,200
K5	1·62	1·51	1·80	3,200
M	1·62	1·68		3,100
N		2·5		2,300

If the spectral sensitiveness of the plates used in such investigations has been determined (as Parkhurst has done) it is possible to calculate the temperature at which a black-body would emit light of the same colour as that observed; and similar calculations can be made, with greater accuracy, from the spectrophotometric data. The last column of Table I. gives the effective temperatures thus derived (based mainly on the work of Wilsing and Scheiner). The absolute

values of the temperatures here given may be considerably in error, especially at the top of the scale (in fact, Rosenberg's work indicates a much greater range), but there can be no doubt about the relative order.

Of a third independent confirmation of the temperature hypothesis, based on the determination of the surface brightness of the stars, I shall have occasion to speak later.

It should be expressly stated that the "temperatures" here spoken of are the effective "black-body" temperatures corresponding to the spectral distribution of the radiation. Unless the surfaces of the stars possess decided selective emissivity for certain wavelengths, these effective temperatures should also indicate with tolerable accuracy the energy-density of the flux of radiation which escapes from them. This tells us little about the temperature of the deeper regions; but it must be the main, if not the only, factor in determining the temperature of those outer and nearly transparent layers of the atmospheres in which the characteristic line absorption takes place. If we further assume, in accordance with Abbot's studies of the solar atmosphere,[7] that the absorption is nearly complete in so small a thickness of the atmosphere that wide variations in its depth and density would modify its total absorption but little, it becomes easy to see how the influence of its temperature (which presumably determines the relative strength of absorption in different lines) may predominate so greatly over all that of all other factors in determining the spectral type.

We may now review rapidly some of the relations which have been brought to light between other characteristics of the stars and their spectral types. First, as regards the relative numbers of stars of the different classes, we have in Table II. some results of counts made at Harvard.[8]

TABLE II.

Spectrum	O	B	A	F	G	K	M	N
No. above 3·25m.	3	52	32	16	20	35	21	0
,, 6·25m.	20	696	1885	720	609	1719	457	8
Percentage in Galactic region	100	82	66	57	58	56	54	87

Classes A and K make up more than half of all the stars brighter than 6·25 m—that is, of the stars visible to the naked eye. The remaining stars are divided fairly evenly among the other four principal classes, while only one star in 300 is of Class O, and only one in 800 of Class N. The relative proportions of the different classes are, however, different in different parts of the heavens, as is indicated by the last line of the table, which give the percentage of stars of each class which lie in a belt covering one-half of the celestial sphere, and extending for 30° each side of the Milky Way. All the stars of Class O are close to the central line of the Galaxy (except for a few in the Magellanic Clouds). The stars of Class B are very strongly concentrated in the galactic region; those of Class A are considerably so; those of the following classes very little, except in the case of Class N (for which the tabular percentage is derived, not from the eight brightest stars of this class alone, but from a much larger number of fainter ones).[9]

The relative proportions of the different classes vary also with the apparent brightness of the stars. Among the stars brighter than 3·25m., as the table shows, Class B has more representatives than any other; but the percentage of this type steadily diminishes as we pass to fainter stars. The percentage of stars of Class A at first increases with diminishing visual brightness; but there is good reason to believe that, at least in regions remote from the Galaxy, the relative proportion of these too falls off rapidly in the neighbourhood of the ninth magnitude[10]; and Fath's work on the integrated spectrum of the Milky Way[11] shows that, even there, the bulk of the very faint stars which form the galactic clouds must be of Secchi's second type (F, G, or K).

Counts of the stars down to any given magnitude may, however, be very misleading unless we bear in mind the enormous preference which this method of observation gives to the stars of great actual luminosity, which can be seen afar off, and hence are being sought in a much greater volume of space than those of small luminosity. A difference of but five magnitudes in the real brightness of two groups of stars gives the brighter kind (if both are uniformly distributed in space) a thousand-fold better chance of getting into our catalogues; and this example understates the actual conditions in some cases. Mere counts of stars need therefore to be supplemented by such knowledge as we can obtain concerning their distances.

Much information can be obtained from the average proper-motions of the stars of the various classes, and still more by deriving their average parallaxes from the mean parallactic drift due to the motion of the solar system in space. Studies of this character have been made by several investigators of the first rank. Their results, which are summarised in Table III., show certain apparent discrepancies, which, however, arise principally from differences in the methods according to which the various workers have selected the groups of stars for investigation.

TABLE III.

Spectrum	Mean centennial proper-motion			Mean parallax			
	Kapteyn	Boss	% rejected	Kapteyn	Boss	Campbell	% rej.
	"	"		"	"	"	
O		1·6	0		0·004		
B	2·6	2·4	0	0·007	0·007	0·006	0
A	5·8	4·6	3	0·010	0·010	0·016	3
F	14·5	7·7	28	}	0·012	0·035	3
G	27·0	5·2	20	} 0·022	0·008	0·022	8
K	13·0	5·7	6	}	0·010	0·015	9
M	5·9	5·0	6	0·011	0·008	0·011	3
N		3·2		0·0007			

Kapteyn's data[12] represent the mean proper motions and parallaxes of all the stars of the fifth magnitude of each class, except for Class N, in which, to get enough stars, it was necessary to include faint objects, so that the average magnitude is here 8·3. His results show a conspicuous maximum of average proper-motion and parallax for Class G, with a rapid fall on both sides of it. The stars of Class N would have to be brought about five times nearer to appear as bright as the others, but even then they would have the smallest mean parallax of all.

Boss,[13] in his investigation of the solar motion, had at his disposal very accurate proper-motions of all the stars down to 5·7m., and about half as many more between this and the seventh magnitude. The average magnitude of his stars is therefore nearly the same as that of Kapteyn's. But, for very good reasons, he excluded from his main solution all stars with proper-motions exceeding 20″ per century. The percentage of stars thus excluded (which differs greatly from class to class) is given in the fourth column of Table III. It is natural that this often drastic rejection of the large proper-motions, and hence in general

[7] Abbot, "The Sun," p. 252, 1911.

[10] *Astronomical Journal*, vol. xxvi., p. 153, 1910.
[11] *Astrophys. Journal*, vol. xxxvi., pp. 362–367, 1912.
[12] *Astrophys. Journal*, vol. xxx., p. 295 : vol. xxxii., p. 91, 1909–10.
[13] *Astronomical Journal*, vol. xxvi., pp. 187–201, 1911. The mean proper-motions of the few stars of Classes O and N which appear in Boss's Catalogue have been added by the writer.

of the nearer stars, should greatly diminish his mean values. Among the classes in which the mean proper-motion is small, the percentage of exclusion is also small, and the results are but little modified. But it is noteworthy that the exclusion of 6 per cent. of the stars of Class K has reduced the mean proper-motion in a greater ratio than that of 28 per cent. of those of Class F, and also that the removal of one-fifth of the stars of Class G decreases the mean for the remainder to less than one-fifth of its initial value. It appears from these results that a large majority of the stars of Classes F, G, and K have nearly, if not quite, as small parallaxes and proper-motions as those of Classes A and M, though they are not quite so remote as the stars of Class B. The large mean values obtained for all the stars of these classes are due to the presence of a relatively small proportion of near and apparently rapidly moving stars, of which the percentage decreases, but the mean proper-motion and parallax increase, from F to K.

Campbell's results [14] are derived from a comparison of the radial velocities and proper-motions of nearly 1200 stars, mostly brighter than the fifth magnitude, and averaging about a magnitude brighter than Boss's stars, which would lead us to expect that their mean parallaxes should be 40 or 50 per cent. greater. In his work, "a few stars having proper-motions abnormally large for their classes were omitted in accordance with definitely set limits" (which unfortunately are not described more specifically). The approximate percentage of exclusion is given in the last column of the table. It appears on inspection that the differences between Campbell's and Boss's results for stars of Classes A, K, and M arise mainly from the greater brightness of Campbell's stars; those for Classes F and G are due mainly to the different percentages of exclusion, and that the only significant difference is that Campbell's B stars, though averaging much brighter to the eye than Boss's, have a slightly smaller mean parallax, and therefore must be, on the average, of greater real brightness.

Closely allied with these investigations is the determination of the mean peculiar velocity of the stars of each spectral class. The results of Boss and Campbell, reached almost simultaneously, and from quite independent data—proper-motions in one case and radial velocities in the other—are in extraordinary agreement. The values found for the average component of motion in any arbitrary direction are (in kilometres per second):—

Spectrum	B	A	F	G	K	M
Campbell	6·5	10·5	14·4	15·9	16·8	17·1
Boss	6·3	10·2	16·2	18·6	15·1	17·1

The rapid increase of the mean velocity from B to F is very remarkable. The slow further gain from F to M would attract little attention if it were not in the same direction.

It should here be added that the phenomenon known as preferential motion, or "star-streaming"—the excess of the average peculiar velocity of the stars in a certain direction above those in the perpendicular directions—is almost absent in Class B, very conspicuous in Class A, and somewhat less so in the following classes, being partially concealed by the greater average magnitude of the velocities.

Another notable difference between the various spectral classes may be found in the number of binary stars, both visual and spectroscopic, among them. We may distinguish two classes of visual double stars; binary stars for which orbits have been computed (with periods rarely exceeding two centuries), and physical pairs, the real connection of which is proved by common proper-motion, but the relative motions of which are slow, and periods long—probably often thousands of years. The counts of the two classes here given are from a list prepared in the course of my work, and include all stars for which the necessary data could be obtained, including many stars for which unpublished observations of spectra have been generously furnished me from Harvard. For the spectroscopic binaries, Campbell's counts have been taken from his catalogue of 1910.[15] They include all the systems the periods of which were then known, and are divided into two groups, one including all the periods of which are less than ten days, and also all those the periods of which, though not exactly known, are described as short; the other all the known periods exceeding ten days, and those which, though not precisely determined, are known to be long.

TABLE IV.

Spectrum	Visual binaries	Physical pairs	Spectroscopic binaries Short period	Spectroscopic binaries Long period
B	0	52	33	15
A	14	152	15	14
F	33	115	11	9
G	24	74	8	14
K	12	62	0	13
M	0	11	0	2

It appears that, in Campbell's picturesque phrase, visual double stars of relatively short period "abhor" Classes B and M, the greatest number being of Class F, with G a good second. Among the physical pairs, of long period, the most favoured class is A. Class B is abundantly represented, and Class M very sparingly.

The percentage of stars which are found to be spectroscopic binaries is very probably greater among Classes B and A than lower down the list. As time goes on, indeed, more and more of the stars of these "later" types are found to be spectroscopically double, but of long period; but among these classes the detection of such systems, where the range of velocity is small, is much easier than among the stars of the first type, the lines of which are diffuse. In any case it is certain that short periods are almost confined to Classes B, A, and F, and are especially abundant in the first of these. The few short-period stars of Class G which appear in the table are all Cepheid variables, most of which were selected for observation on this account, and would not otherwise have got into the list.

Finally, we may note that, among variable stars, those of the eclipsing type, such as Algol or Beta Lyræ, are for the most part of Classes A and B, though there are a number of Classes F and G, and one at least of Class K; that the Cepheid variables are almost all of classes F and G, with a few A's and K's; and that almost all the irregular variables, and all the variables of long period, are of Classes M or N. Stars of Class M the spectra of which show bright hydrogen lines are without exception variable, and almost all the stars of Class N are also subject to changes in brightness.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—Dr. James Ward, professor of mental philosophy and logic, has been nominated to represent the University on the occasion of the celebration at Oxford on June 10 of the seventh centenary of the birth of Roger Bacon, and Dr. Sorley, Knightbridge professor of moral philosophy, to represent the Univer-

[14] Lick Observatory Bulletin, vol. vi., p. 134, 1911.

[15] Lick Observatory Bulletin, vol. vi., p. 38, 1910.

sity at the fifth International Congress of Philosophy to be held in London next year.

EDINBURGH.—It is announced that the honorary degree of LL.D. is to be conferred on Dr. F. W. Mott, F.R.S., and Dr. Byrom Bramwell on July 3.

OXFORD.—The Romanes Lecture for this year will be delivered in the Sheldonian Theatre on Wednesday, June 10, by Sir J. J. Thomson, upon the subject of "The Atomic Theory."

MR. J. D. ROCKEFELLER has given the sum of 200,000*l.* to the Rockefeller Institute for Medical Research, New York, as an endowment for a new department which is to deal with the diseases of animals.

THE following Chadwick lectures have been arranged for London:—Thursday, April 30, "Water Supply: Sources, Reservoirs, and Distribution," E. P. Hill; Wednesdays, May 6, 13, and 20, a course of three lectures, "Altitude and Health," Prof. F. F. Roget, of the University of Geneva; Wednesday, May 27, "Milk Supply: a Public Health Criticism," Prof H. R. Kenwood. Admission to all or any of the lectures is free. Information concerning future Chadwick Lectures may be obtained of the secretary, Mrs. Aubrey Richardson, at the offices of the trust, 8 Dartmouth Street, Westminster.

A UNIVERSITY College of Science is shortly to be started in Calcutta as the result of generous gifts by Sir T. Palit and Dr. Rashbehary Ghose. The services of Dr. P. C. Rây, professor of chemistry in the Presidency College, Calcutta, will be lent by Government to the college, and as such he will be made the Palit professor of chemistry in the University of Calcutta. In a note on this appoinment in NATURE of March 19 (p. 75) it was incorrectly stated that Dr. Rây had been appointed to the Palit professorship in the Presidency College, whereas, as is well known, he has been professor of chemistry in that college for many years. We learn from the *Pioneer Mail* of April 3 that the foundation stone of the new college in connection with the Calcutta University was laid on March 27 last by Sir Asutosh Mookerjee, Vice-Chancellor of the University. In performing the ceremony, Sir Asutosh said that the scheme was first rendered practicable by the execution of a trust deed by Sir Taraknath Palit, by which he transferred money and land for the promotion of pure and applied science among his countrymen. A few weeks later Sir Taraknath executed a second deed for the purpose of supplementing the trusts mentioned in the first deed. The University Syndicate had received Government's permission to apply 800*l.* annually for the maintenance of the laboratory, and Dr. Rashbehary Ghose has offered 67,000*l.* for the foundation of four professorships and eight research studentships.

THE Department of Agriculture and Technical Instruction for Ireland will, in July, 1914, award a limited number of commercial scholarships (not more than six) to young men who have had a sound general education and some commercial experience. The object of the scholarships is to afford facilities for the holders to obtain training in some higher institution, approved by the Department, with a view to their employment as teachers of commercial subjects in Ireland. The scholarships are of the value of 100*l.* per annum each, and are tenable for two years. Candidates must be at least twenty-one years of age on July 1, 1914, and must have been born in Ireland, or have been resident in Ireland for three years immediately preceding July 1, 1914. Successful candidates will be required to enter into an undertaking that they will engage in the teaching of commercial subjects after the termination of their scholarships. Candidates must fill in Form S. 195 and return it to the secretary of the Department not later than May 30, 1914. Copies of this form may be had on application.

THE Standing Committee of the House of Commons has now concluded its consideration of Mr. Denman's Children (Employment and School Attendance) Bill, and the Bill will be reported to the House for third reading. Several important changes have been made, and new clauses added. As amended, the Bill proposes the following changes in the existing law:—Limitation of powers of local education authorities: (1) No exemption from school attendance allowed for children under thirteen years of age; (2) restrictions in exemption above thirteen. Extension of powers of local education authorities: (1) Optional powers granted to extend school leaving age to fifteen; (2) optional powers granted to make employment by-laws for children up to age of sixteen (instead of fourteen as at present). Abolition of existing half-time system and a restriction on street trading. The Bill renews proposals passed by Standing Committees of the House of Commons in 1912 in the Education (School Attendance) and the Employment of Children Bills. The chief objects of the Bill not contained in those Bills are the transference of the duty of approving by-laws relating to the employment of children from the Home Office to the Board of Education, and the raising to fifteen of the school leaving age and the minimum age for boys engaged in street trading.

SOCIETIES AND ACADEMIES.

LONDON.

Physical Society, March 27.—Sir J. J. Thomson, president, in the chair.—F. W. **Jordan**: A new type of thermogalvanometer. The puff of air from an orifice in an air chamber when the air within is heated suddenly is utilised to deflect a small suspended vane. The current to be measured is made or broken through a heater of small thermal capacity in the air chamber and the outrush or inrush of air through the orifice delivers an impulse to the vane. In one instrument the sensibility was 4 mm. per microwatt, and the extremity of the throw of the vane was attained in two seconds.—J. D. **Morgan**: An instrument for recording pressure variations due to explosions in tubes. A mechanical oscillograph for recording the pressure variations which accompany a gas explosion in an open tube. A steel vane of rectangular form is employed and is mounted parallel to the explosion tube in a cell presenting a lateral opening to the interior. Along three edges the vane is free, and along the fourth is attached to a torsion wire. The vane fits the cell as closely as possible without touching the sides of the cell. The diagram is produced by a style on smoked paper wrapped round a clock-driven drum, and on the strip is described a time curve. To make the instrument dead-beat a dash-pot is mounted on the front of the vane cell and attached to the style.—R. **Appleyard**: The direct measurement of the Napierian base. A simple apparatus was described intended to convey an idea of the way in which the base e of the Napierian logarithms enters into physical problems. A length of chain hung from a loop of thread, and the remaining part of the chain pulled aside until the thread is at 45° to the vertical. The curved portion becomes a true catenary when the angle between the vertical and curved portions of chain at the attachment of the loop is 90°. To ensure this, the circle of curvature of the catenary at that point is drawn, and found to have a radius equal to the vertical portion. If the vertical length is taken as unity, and its lower end as origin, it is shown that e is the sum of the y-ordinate at $x=1$, and the length of the curved chain between the point where that y-ordinate cuts the curve and the top of the vertical portion. The application of this result to the relationship and meaning of hyperbolic functions was also shown.

Zoological Society, April 7.—Prof. E. W. MacBride, vice-president, in the chair.—Dr. F. E. **Beddard**: The anatomy and systematic arrangement of the Cestoidea. Two new species of tapeworms belonging to the genera Linstowia and Oochoristica were described.—E. W. **Shann**: The lateral muscle of Teleostei. The author has undertaken the present work in view of the conflicting statements extant as to the nature of the lateral muscle in Teleostean fishes; the primary object of the paper is to uphold the single-layer theory of its composition.—Dr. W. T. **Calman**: Report on the river-crabs (Potamonidæ) collected by the British Ornithologists' Union and Wollaston Expeditions in Dutch New Guinea. Two new species were described.—Oldfield **Thomas**: Report on the mammals collected by the British Ornithologists' Union and Wollaston Expeditions in Dutch New Guinea. The species obtained numbered thirty-one, of which the types of twelve had been brought home by the expeditions. The two expeditions had obtained a very valuable series of ground-animals, notably of the genus Uromys, but there seemed to be, in the part of New Guinea explored, a remarkable absence of arboreal species, these forming in other parts of New Guinea a large proportion of the mammal fauna.—Guy **Dollman**: Mammals obtained by Mr. Willoughby P. Lowe during the recent East African Expedition organised by Mr. G. P. Cosens. The entire collection, some two hundred specimens in all, was presented by Mr. Cosens to the national collection. Besides examples of many rare and important species, specimens of several new forms were included.

Geological Society, April 8.—Dr. A. Smith Woodward, president, in the chair.—Prof. J. W. **Gregory**: The evolution of the Essex river-system, and its relation to that of the Midlands. The post-Eocene geology of Essex must be learnt from its gravels and their non-local constituents. In the absence of any rock which affords a certain proof of its route, the effort was made to determine the direction of transport by tracing the variations in the proportions and size of the non-local constituents; this test shows that the quartzites and felsites came from the north-west, and the Lower Greensand cherts from the south and south-east. The gravels are classified as follows:—(1) The oldest series. The Brentwood group, which consists of redeposited Bagshot Beds and of local materials only. (2) The Danbury Gravel, which was deposited before the arrival of the felsites, and at the beginning of the arrival of the Lower Greensand cherts. (3) The Braintree Gravel, which is largely composed of quartzitic drift, with abundant Lower Greensand cherts and some felsites that were probably derived from the Lower Greensand conglomerates north-west of Essex. (4) and (5) Glacial and post-Glacial gravels. Judged from the distribution and dates of appearance of the non-local constituents in these gravels, the evolution of the Essex river-systems is traced. The Lower Thames and Essex river-systems appear to be due to the Eocene earth-movements which formed the London Basin; and the coeval uplift of the English Midlands started thence a radial drainage. The streams to the south-east cut the wind-gaps on the Chiltern Hills, and the drainage to the south-west flowed along a subsidence on the north-western side of the Jurassic escarpment as the Warwickshire Avon and the Lower Severn.—J. B. **Scrivenor**: The topaz-bearing rocks of Gunong Bakau (Federated Malay States). Gunong Bakau is a peak, 4426 ft. high, in the main range of the Malay Peninsula. It is composed of porphyritic granite, into which have been intruded veins of quartz-topaz rock, and, at a later date, masses and veins of topaz-aplite.

Royal Meteorological Society, April 22.—J. E. **Clark** and R. H. **Hooker**: Report on the phenological observations from December, 1912, to November, 1913. This dealt with the dates of the flowering of plants, the song and migration of birds, the appearance of insects, and also the character of farm crops. Considering England as a whole, the main feature of the weather, so far as it affected crops, was the cold wet summer of 1912, the abundant precipitation during the spring, which resulted in a bountiful hay crop, and the dry summer.—A. J. **Bamford**: A small anemometer for tropical use.

Mathematical Society, April 23.—Prof. A. E. H. Love, president, in the chair.—Major P. A. **MacMahon**: (1) A modified form of pure reciprocants possessing the property that the algebraical sum of the coefficients is zero. (2) Lattice and prime-lattice permutations.

Dublin.

Royal Dublin Society, April 21.—Dr. J. H. Pollok in the chair.—Prof. W. **Brown**: Note on the change of length in nickel wire due to small longitudinal loads and low alternating magnetic fields. It is shown in this note that the contraction of the nickel wire is from 63 to 44 per cent. greater than for equivalent direct continuous magnetic fields. The loads employed were from $0{\cdot}1184 \times 10^5$ to 10^5 grams per sq. cm., and magnetic fields up to 200 c.g.s. units.

Paris.

Academy of Sciences, April 20.—M. P. Appell in the chair.—Maurice **Hamy** and M. **Millochau**: The effects of variations of voltage on the intensity of the radiations of the arc obtained with an arrangement utilising an alternating current. The time of exposure of a photographic plate for a constant impression was found to be proportional to V^{-9}, where V is the voltage.—A. **Haller** and Edouard **Bauer**: The action of sodium amide on the allyldialkylacetophenones. General method of synthesis of the trialkylpyrrolidones. This ketone does not follow the normal reaction, production of benzene and trialkylacetic acid, but forms a condensation product, $C_7H_{13}ON$. The reactions of this substance were in agreement with those of a 3:3:5-trimethylpyrrolidone, and this constitution was confirmed synthetically.—Charles **Moureu** and Jacques Ch. **Bongrand**: Carbon subnitride. The action of ammonia and amines. The nitride, $CN-C\equiv C-CN$, enters violently into combination with ammonia and amines. Ammonia gives aminobutenedinitrile, $CN.C(NH_2)=CH.CN$, and homologues of this are produced when amines are substituted for ammonia.—M. **Considère**: The contraction of armoured concrete: its influence on the forces developed in armoured concrete constructions. A comparison of experimental results obtained by Otto Graf at Stuttgart with some made at the laboratory of the Ecole des Ponts et Chaussées at Paris, and a discussion of a recent note by M. Rabut on the same subject.—O. **Lehmann**: The suction effects observed in liquid crystals in the course of growth (myelinic forms).—J. A. F. **Balland**: The lowering of the proportion of gluten in flour. The bread-making properties of Parisian flour have deteriorated during recent years, and this is in part due to the decline in the proportion of gluten in the flour. The causes of this decline are discussed.—P. **Chofardet**: Elements and ephemerides of the Kritzinger comet, 1914*a*.—M. **Gunther**: The general theory of systems of partial differential equations.—Marcel **Moulin**: Influence of the rachet on the concentric development of the spiral springs of chronometers.—Jean **Bielecki** and Victor **Henri**: The calculation of the absorption spectrum of a body from its chemical composition. A general formula is given for the absorption spectrum of a substance containing two chromophores.—F. **Dienert**: A new nephelometer for use in analytical chemistry.—E. **Cornec** and G. **Urbain**: The application of cryoscopy to the determination of double salts in aqueous solution. A study of the double salts of cadmium chloride, bromide, and iodide with the alkaline haloid salts.—F. **Pisani**: Some calcites showing marked phosphorescence under the action of heat.—N. **Bezssonoff**: Some facts relating to the formation of the perithecium and the delimitation of the ascospores in the Erysiphaceæ.—J. **Wolff**: The mechanism of oxidation and reduction phenomena in plant tissues. A study of the oxidation and reduction phenomena produced by the oxydase present in the apple and pear.—F. Le **Cerf**: A grub of the family Lycænidæ raised in Acacia galls by ants of the genus Cremastogaster. The grub is fed inside the gall with acacia leaves provided by the ants.—L. **Joleaud**: The eastern termination of the Numidian chain (Algeria).—Robert **César-Franck**: The relations between the form of the southern coast line of England and its geological constitution.

Calcutta.

Asiatic Society of Bengal, April 1.—A. **d'Orchymont**: Hydrophilidæ from the Lake of Tiberias. The hydrophilid beetles are represented in Dr. Annandale's collection by sixteen specimens, including examples of six species.—M. S. **Ramaswami**: Note on leaf-variation in *Heptapleurum venulosum*, Seem. This paper illustrates the remarkably wide range of leaf-variability in the above species. The author shows that the method used in "The Flora of British India" for differentiating between the two sections of the subgenus Euheptapleurum, namely, the simply digitate or twice digitate character of the leaves, is incorrect so far as this species is concerned.—Dr. W. M. **Tattersall**: Amphipoda and Isopoda from the Lake of Tiberias. Three species of Amphipoda and three of Isopoda are included in Dr. Annandale's collection. It seems probable, on comparing these with the collections made by Barrois and by Festa, that the complete fauna of the Lake of Tiberias is now known, so far as the aquatic and semi-aquatic representatives of the two groups are concerned. Of the species in the collection, one Amphipod, *G. syriacus*, and one Isopod, *A. soxalis*, are endemic and have not so far been found outside Syria. The remaining species are distinctly "Mediterranean" in character, though one (*Orchestea platensis*) is known also from the Atlantic coasts of America.

CANCER.

(1) *The Pathology of Growth: Tumours.* By Dr. C. P. White. Pp. xii+235. (London: Constable and Co., Ltd., 1913.) Price 10*s*. 6*d*. net.

(2) *Researches into Induced Cell-reproduction and Cancer, and other Papers.* Vol. iii. By H. C. Ross, J. W. Cropper, E. H. Ross, H. Bayon, W. J. Atkinson Butterfield, E. Jennings, and S. R. Moulgavkar. The John Howard McFadden Researches. Pp. 149+xvii plates. (London: John Murray, 1913.) Price 5*s*. net.

(1) THIS volume seems to promise a series on the pathology of growth, under the editorship of Prof. A. E. Boycott. The venture is a welcome one showing that the move towards a closer union between pathology and physiology is making progress. Pathology is still so often restricted to, or actually confounded with, mere morbid anatomy that the wider recognition of disturbance of function—in the case of this volume of abnormality of growth—as a department of physiology proper, can only contribute both to a more wide-visioned outlook on the processes of disease, and also equally to a more critical attitude on the part of those whose sphere of activity proper is the investigation of disease, and not of normal function or structure.

For the volume as a whole we have nothing but praise, although in one relating to the pathology of growth it seems that taking up about half of it with the classification and histological structure of tumours is a liberal allowance. Especially the space devoted to Hodgkin's disease may, with profit, be omitted in future editions, since it is doubtful whether it is rightly included in a discussion of tumours proper. Since also the book is intended for students, it appears that some of this space might with profit have been yielded to the description of naked-eye appearances.

The chapters on growth, hypertrophy, atrophy, regeneration, and kindred topics are well and lucidly written. The inclusion in a text-book of pathology of a full discussion of the statistics of cancer is a welcome innovation, to which even more space might have been spared from classification, since the full significance of the statistical facts can only be brought out by giving detailed consideration to the anatomical or site distribution of cancer. Had this been done, the author would scarcely have committed himself to the general statement that cancer is increasing, since the last three annual reports of the General Register Office show that the question of the increase of cancer exists only for certain parts of the body, but not for others.

The book is, notwithstanding these criticisms, a valuable one for the student and for all who wish to have an objective review of what morbid anatomy and histology, experiment, and statistics have yielded together in the effort to elucidate cancer.

(2) The modest short title of this volume—"Researches into Induced Cell Proliferation and Cancer"—and, indeed, also the full title, do not convey adequately the enormously wide scope of the fourteen original papers which form its contents. The word "cancer" occurs in the title of one paper only: "Epithelial cell proliferation"; "The cell division of leucocytes demonstrated"; "Fibro-adenomatous nodules induced *de novo*"; "Cell division figures induced in human blood platelets"; "Treatment of wounds"; also each occur once, and presumably these are the papers for which it is claimed that "The Howard Mcfadden Researches" into induced cell proliferation bear upon cancer. The other eight papers deal with scarlet fever, measles, and syphilis, the cultivation of trypanosomes, a parasite of the earthworm, and the nature of "Kurloff's bodies" found in the leucocytes of guinea-pigs, etc.

Each subject taken up is a big one. The extent and diversity of the ground covered in this small volume of 149 pages will not cause cavil at its contents being described as researches, on the part of anyone not having precise knowledge of any of the many subjects of which it treats. Indeed, they may well marvel at the versatility displayed and the exact statements made about pitch, cancer, the classification and nomenclature of the "protozoal parasite in syphilis," and the division of polymorphonuclear leucocytes and of blood platelets. As regards syphilis, those who were present at the last meeting of the Pathological Society of Great Britain will recall the destructive criticism passed upon very similar claims regarding what was put forward as the life cycle of the cause of syphilis. The statements regarding the parasitic nature of Kurloff's bodies have not been confirmed by a recent German worker.

As regards cancer, the more critical reader will ask what leucocytes and blood plates have to do with it, and if any cancerous growth has been known ever to consist of blood platelets or polymorphonuclear leucocytes. When the statement is made that Khangri cancer "affects the women" in Cashmere, he will wonder why the men have been forgotten. When it is stated that the efforts made in the past to explain that "cancerous tissue is epithelium which has acquired malignant properties . . . have so far lacked the experimental support which enables them to rank as theories in contradistinction from hypothesis or speculations," the critical reader will again wonder if he reads aright, because there is absolutely nothing new in the particular "experimental support" adduced, namely, the results of subcutaneous injection in the ear of the rabbit. The appearances obtained are duplications of those described for the same site after the same procedure by Fischer as long ago as 1906, and by many other authors since. Furthermore, these appearances have been the subject of years of discussion among pathologists, who are agreed they have nothing to do with cancer.

As regards "adenomatous nodules produced *de novo*," the description of nodules in the ducts of the mammary gland of goats is most superficial and imperfect; but it recalls the papillomata in the bile ducts of the rabbit, found in association with coccidiosis, another familiar appearance having nothing to do with cancer.

The whole superstructure is raised on the basis of the authors' assumption that they made polymorphonuclear leucocytes divide on a microscopical slide in 1909; the result described does not separate the cover glass from the slide by its surprising amount and rapidity, but only amounts to an increase of 10 per cent. of the number of leucocytes. This, even if correct, is but a sorry achievement when it is sought to explain normal or malignant growth, and it is forgotten that bacteria add 1000 per cent. to their weight in a few hours, and the embryos of rabbits and other mammals and birds grow at least 1000 per cent. daily, without the assistance of the results of researches into induced cell proliferation.

E. F. B.

PURE AND APPLIED MATHEMATICS.

(1) *A Textbook of Elementary Statics.* By Prof. R. S. Heath. Pp. xii+284. (Oxford: Clarendon Press, 1913.) Price 4*s.* 6*d.*

(2) *A Shorter Algebra.* By W. M. Baker and A. A. Bourne. Pp. viii+320+lix. (London: G. Bell and Sons, Ltd., 1913.) Price 2*s.* 6*d.*

(3) *Key to "A New Algebra."* By S. Barnard and J. M. Child. Vol. ii., containing parts iv., v., and vi. Pp. 447–915. (London: Macmillan and Co., Ltd., 1913.) Price 8*s.* 6*d.*

(4) *Practical Surveying and Elementary Geodesy.* By Prof. Henry Adams. Pp. xii+276. (London: Macmillan and Co., Ltd., 1913.) Price 4*s.* 6*d.* net.

(5) *Practical Science for Engineering Students.* By H. Stanley. Pp. vii+166. (London: Methuen and Co., Ltd., n.d.) Price 3*s.*

(6) *Bell's Outdoor and Indoor Experimental Arithmetics.* By H. H. Goodacre, and E. F. Holmes, C. F. Noble, P. Steer. *First Year's Course* (Standard iii.), pp. 30. Price 3*d.* and 4*d.* *Second Year's Course* (Standard iv.), pp. 32. Price 3*d.* and 4*d.* *Third Year's Course* (Standard v.), pp. 39. Price 3*d.* and 4*d.* *Fourth Year's Course* (Standard vi.), pp. 39. Price 4*d.* and 6*d.* *Fifth Year's Course* (Standard viii.), pp. 48. Price 4*d.* and 6*d.* (London: G. Bell and Sons, Ltd., 1913).

(1) THIS is a delightful book that will rejoice the heart of the students of Birmingham and of many another university. No longer have we the problem of the elephant balancing upon a ball, the ball a foot in diameter and the elephant of negligible mass. In place of the old artificial kind we have, all the way through the book, entrancing problems from everyday life. In method of treatment also Dr. Heath's sympathies are of the widest. We find the link-polygon freely used, and that useful lettering device of Bow's not despised. We find graphical methods given their due place; we find bending moments duly treated; we find so many good things that the book, though apparently designed for the pure mathematician, ought to be adopted by the engineer also.

One suggestion we offer for the next edition, that kinetic friction, as in a journal (p. 208), should be distinguished from static friction, as in the freewheel friction clutch (p. 201).

(2) The Shorter Algebra is a good book of the old style. It gets all the tools ready first, beginning with seven pages of definitions and similar fundamentals. The preparation of the tools takes six chapters, formal equations come in chapter vii., and the first contact with life is found in chapter ix., in the application of equations to problems.

The method of this book is quite a good one for the able pupil who grasps the rules and enjoys the game. We fear it is valueless for the mediocre pupil, who does not see that it is a game and cannot understand the rules. He learns only to think himself a fool, which is often not the case; even if it is the case it is a mistake to let him think so. Constant contact with life is the only successful way to teach an abstruse subject like algebra to the mediocre boy.

The authors sternly refuse, while dealing with algebra, to recognise the existence of geometry. Two results dropped from the sky appear on page 103; do the authors hope to conceal their geometrical origin? If the pupils have even a suspicion, the watertight bulkheads are seriously endangered; and the authors write so clearly that we fear the pupils will actually know that a jet of geometry has pierced the algebra bulkhead.

But we must not let amusement at these foibles hide the real excellence of the book. As is to be expected from the ability of its authors, the book is one of the best of its kind. As signs of their good judgment we may mention that long multiplication and long division are marked for omission on a first reading, and that in graphs statistical curves come first.

We do not understand why the authors should say that 3·5 is nearer to 4 than to 3. If words have any meaning, either 3 or 4 may be given as the "nearest integer to 3·5."

(3) Barnard and Child's "Key" is clearly and concisely written, printed in very good type and nicely set out, and (so far as our sampling shows) correct. The good appearance is increased by appropriate use of the solidus, a symbol which is used by remarkably few writers in proportion to its real value.

(4) Prof. Adams's book contains in concise form and on the whole well-expressed all that the surveyor can possibly need for work in the town and in the country, for engineering or for railway work. We are sorry to see that the recurring decimal is still in use (p. 161). In the appendix, some questions (*e.g.*, 94, 166, 169) contain references to matter that is not supplied; it would be better to omit such questions altogether.

(5) The Practical Science consists of suitably chosen experiments, the printer's type is pleasing, and, except in the introductory chapter, the headings stand out effectively. The book covers heat, mechanics, electricity, and a number of miscellaneous things, and the student who carries out the experiments will have a good elementary equipment. The treatment of friction and the funicular polygon deserves special praise; the friction treated is kinetic, which for engineers is more important than static. The text is in general clear, but here and there it is condensed to the verge of unintelligibility. The references to the diagrams should be clearer, and the lettering of the diagrams be made to correspond to the text. Numerical results should be calculated to a suitable number of significant figures, and not left in a form involving the signs of multiplication, division, and square root.

With a little care in revision, the next edition should be really valuable.

(6) The idea of the Experimental Arithmetics is excellent. The pupil trained in this experimental way will obtain a grasp of arithmetical operations incomparably greater than was possible for the average pupil in the bookish days. And the idea is well carried out by experiments to be performed indoors and out of doors on the measurement of length, area, volume, weight, and angle.

Some secondary schools follow the rule "every lesson an English lesson," and we should like to see this rule adopted in elementary schools. When that day comes, the language of these books will need to be given greater precision; for the present time the language is sufficiently clear.

D. B. M.

BOTANICAL CATALOGUES AND MANUALS.

(1) *Catalogue of Hardy Trees and Shrubs Growing at Albury Park, Surrey.* Compiled by A. B. Jackson. Pp. viii+66. (London: West, Newman and Co., 1913.)

(2) *Lowson's Text-book of Botany.* Indian edition. Adapted by M. Willis. With a preface by Dr. J. C. Willis. Pp. xii+602. (London: W. B. Clive, 1913.) Price 6*s.* 6*d.* net.

(3) *Coconut Cultivation and Plantation Machinery.* By H. Lake Coghlan and J. W. Hinchley. Pp. xii+128+x plates. (London: Crosby Lockwood and Son, 1914.) Price 3*s.* 6*d.* net.

(4) *Genera of British Plants: with the Addition of the Characters of the Genera.* By H. G. Carter. Pp. xviii+121. (Cambridge: University Press, 1913.) Price 4*s.* net.

(5) *The Story of Plant Life in the British Isles.* Introductory volume. By A. R. Horwood. Pp. xiv + 254 + plates. (London: J. and A. Churchill, 1914.) Price 6*s.* 6*d.* net.

(6) *Catalogue of the Plants Collected by Mr. and Mrs. P. A. Talbot in the Oban District, South Nigeria.* By Dr. A. B. Rendle, E. G. Baker, H. F. Wernham, S. Moore, and others. Pp. x+157+17 plates. (London: British Museum (Natural History); Longmans and Co., 1913.) Price 9*s.*

(7) *Plant Physiology.* By Dr. Ludwig Jost. Authorised English translation by R. J. Harvey Gibson. Supplement. Pp. 168. (Oxford: Clarendon Press, 1913.) Price 2*s.* 6*d.* net.

(8) *Plant Life.* By T. H. Russell. Pp. 71. (Birmingham: Cornish Brothers, Ltd., n.d.) Price 2*s.* 6*d.* net.

(1) MR. JACKSON'S catalogue of the trees at Albury is an interesting document, especially when considered in comparison with the somewhat similar list compiled by him of the trees and shrubs at Syon. The value of the Albury list is enhanced by notes about particular trees and details as to the dates of introduction of the various species, characteristics of particular plants, uses, hardiness, etc. It is of interest to

notice that there are some remarkably fine trees at Albury, no doubt due to the soil and sheltered situation, a black Italian poplar, for instance, being about 150 ft. high, and therefore one of the tallest trees in England. The white lime and other limes, the London planes and cedars, and a special variety, var. *alburyensis* of the black walnut, a specimen of the chestnut oak of North America, *Quercus prinus*, in addition to other trees, are worthy of special mention.

(2) Of Mr. Lowson's text-book there is not much that need be said; it is one of the series published by the University Tutorial Press, and follows the usual lines of the compressed botanical text-book. This particular edition has been prepared more especially for Indian students, but this fact is not very prominent in the text, except where the more systematic side of the subject in relation to phanerogams is treated. Otherwise, both text and figures bear a very familiar, and not very inspiring, appearance.

(3) Messrs. Coghlan and Hinchley are to be congratulated on having produced a very useful and interesting work on the coconut, which should prove of considerable value at the present time when so much attention is being directed to the cultivation of the coconut palm and the utilisation of its products. The book is thoroughly practical, and also well illustrated with reproductions of photographs, which are explanatory to the text. Soil, preparation of the land, seed-nuts, pests, copra, and machinery are among the subjects of the chapters. Careful estimates are given of the profit and loss of coconut planting, from which it would seem clear that, provided a suitable site has been chosen for the plantation, its ultimate success as a paying investment is assured. In an interesting chapter on catch crops, the value of *Coffea robusta* is emphasised. Errors appear to be few, but one misprint of *s. d.* for *l. s.* in the last column of the exchange tables at the beginning of the book should be noted.

(4) Mr. Carter's book is written with the intention of familiarising students of British flowering plants and ferns with the genera arranged according to Engler's system. In dealing with the genera of ferns, the arrangement enunciated by Bower is followed.

The characteristics of the natural families are set out clearly in detail, and the genera are arranged under their tribes in key form. The book aims at directing the attention of students to a closer study of the genera of plants, a purpose which it appears admirably calculated to fulfil.

(5) Seventy-three photographs, several of which are quite pretty, appear to be the *raison d'être* of "The Story of Plant Life in the British Isles"; we cannot see otherwise why this discursive volume was published. The author in his introduction is careful to point out the faults which underlie the systems of the great botanists of history, and seems to suggest that a study of his own work will show the way of salvation. Whether the student will really become acquainted with the distinctive characters of the different families of plants by using this work would seem a matter of doubt, but he will find in these pages a considerable amount of miscellaneous information, such as the fact that daisies grow in churchyards, that there is no need to point out the characteristic features of the ivy as "any boy or girl can name it," and so on. A large number of common and local plant names are given, which is a feature of some interest, and there is a glossary of terms at the end of the volume.

(6) The Oban district of Calabar, Southern Nigeria, has yielded a rich harvest of new species and genera of plants to the indefatigable collectors, Mr. and Mrs. P. Amaury Talbot. The district, botanically, belongs to the Cameroon region, and the flora is continuous with that of the similar geological country included within German territory. In the British area, however, there is a certain admixture of plants from the Gulf of Guinea region. The Oban district is densely covered with forest, and is the home of a great diversity of species of plants; Mr. Talbot considers there are some four hundred to five hundred per square mile. With a rainfall of about 175 in., and a soil of decomposed granite and gneiss, it is scarcely remarkable that the flora should be a rich one. A striking feature of these forests is the number of cauliflorous trees, many of which were previously undescribed, six being new species of the remarkable myrtaceous genus Napoleona, the flowers of which resemble somewhat those of the parasitic Rafflesia of the east. The collection consists of 1016 species and varieties, of which 195 are new, and there are nine new genera. The plants have been determined with but few exceptions by the staff of the British Museum, and the results with various notes by Mr. and Mrs. Talbot are presented in the volume under review, which form a fitting tribute to the industry of the collectors. It should be remembered that Mrs. Talbot while in the country made a remarkable series of water-colour drawings of a great number of the plants, and in particular of the flowers of the cauliflorous tree, which it is to be hoped will soon be published in colour. The present volume is illustrated with seventeen plates of figures, in which the more striking of the new plants are figured.

The descriptions of new species occupy 119 pages, and are followed by a systematic list of the plants collected; among these may be noted *Poga oleosa* (Rhizophoraceæ), hitherto only known from the Gaboon, which is an interesting discovery, as its seeds are rich in oil. Lists of the ferns, mosses, fungi, and lichens which were collected by Mr. and Mrs. Talbot complete the enumeration.

(7) The supplement to Jost's "Plant Physiology" consists of a translation of the alterations of the second edition of the German original, and to be appreciated must be studied hand in hand with the translation of the book. Without the original translation the supplement is, of course, valueless, and even with the book it is a singularly tiresome way of presenting new information or of correcting errors. It would, we should have thought, been of more value to produce in course of time a complete new edition of Jost's lectures, since it will be impossible to continue to bring out further supplements embodying the changes in the newer German editions as they are published.

(8) The publication of the little book entitled "Plant Life" is the outcome of a desire of those who heard these lectures at an adult school to have them in permanent form. They have been published, therefore, with many of the original illustrations, and form a clear, simple, and useful account of plant life for an audience such as that to whom they were given. No doubt much of their value and charm lay in their delivery, and we cannot think that any very useful purpose has been served by the publication of these lectures beyond that of honouring the memory of one who was, no doubt, as good a teacher as he must have been an ardent friend.

OUR BOOKSHELF.

The Physician in English History. By Dr. Norman Moore. (Linacre Lecture, 1913, St. John's College, Cambridge.) Pp. 57. (Cambridge: University Press, 1913.) Price 2*s.* 6*d.* net.

THE charm of Dr. Norman Moore's historical writing rests, as such virtue must rest, on many qualities; on his wide and curious learning sitting lightly upon his pen, his humanity living in his biographical gift, and enriched by his retentive memory, and his appreciation of the past, always informed by his mastery of modern clinical medicine. As his subject for the last Linacre Lecture Dr. Moore chose "The Physician in English History"; that is to say, not a string of all the physicians of English history, but, like the sheep in the painting of the Primrose family, so many as the confines of his hour would admit. The chosen physicians were either distinguished in themselves or came into note at momentous or picturesque occasions. Thus the lecturer gave to his audience not a procession of English physicians, a great story which would indeed be welcome at his hands, but a small gallery of medical pictures set in a historical background. With the propriety of a lecturer in his university of Cambridge, he opened his discourse with Bede's unusually interpretable narrative of the disease and death of Ethelreda of Ely. The skill of Cynifrid, who, apart from the arid cram of Isidore, was probably a fairly competent "Wundaerzt," failed to save her life. Probably Cynifrid was called in too late, after long courses of monastic quackery.

Next we are taken to the death-bed of William the Conqueror, whose mortal malady is illumined by the lecturer's parallel instances from twentieth-century St. Bartholomew's.

The pages given to Linacre himself are by no means a perfunctory tribute to the founder, but a happy blend of the physician as a man of letters moving in pleasant groups amid his brilliant contemporaries of the Renaissance, Erasmus, for example, Tonstall, and More. By a deft selection of materials from a well-stored memory, Dr. Moore thus carries us century by century to the middle of the eighteenth, giving us by the way bright glimpses of Wadham in the mid-seventeenth; then to the horizon of Swift and Pope with the flash of that tantalising meteor Arbuthnot, and bringing us at length to the great lexicographer and Dr. Brocklesby. A dainty entertainment. May the author in his spare hours give us many more of such.

Text-book on Railroad Surveying. By G. W. Pickels and C. C. Wiley. Pp. ix+263. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1914.) Price 10*s.* 6*d.* net.

THIS book gives a fair representation of American practice in railroad surveying. The subject-matter includes brief directions for carrying out the preliminary reconnaissance in various types of country, and the location of the best route. Fuller explanations follow of the setting out of circular and spiral transition curves; this section includes turn-outs, connections, and crossings. Earthwork problems are also treated. Methods are explained of shifting the location of curves in the field from that shown on the plan in order to secure better conditions of cutting or filling. The text occupies 125 pages, and the remaining 138 pages are taken up with tables giving curve functions, logarithms of numbers, trigonometrical functions of angles and earthwork. Detailed mathematical solutions are omitted, and an elementary knowledge of surveying is assumed. Judging from the terse nature of the contents, the title "Pocket-book of Railroad Surveying" would probably be more appropriate, and would convey to engineers the fact that the book will be found to be a useful companion in his field operations.

Crô Magnon Man: Imprints of his Hand.

While visiting lately the painted caves of the Cantabrian Mountains (north Spain) with Prof. Boule, who had kindly invited me to accompany him, I took advantage of this opportunity to study the imprints of the human hands which occur on the walls of some of those caves, notably of Castillo.

It is well known that at Gargas and elsewhere the imprints are those of a small hand, such as might have belonged to the Grimaldi race, and one such small imprint I observed in the cavern of Altamina.

But in Castillo—so admirably described and illustrated by the Abbé Breuil—I was surprised to find that all the impressions indicate an unusually large hand. With the permission of Dr. Obermaier, and the kind assistance of Mr. Burkitt, I was able to obtain tracings of seven of these, and two of them are complete enough for detailed study. One is 190 mm. in length, measured from the tip of the middle finger to the wrist, the other about 200 mm. This accords with the length of the Crô Magnon hand as indicated by the description of the skeleton given by Dr. Verneau.

This, however, is not all. When a tracing of one of the Castillo imprints is superposed on a tracing of the hand of a living subject (Englishman) having the same length, a characteristic difference is at once perceived. The fingers of the Castillo hand are shorter than those of the Englishman, and the equality in the total length is produced by the greater length of the palm. But this is a peculiarity which must have occurred in the Crô Magnon hand, for Dr. Verneau has shown that in the Mentone skeletons the metacarpals are disproportionately long when compared with the phalanges.

I have made some preliminary measurements of tracings taken from the hands of twelve tall Englishmen, ranging from 5 ft. $8\frac{1}{2}$ in. to 6 ft. $0\frac{1}{2}$ in., with a mean of 5 ft. 11 in. (thus of about the Crô Magnon stature). Dividing the length of the middle finger by the length of the palm, I obtain 0·87 as the mean index, with a range of 0·77 to 1·0; while the most complete of the Castillo hands gives 0·765 and the next best 0·72 to 0·76.

Thus the existence of two distinct races in the Aurignacian age, already indicated by the Mentone skeletons and the carved statuettes, receives additional confirmation.

Cellular Structure of Emulsions.

In reply to the letter of Prof. Kerr Grant in Nature of April 16, similar phenomena to those which he describes have been found to occur with minute motile organisms in water, and with sediments of various kinds in water and other liquids. I have given an account of some of these appearances in my paper on the effect of gravity on the movements of micro-organisms in the Transactions of the Royal Society, series B, vol. cci., pp. 333–390. I have also obtained similar groupings with the fine sediment which is formed in a hypo-alum bath, used for toning and fixing P.O.P. prints. If a small quantity of this is poured into a shallow vessel, the particles which are at first evenly distributed through the liquid soon become aggregated into groups similar to those described by Prof. Grant.

In the case of *Euglena viridis*, the living organisms in the dark become aggregated into groups as shown in Fig. 1, the central dark mass in each group consisting of a stream of Euglenæ moving downwards, the lighter peripheral area consisting of Euglenæ moving upwards. Various sediments when allowed to settle in liquids become aggregated in a similar manner, but without the continuous up and down movements. Thus Fig. 2 shows a sediment of osmium dioxide settling in dilute glycerine, which closely resembles the aggregation of the living cells shown in Fig. 1

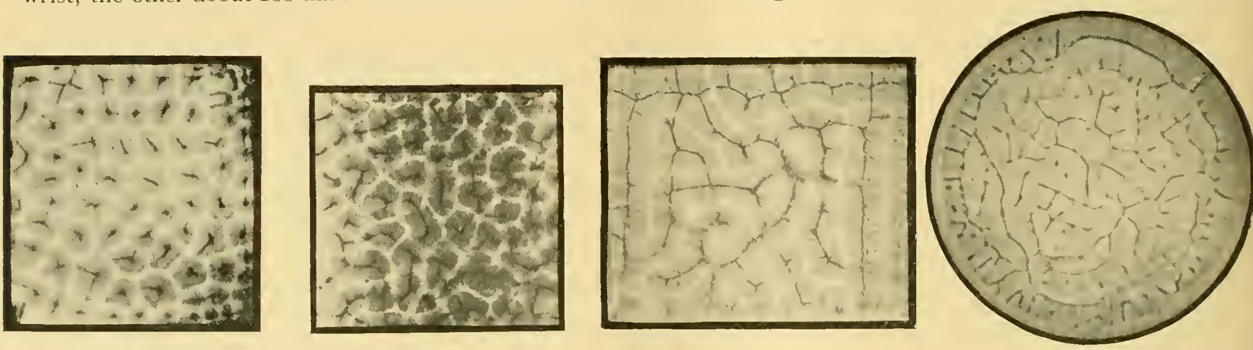

Fig. 1. Fig. 2. Fig. 3. Fig. 4.

In all the cases observed by me the regular grouping appears to be preceded by the formation of a network, as shown in Fig. 3, formed by manganese dioxide settling in a solution of gum arabic. Again, if a readily oxidisable photographic developer is poured into a flat dish to form a layer about 1/16 in. deep, the brown oxidised film which forms at the surface is at once broken up into a network, Fig. 4, which gradually becomes resolved into separate groups.

I have suggested that these groupings are in all probability cohesion figures, and that they may be related to the beautiful cohesion figures described by the late Mr. C. Tomlinson in the *Philosophical Magazine* for 1861 and 1864. They are probably formed whenever we have fine particles free to move, placed under such conditions that a force or forces, acting in opposition to the cohesion of the particles, can be brought into play. Cohesion, surface tension, diffusion currents, and gravity are among the forces probably concerned in the effects observed.

Prof. Grant's suggestion that the flocculi in the solar photosphere and in cloud formations of flocculent type may be related to this phenomenon is interesting. Such flocculent appearances can also be observed, under certain conditions, in ponds and pools which contain dense aggregations of motile micro-organisms, and I have very little doubt that the network-like and flocculent appearances so often observed in the froth which is formed when the tide breaks on the seashore may be explained in a similar manner.

HAROLD WAGER.

West Park, Leeds, April 14.

An Extension of the Spectrum in the Extreme Ultra-Violet.

THE researches of Schumann led him to extend the spectrum to the neighbourhood of wave-length 1250. His limiting wave-length was determined by the absorption of the fluorite which formed a necessary part of his apparatus. In 1904 I succeeded in pushing the limit to wave-length 1030 by the use of a concave diffraction grating.

Recently I have renewed the attack on the problem, with the result that I have succeeded in photographing the spectrum of hydrogen to wave-length 905. The extension is due, not so much to any fundamental change in the nature of the apparatus as to an improvement in technique consequent on an experience of ten years.

It is a characteristic of the region investigated by Schumann between wave-lengths 1850 and 1250 that, while hydrogen yields a rich secondary spectrum, with the possible exception of one line, no radiation has been discovered belonging to the primary spectrum. On the other hand, in the new region between the limit set by fluorite and wave-length 905, a disruptive discharge in hydrogen produces a primary spectrum of great interest made up of perhaps a dozen lines. These lines are always accompanied in pure hydrogen by members of the secondary spectrum, but they may be obtained alone if helium containing a trace of hydrogen is employed.

Results obtained from vacuum tubes when a strong disruptive discharge is used, must always be interpreted with caution since the material torn from the tube itself sometimes furnishes impurities. In the present case, it will be some time before the effect of such impurities can be estimated. However, it may be stated with some degree of certainty that the diffuse series predicted in this region by Ritz has been discovered. The first member at 1216 is found to be greatly intensified by the disruptive discharge, and the next line at 1026 appears also, though very faintly. This diffuse series bears a simple relation to Balmer's formula. Following the same kind of argument, a sharp series corresponding to the Pickering series might be expected. The new region appears to yield two lines belonging to such a relation at the positions demanded by calculation.

Harvard University, April 20.

The Structure of Atoms and Molecules.

SINCE in an elaborate criticism of Bohr's theory on the constitution of atoms and molecules, Prof. J. W. Nicholson, as in his letter to NATURE (February 5, p 630), comes to the conclusion (*Phil. Mag.*, xxvii., p. 560, 1914) that the valencies of lithium, beryllium, boron, etc., on Bohr's theory are not in accord with experience, and if the electrons in the atoms are to be in one plane, we must either abandon Bohr's method of calculating valency—and (generally) Bohr's theory of the atoms more complex than hydrogen and helium—or give up van den Broek's hypothesis, that the charge of the nucleus of Rutherford's atom is equal to the atomic number (which hypothesis was accepted by Bohr as one of his fundamental assumptions), I may be allowed to add some remarks to my previous letter on this subject (NATURE, March 5, 1914).

For these atoms at least this hypothesis is a mere expression of experimental facts. The hydrogen atom is known to lose never more than one electron, and the helium atom never more than two, and, of course, never one to form an electrolytic ion, while lithium, beryllium, boron, and carbon can lose, or, in chemical combination, dispose of 1, 2, 3, 4 electrons respectively. Further, the number of electrons per atom has been proved to be nearly equal to half the atomic weight (Rutherford, Barkla), and in the case of carbon to be six (Rutherford, *Phil. Mag.*, vol. xxvi., p. 711, 1913). Since the number of electrons per atom must be an integer, here, at least, no other solution seems to be possible than that the number of electrons per atom surrounding the nucleus, and hence the nuclear charge, is equal to the atomic number.

Further mentioning Moseley's previous experiments on high-frequency spectra (undertaken for the express purpose of testing the atomic number hypothesis), and criticising the theoretical deductions, derived by Moseley from these experiments, Nicholson concludes that they have shown no relation to Bohr's theory (*loc. cit.*, p. 564). Now in another paper Moseley, from further experiments on high-frequency spectra, proves (*Phil. Mag.*, vol. xxvii., p. 703, 1914) that the frequency of any line in the X-ray spectra is approximately proportional to $A(M-b)^2$, where A and b are constants for each series, and M, the atomic number (called by Moseley N) of the element, is identified with the number of positive units of electricity contained in the atomic nucleus, so that these experiments "give the strongest possible support" to this atomic number hypothesis (*loc. cit.*, p. 712). The number of rare-earth elements as given by Moseley is the only exception.

That b is much larger for the "L" lines than for the "K" lines suggests, according to Moseley (in agreement with my own views, NATURE, December 25, 1913) that the "L" system is situated the further from the nucleus. If so, b=the number of electrons nearest the nucleus, and not$=\sigma_n$, the term arising from the influence of the electrons in a ring on each other, and, for the "K" lines, n, like b, must be unity, as calculated by Nicholson on Bohr's theory. For the "L" lines, according to Moseley, $b=7\cdot4$, but it can easily be seen from the tables that if $(M-b)$ be here augmented by 0·8 per cent., all values are integers ($\pm0\cdot2$), and $b=7$ and $n=1$ again, but perhaps the factor 5/36 in Moseley's interpretation cannot be retained.

Hence, though this number 7 requires confirmation, principally, for the "K" line at least, Bohr's theory is here in agreement with Moseley's experiments, and with the atomic number hypothesis. Not only the frequencies, but also the minimum velocity of electrons required to excite this radiation, and the absorption of it (in aluminium) have been proved (*loc. cit.*) to depend on the atomic number very nearly, and Nicholson's conclusion that the atomic numbers are not correct does not hold, for $(M-b)$, not M, is one unit less for the K radiation than the corresponding atomic number. But, from analogy, Bohr's lithium atom, as well as Nicholson's ring of three electrons, must be given up, for of three, one electron (b) must be very near the nucleus, one (n) near but outside this first one, and one as electron of valency must be peripheric.

Further, the velocity of electrons, required to excite this radiation, according to Widdington equal to $10^8\times$atomic weight cm./sec., is more accurately equal to $2\cdot24\times10^8(M-1)$ cm./sec., than for Cr, Fe, Ni, Cu, Zn, and Se; the last formula gives for the constant reduced to unity 0·99, **1·04**, 1·02, 1·00, **0·97**, 1·00, while the first gives 0·99, 1·05, **1·06**, 0·99, 0·98, **0·94** respectively. Since the absorbability of the excited radiation is only about 3 per cent. greater than that of the exciting one, and is about inversely proportional to the sixth power of the atomic number, we get $v=2{\cdot}23\times10^8(M-1)$ cm./sec., while Bohr finds $(M=N)$:

$$v=2{\cdot}18\times10^8N \text{ cm./sec.}$$

Now from this value of v, and $\nu=2{\cdot}47\times10^{15}(M-1)^2$, we can calculate x from $xmv^2=2h\nu$, which must be a constant, because both v^2 and ν depend on $(M-1)^2$. As $mv^2/2$ is energy to be, at least in part, radiated away periodically, on the right side of the equation, not only the number of times energy is radiated away per second (ν), but also the total time of radiation (t) and the mean energy radiated away per period (E) must occur, so that $xmv^2=2t\nu E$, and tE is a constant (which may mean only that the time during which radiation is emitted is inversely proportional, for a given frequency, to the quantity of energy that is radiated away during each period). Hence

$$x=2h\nu/mv^2=2.6{\cdot}62\times10^{-27}.2{\cdot}47\times10^{15}(M-1)^2/0{\cdot}88\times10^{-27}.2{\cdot}23^2\times10^{16}(M-1)^2=0{\cdot}748, \text{ or } 3/4,$$

as assumed by Moseley.

From $mv^2/a=e^2(M-1)/a^2$ we can calculate $mav=e^2.(M-1)/v=4{\cdot}78^2\times10^{-20}(M-1)/2{\cdot}23\times10^8(M-1)=1{\cdot}03\times10^{-27}$, while $h/2\pi=6{\cdot}62\times10^{-27}/2\pi=1{\cdot}05\times10^{-27}$, so that $mav=h/2\pi$, as assumed by Bohr, and

$$a=5{\cdot}12\times10^{-9}(M-1)^{-1} \text{ cm.}$$

All this is in agreement with Bohr's theory.

As may be seen from a previous letter (NATURE, March 5, 1914, p. 7), some properties of the elements depend not on the atomic but on the "periodic" number $P=8r\pm p$ (r is the number of horizontal rows preceding that of the element period of rare-earth elements not counted, and p the maximum or positive valency). Now the sum of these electrons of valency may be easily seen to be for all regular (non-elementar) inorganic molecules an integer multiplum of eight. Hence the same holds for the sum of all P electrons in these molecules (ions and rare-gases-atoms included). Affinity is then the tendency to build up systems of $8n$ P-electrons, and, of course, if such a molecule breaks up into atoms with each similar systems of $8n$ P-electrons, such ions must be formed as known from electrolysis. The great facility with which molecules like H_2O, NH_3, HCl, though neutral, are added to such systems, may be due to each of them, containing 8 P-electrons. According to Bohr, rings of electrons, whether belonging to one or to more atoms, may unite if the number of electrons in both is equal, so that rings of 2, 4, and ultimately 8 will be the most probable (16 only if the charge is very great).

Of course, the objections to the "Saturnian" atom hold for such systems also. Indeed, the structure of the periodic system as a whole, and the curious relation between the number of the non-periodic (Q) elements, H, He, Co, Ni, Rh, Pd, and that of the horizontal rows in the periodic system: 2/1, 2/2, 2/3, 4/3, 4/4, 4/5, 6/5, 6/6, 6/7, suggests systems of n equal non-coplanar rings of 8 electrons surrounding one or more (even n), positive nuclei, with n or $n\pm1$ electrons in or near the axis, and additional rings of electrons of valency, rather than a Saturnian atom. But, generally speaking, Bohr's theory is not in disagreement with the atomic number hypothesis.

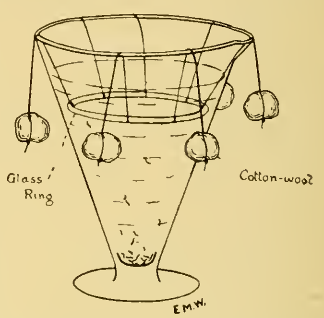
A. VAN DEN BROEK.

Gorsel (Holland), April 15.

Means of Collecting Eelworms.

THE rhubarb, when cultivated as a field crop, is subject to a wasting disease, which, attacking the root-stock and causing it to decay, occasions considerable loss to the grower. The diseased tissue, when examined, is frequently found to be infested with the stem eelworm, *Tylenchus devastatrix*, Kuhn, and, in districts where this disease is prevalent, a supply of Tylenchus material is at hand which, since the rhubarb is a perennial plant, is available not only in summer but during winter also.

When pieces of decaying rhubarb tissue are enclosed in a corked tube, any Tylenchus worms that are present migrate to the surface and, provided they have not been corked up too long, will, if placed in water, remain alive for weeks. Material can be obtained in quantity, and with very little delay, by placing pieces of rhubarb in a strainer covered with fine gauze, and suspended in a vessel of water. The eelworms, forsaking their feeding-ground, wriggle through the muslin and accumulate in a writhing mass on the floor of the vessel. This water method, it may be added, is also useful in examining the eelworm fauna of soil samples, and provides a simple means of ascertaining roughly what forms are present.



When thus collected from rhubarb, the eelworms are usually mixed with sediment, but this defect can be remedied by placing the material, while still unsorted, in a porous vessel, such as a candle-filter, which, when placed in water, allows only living eelworms to pass through. A better method of cleansing the material, however, is obtained by taking advantage of the habit that eelworms have of climbing up capillary films when these are present. For this purpose, silk threads are employed, to each of which is suspended a blob of cotton-wool, the cotton-wool serving as a receptacle for holding the crude material obtained from the rhubarb. The upper ends of the threads are attached to a glass ring which is supported upon the sloping sides of a funnel-shaped vessel containing water—this shape being chosen in order that the blobs may hang clear.

As the threads become saturated, the eelworms, leaving all impurities behind in the cotton-wool, ascend amongst the silken strands, and, passing over the brim into the water, congregate on the floor of the vessel—a feat on their part which, besides providing the student with clean material, raises the question whether, in respect of their acrobatic accomplishments, eelworms vary to any appreciable extent; and, if so, whether the rough method here described can be extended so as to provide a means of sorting out one species from another, when two or more species are present in the material employed.

The University, Leeds.

THE PROHIBITION OF EXPERIMENTS ON DOGS.

THE Dogs' Protection Bill for the second reading of which 122 members of Parliament were induced to vote the other day is one of those measures which are born of ignorance and fostered on misrepresentation. All our knowledge of the functions of the body is fundamentally based on experiments which have been made upon dogs. The action of the heart and its nerves; the mechanisms of circulation, respiration, digestion, and secretion; the functions of the liver, pancreas, and kidney; the processes of metabolism, the causation of diabetes; the utility of the internally-secreting glands; the manner in which the organs of the body are governed and their functions regulated—none of these could have been elucidated nor could the knowledge which has been obtained have been applied to man from experiments upon animals other than dogs. The prohibition of the employment of dogs for these investigations would put a complete stop to the progress of physiology in Great Britain—which, in this particular science, has, from the time of Harvey onwards, always held a peculiarly honourable position. It would put medicine in this country at an enormous disadvantage as compared with other countries; and our professors and students would have to go abroad to gain that practical knowledge of the functions of the body for the investigation of which the dog is the only animal available. For medicine is founded upon an exact knowledge of these functions: without it the physician gropes in the dark and works by guesses which are generally far removed from the actual truth. Moreover many diseases which are common to man and animals can only be fully investigated in an animal like the dog, unless man himself is to be made the subject of experiment. And it is scarcely necessary to point out even to our opponents that the prohibition they demand would prevent any further investigation of the causation and treatment of diseases which are peculiar to the dog, so that the race they are professing to protect would ultimately suffer from such prohibition even more than mankind.

The question really at issue is whether a knowledge of the functions of the body in health and disease is to continue to be gained at the expense of a certain number of stray and worthless dogs, which are in any case condemned by law to be destroyed, or at the expense of humanity. Nothing is more certain than that important branches of medical knowledge if not advanced by experiments on these animals can only be advanced by taking toll of the lives of patients, who would be treated in ignorance of the conditions under which remedies should be applied and of the results which such remedies are likely to yield.

It is difficult for a layman to understand the full bearing of this question, because he is unaware of the extent to which medical knowledge profits and has profited by experiments on animals. Some doctors even, mostly belonging to what is often spoken of as the "old school," are uninformed regarding the manner in which their knowledge of the functions of the body and of the changes which are produced in disease has been acquired. It is, moreover, true that the ordinary practising physician does not himself make experiments upon animals: he has as a rule neither the time nor the opportunity. But however well-trained he may be, it is not the practitioner who advances our knowledge of medicine and surgery; or if he does so it is at the expense of the patient upon whom he first makes a trial of the remedies by aid of which he hopes to cure the particular disease he is treating. There are, admittedly, operations which have been tried from the first upon the human subject and have ultimately resulted in singular success, so that cases which previously would have been relinquished as hopeless are in large numbers restored to health. But the toll of human lives required to achieve this success is lamentable. Surgeons who devise a new method of operation are in the habit of publishing statistics regarding the cases which they have treated by it. An examination of such statistics always shows a relatively large percentage of failures and death in the earlier cases, whilst that percentage is greatly reduced or even abolished in the later cases. This means that the earlier cases have partaken of the nature of experiments by the aid of which the technique of the method has been established. If this technique had been worked out in dogs the toll of human life required to arrive at the same degree of perfection would have been vastly less.

There are, however, surgeons of the present day—and their number is likely to increase in the future—who consider it improper to acquire at the expense of their patients the technical knowledge necessary for the establishment of a new operative method and who would willingly resort to dogs for the purpose of obtaining such knowledge. This procedure can, however, be but rarely carried out in this country, because the anti-vivisectionist legislation of recent years places serious obstacles in its path. But in the United States, where a more enlightened view is taken of the position of mankind in relation to the lower animals, it is the recognised method of procedure, and is beginning to make itself felt in the extraordinary progress which the science and practice of surgery has made of late years in America.

Sir Frederick Banbury has attempted to excite sympathy for his Bill by citing the case of a dog which had been operated on by an eminent Edinburgh surgeon, with the object of testing a new method of inducing union of fractures of bone. Surely nothing could be more proper than that a new method should be first performed upon a dog rather than upon man. Does Sir Frederick Banbury think that it would have been right for the test to be first made upon a patient? Would he prefer to have an untried method applied to himself before it had been determined, by experiments upon dogs, whether it could be successfully performed or would be likely to yield a good result? I think the Edinburgh dog is an unfortunate instance for Sir Frederick to have selected. And I cannot, of course, expect him to see that the fact that the dog, which was bought in good faith from a known dealer in animals, happened to have been picked up in the street by the vendor, has nothing to do with the question whether it is or is not expedient to employ dogs for this and similar purposes.

Sir Frederick Banbury is commonly believed to be impervious to argument and one can well understand that this may be so; otherwise he would surely be able to see that the very statistics which he gives regarding the number of dogs utilised in this country for medical research furnish the strongest of arguments against his Bill. Does he think that men who are engaged in these researches *prefer* to employ dogs, and insist on using them, rather than cats or rabbits or guinea-pigs—for which Sir Frederick evidently has but little sympathy—for no other reason than the sheer desire to vivisect them rather than other animals which are far cheaper and more easily obtained? Is he not able to understand that dogs are never employed and are never likely to be employed for experiments unless there is some special necessity for using these animals rather than others? At any rate he may accept my assurance that it is so. And it follows that the greater number of dogs he can show to have been used the stronger is the argument for the necessity of using them. Not that his statistics are of much account, for in attempting to strengthen his case for dogs, he mixes cats up with them—unless the report of his speech is in this respect inaccurate.

But Sir Frederick Banbury's inability to assess evidence is sufficiently manifested by his argument that because the Royal Commission did not specifically state in its report that it is necessary for dogs to be employed it found no evidence sufficiently strong to authorise it to make such a statement. We know, as a matter of fact, that the Commission did discuss the question whether the exclusion of dogs might be recommended and definitely concluded against the adoption of this course. Is it, perhaps, possible that Sir Frederick Banbury—who puts himself forward as a judge in this matter—has not himself read the evidence which was presented to the Commission on the subject? This is the only hypothesis that I can suggest to render his position intelligible. But this hypothesis cannot be applied to Col. Lockwood, who appears as Sir Frederick's chief supporter—since he was a member of the Commission. Although he does not dare to say that the evidence before the Commission proved that the use of dogs is not necessary, he alleges that it did not distinctly prove "to anyone with a fair mind" that the dog alone is necessary for those "so-called scientific experiments" (*sic*). And this in spite of the fact that it had been proved to demonstration before the Commission—what is, of course, well known to any person who has any medical knowledge worth speaking of—that most of what we know regarding the functions of the body could only have been elucidated with the aid of experiments on dogs.

Col. Lockwood is, however, good enough to inform us by what consideration he is guided. He is "not ashamed to say that he is actuated by sentiment." But there is sentiment and sentiment, and we may be permitted to inquire what kind of sentiment it is that actuates Col. Lockwood. Sentiment is feeling and Col. Lockwood's feeling is for the lower animals in general, for dogs in particular, and probably—if it were to be still further analysed—most particularly for the special dog which, as he tells us, he leads about London on a string. His sentiment does not extend to humanity. He has no feeling for his own species. He prefers that mankind shall continue to be ignorant, and shall continue to suffer as a result of that ignorance, rather than that his feeling for dogs, most of which do not in any way suffer, shall be harrowed.

Sentiment of this sort has no true ring: it is *false* sentiment; and any man—let alone a legislator—should be ashamed to confess that he is actuated by it.

Further, Col. Lockwood is good enough "not to wish to accuse his opponents of not being so humane as himself." But Col. Lockwood's humaneness is—like his sentiment—*false*: it leaves humanity out of consideration. He may take it from me that his opponents repudiate this kind of humaneness and thank him neither for the comparison nor for his eulogium of their profession. Of what value is eulogium coming from such a quarter? If he and his 121 fellow-members accept the services of medical men, are they not benefiting by the very experiments they denounce? To be consistent they should resolutely decline to call in the aid of physician or surgeon and betake themselves to the Christian Scientist or to any other quack they may fancy. But it is as hopeless to look for consistency from anti-vivisectionists as to expect to gather figs from thistles. As for the voters who send such persons to Parliament, one may well apply to them Carlyle's estimate of most of his fellow-citizens. But perhaps they are, on the whole, not inappropriately represented there.

E. A. SCHÄFER.

THE TREVOR LAWRENCE ORCHID COLLECTION AT THE ROYAL GARDENS, KEW.

WHEN the late Sir J. J. Trevor Lawrence, Bart., died, an announcement was made that his well-known orchid collection at Burford had been bequeathed to Lady Lawrence with an expression of his wish that such of the plants as were especially of botanical interest should be presented to the Royal Botanic Gardens, Kew. This gift has now been made to the national orchid collection there, which has received from Lady Lawrence a large selection consisting of 580 plants, belonging to 89 genera, and representing 350 species mainly, but by no means exclusively, of botanical interest.

The character of the collection brought together by Sir Trevor at Burford during many years was a matter of general knowledge. It was singularly rich in rare and interesting species, owing to the fact that Sir Trevor at all times paid especial attention to whatever in the natural family was striking or unusual from a morphological point of view, apart entirely from any decorative value which it might possess. The result of this was that the Burford collection was not only thoroughly representative of the usual showy species and hybrids and on this account to be reckoned with in the horticultural world, but also possessed examples of most of the cultivated genera, some of which are seldom met with, and, on this account, was perhaps as important from the scientific as from the gardening point of view. It included plants from almost every quarter of the globe demanding the most diverse cultural treatment.

The magnificent selection from the collection at Burford now transferred to Kew is rich in such genera as Bulbophyllum, Cirrhopetalum, Pleurothallis, Maxillaria, Epidendrum, Eria, Angræcum, Dendrobium, and Cœlogyne, and includes many species and a few genera not previously represented at Kew, some of these being rarely seen in cultivation. The genera not previously present in the Kew collection include Trichoceros, a high Andine genus very difficult to bring home alive and very difficult to cultivate afterwards, Nasonia and Quekettia, two small American genera, and Stereochilus and Sigmatogyne from Northern India. The collection also includes a number of undetermined species which have not yet flowered; in a few cases the genus to which these belong is still doubtful. These unknown plants have been derived from various sources; some of them are plants contributed to the Burford collection by Sir Trevor's son, Captain C. T. Lawrence, by whom they were obtained in West Africa.

PROF. EDUARD SUESS, FOR.MEM.R.S.

BY the death of Eduard Suess on April 26, Austria loses her most eminent man of science, and the world one of its greatest naturalists. The son of a German merchant, domiciled in this country, Suess was born in London on August 20, 1831. The family removed, while he was still young, first to Prague and then to Vienna—but to the end of his life Suess retained his affection for what he used to call his "native land," and maintained the most cordial relations with his numerous English friends. His university career was commenced at Prague, but completed in Vienna, and at the age of twenty-one he became an assistant in the geological department of the famous Natural History Museum of the latter city. Here he worked for five years on the collections, and, as the result of his studies, published a number of important papers on graptolites, brachiopods, and other fossil forms.

It was in 1857, however, that Suess entered upon what was his life's great work—that of a teacher. After serving ten years as an extraordinary professor in the University of Vienna, he was in 1867 appointed to the full professorship of geology, a post which he held for thirty-four years, retiring as emeritus professor in 1901. Of his success as a teacher it is needless to speak, for he numbered among his pupils Neumayr, Mojsisovics, Fuchs, Waagen, Penck, and other distinguished geologists, many of whom caught from their master that grasp of detail, combined with powers of generalisation, that so eminently distinguished him. The writer of this notice recalls with pleasure the happy time he spent with Suess forty years ago, when he had the opportunity of witnessing the delightful relations that existed between the professor and his students. Not only during geological excursions in the neighbourhood of Vienna was the charm of Suess's society felt, but in the Wurstel-Prater, where we joined the young fellows during hours of relaxation—in the beer-gardens, and even on the "merry-go-rounds." Yet, amid all the fun and frolic, the signs of affectionate respect and devotion to the great teacher were never for a moment wanting.

It was at this time that Suess's daughter became engaged to his most distinguished pupil, the young Bavarian, Melchior Neumayr. After working for a time on the Geological Survey of Austria, Neumayr had established a great reputation as a palæontologist, and at the age of twenty-eight became a colleague of Suess, as professor of palæontology in the Vienna University. Greatly impressed by reading the "Origin of Species," he entered into correspondence with Darwin, by whom his work was held in high estimation, and in the end he came to be regarded as the stoutest champion of evolution on the geological side.

Suess's own researches ranged over every branch of geological science, as may be seen from the titles of sixty memoirs and books published by him prior to 1875. But in this year there appeared his remarkable work, "Die Entstehung der Alpen," to be followed five years later by the first part of the still more famous "Antlitz der Erde." In this great work, which engaged his labours during twenty-five years, Suess aimed at no less a task than taking a comprehensive survey of all that has been accomplished in elucidating the geological structure of every part of the globe, and drawing general conclusions from that survey. How admirably this herculean undertaking was performed is told—with an estimate of the great merits, the small defects, and the enormous influence exerted by this monumental work—by Sir Archibald Geikie in a contribution to the series of "Scientific Worthies" (see NATURE, vol. lxxii., May 4, 1905). It will suffice here to say that the book will undoubtedly take its place as a scientific classic, side by side with Hutton's "Theory of the Earth" and Lyell's "Principles of Geology."

In 1890 there came a sad interruption to Suess's scientific labours. His distinguished son-in-law and colleague, Neumayr, died at the early age of forty-four, when only the first volume of the great work on which he was engaged, "Die Stämme des Thierreichs," had been published. It is very touching, even at this date, to read the letters in which Suess wrote of his great sorrow to his friends; but fortunately these same letters contained the expression of a new hope, founded on the fact that his own son had just taken his doctor's degree in geology. Happily, Suess lived to see his son become an extraordinary professor in the University, to find him the author of valuable geological papers, and, shortly before he passed away, to witness the son installed in the chair vacated by himself only a few years previously.

The great task of his life completed in 1910, Suess's closing years have been happy and restful, for only quite recently came the bronchial affection which terminated his life in his eighty-fourth year.

Suess held much the same position among German-speaking peoples as did Huxley among English and Americans. They both held that, in addition to their scientific labours, however exacting these might be, something in the way of service was due to the cities in which they lived and the states to which they belonged. In 1862 Suess had directed attention to the unsatisfactory condition of the water-supply of Vienna, and, from 1863 to 1873, he was called upon to serve as a member of the Municipal Council of Vienna; it was due to his initiative in this capacity that an aqueduct, 110 kilometres long, was built to bring water from the Alps to the city, and that other great improvements in the sanitary conditions of Vienna were undertaken. For more than thirty years he was a member of the Lower House of the Reichsrath, and proved himself a doughty champion against the defenders of political privileges and of clericalism. Like Huxley, he declined many offers of honours and titles from the State, but was amply compensated by the marks of esteem from his fellow-workers in science. He was president of the Austrian Academy of Sciences, a member of the French Institute, Foreign Member of the Royal Society since 1894, and member of scientific societies in every part of the world. He received the Wollaston medal of the Geological Society in 1896, and the Copley medal of the Royal Society in 1903.

John W. Judd.

ROBERT KAYE GRAY.

It is with deep regret that we have to record the death of Mr. Robert Kaye Gray, who passed away on April 28, at Brighton, after a long illness, at the age of sixty-two. He was well known as the managing director of the India-Rubber, Gutta-Percha, and Telegraph Works Co. at Silvertown, but his interests extended far beyond the range of commerce, and he became associated with many institutions and societies for the improvement of natural knowledge, and for the welfare of the sick and needy. His attractive personality, his quiet way of doing good, his unbounded generosity, the breadth of his mind, and his exceptional store of worldly wisdom, made him the centre of a multiplicity of activities; and there is no doubt that in recent years the constant demand made upon his powers and judgment hastened the end of his remarkable career.

Readers of Nature will recall how large a share Mr. Gray took in establishing and supporting the National Physical Laboratory. He had the satisfaction of seeing the laboratory extend in scope and usefulness, and his name will always be associated with that of the late Sir William White in the pioneer work of giving direction to its latent possibilities. His loss will be keenly felt by the Institution of Electrical Engineers, of which he was a past president, by the Royal Society of Arts, and the Institute of Metals, to which he rendered substantial help.

The cause of technical and university education in London has also suffered by the loss of Mr. Robert Gray, who gave freely of his time and from the fund of his experience to aid in their advance. His association with submarine telegraphy brought him into touch with engineers and others in every quarter of the globe, and it is not too much to say that he was universally esteemed and honoured.

From his father, the late Matthew Gray, an engineer of high ideals and remarkable strength of character, Mr. Gray inherited a mind intent upon accomplishing large things by straight means. Early in his professional life he set himself to master every branch of submarine telegraph engineering, including the manufacture, laying, and testing of cables. This knowledge and experience was the basis of his subsequent professional work, and it led him ultimately towards that field of natural science of a practical kind, which afforded him full scope for his energies. In the history of the progress of the age through which he passed he must be assigned a place as a representative man, and as a man of affairs. He was representative of the age in which commerce became a science, and science a refining influence —the age in which science was at last seen to be consistent with benevolence.

NOTES.

America has lost one of her foremost astronomers by the death, in his seventy-seventh year, of Dr. George William Hill. He graduated at Rutgers College in 1859, and in 1861 became an assistant in the office of the American Ephemeris and Nautical Almanack. He afterwards became chief of this publication. From 1898 to 1901 he was lecturer in celestial mechanics at Columbia University, New York. In 1887 the Royal Astronomical Society awarded him its gold medal for his researches in connection with the lunar theory. He was a foreign member of that society, and also of the Royal Society, and a corresponding member of the Institute of France. In 1892 Cambridge University conferred on him its honorary Sc.D. He was president of the American Mathematical Society from 1894 to 1896. In 1905 the Carnegie Institution published a volume of his collected mathematical works, with an introduction by Henri Poincaré. Dr. Hill was also the author of a work on "The Theory of Jupiter and Saturn."

Mr. C. S. S. Peirce, an American mathematician and logician of international reputation, has died at the age of seventy-four. He was a son of Prof. Benjamin Peirce, of Harvard, and was himself educated at that University. For a few years he was a teacher of logic in Johns Hopkins University, and he gave occasional lectures at Harvard, but the greater part of his life was devoted to study and research. Since 1887 he had lived in seclusion in a little cabin in the mountains near Milford, Pennsylvania, where he had collected what is believed to be one of the most complete private reference libraries in the world on the subjects in which he was interested. He edited several of his father's mathematical works, and was the author of "Photometric Researches," as well as of numerous papers on logic, the history of science, psychology, astronomy, optics, colour sense, map projections, chemistry, engineering, early English pronunciation, library cataloguing, etc. Mr. Peirce was one of the pioneers of symbolic logic, and was the first to formulate the philosophical principle which he named "pragmatism." He dissented, however, from Prof. William James's development of this principle.

WE regret to record the death, in Paris, of M. Wilfred de Fonvielle. Few men have done more to popularise the subject of aeronautics than M. de Fonvielle, who not only wrote numerous books and articles, both popular and scientific, upon the subject, but also did much practical work, especially in regard to balloons. Commencing life as a journalist, he joined the staff of a journal, *La Presse Scientifique*, edited by M. Barral. The latter had just been making his well-known balloon ascents for scientific observation, which greatly interested the young enthusiast and started him writing articles on the subject. Since then, until recently, his pen had but little rest. His principal works are:—"La Science en Ballon" (1869); "Voyages Aériens" (with Glaisher and others) (1871), translated into English; "Les Ballons pendant le Siège" (1871); "Traité Pratique de Navigation Aérienne" (1872); "Aventures Aérienne" (1876), translated into English; "La Conquête de l'Air" (1882); "Notre Flotte Aérienne" (1908); and a vast number of articles in French and English papers and magazines, including many contributions to our columns. De Fonvielle's first balloon ascent was made in the great *Géant*, with M. Nadar, in 1867. Numerous other journeys followed, until he became considered one of the leading aeronauts in France. During the siege of Paris he piloted one of the balloons which left that city, descending in Belgium, whence he crossed to England. In later years he paid frequent visits to this country, where he several times made balloon ascents. For some years he was president of the Société Française de Navigation Aérienne.

BOTANISTS will learn with regret of the death, at seventy-five years of age, of M. van Tieghem, member of the Institute of France, professor at the Natural History Museum, Paris, and one of the most eminent of modern workers in the field of botany. As a young man he worked under Pasteur, and he made valuable contributions to science in the domain of bacteriology. In 1873 he published, in conjunction with his pupil, G. Le Monnier, a monograph on the Mucorineæ, in which the morphology and physiology of the family were carefully studied, and a detailed systematic account was given for the first time. Two further contributions on the same subject appeared in 1875 and 1876. But van Tieghem is best known for his work on the anatomy and morphology of the seed-plants. In 1866 appeared an important paper on the anatomical structure of the Aroideæ, and his concluding remarks supply the key to his work in this field. He says:—"Nos observations semblent démontrer aussi par une preuve nouvelle qu'il est indispensable de joindre l'étude anatomique comparée de l'appareil végétatif à celle de la fleur, si l'on veut construire le système idéel à liaisons fixes qui est l'objet de la méthode naturelle." The systems of classification which he proposed were, however, the least valuable part of his work; they indicated lack of appreciation of the relative value of characters, and were hampered by a cumbersome terminology. On the other hand, his work on the comparative anatomy of the female flower and fruit of the Gymnosperms was of fundamental value. In 1882 he succeeded Decaisne as botanical editor of the *Annales des Sciences Naturelles*, a post which he held until his death, and the long series of memoirs in this journal by himself and his pupils on the morphology and anatomy of various families and genera of seed-plants will form a permanent monument of his industry and botanical work.

THE Bruce medal of the Astronomical Society of the Pacific has been awarded to Dr. O. Backlund, director of the Pulkowa Observatory.

Science announces the retirement, on July 1, after twenty-one years' connection with the Yerkes Observatory, of Prof. S. W. Burnham.

THE Wellcome Historical Medical Museum is to be reopened on May 28, at 54*a* Wigmore Street, as a permanent institution in London. Since the closing of the museum in October last the collections have been much augmented and entirely rearranged.

IT is announced in *Science* that the amount subscribed in connection with the jubilee celebration of Dr. A. Auwers has been handed to the Berlin Academy for the foundation of a prize (to be known as the Bradley Prize) to be awarded once every five years.

ACCORDING to the *Lancet*, it has been decided by the Liverpool School of Tropical Medicine to establish a permanent laboratory in Sierra Leone for the purpose of carrying on research work. It is hoped that the laboratory will act as a base from which expeditions to other regions of tropical Africa may be dispatched from time to time.

AN International Conference of Telegraph Engineers is to be held in Berne from September 14 to 20 next. Among the subjects open for discussion are the prospects of telephony over longer distances, the protection of telegraph and telephone wires from other electrical conductors, and how far automatic apparatus in telephone exchange working is desirable.

THE summer meeting of the Institution of Naval Architects will be held in Newcastle-on-Tyne on July 7–10, at the invitation of the institution by the president and council of the North-East Coast Institution of Engineers and Shipbuilders. Meetings for the reading of papers will be held, and arrangements will be made to visit some of the principal works in Newcastle and its vicinity.

IN order to commemorate the work of Wilbur Wright, who, with his brother, Orville Wright, evolved the first successful power-driven aeroplane, the Wilbur Wright Memorial Fund was created under the auspices of the Aeronautical Society for the purpose of providing for the annual delivery of a premium lecture. The second memorial lecture will be delivered by Dr. R. T. Glazebrook, director of the National Physical Laboratory, on May 20, at the Royal United Service Institution, Whitehall, S.W. The Right Hon. Lord Sydenham will preside.

MR. A. N. HALL has been appointed Government curator of the Ancient Monuments of Rhodesia. According to the *Geographical Journal*, the objects under his charge will include not only ruins, but all relics wherever found, and also the Bushman paintings, all of which are in future to be protected from vandalism and preventible destruction. The headquarters of the curator will be at Great Zimbabwe, but Mr. Hall hopes, it is stated, to spend four months of each year in examining or searching for other remains.

THE Board of Agriculture and Fisheries desires to bring to the attention of the public the arrangement now established at the Royal Botanic Gardens, Kew, whereby a competent guide accompanies visitors on weekdays through the gardens and explains the many objects of botanical interest. A small charge is made for the services of the guide, 6*d.* for each person attending a morning tour, and 3*d.* for each person attending an afternoon tour. The present arrangements are of the nature of an experiment, and their continuance beyond September next will depend on the extent of the public demand for the services of the guide. A leaflet giving detailed information on the subject can be obtained on application to the director, Royal Botanic Gardens, Kew.

THE thirteenth annual general meeting of the Marine Biological Association of the United Kingdom was held in the rooms of the Royal Society on April 29, Sir E. Ray Lankester, president of the association, being in the chair. Dr. P. Chalmers Mitchell and Mr. F. A. Potts were elected to fill two vacancies on the council. In the annual report reference was made to the discovery at Plymouth of the puerulus stage of the sea crayfish (Palinurus) by Prof. Bouvier, of Paris, to the investigations on eggs and young stages of British food fishes, by Mr. R. S. Clark, on the feeding habits and rate of growth of invertebrates, by Mr. J. H. Orton, and on the culture of plankton diatoms, by Dr. E. J. Allen. Mention was also made of work carried out at the laboratory by Mrs. Matthews on the development of Alcyonium, by Dr. Mortensen on the larvæ of Echinoderms, by Dr. Shearer, Mr. De Morgan, and Mr. Fuchs on the hybridisation of Echinoderms, by Mr. J. Gray on the electrical conductivity of Echinus eggs, and by Dr. Stuart Thomson on the brain of Elasmobranchs. It was reported that Mr. D. J. Matthews and Mr. L. R. Crawshay had returned to the laboratory from the expedition of the *Scotia* to the coast of Labrador, and Mr. E. W. Nelson from the British Antarctic Expedition, and that these gentlemen had been employed in working up the material which they had obtained.

AT Greenwich the mean temperature for the month of April was 50·8°, which is 2·7° above the average. This is the warmest April for the last ten years, but there have been six warmer Aprils since 1841, the warmest being 53·9° in 1865. The mean of the maximum temperatures was 61·1°, and the mean of the minimum 40·5°. There were three days with a temperature of 70° or above; in 1865 there were fourteen days above 70°. The total rainfall was 1·12 in., of which 1·10 in. was measured during the first ten days and only 0·02 in. at Greenwich in the remainder of the month. The duration of sunshine at Greenwich was 231·6 hours, which is 166 per cent. of the average. It is the sunniest month at any time of the year since the memorable summer of 1911, and has only once been surpassed previously in April at Greenwich, 1909 having 250 hours of bright sunshine. There were thirteen days with more than ten hours of sunshine, and April 30 was the only day during the month on which the sun did not shine.

IN the recent annual report of the Decimal Association there is a reference to the legalisation of the metric carat in this country. Although the Order in Council came into operation so recently as April 1, it is satisfactory to note that the adoption of the new unit by dealers in diamonds and precious stones is already practically complete, and has occasioned little or no inconvenience. The manufacturers of weights in this country do not appear to have realised that the change would be effected so readily, and in consequence of this a large proportion of the sets of metric carat weights have been imported from the Continent to meet the sudden demand. The largest metric carat weight legalised is the 500 C.M., which is equivalent to 100 grams. Many diamond dealers who have been accustomed to use weights up to 5000 carats were inclined at first to imagine that such large single weights would not be permissible in future, but they now understand that above 500 C.M. the ordinary metric series, 200 grams, 500 grams, kilogram, etc., may be employed, and little difficulty is experienced by them in adapting their operations to the new conditions.

THE Peabody Museum of American Archæology and Ethnology, Harvard University, publishes a fine monograph by Mr. A. M. Tozzer on the prehistoric ruins of Nakum, in Guatemala. The museum expeditions since 1888 have been engaged in exploring the Maya area in Mexico, Guatemala, Honduras, and British Honduras. Unfortunately, these interesting ruins have suffered much from fires lighted by natives to clear the ground for cultivation, and from sheer vandalism. Quite recently some of the sculptured stelæ at Copan were destroyed to make the foundations for an adobe wall. Several ruined cities have been discovered, and it is well that the surveys now in progress should be undertaken while the material remains undisturbed.

THE *Times* of April 25 publishes a preliminary report on the excavations at the Great Stone Circle at Avebury. The work has extended to the silting of the fosse on the east side, and against the solid chalk entrance causeway on the south of the great circle. A few antler picks and hammers and a finely worked flint implement have already been found in the chalk rubble, and in the Roman stratum nearer the surface a ring and part of a bracelet, both of bronze. In the cutting of the vallum have been decovered two red deer antlers and an interesting bone pin nicely worked and polished. The old surface line has been reached in places, and is clearly defined; on it have been found several small fragments of prehistoric pottery, a flint scraper, and two flint saws, as well as clear traces of charcoal.

ACCORDING to the April number of the *Museums Journal*, the chief loan collections at the twenty-fifth conference of the Museum Association, to be held at Swansea in July, will comprise Welsh pottery and porcelain, paintings by old masters and modern Rouen artists, Rouen decorative metal-work, and old Welsh furniture and lacquer.

AMONG questions discussed in Publication No. 2169 (Opinions 52–56) of the International Commission on Zoological Nomenclature is the validity of the names, which were edited by Linnæus, in Hasselquist's "Iter Palæstinum"—published prior to 1757. It is ruled that these are invalid, despite the publication of a German translation of the volume in 1757, which, it had been urged, might justify their recognition.

THE surface-swimming copepod crustaceans of the Gulf of Manaar form the subject of the longest article, by Capt. R. B. S. Sewell, in No. 35 (vol. ix.) of *Spolia Zeylanica*. The account is mainly based on two collections—one made between 1906 and 1909 inclusive, and the other in 1913; these embrace a total of eighty-seven species and subspecies, of which five are described as new. This number also includes the second part of a paper by Dr. J. Pearson on the holothurians of the Indian Ocean, together with a revision, by the same writer, of the genera Muelleria and Holothuria.

IN the introduction to a long reply on certain criticisms of the theory of mimicry, the greater portion of which appears in the January issue of the Proceedings of the Academy of Philadelphia, Prof. Poulton remarks that more definite evidence than we at present possess with regard to the butterfly-eating habit in birds, and that some species of butterflies are nauseous to them, is urgently required. Such evidence is, however, steadily increasing, an important item coming from Uganda, where a wagtail, after eating butterflies belonging to two groups, rejected one representing a third.

"ELVERS," writes Mr. J. S. Elliott in an article on eels and eel-catching in Bedfordshire in the April number of the *Zoologist*, ascend the Ouse and its tributaries in swarms from the Wash. From the time of Domesday Book most Bedfordshire mills have been provided with eel-traps, which in early days furnished a considerable instalment of the rent. Although apparently less than formerly, the total average catch in the county is now about 3 tons 18 cwt., representing something like 17,500 eels, with a value, at the local price of 6*d*. a pound, of practically 220*l*.

To the March number of *Naturen* Mr. Orjan Olsen contributes an illustrated account of the whales of South Africa, and whaling as carried on at Durban and Saldanha Bay on the east, and at Port Alexandre, Benguela, on the west coast. A considerale amount of space is devoted to *Balaenoptera brydei*, the new rorqual described by Mr. Olsen last year, of which 169 individuals were taken in 1912. In the following year, up to July, 92 common fin-whales and 36 blue whales were captured at the Saldanha Bay station. The other species taken were the southern humpback (*Megaptera boöps*, or *nodosa, lalandei*), the southern right whale (*Balaena australis*), which is very rare, and the sperm-whale.

PHOTOGRAPHS of two recently added animal groups appear in the report of the American Museum of Natural History, one representing the reptile life of the Californian cactus-desert tract, and the other showing portions of two piles grown over with mussels and sea-anemones from a group illustrating the fauna of submerged timber. An item in the report well worthy the attention of museum curators in this country is a photograph of fireproof cases recently installed for the storage of mammal skins. If this is worth doing in America, it is still more so in our our own Natural History Museum, with its priceless series of "type" specimens. Even if the new method of storage could not be applied to the whole study-collection, it might be employed for types.

DR. ENRICO FESTA has utilised the opportunity presented by the Italian occupation of Rhodes to visit the island for the purpose of studying its fauna. An account of his observations, and reports on his collections have recently been published (*Bolletino dei Musei di Zoologia ed Anat. comp. della R. Università di Torino*, vols. xxviii.–xxix). Most of the animals recorded belong to species already known from other parts of the Mediterranean region, but a few are new or of special interest. A hundred and thirteen species of birds were obtained, including a new species of jay (Garrulus) and a new species of redbreast (Erithacus). There are two new earthworms (Helodrilus), two new woodlice (Armadillidium), three new locustids, one of which is referred to a new genus, and a new variety of the river crab (*Potamon edule*) of southern Europe. The other groups reported upon are the hymenoptera, fleas, earwigs, scorpions, and the mosses and liverworts (these last in *Annali di Botanica*, vol. xii.).

AN account of work on the control of damping-off disease in plant beds has been recently published in bulletin form (No. 31, University of Wisconsin Agricultural Experiment Station). According to the observations of the author, Mr. James Johnson, the two most common fungi giving rise to the disease are Pythium de Baryianum and Rhizoctonia, and these have been found on seedlings of a large number of different plants, including cress, tobacco, lettuce, tomato, etc. The effect of various cultural conditions, such as moisture, temperature, aeration on the growth and spread of the disease, is discussed, and the results of experiments as to preventive measures are given.

Treatment of infected soils with formalin 1 : 50 has been found efficient in checking the disease, but from the point of cheapness and efficiency steam-heating is recommended. Certain secondary effects, such as the killing of weed seeds and the destruction of insect pests in the soil, and greatly increased size and vigour of plants grown in treated soils, were also noted.

In a recent Bulletin of the U.S. Weather Bureau the Rev. M. Saderra Masó describes an interesting series of earthquakes which occurred in the sub-province of Benguet (Luzon) in August and September, 1913. They were very numerous (about 350 occurring in little more than a month), as a rule of slight intensity, and, even with the strongest, of very small disturbed area. It is probable that they originated at a very slight depth. As the earthquakes occurred at the close of the rainy season, in a limestone district in which the annual rainfall is about 160 inches, and in which there are frequent subsidences of the ground, the author concludes that the earthquakes are neither tectonic nor volcanic in their origin, but probably due to underground rock-falls and secondary faults.

The Meteorological Office of Canada has recently issued an interesting monograph, "Canadian Weather Forecasting," as an addendum to "Gales from the Great Lakes to the Maritime Provinces," covering the years 1905–12, prepared by Mr. B. C. Webber, under the superintendence of the director of the Meteorological Service. In a preceding monograph for the period 1874–1904 Mr. Webber suggested some aids to assist the forecast officials, and these have now been supplemented, and the tables show, in addition, the percentages of low-pressure areas causing storms in various months and districts and the directions in which the depressions moved, together with other useful information. November is the most stormy month on the Great Lakes during the season of navigation, but January and February are the stormiest in the Gulf of St. Lawrence and the Maritime Provinces; March is not an unusually stormy month. Within the eight years in question the area of the Canadian weather map has been much enlarged, and knowledge of movements of high- and low-pressure areas has been enhanced by the introduction of a daily meteorological chart of the northern hemisphere since January 1, 1912. It is, however, reluctantly admitted that the advancement of weather forecasting has been more or less disappointing. The author considers that the study of the upper air and of solar physics will eventually undoubtedly assist in solving some of the vexed problems which confront the meteorologist.

The necessity of bringing modern mathematical concepts within the range of study of comparatively elementary students has led Mr. C. Elliott, of King Edward VII. School, Sheffield, to produce a book of 116 pages, entitled "Models to Illustrate the Foundations of Mathematics" (Edinburgh: Lindsay and Co., 1914, price 2*s.* 6*d.*). It consists of four chapters dealing respectively with the meaning of correspondences, multiplexes, spaces defined as ordered multiplexes, correspondence of operands to functions, and multiple correspondence. Although a selection of classificatory models was exhibited at the 1912 Mathematical Congress, the use of the term "models" in the title of this book may perhaps be rather misleading, for it consists mainly of definitions and explanations, and the nearest approach to models generally consists in mere references to illustrations of classes, like and unlike things, correspondences, and so forth, where these can be exemplified by objects of everyday life. The question as to how far the subject can be understood and appreciated by schoolboys is a very interesting one.

The first of a series of illustrated articles descriptive of a 300,000-h.p. hydro-electric plant on the Mississippi appears in the *Engineer* for May 1. These works are situated at Keokuk, on the Iowa side of the river, about 130 miles north of the mouth of the Missouri River, and 137 miles from the city of St. Louis. One purpose of the power development is to deliver current in large quantities to distant points by transmission lines up to 200 miles in length, and in August last the supply of current to St. Louis was commenced. The electric light and tramway company of St. Louis has contracted to take 60,000 h.p. for a term of ninety-nine years. The works comprise three main sections. First, a dam 4700 ft. long, extending from the east bank at Hamilton to within a thousand feet of the west bank at Keokuk. Secondly, a power-house, extending downstream from the end of the dam for a length of 1700 ft. Thirdly, a dam extending from the lower end of the power-house to the west bank, forming the fore-bay and having a large single-lift lock for navigation. The total length of monolithic concrete construction is more than two miles. The working head of water available for the machines ranges from 23 to 40 ft.

OUR ASTRONOMICAL COLUMN.

May Meteors.—It is hoped that favourable conditions will be experienced for the observation of Coronid meteors in May. Mr. W. F. Denning directs attention to this shower in *Astronomische Nachrichten*, No. 4726. In recent years he found the chief radiant point to be about $246^\circ + 30^\circ$ near ζ Coronæ, and a few degrees west of ρ Herculis. According to his observations in 1903 and 1911, the meteors were white, swift, and usually trainless. The most suitable time for their observation is between May 18 and 26, and the absence of the moon will render the observation more easy.

Comet 1914*a* (Kritzinger).—The following is the continuation of the ephemeris of comet 1914*a* (Kritzinger) which was given in this column last week, the information being gathered from Prof. H. Kobold's communication to the *Astronomische Nachrichten*. No. 4729:—

12*h.* *M.T.* *Berlin.*

	R.A. (true) h. m. s.	Dec. (true) ° ′	Mag.
May 7	18 46 9	+23 29·0	
8	50 57	24 25·9	8·5
9	55 45	25 21·9	
10	19 0 34	26 16·7	
11	5 24	27 10·4	
12	10 14	28 2·8	8·4
13	15 4	28 53·9	
14	19 19 54	+29 43·6	

The comet is situated near the boundaries of the four constellations, Hercules, Vulpes, Cygnus, and Lyra.

A CONVENIENT COMPARISON SPECTRUM.—For the study of both terrestrial and celestial spectra, it is useful for many purposes to photograph a comparison spectrum alongside the spectrum under investigation. The spectrum of iron is most generally used as the lines are well distrubuted along the spectrum, are sharp, and their wave-lengths are accurately determined. The iron, however, may not be pure, so several strange lines may appear in the spectrum, and these have to be investigated. Dr. Joseph Lunt, in searching for a convenient means of obtaining the spectrum of cyanogen has incidentally found that the spectrum of lead pencils gives an extremely fine set of lines, very sharp, well distributed along the spectrum, exhibits a remarkable constancy of spectroscopic composition, and consists of lines which are almost without exception present in the solar spectrum, the wave-lengths of which have been well determined. The account of this investigation on the spectra of graphites and lead pencils is given in vol. x. of the Annals of the Cape Observatory, part iv., and should be read by all those who work with the spectroscope. A plate reproduces the lead pencil spectrum from λ 4071·91 to λ4742·98. The sharp metallic lines are for the most part due to iron, titanium, vanadium, chromium, and the alkaline earths, barium, strontium, and calcium, while the spectrum shows also the presence of the rarer elements, gallium, scandium, and yttrium, as well as silicon, magnesium, and manganese. The carrier of a lead pencil thus possesses a small portion of the very rare elements gallium and scandium.

REPORT OF HARVARD COLLEGE OBSERVATORY.—The report of the director of the Astronomical Observatory of Harvard College for the year ending September, 1913, gives one a good idea of the great field of work projected and of the large amount of work accomplished during the past months. It is hoped that means will be found to concede to the director's wishes stated in this report by increasing the income of the observatory, for the situation is not very satisfactory when, as Prof. Pickering states, "during the last twenty years the income of the University has more than doubled, while that of the observatory has diminished rather than increased." The report shows, in the first instance, the progress made in the Henry Draper memorial department, the revised Draper Catalogue being the principal work. More than half the sky has been covered, and 100,155 stellar spectra have already been classified. The 11-in. Draper telescope, in the hands of Prof. W. H. Pickering, has produced valuable results, among which may be mentioned the periodic changes in form of the discs of Jupiter's satellites. The work of the Boyden department at the Arequipa Station, of the Blue Hill Meteorological department (recently transferred to Harvard University), etc., are all briefly summarised, and indicate the wide range of activities.

THE SCHILOWSKY GYROSCOPIC TWO-WHEELED MOTOR-CAR.

A LARGE two-wheeled motor-car, constructed from the design of Dr. Schilowsky, a Russian Doctor of Laws, by the Wolseley Tool and Motor Company, Ltd., was given a trial run in London last week. The car is a six-seated car, and it carried six people as it slowly made a circuit of Regent's Park. The gyroscopic mechanism is placed in the cupboard under the middle four seats. This consists of a heavy gyrostat rotating at the moderate speed of 1100 revolutions a minute, and driven by an electric motor of $1\frac{1}{2}$ horse-power. The axis is vertical, and it is mounted in a ring supported on transverse trunnions, so that it may tilt in a fore and aft plane. As the car is necessarily unstable on its two wheels, the gyrostatic ring must also be carried unstably for it to have corrective influence. If, as a ship, the car could have been carried stably, then the gyrostatic ring would also have to be stably mounted. If one is stable and the other unstable then the gyrostat operates in the opposite sense to that intended.

The unstably mounted gyrostat will not maintain the car in its upright position for long, as the precessional oscillations increase in amplitude. Dr. Schilowsky counteracts this by an ingenious piece of mechanism. Driven by worm-gearing from the gyrostat axle are two spur wheels, each just out of gear with a segmental rack, but capable of being brought into gear by a heavy pendulum which feels any tilting of the car away from the dynamical vertical. This is only allowed to engage at such times as the gyrostat ring is approaching the neutral position. During this time the engagement causes a hurrying of the precession and a consequent steadying of the motion. At the moment the neutral position is reached the pinion and rack are disconnected by a snap mechanism reminding one of that used for closing the valves of a Corliss engine. One pendulum controls the engagement when the gyrostatic ring is approaching the neutral position from one side, while the other effects the control on the other side of the neutral position. Either alone might be used, but the two alternate with one another and maintain a more continuous control. It is a curious fact that the controlling mechanism is more easily adjusted so as to maintain the equilibrium of the car when it is turning in the opposite direction to the rotation of the wheel. For turning in the same direction more exact adjustment is necessary. A working model railway on this system has been presented by Dr. Schilowsky to the South Kensington Museum, where it may be seen by anyone interested.

The car weighed three tons, having been designed for running on a rail, while the engine was one of the maker's standard 16-h.p. engines. This was insufficient in power to drive the heavy car, as well as the motor of the flywheel, more than about four miles an hour. At this speed and at rest or moving backwards the car maintained its position with passengers jumping on or off. When a new load was applied to one side the car moved almost imperceptibly so as to raise it and maintain the centre of gravity over the line of support as has already been made familiar by Mr. Brennan with his monorail.

It will be interesting to see how the car behaves when a more powerful engine is fitted and higher speeds are possible. The inventor is, of course, aware of the very great couple, ordinarily resisted by the four-wheel support of the motor-car when ordinary curves and speeds are negotiated together, which he will have to contend with in like circumstances. The demonstration in the Regent's Park did not show that the gyrostatic control then existing would be sufficient for this, but it did show, and that perfectly, that the first step has been successfully accomplished. It may be worth while to add that the bicycle balance is not used, the gyrostatic control being independent of speed or direction of motion.

C. V. BOYS.

RELATIONS BETWEEN THE SPECTRA AND OTHER CHARACTERISTICS OF THE STARS.*

II.

Brightness and Spectral Class.

HAVING thus made a rapid survey of the general field, I shall now ask your attention in greater detail to certain relations which have been the more special objects of my study.

Let us begin with the relations between the spectra and the real brightness of the stars. These have been discussed by many investigators—notably by Kapteyn and Hertzsprung—and many of the facts which will be brought before you are not new; but the observational material here presented is, I believe, much more extensive than has hitherto been assembled. We can only determine the real brightness of a star when we know its distance; but the recent accumulation of direct measures of parallax, and the discovery of several moving clusters of stars the distances of which can be determined, put at our disposal far more extensive data than were available a few years ago.

Fig. 1 shows graphically the results derived from all the direct measures of parallax available in the spring of 1913 (when the diagram was constructed). The spectral class appears as the horizontal coordinate, while the vertical one is the absolute magnitude, according to Kapteyn's definition—that is, the visual magnitude which each star would appear to have if it should be brought up to a standard distance, corresponding to a parallax of 0·1″ (no account being taken of any possible absorption of light in space). The absolute magnitude, −5, at the top of the diagram, corresponds to a luminosity 7500 times that of the sun, the absolute magnitude of which is 4·7. The absolute magnitude 14, at the bottom, corresponds to 1/5000 of the sun's luminosity. The larger dots denote the stars for which the computed probable error of the parallax is less than 42 per cent. of the parallax itself, so that the probable error of the resulting absolute magnitude is less than ±1·0m. This is a fairly tolerant criterion for a "good parallax," and the small dots, representing the results derived from the poor parallaxes, should scarcely be used as a basis for any argument. The solid black dots represent stars the parallaxes of which depend on the mean of two or more determinations; the open circles, those observed but once. In the latter case, only the results of those observers whose work appears to be nearly free from systematic error have been included, and in all cases the observed parallaxes have been corrected for the probable mean parallax of the comparison stars to which they were referred. The large open circles in the upper part of the diagram represent mean results for numerous bright stars of small proper-motion (about 120 altogether) the observed parallaxes of which scarcely exceed their probable errors. In this case the best thing to do is to take means of the observed parallaxes and magnitudes for suitable groups of stars, and then calculate the absolute magnitudes of the typical stars thus defined. These will not exactly

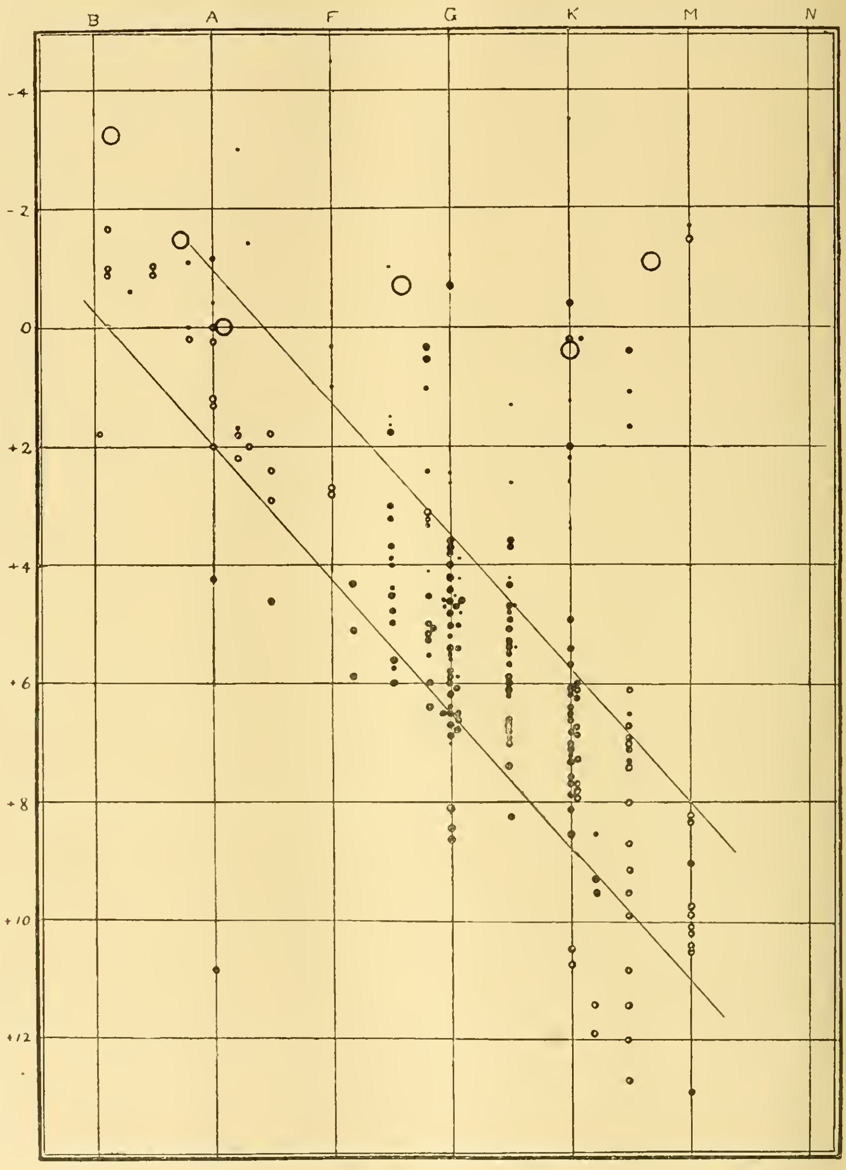

FIG. 1.

* An address delivered before a joint meeting of the Astronomical and Astrophysical Society of America and Section A of the American Association for the Advancement of Science, at Atlanta, Georgia, December 30, 1913, with a few additions, by Prof. H. N. Russell. Continued from p. 230.

correspond to the mean of the individual absolute magnitudes which we could obtain if we knew all the parallaxes exactly, but they are pretty certainly good enough for our purpose.

Upon studying Fig. 1 several things can be observed.

(1) All the white stars, of Classes B and A, are bright, far exceeding the sun; and all the very faint stars—for example, those less than 1/50 as bright as the sun—are red, and of Classes K and M. We may make this statement more specific by saying, as Hertzsprung does,[16] that there is a certain limit of brightness for each spectral class, below which stars of this class are very rare, if they occur at all. Our diagram shows that this limit varies by rather more than two magnitudes from class to class. The single apparent exception is the faint double companion to O_2 Eridani, concerning the parallax and brightness of which there can be no doubt, but the spectrum of which, though apparently of Class A, is rendered very difficult of observation by the proximity of its far brighter primary.

(2) On the other hand, there are many red stars of great brightness, such as Arcturus, Aldebaran, and Antares, and these are as bright, on the average, as the stars of Class A, though probably fainter than those of Class B. Direct measures of parallax are unsuited to furnish even an estimate of the upper limit of brightness to which these stars attain, but it is clear that some stars of all the principal classes must be very bright. The range of actual brightness among the stars of each spectral class therefore increases steadily with increasing redness.

(3) But it is further noteworthy that all the stars of Classes K5 and M which appear on our diagram are either very bright or very faint; there are none comparable with the sun in brightness. We must be very careful here not to be misled by the results of the methods of selection employed by observers of stellar parallax. They have for the most part observed either the stars which appear brightest to the naked eye, or stars of large proper-motion. In the first case, the method of selection gives an enormous preference to stars of great luminosity, and, in the second, to the nearest and most rapidly moving stars, without much regard to their actual brightness. It is not surprising, therefore, that the stars picked out in the first way (and represented by the large circles in Fig. 1) should be much brighter than those picked out by the second method (and represented by the smaller dots). But if we consider the lower half of the diagram alone, in which all the stars have been picked out for proper-motion, we find that there are no very faint stars of Class G, and no relatively bright ones of Class M. As these stars were selected for observation entirely without consideration of their spectra (most of which were then unknown) it seems clear that this difference at least is real, and that there is a real lack of red stars comparable in brightness with the sun, relatively to the number of those 100 times fainter.

The appearance of Fig. 1 therefore suggests the hypothesis that, if we could put on it some thousands of stars instead of the 300 now available, and plot their absolute magnitudes without uncertainty arising from observational error, we would find the points representing them clustered principally close to two lines, one descending sharply along the diagonal, from B to M, the other starting also at B, but running almost horizontally. The individual points, though thickest near the diagonal lines, would scatter above and below it to a vertical distance corresponding to at least two magnitudes, and similarly would be thickest near the horizontal line, but scatter above and below it to a distance which cannot so far be definitely specified, so that there would be two fairly broad bands in which most of the points lay. For Classes A and F these two zones would overlap, while their outliers would still intermingle in Class G, and probably even in Class K. There would, however, be left a triangular space between the two zones, at the right-hand edge of the diagram, where very few (if any) points appeared, and the lower left-hand corner would be still more nearly vacant.

We may express this hypothesis in another form by saying that there are two great classes of stars, one of great brightness (averaging, perhaps, a hundred times as bright as the sun), and varying very little in brightness from one class of spectrum to another; the other of smaller brightness, which falls off very rapidly with increasing redness. These two classes of stars were first noticed by Hertzsprung,[17] who has applied to them the excellent names of *giant* and *dwarf* stars. The two groups, on account of the considerable internal differences in each, are only distinctly separated among the stars of Class K or redder. In Class F they are partially, and in Class A thoroughly, intermingled, while the stars of Class B may be regarded equally well as belonging to either series.

In addition to the stars of directly measured parallax, represented in Fig. 1, we know with high accuracy the distances and real brightness of about 150 stars which are members of the four moving clusters the convergent points of which are known, namely, the Hyades, the Ursa Major group, the 61 Cygni group, and the large group in Scorpius, discovered independently by Kapteyn, Eddington, and Benjamin Boss, the motion of which appears to be almost entirely parallactic. The data for the stars of these four groups are plotted in Fig. 2, on the same system as in Fig. 1. The solid black dots denote the members of the Hyades; the open circles, those of the group in Scorpius; the crosses, the Ursa Major group; and the triangles, the 61 Cygni group. Our lists of the members of each group are probably very nearly complete down to a certain limiting (visual) magnitude, but fail at this point, owing to lack of knowledge regarding the proper motions of the fainter stars. The apparently abrupt termination of the Hyades near the absolute magnitude 7·0, and of the Scorpius group at 1·5, arises from this observational limitation.

The large circles and crosses in the upper part of Fig. 2 represent the absolute magnitudes calculated from the mean parallaxes and magnitudes of the groups of stars investigated by Kapteyn, Campbell, and Boss, concerning which data were given in Table III. The larger circles represent Boss's results, the smaller circles Kapteyn's, and the large crosses Campbell's.

It is evident that the conclusions previously drawn from Fig. 1 are completely corroborated by these new and independent data. Most of the members of these clusters are dwarf stars, and it deserves particular notice that the stars of different clusters, which are presumably of different origin, are similar in absolute magnitude. But there are also a few giant stars, epecially of Class K (among which are the well-known bright stars of this type in the Hyades); and most remarkable of all is Antares, which, though of Class M, shares the proper motion and radial velocity of the adjacent stars of Class B, and is the brightest star in the group, giving out about two thousand times the light of the sun.

16 *A. N.*, 4422, 1910.

17 *Zeitschrift für Wissenschaftliche Photographie*, vol. iii., p. 442, 1905.

It is also clear that the naked-eye stars, studied by Boss, Campbell, and Kapteyn, are, for the most part, giants. With this in mind, we are now in a position to explain more fully the differences between the results of these investigators.

All the stars of Class B are giants, and, so far as we may judge from the Scorpius cluster, they do not differ from one another very greatly in absolute brightness. It is therefore natural that the results of all three investigators are in this case fairly similar, though Campbell, in employing stars that averaged brighter to the eye than did the others, has evidently been working with stars that are really brighter. In Class A the giants and dwarfs differ so little, and are so thoroughly intermingled, that the situation is about the same. In Class M, even the nearest and brightest of the dwarf stars are invisible to the naked eye: hence the stars of this class studied by the three investigators are all giants, and once more their results agree.

A number of the dwarf stars of Class K are visible to the naked eye; but these all lie very near us, and have such large proper motions that they are excluded as "abnormal" by both Campbell and Boss. The results of the two agree in indicating that the stars studied by them are typical giants. The few dwarfs, however, have such large parallaxes and proper-motions that their inclusion more than doubles the mean proper-motion, and presumably, also, the mean parallax of the whole, as shown by Kapteyn's figures in Table III. For Class G, the dwarf stars average much brighter, and a much greater number of them is visible to the naked eye. These have large parallaxes and proper-motions, and raise the average for all the stars of this class to greater values than for any other. But Boss's rigorous limitation to small proper-motions weeds them practically all out, leaving giant stars once more. Campbell's less drastic procedure omits only the nearer of the dwarfs (to be precise, those with the larger proper-motions), and his result lies about half-way between the others. In the case of Class F, the dwarf stars are still brighter—intermingling, in fact, with the giants. We can therefore see them farther off, and we get more of them in our catalogues, in proportion to the giants, than in any other class. Their mean parallax is, however, smaller than for the dwarfs of Classes G and K, and hence the mean proper-motion and parallax of all the stars of this class is less than for Class G. Campbell's criterion here excludes very few stars, and even Boss's admits a good many of the remoter and slower moving dwarfs, causing his mean parallax and proper-motion to be considerably greater for this class than for any other.

It should finally be added that Kapteyn's discussion shows that the stars of Class N are exceedingly bright, possibly surpassing any of the other giant stars.

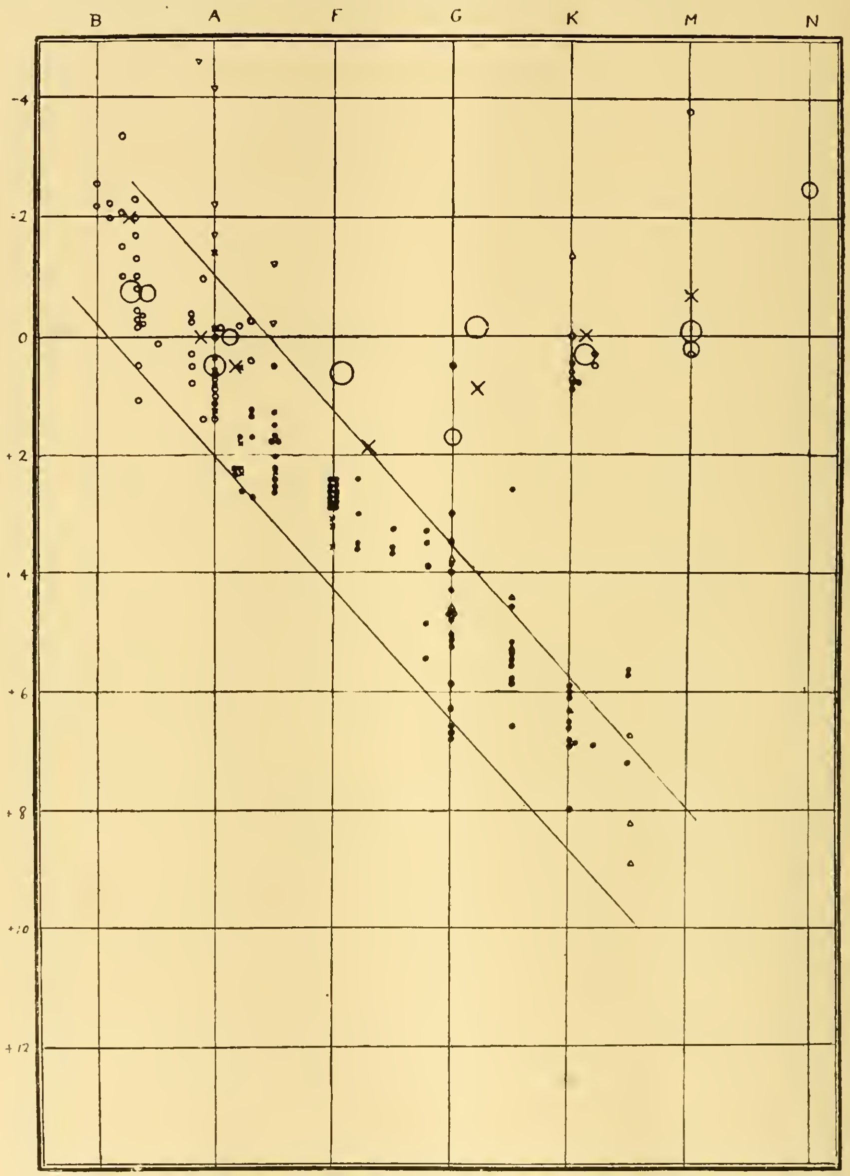

Fig. 2.

We are now in a position to define more precisely the brightness of a typical giant or dwarf star of a given class of spectrum, and also to obtain a measure of the degree of divergence of the individual stars from this typical brightness. Taking first the stars of Class B and the dwarf stars of the other classes, we find, for the mean absolute magnitudes of all the stars of each class, the following values :—

TABLE V.
Mean Absolute Magnitudes.

Spectrum	Stars of measured parallax No.	Abs. mag.	Formula	O–C	Stars in clusters No.	Abs. mag.	Formula	O–C
				m.				m.
B2	—	—	—	—	21	−1·2	−1·1	−0·1
B8	—	—	—	—	8	+0·3	+0·2	+0·1
A0	6	+1·4	+1.4	0·0	13	0·5	0·6	−0·1
A4	7	2·5	2·3	+0·2	26	1·7	1·5	+0·2
F0	—	—	—	—	15	2·4	2·7	−0·3
F1	5	4·2	3·7	+0·5	—	—	—	—
F3	—	—	—	—	7	3·3	3·3	0·0
F5	9	4·3	4·5	−0·2	—	—	—	—
F8	8	5·1	5·2	−0·1	5	4·2	4·4	−0·2

G5	19	5·7	6·6	−0·9	9	5·1	5·8	−0·7
K0	28	7·1	7·7	−0·6	9	6·4	6·9	−0·5
K4	19	9·2	8·6	+0·6	7	+7·0	+7·7	(−0·7)
Ma	10	+9·9	+9·8	+0·1	—	—	—	—

The rate of decrease of brightness with increasing redness is very nearly the same for the stars with directly measured parallaxes and the stars in clusters, but the latter appear, with remarkable consistency, to be about 0·8m. brighter than the former. This seems at first sight very puzzling, but it is undoubtedly due to the way in which the stars observed for parallax were selected. Most observers, in preparing their working lists, have included mainly those stars which were brighter than a given magnitude and had proper-motions exceeding some definite limit. Of the stars above this limiting magnitude, those of greater actual luminosity will be, on the average, farther away, and have smaller proper-motions, than those of small luminosity, and selection by proper-motion favours the latter. The limitation of our present lists to stars the parallaxes of which have been determined with a probable error not exceeding 42 per cent. of their own amounts, though necessary to diminish the effects of casual errors of observation, works in the same direction, for, among the stars of any given visual magnitude, those of greatest luminosity have the smallest parallaxes, and are least likely to pass the test. The difference shown in our table need not therefore alarm us, but it is clear that the stars in clusters, rather than the others, should be taken as typical of the dwarf stars as a whole. For both sets of stars the absolute magnitude appears to be very nearly a linear function of the spectral class (if B is regarded as 1, A as 2, etc.) The columns headed "formula" in Table V. give the values calculated from the expressions M = 1·4m. + 2·1m. (Sp. − A) for the stars of directly measured parallax, and M = 0·6m. + 2·1m. (Sp. − A) for the stars in clusters. The residuals from these empirical formulæ, for the mean absolute magnitudes of the observed stars of different classes, average ±0·33m. in the first case and ±0·29m. in the second. They appear to be accidental in character, though in some cases (notably in Class G5) the residuals for the stars of the two sets are similar in sign and magnitude. The large negative residuals for Classes K and K5 in the clusters arise from the fact that in the Hyades, which contribute most of these stars, only the brighter ones have had their proper-motions determined, and get into our lists, as is clear from examination of Fig. 2.

Among the dwarf stars, therefore, a typical star of any spectral class is about seven times fainter than one of the preceding class, and seven times brighter than one of the following class.

The giant stars of all the spectral classes appear to be of about the same mean brightness, averaging a little above absolute magnitude zero, that is, about a hundred times as bright as the sun. Since the stars of this series which appear in Fig. 2 have been selected by apparent brightness, which gives a strong preference to those of the greatest luminosity, the average brightness of all the giant stars in a given region of space must be less than this, perhaps considerably so.

By tabulating the residual differences between the absolute magnitudes of the individual dwarf stars and the values given by the formulæ just described, we find that the average difference, regardless of sign, for the stars of measured parallax is ±0·88m. for spectra A to F8, ±1·02m. for spectra G and G5, and ±1·15m. for K and M. For the stars in clusters, the average differences are ±0·70m. for spectra B0 to B9, ±0·66m. for A and A5, ±0·56m. for spectra F to F8, and ±0·80m. for G and G5.

These differences are larger for the stars of measured parallax than for the others (probably on account of the greater average uncertainty of the individual parallaxes and spectra in this case), but show no marked systematic variation with the class of spectrum. Their distribution follows very approximately the law of accidental errors, as is shown by Table VI., in which the observed numbers lying between certain limits are compared with those given by this law

TABLE VI.
Distribution of Differences from the Typical Absolute Magnitudes.

Stars with measured parallax Limits	Observed	Theory	Stars in clusters Limits	Observed	Theory
m. m.			m. m.		
±0·0 to ±0·8	65	61	±0·0 to ±0·5	59	58
±0·8 to ±1·6	41	44	±0·5 to ±1·0	42	42
±1·6 to ±2·4	21	23	±1·0 to ±1·5	21	24
±2·4 to ±3·2	10	9	±1·5 to ±2·0	10	8
±3·2 to ±4·0	3	3	±2·0 to ±2·5	4	4

The theoretical distribution for the stars in clusters corresponds to a probable error of ±0·61m., and that for the others to one of ±0·94m. Correction for the known influence of uncertainties of the parallaxes and spectra would reduce the latter to about ±0·75m. It appears, therefore, that the absolute magnitude of a dwarf star can be predicted with surprising accuracy from a mere knowledge of its spectrum. Half of all the dwarf stars are not more than twice as bright or as faint as the typical stars of their spectral classes. The corresponding uncertainty in the estimated parallax would be about one-third of its amount.

The parallaxes of the giant stars are so small, in comparison with the errors of even the best present methods of observation, that direct observations are not well adapted to determine to what degree they differ in brightness among themselves. An indirect method of determining this is, however, practicable, among those classes in which all the naked-eye stars are giants, by comparing the parallactic motions of those stars the proper-motions of which at right angles to the direction of the parallactic drift are large and small. A discussion by this method of the typical case of Class M (the details of which will be given elsewhere) shows that, if the distribution of the absolute magnitudes of these stars also follows the "law of errors," the probable error corresponding to it is approximately ±0·6m.—almost exactly the same as has already been found for the dwarf stars. The mean absolute magnitude of all the stars of this class which are visible to the naked eye is −0·5, and that of all the stars in a given region of space is +0·6. This method can scarcely be applied to the naked-eye stars of the other spectral classes (unless some way can be devised for weeding out the dwarf stars from among the giants); but it seems probable that they do not differ greatly from the stars of Classes B and M as regards the degree of their similarity to one another in brightness With such a probable error of distribution of the absolute magnitudes as has here been derived, the giant and dwarf stars would overlap perceptibly in Class G, be just separated in Class K, and widely so in Class M, as the observational data indicate.

The questions now arise: What differences in their nature or constitution give rise to the differences in brightness between the giant and dwarf stars? and Why should these differences show such a systematic increase with increasing redness or "advancing" spectral type?

We must evidently attack the first of these questions before the second. The absolute magnitude (or the actual luminosity) of a star may be expressed as a function of three physically independent quantities—its mass, its density, and its surface-brightness. Great mass, small density, and high surface-brightness make for high luminosity, and the giant stars must possess at least one of these characteristics in a marked degree, while the dwarf stars must show one or more of the opposite attributes.

A good deal of information is available concerning all these characteristics of the stars. The masses of a considerable number of visual and spectroscopic binaries are known with tolerable accuracy, the densities of a larger number of eclipsing variable stars have recently been worked out, and the recent investigations on stellar temperatures lead directly to estimates of the relative surface brightness of the different spectral classes (subject, of course, to the uncertainty whether the stars really radiate like black bodies, as they are assumed to do). We will take these matters up in order.

First, as regards the masses of the stars, we are confined to the study of binary systems, which may or may not be similar in mass to the other stars. There appears, however, to be no present evidence at all that they are different from the other stars, and in what follows we will assume them to be typical of the stars as a whole.

The most conspicuous thing about those stellar masses which have been determined with any approach to accuracy is their remarkable similarity. While the range in the known luminosities of the stars exceeds a millionfold, and that in the well-determined densities is nearly as great, the range in the masses so far investigated is only about fiftyfold. The greatest known masses are those of the components of the spectroscopic binary and eclipsing variable V Puppis, which equal nineteen times that of the sun; the smallest masses concerning which we have any trustworthy knowledge belong to the faint components of ζ Herculis and Procyon, and are from one-third to one-fourth of the sun's mass. These are exceptional values, and the components of most binary systems are more nearly similar to the sun in mass.

There appears, from the rather scanty evidence at present available, to be some correlation between mass and luminosity. Those stars which are known to be of small mass (say, less than half the sun's) are all considerably fainter than the sun. On the other hand, Ludendorff[18] has shown conclusively that the average mass of the spectroscopic binaries of spectrum B (which are all of very great luminosity) is three times as great as that of the spectroscopic binaries of other spectral types, and may exceed ten times that of the sun. Further evidence in favour of this view is found in the fact that the components of a binary, when equal in brightness, are nearly equal in mass, while in unequal pairs the brighter star is almost (if not quite) always the more massive, but the ratio of the masses very rarely exceeds 3 : 1, even when one component is hundreds of times as bright as the other. Very large masses (such as one hundred times the sun's mass) do not appear, though they would certainly be detected among the spectroscopic binaries if they existed. It is equally remarkable that there is no trustworthy evidence that any visible star has a mass as small as one-tenth that of the sun. The apparent exceptions which may be found in the literature of the subject may be shown to arise from faulty determinations of parallax, arbitrary estimates of quantities unobtainable by observation (such as the ratio of the densities of the two components of Algol), and even numerical mistakes.

[18] *A. N.*, 4520, 1911.

It follows from this similarity of mass that we can obtain a very fair estimate of the parallax of any visual binary (called by Doberck the hypothetical parallax) by guessing at its mass, and reversing the familiar relation between mass and parallax. If we assume that the mass of the system is twice that of the sun (about the average value), our hypothetical parallaxes, as the existing evidence shows, will usually be well within 40 per cent. of the truth, and the deduced absolute magnitudes of the components will rarely be more than one magnitude in error. We may thus extend our study of the relation between absolute magnitude and spectrum to all the visual binaries for which orbits have been computed. The hypothetical absolute magnitudes which we will obtain for them will indeed be somewhat in error, owing to the differences in their masses; but, for our present purpose, *the hypothetical values are actually more useful than the true values would be.* This sounds remarkable; but it is easy to show that, if we assume that the brighter components of the systems have all the same mass (say that of the sun), the resulting hypothetical absolute magnitudes will be the actual absolute magnitudes of stars identical in density and surface-brightness with the real stars, but all of the assumed mass. In other words, *the effects of differences of mass among the stars are eliminated from these hypothetical absolute magnitudes,* leaving only those of differences in density and surface-brightness. (This is simply a statement in different form of a theorem which has been known for many years.) It is therefore desirable to extend our study to as many binary stars as possible. The number for which binary orbits have been computed is relatively small, but by a simple statistical process we may include all those pairs which are known to be connected really physically, however slow their relative motion may be.[19]

Consider any pair of stars, of combined mass m times that of the sun, at a distance of r astronomical units, and with a relative velocity of v astronomical units per annum. By gravitational theory, we have

$$v^2r=(2\pi)^2m(2-r/a)=39{\cdot}7m(2-r/a),$$

where a is the semi-major axis of the orbit Now let π be the parallax of the system, s the observed distance in seconds of arc, w the observed relative motion in seconds of arc per annum, and i_1 and i_2 the angles which r and v make with the line of sight. Then $s=r\pi\sin i_1$, $w=v\pi\sin i_2$, and our equation becomes

$$sw^2=39{\cdot}7\pi^3m\sin i_1\sin^2 i_2(2-r/a).$$

In the individual case, the last three factors of the second member are unknown, and we are no wiser

[19] An outline of this method was given by the speaker at the meeting of the Astronomical and Astrophysical Society of America at Ottawa, August 25, 1911, and published in *Science*, N.S., vol. xxxiv., pp. 523–25, October 20, 1911. A similar method was worked out quite independently and almost simultaneously by Hertzsprung, and published in *A. N.*, December 19, 1911 (the date of writing being October 11, 1911).

than at the start; but the average value which their product should have, in a large number of cases, and the percentage of these cases in which it should lie within any given limits, may be computed on the principles of geometrical probability. It is thus found that the formula $\pi^3 = sw^2/14{\cdot}6m$ gives values for the hypothetical parallax the average for a large number of cases of which will be correct, and that, while in individual cases these values will be too large or too small, half of them will be within 19 per cent. of the true values, and the numbers of larger errors will fall off in very nearly the manner corresponding to this probable error. If we compute absolute magnitudes from these parallaxes, their average for all the stars will be a little too bright (since the cases in which the computed parallax comes out too small have more influence than those in which it is too large). This may be allowed for by adding 0·15m. to all the hypothetical magnitudes so computed—an amount almost negligibly small for our present purpose.

We thus obtain a series of hypothetical absolute magnitudes the average for a large number of cases of which will be correct. In 59 per cent. of the individual cases the error arising from the statistical process—that is, from the substitution of a mean value of

$$\sin i_1 \sin^2 i_2 (2 - r/a)$$

for the true value—will affect the deduced magnitude by less than $\pm 0{\cdot}5$m., and in 89 per cent. of all cases the error will not exceed $\pm 1{\cdot}0$m. The approximation is therefore quite sufficient for our purpose. It should, however, be noted that, while the error of the statistical process can never make the computed absolute magnitude of any star too faint by more than 1·5m., it may in rare cases make it too bright by any amount whatever—more than 2·0m. in one case in sixty, more than 3·0m. once in 250 cases, and so on.

We may now proceed to compute hypothetical absolute magnitudes for all the physical pairs which show even a trace of relative motion—including many which are ordinarily described as "fixed," but, on careful study of the observations, show very slow relative change. With the aid of the splendid collection of observational data contained in Burnham's great catalogue and other recent works on double stars, and of many observations of spectra made at Harvard in generous response to requests for information, it has been possible to derive results for more than 550 stars. Assuming that the brighter component of each of these (which is usually the only one of which the spectrum is known) is equal in mass to the sun, estimating that of the fainter component on the basis of the difference of brightness (with the data for the systems in which the mass-ratio is known as a sufficient guide), and proceeding as indicated above, we obtain the data plotted in Fig. 3. The co-ordinates have here the same meaning as in the previous diagrams, and the figure shows at a glance the relations which would exist between the absolute magnitudes and spectra of these 550 stars if all differences of mass were eliminated, leaving only those of density and surface-brightness operative. Binaries for which orbits have been computed are shown by solid dots, and physical pairs, to which the statistical process has been applied, by open circles.

FIG. 3

Our new diagram is strikingly similar in appearance to the previous ones, even in its minor details.

The two series of giant and dwarf stars appear once more; the giants are all of about the same brightness, except that those of Class B are brighter than the rest; the dwarf stars diminish in brightness by about two magnitudes for each spectral class; the two series overlap up to Class G and separate at Class K, and so on. We have clearly come, for the third time, and again from independent data, upon the same phenomena as before; and, with the more extensive observational material, some of the characteristics and relations of the two groups are shown better than ever.

But this new evidence does much more than to confirm that which we have previously considered—it proves that the distinction between the giant and dwarf stars, and the relations between their brightness and spectral types, do not arise (primarily at least) from differences in mass. Even when reduced to equal masses, the giant stars of Class K are about one hundred times as bright as the dwarf stars of similar spectrum, and for Class M the corresponding ratio is fully 1000. Stars belonging to the two series must therefore differ greatly either in surface brightness or in density, if not in both.

There is good physical reason for believing that stars of similar spectrum and colour-index are at least approximately similar in surface brightness, and that the surface brightness falls off rapidly with increasing redness. Indeed, if the stars radiate like black bodies, the relative surface brightness of any two stars should be obtainable by multiplying their relative colour-index by a constant (which is the ratio of the mean effective photographic wave-length to the difference of the mean effective visual and photographic wave-lengths, and lies usually between 3 and 4, its exact value depending upon the systems of visual and photographic magnitude adopted as standards). Such a variation of surface brightness with redness will evidently explain at least the greater part of the change in absolute magnitude among the dwarf stars (as Hertzsprung and others have pointed out), but it makes the problem of the giant stars seem at first sight all the more puzzling.

The solution is, however, very simple. If a giant star of Class K, for example, is one hundred times as bright as a dwarf star of the same mass and spectrum, and is equal to it in surface brightness, it must be of ten times the diameter and 1/1000 of the density of the dwarf star. If, as in Class M, the giant star is one thousand times as bright as the dwarf, it must be less than 1/30,000 as dense as the latter. Among the giant stars in general, the diminishing surface brightness of the redder stars must be compensated for by increasing diameter, and therefore by rapidly decreasing density (since all the stars considered have been reduced to equal mass).

But all this rests on an assumption which, though physically very probable, cannot yet be said to be proved; and its consequences play havoc with certain generally accepted ideas. We will surely be asked, Is the assumption of the existence of stars of such low density a reasonable or probable one? Is there any other evidence that the density of a star of Class G or K may be much less than that of the stars of Classes B and A? Can any other evidence than that derived from the laws of radiation be produced in favour of the rapid decrease of surface brightness with increasing redness?

We can give at once one piece of evidence bearing on the last question. The twelve dwarf stars of Classes K2 to M, shown in Fig. 3, have, when reduced to the sun's mass, a mean absolute magnitude of 7·8—three magnitudes fainter than the sun. If of the sun's surface brightness, they would have to be, on the average, of one-fourth its radius, and their mean density would be sixty-four times that of the sun, or ninety times that of water—which is altogether incredible. A body of the sun's mass and surface brightness, even if as dense as platinum, would only be two magnitudes fainter than the sun, and the excess of faintness of these stars beyond this limit can only be reasonably ascribed to deficiency in surface brightness. For the four stars of spectra K8 and M, the mean absolute magnitude of which, reduced to the sun's mass, is 9·5, the mean surface brightness can at most be one-tenth that of the sun.

(To be continued.)

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Cambridge.—The office of superintendent of the museum of zoology will shortly become vacant by the resignation of Dr. Doncaster. The stipend at present attached to the office is 200*l.* per annum.

Applications to occupy the University's table in the Zoological Station at Naples, and that in the laboratory of the Marine Biological Association at Plymouth should be addressed to Prof. Langley, The Museums, Cambridge, on or before June 4.

Mr. C. G. Darwin, eldest son of the late Sir George Darwin, has been appointed mathematical lecturer at Christ's College.

Glasgow.—It is announced that honorary degrees are to be conferred on Dr. Archibald Barr, late regius professor of civil engineering and mechanics in the University, Colonel Sir William B. Leishman, F.R.S., professor of pathology in the Royal Army Medical College, and Sir Ernest H. Shackleton, C.V.O. The degrees will be conferred on Commemoration Day, June 23, when an oration on Lord Lister will be delivered by Sir Hector C. Cameron.

London.—The Page-May Memorial Lectures for the current session will be delivered by Dr. Keith Lucas, whose subject will be "The Conduction of the Nervous Impulse." The course will be held at University College, on Fridays, beginning on May 15. The lectures are open to all internal students of the University of London and to such other persons as are specially admitted. Applications should be addressed to the secretary, University College, London (Gower Street, W.C.).

Oxford.—Congregation on May 5 passed a statute authorising the establishment of an additional professorship in chemistry, to be called Dr. Lee's Professorship of Chemistry. In the same Congregation the statutes providing for the establishment of Dr. Lee's Professorships of Anatomy and Experimental Philosophy, in place of the existing Lee's Readerships, passed their first stage. Should these statutes be finally approved, the University will be relieved of its present contribution of 1470*l.* towards the stipends of the professors of human anatomy and experimental philosophy, and will gain an additional professor of chemistry, the consequent charges being borne in all these cases by Christ Church.

The Halley Lecture for 1914 will be delivered by Colonel C. F. Close, director of the Ordnance Survey, at the Examination Schools at 8.30 p.m. on May 20. Subject, "The Geodesy of the United Kingdom."

The celebration of the seven hundredth anniversary of the birth of Roger Bacon will be held on Wednesday, June 10.

Brown University, Rhode Island, is to receive a visit in November next from Prof. W. H. Bragg, of Leeds University, who will deliver a course of four lectures on "X-Rays and Crystals."

DR. R. S. ROGERS, a graduate of Edinburgh University, has been appointed lecturer on forensic medicine in the University of Adelaide, and Dr. Swift succeeds Dr. W. T. Hayward as lecturer on clinical medicine in the same University.

THE committee of Livingstone College have decided to appoint Dr. L. E. Wigram to succeed Dr. C. F. Harford as principal of Livingstone College when the latter resigns his post at the end of July. Dr. Wigram was educated at Harrow School, Trinity College, Cambridge, and St. Thomas's Hospital, and he is a graduate in medicine and arts of the University of Cambridge. He was formerly a medical missionary at Peshawar, on the north-west frontier of India, under the Church Missionary Society.

IN the House of Commons on Monday, the Chancellor of the Exchequer explained his Budget proposals. The education grant is to be reconstituted on the principle of making a distinction between the richer and the poorer areas, and between the areas that spend much and those that spend little on education. The increased cost to the Exchequer of the education grant will be 2,750,000*l.*, but this year the grant will be confined to the necessitous school areas. The Government is to contribute one-half of the cost of the feeding of hungry school children, and also to make grants for physical training, open-air schools, maternity centres, and technical, secondary, and higher education. Referring to these grants, Mr. Lloyd George said:—"The grants for technical, secondary, and higher education are to make it more accessible to the masses of the children, and to extend its sphere of influence where children show any aptitude to take advantage of it. We compare very unfavourably with Germany and the United States of America in this respect. There there is adequate provision for technical training, secondary and higher training for every child who shows any special gift for taking advantage of it, and I consider that this fact is a greater menace to our trade than any arrangements of tariffs. We propose that there should be a very substantial grant for this purpose which will include a grant for pensions for secondary-school teachers in order to attract the best men to that most important profession. There will be a grant for the special training of teachers already in schools in subjects specially appropriate to rural areas, manual instruction, cookery, physical exercise, and commercial subjects. The total cost for the first year will be 560,000*l.* for these grants, and 282,000*l.* for the other grants which I mentioned. That will be for the first full year, and will be for England and Wales." There will be a special grant of 750,000*l.* for public health purposes in connection with tuberculosis, nursing, and pathological laboratories. Upon the subject of laboratories, Mr. Lloyd George said:—"Another deficiency has been exposed in our health service by the operation of the Insurance Act. There is no provision for the scientific diagnosis of disease. In Germany, in almost every town, and I think in France, you have pathological laboratories which are of enormous assistance to doctors in ascertaining the real character of a disease when they are in any doubt upon the subject. There are a few boroughs in the United Kingdom where something has been done—even in London—but we propose to make a grant for the purpose of aiding the local authorities to set up these laboratories throughout the United Kingdom."

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, April 30.—Sir William Crookes, O.M., president, in the chair.—Prof. B. **Moore**: The presence of inorganic iron compounds in the chloroplasts of the green cells of plants, considered in relationship to natural photo-synthesis and the origin of life.—Dr. J. C. **Willis**: The lack of adaptation in the Tristichaceæ and Podostemaceæ.—R. P. **Gregory**: The genetics of tetraploid plants in *Primula sinensis*. The paper describes results of experiments with two giant races of *Primula sinensis*, which have been shown to be in the tetraploid condition—that is, the plants have $4x$ (48) chromosomes in the somatic cells and $2x$ (24) chromosomes in the gametic cells, whereas in the ordinary (diploid) races of the species the numbers are $2x$ (24) and x (12) respectively. The result of most general interest is the discovery that reduplication of chromosomes has been accompanied by reduplication of series of factors, so that, whereas in the diploid zygote each factor is represented twice, AA; in the tetraploid zygote it is represented four times, AAAA; and there are three distinct hybrid types, namely, AAAa, AAaa, and Aaaa. The reduplication is made manifest by the occurrence of F_2 ratios in the form 15D : 1R, when in the diploid races the ratio is 3D : 1R. This result recalls those obtained by Nilsson-Ehle in oats and wheat, and by East in maize, but in the tetraploid Primulas the reduplication affects not merely the factors for isolated characters, but all the factors which it has been possible to study.—J. A. **Gunn**: The action of certain drugs on the isolated human uterus. It has been found that the involuntary contractile tissues (such as the heart, intestine, and uterus) of *mammals* can be kept exsected in Locke's solution at ordinary room temperatures for many hours, while still retaining the power of executing normal rhythmic movements when subsequently placed, under the proper conditions, in oxygenated Locke's solution at body temperature. With this knowledge, it is possible, without difficulty, to perform experiments on certain isolated human tissues, removed in the course of surgical operations; and those experiments can be made under similar conditions to, and therefore entirely comparable with, experiments made on corresponding tissues of those mammals ordinarily used for investigation. In this paper this method of investigation has first been utilised to determine the response of the isolated human uterus to certain drugs.—D. J. **Lloyd**: The influence of osmotic pressure upon the regeneration of *Gunda ulvae*. *G. ulvae* is capable of living indefinitely in water having an osmotic pressure of more than 2 and less than 33 atmospheres. The rate of regeneration of the posterior end in *G. ulvae* depends on the osmotic pressure of the medium. This osmotic pressure has an optimum value for regeneration at 18 atmospheres, *i.e.* just below that of sea-water, and limiting values at 5 and 33·5 atmospheres. Restoration of lost parts in *G. ulvae* is brought about entirely by the undifferentiated parenchyma cells which migrate to the region of the wound and build up the lost parts.—Surg.-Gen. Sir D. **Bruce**, Major A. E. **Hamerton**, Capt. D. P. **Watson**, and Lady **Bruce**: (*a*) *Glossina brevipalpis* as a carrier of trypanosome disease in Nyasaland. (*b*) Trypanosome diseases of domestic animals in Nyasaland. *Trypanosoma pecorum*. Part iii.—Development in *Glossina morsitans*.—H. E. **Armstrong** and H. W. **Gosney**: Studies on enzyme action. XXII.—Lipase. (IV.).—The correlation of synthetic and hydrolytic activity.

Zoological Society, April 21.—Dr. Henry Woodward, vice-president, in the chair.—Surgeon J. C. **Thompson**: Further contributions to the anatomy of the Ophidia.—Rev. T. R. R. **Stebbing**: Crustacea from the Falkland Islands. At intervals during a period of some fifteen years Mr. Rupert Vallentin has used prolonged opportunities for collecting, among other things, the crustacean fauna of the Falkland Islands. An initial report on this subject was made to the society in the year 1900. In January of the present year Dr. Thomas Scott, in the "Annals and Magazine of Natural History," has discussed some of the Copepoda. The contribution now offered has to do chiefly with the Malacostraca. Five new species are proposed.—J. S. **Huxley**: The courtship of the great crested grebe; with an addition to the theory of sexual selection.—S. **Hirst**: The Arachnida (other than spiders) and Myriopoda obtained by the British Ornithologists' Union and Wollaston Expeditions to Dutch New Guinea. The collection is only a small one, but contains two new species of Acari parasitic on mammals and three new species of millipedes. A new species of parasitic mite collected by Prof. F. Forster on various mammals in German New Guinea is also described.—Major J. Stevenson **Hamilton**: The coloration of the African hunting-dog (*Lycaon pictus*).—C. Tate **Regan**: Note on *Aristeus goldiei*, Macleay, and on some other fishes from New Guinea.—Miss A. **Carlsson**: Two species of fossil Carnivora, from the Phosphorites of Quercy, contained in the collections of the Zootomical Institute at Stockholm.

Challenger Society, April 29.—Prof. E. W. MacBride in the chair.—Prof. E. W. **MacBride**: Conditions of cross-fertilisation in the sea. The factors hindering crossing between different species of Echinoderms were discussed.—C. Tate **Regan**: The distribution of antarctic fishes. It was pointed out that the distribution of coast fishes south of the tropics calls for the recognition of three zones—south temperate, subantarctic, and antarctic. The subantarctic zone includes the Magellan and Antipodes districts; the antarctic zone the Glacial and Kerguelen districts. Nearly all the antarctic fishes are Nototheniiformes, and nearly all the genera and species are peculiar to the zone; in the subantarctic zone Nototheniiformes are present, but there is also a number of south temperate types.

Dublin.

Royal Irish Academy, April 27.—Rev. J. P. Mahaffy, president, in the chair.—Rev. Canon **Lett**: A census catalogue of the mosses of Ireland. Part i. This paper gives a short account of all deceased botanists who have paid any attention to the mosses of Ireland, together with a note of all known publications on the subject, from the Rev. John Ray, whose synopsis (1690) is the earliest work in which Irish mosses are mentioned, down to the present day. The list given by the writer contains the names of 636 mosses indigenous to Ireland, and with each is given the first known and the latest records, together with the date and name of the collection.—W. D. **Haigh**: The Carboniferous volcanoes of Philipstown, in King's County. This paper deals with the small volcanic district of Croghan Hill, north of Philipstown, in King's County. In an area of about four square miles a number of volcanic necks breaks through the Carboniferous Limestone. The ash is interbedded with the limestone at and above the cherty zone which separates the Lower from the Middle Limestone. The volcanic activity was thus contemporaneous with the major outbursts in the Limerick district. The latter portion of the paper deals with the petrography of the igneous rocks, which consist chiefly of dolerites and basalts passing into the more basic variety, limburgite. Glomero-porphyritic structure is a common feature of these intrusive rocks.—A. C. **Forbes**: Tree growth (in connection with the Clare Island Survey). Although no plant worthy of the name of tree now exists on Clare Island, abundance of scrub, consisting of oak, birch, mountain ash, holly, hazel, willow, etc., occurs on the east side of the island, suggesting that at no very distant date woodland was more or less general both over Clare Island and the adjacent islands and mainland. Tree remains in the bogs show that pine and birch were originally common on the lower parts of the island, followed at a later date by oak, which is found under mountain peat up to an altitude of 400 ft. The disappearance of this woodland was primarily due to a lowering of the summer temperatures, and an increase of wind off the sea, probably brought about by a higher sea-level in recent times. The original forest flora of the island undoubtedly dates back to a time when a connection with the mainland existed on the south-east, which was probably not interrupted until oak, hazel, and other species had established themselves, and suppressed or took the place of the pine of an earlier period. The most remarkable omissions from the present forest flora of the island are ash and elder, the latter being not only common on the mainland, but difficult to eradicate from grazed or uncultivated land.—G. P. **Farran**: Tunicata and Hemichorda (in connection with the Clare Island Survey). The paper summarised the published records of the group, together with some additional records added in the course of the Clare Island Survey.

Paris.

Academy of Sciences, April 27.—M. P. Appell in the chair.—The **President** announced the death of Prof. Suess, foreign associate.—H. **Deslandres**: Experimental research of a solar electrical field. Stark has recognised a new effect of the electric field on the light emitted by the canal rays; the bearing of the Stark effect on the study of the solar radiations is fully discussed.—Fred **Wallerant**: The mobility of the molecules in a solid crystal. A crystal of potassium nitrate is fused between two glass plates and allowed to solidify. It is now heated to a temperature well below its melting point, and slightly compressed by pressure at one point of the plate. New crystals appear which grow at the expense of the original crystal, and there is no relation between the orientations of the new and the old crystals. From this the author is led to modify his views on the polymorphism of camphor, which he now holds to be trimorphic and not quadrimorphic.—F. **Becke** was elected a correspondant for the section of mineralogy in the place of the late M. Rosenbusch.—Henri **Chrétien**: A mirror astrolabe. The prism of the ordinary instrument is replaced by two mirrors placed at an angle of 60°, one being fully silvered and the other half silvered. The arrangement possesses the following advantages: homocentricity of the two rays, increase of power of definition, possibility of constructing large astrolabes cheaply, and the suppression of the difficulties arising from the want of homogeneity of the glass of the prisms.—J. **Clairin**: Certain systems of partial differential equations of the second order with two independent variables.—W. **Blaschke**: New evaluation of distances in functional space.—Marcel **Riesz**: An interpolation formula for the differential of a trigonometrical polynomial.—Bertrand **Gambier**: The surfaces susceptible of being formed in several different ways by the displacement of an invariable curve.—Louis **Roy**: The motion in three dimensions of indefinite viscous media.—F. **Jager**: The application of the method of Ritz to certain problems of mathematical physics, and in particular to the tides.—Léon and Eugène **Bloch**: A new absorption spectrum of oxygen in the extreme ultra-violet. The absorption of air in the extreme ultra-violet commences at a wave-length of 1957, and is shown by a spectrum of regular bands, most probably belonging to oxygen. It is shown that these bands are due to absorption and not to fluorescence.—Thadée **Peczalski**: The differential scale of temperatures.—André **Léauté**: The propagation of surges along a heterogeneous electric line.—Jean **Perrin**: The osmotic compressibility of emulsions considered as fluids with visible molecules. In a previous communication it has been shown that the gas laws apply to dilute emulsions composed of particles of the same magnitude. In the present paper this conception is applied to strong emulsions, making use of Van der Waals equation.—René **Constantin**: The experimental study of the osmotic compressibility of emulsions. The experimental work of the preceding paper. The work was done with uniform spherical grains of radius 0·33 μ. Instantaneous photographs were taken of a column of emulsion 3 μ to 5 μ thick, with a horizontal microscope, sufficient time, three to four days, having been allowed for a state of equilibrium. Up to a certain concentration the fluid follows the law of Van der Waals, but above 2·4 per cent. the internal pressure diminishes, corresponding to a repulsive action between the grains.—A. **Portevin**: Re-heating and annealing after tempering of the alloys of copper and tin and copper and zinc.—Georges **Baume**: Remarks on the mechanism of the chemical reaction.—Auguste **Conduché**: The action of chloroform on metallic sulphates. Method of preparation of anhydrous chlorides. At temperatures above 300° C. chloroform vapour converts the sulphates of various metals into the anhydrous chloride. The reaction with copper sulphate at 300° C. gives pure cupric chloride; other metals require a higher temperature.—Georges **Tanret**: An alkaloid extracted from *Galega officinalis*. The alkaloid is called galigine, and has the composition $C_6H_{13}N_2$. The base is crystalline, and gives crystallised salts. M. **Picon**: The preparation of pure butine. Pure butine (ethylacetylene) has been prepared by the action of ethyl iodide upon sodium acetylide in liquid ammonia at a temperature of $-40°$ C. It was purified by fractional distillation, boils at 8·3°, and melts at $-137°$ C. Its density at 11° C. was found to be 2·47, as against 2·41 theoretical.—M. **Lespieau**: Some derivatives of octadiine-2 : 6-diol-1 : 8. The addition products with bromine, iodine, and hydrogen are described. Hydrogen in the presence of platinum black gives a mixture of the saturated glycol and primary octyl alcohol.—E. **Léger**: The optical isomerides of homonataloin and of nataloin and their reciprocal transformations.—J. L. **Vidal**: Cultural experiments on the vine.—Jacob **Eriksson**: Rust in the seeds of cereals.—R. **Marcille**: The nitrogenous materials of grape must. Both fixed organic nitrogen and volatile ammoniacal or amino-nitrogen are present in relative and absolute proportions which are extremely variable. The quantities are sufficient to ensure regularity in the fermentation.—E. **Maurel**: The influence of climate and season on food requirements. The amount of food required becomes less as the external temperature rises, on account of the smaller heat losses by the skin.—Etienne **Rabaud**: Researches on telegony. From experiments on mice the author is inclined to conclude that telegony is a purely imaginary phenomenon.—Fred **Vlès**: Remarks on the spectral structure of hæmoglobin substances. There are indications that the bands given by this class of substances can be represented by a series similar to that shown by Deslandres to hold for the nitrogen bands.—M. **Vasticar**: The internal auditive region of Corti's organ.—C. **Laurent**: Nervous accidents produced at a distance by projectiles used in war. A discussion of the possibility of nervous diseases being produced by shock without actual wounds by the projectile.—Gabriel **Bertrand**: Silver as a possible stimulant of growth in *Aspergillus niger*. In connection with the effects of traces of zinc and others metals on the growth of moulds, the theory of toxic stimulation has been put forward. Silver salts are known to exert a poisonous action on moulds, and experiments are here described to see if there is a critical concentration at which silver salts exert a stimulating effect on the growth. At no concentration was a stimulating effect observed, and the author contends that the theory of toxic stimulation is improbable.—M. **Javillier**: The utility of zinc for the growth of *Aspergillus niger*, cultivated in deep media. It has been alleged that when this mould is cultivated in deep instead of in shallow layers the favourable effect of zinc vanishes. Experiments are described by the author proving that this is not the case.—Em. **Bourquelot** and M. **Bridel**: The biochemical synthesis of the α-monoglucoside of glycol, by the aid of α-glucosidase. Starting with a solution of *d*-glucose, glycol, and an aqueous extract of low yeast, only the monoglucoside was obtained. Its purification and properties are given in detail.—Charles **Jacob** and Paul **Fallot**: The geology of Montsech, in Catalonia.—F. **Roman**: The Rhinocerídæ of the Mainz basin.

DIARY OF SOCIETIES.

THURSDAY, May 7.

Royal Society, at 4.—Election of Fellows.—At 4.30.—(1) Some Calculations in Illustration of Fourier's Theorem; (2) The Theory of Long Waves and Bores: Lord Rayleigh.—Protection from Lightning and the Range of Protection afforded by Lightning Rods: Sir J. Larmor and J. S. B. Larmor.—Newcomb's Method of Investigating Periodicities and its Application to Brückner's Weather Cycle: Prof. A. Schuster.—The Flow in Metals subjected to Large Constant Stresses: E. N. da C. Andrade.—Eddy Motion in the Atmosphere: G. I. Taylor.—The Properties of Magnetically-shielded Iron as Affected by Temperature: Prof. E. Wilson.

Royal Institution, at 3.—The Last Chapter of Greek Philosophy: Plotinus as Philosopher, Religious Teacher and Mystic: The Very Rev. W. R. Inge.

Royal Society of Arts, at 4.30.—The Punjab Canal Colonies: Sir J. M. Douie.

Child Study Society, at 7.30.—Education in Early Childhood before School-Age: Miss E. A. Parish and Dr. W. P. Sheppard.

Linnean Society, at 8.—The Botany of the Utakwa Expedition in Dutch New Guinea: H. N. Ridley and Others.—The Genus Lernæodiscus, F. Müller: G. Smith.—The Botanic Gardens at Sibpur (Calcutta), and the Government Cinchona Plantations: Major Gage.—A New Natural Order of Flowering Plants: Tristichaceæ: Dr. J. C. Willis.—The Forced or Cultural Production of Free, Spherical Pearls; a Preliminary Note on a New Method: J. Hornell.—Some Terrestrial Isopoda from New Zealand and Tasmania; with the Description of a New Genus, Notoniscus: Prof. C. Chilton.

FRIDAY, May 8.

Malacological Society, at 8.—Description of a New Helicoid from the Red Crag, Ramsholt: B. B. Woodward and A. S. Kennard.—The Radula of British Helicids. IV.: Rev. E. W. Bowell.—(1) Five New Species of Melania from Yunnan, Java, and the Tsushima Islands; (2) Description of a New Species of Strophocheilus, from Peru: H. C. Fulton.

Alchemical Society, at 8.15.—Some Mystical Aspects of Alchemy: Dr. E. Severn.

Physical Society, at 8.—A Graphic Treatment of the Rainbow and Cusped Wave-fronts: W. R. Bower.—Gyrostatic Devices for the Control of Moving Bodies: Dr. J. G. Gray.

Royal Astronomical Society, at 5.—Baxendell's Observations of Variable Stars, III: U Cygni, R Delphini, S Delphini, T Delphini. Edited by H. H. Turner and Mary A. Blagg.—The Resolution of a Compound Periodic Function into Simple Periodic Functions; J. B. Dale.—The Periodogram Analysis of the Variations of SS Cygni: D. Gibb.—A System of Photographic Magnitudes for Southern Stars: J. Halm.—Note on the Double Star OΣ 137: W. S. Franks.—*Probable Paper:* The Nebular Line λ3729: J. W. Nicholson.

SATURDAY, May 9.

Royal Institution, at 3.—Bird Migration: Prof. C. J. Patten.

MONDAY, May 11.

Royal Geographical Society, at 8.30.—The Condition and Prospects of the Panama Canal: Dr. Vaughan Cornish.

Royal Society of Arts, at 8.—Some Recent Developments in the Ceramic Industry: W. Burton.

Society of Engineers, at 7.30.—Notes on the Water Supply of Greater New York: W. T. Taylor.

Royal Institution, at 3.—The Last Chapter of Greek Philosophy: Plotinus as Philosopher, Religious Teacher and Mystic: The Very Rev. W. R. Inge.

TUESDAY, May 12.

Royal Institution, at 3.—The Present State of Evolutionary Theory Prof. W. Bateson.

Royal Society of Arts, at 4.30.—The Singing of Songs: Old and New I.: Folk Songs: H. Plunket Greene.

Royal Anthropological Institute, at 8.15.—Colour Blindness and Race: Dr. W. H. R. Rivers.—Standing Stones and Stone Circles in Yorkshire: A. L. Lewis.

WEDNESDAY, May 13.

Royal Society of Arts, at 8.—Glass Painting in Medieval and Renaissance Times: J. A. Knowles.

Geological Society, at 8.—The Scandinavian Drift of the Durham Coast, and the General Glaciology of South-East Durham: C. T. Trechmann.—The Relationship of the Vredefort Granite to the Witwatersrand System: F. W. Penny.

THURSDAY, May 14.

Royal Society, at 4.30.—*Probable Papers:* The Various Inclinations of the Electrical Axis of the Human Heart. Ia.: The Normal Heart. Effects of Respiration: Dr. A. D. Waller.—Fossil Plants showing Structure from the Base of the Waverley Shale of Kentcky: Dr. D. H. Scott and Prof. E. C. Jeffrey.—The Controlling Influence of Carbon Dioxide in the Maturation, Dormancy, and Germination of Seeds. II.: Franklin Kidd.—The Cultivation of Human Tumour Tissue *in vitro:* D. Thomson and G. J. Thomson.—The Nutritive Conditions Determining the Growth of Certain Freshwater and Soil Protista: H. G. Thornton and G. Smith.

Royal Institution, at 3.—Identity of Laws in General and Biological Chemistry: Prof. Svante Arrhenius.

Concrete Institute, at 7.30.—Sand and Coarse Material and Proportioning Concrete: J. A. Davenport and Prof. S. W. Perrott.

Society of Dyers and Colourists, at 8.—Notes on the Chemistry of Starch and its Transformations: W. A Davis.—The Analysis of Malt Extracts: W. P. Dreaper.—Temperature and Concentration as Affecting Hydration and Soda Absorption during the Process of Formation of Cellulose Monofils: Clayton Beadle and H. P. Stevens.

RECENT EXTENSIONS OF THE QUANTUM HYPOTHESIS.

Die Theorie der Strahlung und der Quanten. Mit einem Anhange über die Entwicklung der Quantentheorie vom Herbst 1911 *bis zum Sommer* 1913. Edited by A. Eucken. Pp. xii + 405. (Halle a. S.: Wilhelm Knapp, 1914.) Price 18.60 marks.

A SHORT account was given in NATURE in November, 1911, of a meeting of the principal authorities on radiation questions held in the autumn of that year in Brussels, under the auspices of M. Ernest Solvay. The present work is the German edition of the papers read at that congress, together with the discussions which took place on them. In the course of the last two years the subject has developed very considerably, and the opinions expressed at Brussels would only give a very incomplete view of the present state of the theory, but this defect has been corrected by the editor, Prof. Eucken, who provides at the end of the book a fairly detailed sketch of the chief advances up to the summer of 1913.

This section provides extraordinarily interesting reading. Though no solution has yet been found of the central problem, several new phenomena have been brought under the quantum *régime*, and the position of the theory of specific heats under that *régime* has been completely altered. The older theory of Einstein and Nernst (an account of which is given in the earlier part of the book), supposed that every atom in a solid vibrates with a certain definite frequency, and so by the quantum principle can only take up energy in certain definite amounts. The resulting value for the specific heat agrees only very roughly with experiment at low temperatures. The new theory, developed independently by Debye and by Born and Kármán, applies the quantum principle not to the separate atoms, but to the elastic waves which can be propagated through the body. The agreement with experiment is very greatly improved, and there can be little doubt that the work provides the right basis for a theory, though the mathematical difficulties have so far prevented its being worked out completely. Debye's application of the quantum principle directly to waves instead of merely to vibrating electrons is one of the most important changes of aspect which have come over the subject. Since energy in a wave is not localised in one spot, the new aspect makes the physical comprehension of the quantum even harder than it was before, but in spite of this there is a gain in generality, and it should probably be counted as a distinct advance towards the final elucidation of the problem.

Another question which has become very prominent is "Nullpunktsenergie"—residual energy at the absolute zero of temperature. This first arose in connection with Planck's second radiation hypothesis, according to which a vibrating electron absorbs energy following the ordinary laws, but can only emit it when its total energy has reached one of a definite series of values. Thus near the absolute zero a vibrator may have quite a finite amount of energy, since it cannot emit at all the energy which it is slowly absorbing. According to a very important paper by Poincaré—almost his last published work—there is grave difficulty in accounting for the observed radiation formula in this way; but in spite of this the question of residual energy has been the subject of a good deal of discussion, and it has been invoked with some success though in a very speculative way, to account for several phenomena. In considering the evidence on these points Prof. Eucken concludes that each separate one might be explained in another way, but that the sum of all gives some probability in favour of the existence of residual energy at the absolute zero. According to a suggestion of Debye the reflection of X-rays may be made to throw light on this, since it may be possible to discover in what way the atoms of the reflecting crystal vibrate. So perhaps this important question may be decided soon.

The most striking development, to which Prof. Eucken refers, is the application of the quantum to the rotation of gas-molecules. Hitherto it had only met with success when applied to vibrations. In a rotating gas-molecule we have a periodic, but not a vibrational motion, and it must be of fundamental importance that the quantum applies to this. The most remarkable result of all is the work of Eva von Bahr, who finds that the absorption of infra-red light by water-vapour may be taken to indicate that the molecules are rotating only with multiples of two definite angular velocities. By the use of the quantum it is possible to calculate two moments of inertia for the molecule, and the values deduced are of the size which would be expected from its known dimensions. When further developed this work may be expected to throw light not only on the meaning of the quantum, but also on the structure of the molecule.

It is unfortunate that the book came out just too early to include a mention of Bohr's theory of spectra. This theory is very speculative, but unlike any of the previous theories it does give a simple reason for the observed series in spectra. Perhaps his most striking result is the theoretical evaluation of Balmer's constant with extraordinary closeness from Planck's constant and the electron constants. Bohr's work may prove very valuable in the solution of the central problem of the quantum; for it has the merit of carrying the principle of Planck, already hard to understand physically, logically to a very extreme point, and it is by the accentuation of difficulties that their solution is usually brought about.

It would be impossible within the limits of this notice to discuss the rest of the book adequately. It is sufficient to say that it deals with all the more firmly established developments in this branch of physics, and that the names of the writers are a guarantee of its value. C. G. D.

BOOKS ON PLANT DISEASES.

(1) *The British Rust Fungi.* By W. B. Grove. Pp. xii+412. (Cambridge: University Press, 1913.) Price 4*s*. net.

(2) *Mildews, Rusts, and Smuts.* By George Massee, assisted by Ivy Massee. Pp. 229+iv plates. (London: Dulau and Co., Ltd., 1913.) Price 7*s*. 6*d*. net.

(3) *The Fungi which Cause Plant Disease.* By Prof. F. L. Stevens. Pp. viii+754. (New York: The Macmillan Co.; London: Macmillan and Co., Ltd., 1913.) Price 17*s*. net.

(1) THE twenty-four years which have elapsed since Dr. Plowright published his classic monograph of the British Uredineæ and Ustilagineæ have seen great progress in our knowledge of the biology and classification of the former group—the rusts. Their heterœcism was a recognised fact; the life-history of *Puccinia graminis* was familiar to most botanical students, but the subject has broadened considerably in the last quarter of a century; *P. graminis* itself has been shown to include several species easily separable by form and colour; and, further, biological differences have been demonstrated, embodying a close adaptation between fungus and host, and the recognition of "physiological races." In this connection Mr. Grove utters his protest against the excessive multiplication of "species" by "biological" nomenclators:—"Physiological unaccompanied by morphological distinctions should never be allowed to constitute a difference of species, unless it be as a temporary measure in cases which have not been investigated." The difficulty arising in the case of heterœcious species from the existence of distinct names for the various phases of the same species has been overcome by the rule agreed to at the Brussels Congress to give preference to the earliest name given to the perfect (in this case the teleutospore) stage.

The book consists of a general and a systematic part. The former comprises a useful account of the variously complicated life-history of the Uredinales, *Puccinia caricis,* the nettle and sedge rust, a species more accessible to students than *P. graminis,* the aecidum stage of which is now rarely found in this country, is taken as a general type, but full accounts of other species are also given. A chapter on the sexuality of the group supplies a review of the work done in recent years by Blackman and others, and its important bearing on the systematic relationships and phylogeny of the group. A chapter on specialisation gives some account of the "biological races" above mentioned, and also severely criticises the mycoplasma theory of Eriksson. There is also a discussion of the phylogeny of the group and of the reasons for deriving it from the red algæ.

The systematic portion contains working descriptions of about 250 species, representing twenty-two genera and five families. The species in the larger genera, Uromyces (38 species) and Puccinia (137 species) are arranged in the order of the families and genera of their host-plants. An adequate synonymy is given, and the spores of a large proportion of the species are figured. At the end of the text are a short glossary, a bibliography, an index of host-plants, and a general index.

(2) In the small volume, "Mildews, Rusts, and Smuts," the author supplies in handy form a synopsis of the families Peronosporaceæ, Erysiphaceæ, Uredinaceæ, and Ustilaginaceæ in so far as the species have been met with in Britain as parasites on native or cultivated plants, or are likely to occur, in so far as they are parasitic on host-plants, indigenous to this country. Some of the latter, by the way, have already arrived. The many years which Mr. Massee has devoted to the study of British fungi should be a guarantee of value and of accuracy, and students of our native fungus-flora from an economic or purely scientific point of view will find the book a useful companion. Keys are given to the genera and species, and under each species there is an ample description and a list of host-plants. The numerous species of Puccinia are arranged under the orders and genera of the host-plant or one of the host-plants, a method which is sometimes misleading. Thus the well-known hollyhock fungus, for instance, will not be found under Althæa, but under Malva, and in the heterœcious species one host only is cited, that bearing the teleutospores. A coloured illustration of the life-history of *Puccinia graminis* makes an attractive frontispiece, and there are also four black and

white plates, mainly illustrating spore-forms at the end of the book.

(3) Dr. Stevens's book is a systematic descriptive account of the fungi which cause diseases of economic plants in the United States, and to some extent a companion volume to his "Diseases of Economic Plants," in which the effect of the disease on the host-plant and methods of prevention and cure are described. The term "fungi" is used in a broad sense, and includes myxomycetes and bacteria, as well as true fungi. Under the myxomycetes the author includes the parasitic plasmodiophorales; otherwise this group is a saprophytic one, and innocuous apart from occasional injury owing to the plasmodium overgrowing other plants. The chapter on bacterial disease is also a short one, and the great bulk of the volume deals with parasitic fungi. The arrangement is under the three classes: phycomycetes, ascomycetes, and basidiomycetes, followed by the fungi imperfecti. Under each class keys are given to the orders and families, and class, order and family are concisely described. A key to the genera follows the description of each family. Individual species are described at varying length according to their importance, and many which are not yet known in the United States are briefly mentioned, especially the more important, or those which are likely to invade America. There are text-illustrations of most of the species, and each section is followed by an extensive bibliography; there is also a good glossary at the end of the volume.

MECHANICAL AND CHEMICAL ENGINEERING.

(1) *The Principles of the Application of Power to Road Transport.* By H. E. Wimperis. Pp. xiv+130. (London: Constable and Co., Ltd., 1913.) Price 4*s.* 6*d.* net.

(2) *Farm Gas Engines.* By Prof. C. F. Hirshfeld and T. C. Ulbricht. Pp. vii+239. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1913.) Price 6*s.* 6*d.* net.

(3) *The Diesel or Slow-combustion Engine.* By Prof. G. James Wells and A. J. Wallis-Tayler. Pp. xvi+286. (London: Crosby Lockwood and Son, 1914.) Price 7*s.* 6*d.* net.

(4) *Cement, Concrete, and Bricks.* By Alfred B. Searle. Pp. xi+412. (London: Constable and Co., Ltd., 1913.) Price 10*s.* 6*d.* net.

(1) IN this work Mr. Wimperis has made available in an expanded form the substance of a series of lectures delivered in 1913 at the Finsbury Technical College on the application of power to road transport. In the chapter devoted to the measurement of power, the author describes fully the principles of construction, and the method of using the ingenious accelerometer, which he invented in 1909; by means of this instrument many measurements have now been made of the tractive effort exerted in moving motor-cars and wagons at various speeds, both on the level and on grades, and thus valuable experimental data have been accumulated as a basis for the design of motor vehicles. In a later chapter Mr. Wimperis shows by actual examples how the data obtained by such an instrument and from bench tests of engines may be utilised to design a motor vehicle from prescribed conditions; both motor wagons and touring cars are dealt with, and this chapter should prove of great assistance to designers of motor-cars.

In appendix ii. the author has reprinted the report on the brake horse-power tests carried out at Brooklands in July, 1912, and discusses the values obtained for the brake mean pressure, and the effects of air resistance. Mr. Wimperis has produced a notable little book, of interest to the amateur and of value to the expert.

(2) In this book the authors have attempted the somewhat difficult task of acting as a guide to the farmer who proposes to purchase an internal combustion engine for any power purpose. Though the book is entitled "Farm Gas Engines," it is really mainly concerned with engines using liquid fuel, such as gasoline and kerosene. Of necessity but little theory is given, and the main part of the book is wisely devoted to discussions of the essential points in the design of the working parts of these engines. When a non-expert is considering the suitability of any particular type of engine for his purposes, there are certain details of construction to which he should devote especial attention, and on this matter excellent advice is given in this little book. Though practically only American types of farm engines are discussed by the authors, nevertheless the information and advice given in the chapters devoted to details of engine construction will be found useful by any British farmer who has already obtained, or thinks of obtaining, an internal combustion engine of any type.

(3) It is just twenty years since Dr. Rudolph Diesel published a pamphlet in which he dealt fully with the principles which must govern engine design when the object aimed at is to secure the maximum possible thermal efficiency, and now the Diesel engine has become such a serious rival of the steam engine that it has even been utilised for locomotive work; it is only natural, therefore, that special text-books should be devoted to the theory and construction of the

Diesel or slow-combustion oil engine, as the authors term it.

The authors, in addition to much original matter, have brought together into convenient form for reference the results of experimental work and the information in regard to constructive details published in the columns of the technical Press of the past ten years, or embodied in the numerous papers read before the leading engineering societies of the world; for this reason alone the book will prove invaluable both to the many engineering firms which now build these engines, and to the engineers who have installed them in power stations, factories, and ships.

The first four chapters deal with the theory of the laws of perfect gases, the work which can be obtained from a given volume of gas when expanding under given conditions, and the application of the well-known entropy diagrams to the study of the internal combustion engine. The next chapter deals with oil fuels suitable for these engines, their physical properties and methods of transport, and storage; in this connection the authors refer to the vast shale deposits in Australia, and to their utilisation for the production of oils for power purposes in that continent. In connection with the question of the cost of power generated by Diesel engines, it may be mentioned that in a test of a 200 b.h.p. two-cylinder four-stroke cycle engine, Mr. Eberle obtained under full load a thermal efficiency of 34·2 per cent. reckoned on the b.h.p., a wonderfully good result. In connection with the testing of Diesel engines the authors give some useful advice as to the care and attention necessary in order to maintain a high state of efficiency.

In view of the importance to designers of Diesel engines of a thorough knowledge of the theory and practice of air compression, the authors have wisely devoted a whole chapter to this subject, and have done their work admirably. The ninth chapter deals with the data and calculations needed in the design of cylinders, crankshafts, valves, flywheels, and reversing gears, while the concluding chapter is devoted to an account, well illustrated, of a number of recently-constructed Diesel engines for all classes of land and marine work; it is in connection with marine work that the greatest advance has taken place in the last two or three years. In an appendix the authors give a most useful abridgment of the principal patents connected with this remarkable motor and its developments.

(4) In this volume, which forms one of a series of text-books on the chemistry of the national industries, Mr. Searle deals with the three important building materials—cements, concrete, and bricks. The importance of a knowledge of chemistry in the manufacture of cement has been long recognised, and to this fact is due the great advance this industry has made during the past twenty years, but it is only recently that the value of chemical research to the brickmaker has been fully realised. In the first five chapters the author deals with cement, most attention being given naturally to Portland cement; he discusses fully the necessary properties of the raw materials, and the various methods of manufacture; Mr. Searle is of opinion that with equal care and skill both the older wet process and the modern dry process produce good results. The chemical and physical changes which occur both in the manufacture and in the setting of cements are most fully and thoroughly discussed, especially the chemical relations between the lime, alumina, and silica. In chapter v. the question of the testing of cement is taken up, the various methods adopted are fully explained, and the importance of cement-sand tests is clearly brought out, the author expressing his opinion that tensile tests of neat cement are largely futile; in dealing with the tests for soundness it is shown that this is a test which it is difficult to carry out with accuracy, and that, as a matter of fact, the majority of the Portland cements now on the market will pass all the ordinary tests for soundness.

Two chapters are devoted to the components of concrete and its preparation, and much excellent practical advice is given; then follows a chapter on reinforced concrete; the author points out that many of the formulæ now used in calculation work contain constants, which in the hands of the experienced man are safely used, but when used by a beginner may lead to serious blunders. The remainder of the book is devoted to brickmaking; the chemical and physical properties of the raw materials are fully discussed, the various processes of manufacture described, and the properties of finished bricks of various classes explained. Mr. Searle has written a thoroughly sound, valuable text-book, which ought to prove of great service to manufacturers, builders, and architects.

T. H. B.

OUR BOOKSHELF.

Lehrbuch der Paläozoologie. Teil ii., Wirbeltiere. By Dr. E. F. Stromer v. Reichenbach. Pp. ix+32. (Leipzig and Berlin: B. G. Teubner, 1912.) Price 10 marks.

The second part of Dr. Stromer's text-book of palæozoology deals with the fossil vertebrates in the same concise and philosophical manner as his previous account of the invertebrates. The descriptive sections comprise only just such conspicuous families and genera as are needed by a student who seeks a broad view of the subject; and at the end of the chapter on each class there is a brief summary of the leading features in the geological distribution and evolution of the class as a whole, with a table of diagnoses of its larger subdivisions. A useful list of the principal papers and books published during the last few years is also appended. The text throughout is well illustrated with drawings of more than usual artistic merit, and although the majority of them are taken, with acknowledgment, from various original works, Dr. Stromer himself has frequently amended them to bring them up-to-date. Some, indeed, are in advance of their formal publication, such as the drawing of the skeleton of the strange clawed ungulate mammal Moropus, contributed by Dr. W. J. Holland. So many are new to a text-book that their appearance is quite refreshing.

In a work designed for elementary teaching it is generally advisable to incline towards conservatism, and Dr. Stromer evidently holds this opinion. Among fishes, for instance, he still recognises the "orders" Ganoidei and Teleostei, though his so-called diagnoses do not define them; and his treatment of the early palæozoic Arthrodira and Ostracodermi is not altogether satisfactory from the modern point of view. His references to the literature, however, will enable the student to examine other views if he wishes to do so.

The last sixty pages of the book are devoted to the general principles of palæontology, and we can recommend this able summary to any zoologist who desires to understand the present position of those who study fossils. A. S. W.

A Treatise on Wooden Trestle Bridges and their Concrete Substitutes. By Wolcott C. Foster. Fourth revised and enlarged edition. Pp. xix + 440. (New York: John Wiley and Sons, Inc.; London: Chapman and Hall, Ltd., 1913.) Price 21*s.* net.

IN the present edition of this work, which was first published in 1891, will be found a very full account of the construction, erection, maintenance, and preservation of timber trestle bridges. The book is profusely illustrated, and contains working drawings showing the details of the standard trestles used on the principal American railroads. Wooden trestles may be disappearing gradually from main lines of heavy traffic, but the increased growth of branch lines, or feeders, and of trestles at manufacturing plants and for electric railways, have probably more than kept pace with its abandonment on main lines. There is, on the average, about 100 ft. of bridges and trestles to each mile of railroad in the United States. The wearing out of wooden trestles and the increasing cost and scarcity of timber suitable for their replacement has taxed the ingenuity of railroad officials to find suitable structures to take their place. In some cases iron or steel structures have been employed, but there are numerous districts where local conditions make these methods so expensive as to be prohibitive.

In the past few years a number of roads have used concrete trestles in replacing those constructed of timber, and the author gives full particulars of reinforced concrete trestles and slabs which form a structure closely in line with the main features of the timber trestle. The book provides a great deal of valuable information regarding the strength, durability, and preservation of timber under all kinds of practical conditions, and therefore will be of service to British engineers, despite the fact that timber bridges do not occur often on British railways.

Durch König Tschulalongkorns Reich. Eine deutsche Siam-Expedition. By Dr. Carl C. Hosseus. Pp. xii + 219 + plates. (Stuttgart: Stecker and Schroder, n.d.) Price 15 marks.

DR. C. C. HOSSEUS, who visited Siam in 1904–06, gives us in the present volume an account of his journey and scientific observations. The route lay up the Mäping, and at various halting-places excursions were made to the neighbouring country. Chiengmai appears to have been his chief base, and from there Doi Intanon, Chieng Dao, Pahombuk, and Chiengrai, to mention only a few of the more important, were visited.

Zoologists, geologists, ethnologists, geographers, and other naturalists will all find much to interest them in the book; for quite a casual glance through its pages will suffice to show that the author was ever on the alert to note points of interest in any branch of science. But it is undoubtedly to the botanist that the author has in the first place appealed.

Previous to this work the author had published lists of his botanical collections, so that here we have no complete catalogue, but references are given to the new species found and to many others interesting for some morphological detail or for their associations. Here it may be noted that the index, copious though it may appear, is not a complete index to all the plants mentioned.

A word of praise is due for the numerous excellent illustrations included at the end of the book. All who are interested in Asiatic botany must feel indebted to Dr. Hosseus, to whom must be attributed the credit of being the first scientific traveller and collector on a large scale north of Bangkok, for supplementing his previous lists with such an interesting book.

Biology: General and Medical. By Prof. Joseph McFarland. Pp. 457, with 160 illustrations. Second edition. (Philadelphia and London: W. B. Saunders Co., 1913.) Price 7*s.* 6*d.* net.

THE first edition of Prof. McFarland's book appeared in 1910, and was reviewed at length in the issue of NATURE for March 23, 1911 (vol. lxxxvi., p. 106). In the present edition the author has endeavoured to eliminate defects discovered in the book, and without much increasing its size to introduce the new matter necessary to bring it up to date.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* Nature. *No notice is taken of anonymous communications.*]

The Constitution of Atoms and Molecules.

Dr. van den Broek's letter (Nature, May 7, p. 241) contains one or two misapprehensions of the views put forward in my paper (*Phil. Mag.*, April, 1914), and I shall accordingly endeavour to make my meaning clearer. The paper does not purport to show that Dr. van den Broek's hypothesis is incorrect—in fact, in my own belief, it is fundamentally correct, though not necessarily in complete detail—but only to show that it is incompatible with the present form of Bohr's theory. Any atomic theory has two main things to explain in connection with optics—the X-ray spectra investigated by Moseley and the ordinary light spectra of atoms. The fact that coplanar rings are mathematically impossible is conclusive against them, whether on Bohr's theory or the present dynamical one. This must be admitted, in the face of any other evidence which appears to support them. There can be rings of electrons in an atom provided that they are not coplanar, but they must be of the same order of radius. There is only one case in which coplanar rings are possible—the case in which bound electrons *do not repel* each other, which is considered in detail in a paper to be published shortly, but such a supposition is in complete contrast to the present form of Bohr's theory.

As my letter to Nature pointed out, we do not require an inner ring in order to explain X-rays having lengths of the order 10^{-8}. They can come from an ordinary ring of atomic size if the nucleus is of strength 10 or more, and the Balmer lines can be considered as an X-ray spectrum of hydrogen. X-rays can even come from the confines of a structural nucleus. Many physicists have not yet realised that the size of the wave-length given by a ring bears no fundamental relation to its radius alone. The *angular velocity* of the ring is the important deciding factor. If we suppose that the frequency of a line is the frequency of the vibration of the ring about its steady rotation, dynamics shows that it is of the same order as the frequency of rotation, w. If C is the velocity of light, the wave-length is of order C/w, and a ring of *any* radius can give any wave-length if it rotates with the proper angular velocity. So also can any portion of a structural nucleus, and, coplanar rings being impossible, the X-rays can come from the nucleus. The wave-lengths on Bohr's theory are also determined by the order C/w, and not in any fundamental way by the radius, as may be seen by an examination of Bohr's mathematics.

Although it is the only published attempt, Bohr's theory does not constitute the only one which can be suggested to deal with Moseley's results. The writer has obtained, for example, a simpler explanation of them by more ordinary dynamics, which will shortly be published, by attaching a definite structure to the nucleus—a structure which can explain a great deal more in connection with such phenomena as the velocity of emitted α particles. In this method, the meaning of N is essentially the same as in Dr. van den Broek's hypothesis. The difference is in detail only. It is not possible to dispute Moseley's contention that there is a fundamental number which changes by steps of 1 in passing from one element to another in the table, nor that it is an "atomic number" related to the charge on the nucleus. But there is an assumption—perhaps correct—made in identifying it with the *exact* place occupied by an element in the table as we now know it, and Bohr's theory is incompatible with this assumption. For the paper showed that if the atomic number of lithium, for example, is 3, it must (1) have no valency on Bohr's theory, and (2) it must have all its electrons in one ring, or moving in a manner prohibiting any two of them from forming a ring. The radii of the orbits of the two inner electrons cannot be more nearly equal than in the ratio 12 to 1.

Again, as in another paper (*Monthly Notices of R.A.S.*, April, 1914), no approach to the ordinary helium spectrum can be obtained from Bohr's theory if the atomic number of helium is 2. These are only illustrations of much more decisive results. They have related, in the work published already, to the supposition that the laws of force between bound electrons are those used by Bohr. But they are equally valid for other laws of force. The one case in which the coplanar rings can exist—when bound electrons experience no force from each other—is the only avenue towards the extension of the theory. But it has difficulties, and, in particular, it gives no place to Moseley's constant b, which is then zero in all atoms. The K radiation then leads to the conclusion that the atomic number usually differs by 1 from the place of the element in the table. Dr. van den Broek lays stress on the fact that $N-b$ changes from one element to another, and not N. But we must repeat, quite definitely, that b is zero in the only modification of Bohr's theory which can have more than one coplanar ring. By this statement, however, we do not imply that b has no existence in fact. Its different values for K and L radiation demonstrate that it is real. The theory would demand an identity of these radiations even if they came from different rings, when such rings can exist. A reconciliation with experiment can only be obtained by putting the electrons as a constituent part of the nucleus itself, or by supposing that X-radiation comes from the confines of the atom—the K type from a neutral atom, and the L type perhaps from an atom which has lost an electron. But this latter alternative is quite at variance with Dr. van den Broek's hypothesis, when calculations are performed, and the first has no relation to Bohr's theory.

The strongest argument in favour of Dr. van den Broek is the recent generalisation of the periodic table put forward by Soddy and Fajans, against which mathematical considerations cannot be raised; in fact, they tend to support it. This generalisation, however, in no case demands a strict identity between the nucleus charge, and the place in the table. The other phenomena depending on the atomic number could depend equally well, within the order of accuracy, on a number which differed from it by 1 or 2. In conclusion, so far as the table is concerned, Dr. van den Broek may be completely correct, but, if so, Bohr's theory cannot be modified to take account of X-ray spectra. The periodic table, however, is not a sufficient test. Astrophysical spectra demand, as proved in many papers in the *Monthly Notices*, the existence of simple "elements" the spectra of which can be calculated, which not only agree with actual spectra, but also have actually led to the discovery of several lines which the formulæ predicted. The atomic weight of one of these, with 6 electrons, is 2·94, as calculated theoretically. By an application of their interference method to a line in nebulæ, MM. Bourget, Buisson, and Fabry (*Comptes rendus*, April 6, 1914) have verified this value for the mass of the atom which emits the line. They have also made preliminary experiments on another element, and found results which support the theoretical value of the atomic weight, 1·31. Very simple elements can exist therefore in which the atomic number differs from the number of electrons, and Dr. van den Broek's hypothesis cannot be a complete principle, although perhaps satisfactory for the stable terrestrial elements. Nevertheless, if it is satisfactory in this range, Bohr's theory is not. J. W. NICHOLSON.

Temperature-Difference between the Up and Down Traces of Sounding-Balloon Diagrams.

IN his paper on the daily temperature change at great heights (January issue of the Quart. Journal of the Roy. Met. Soc.), Mr. Dines deals with the double traces shown by the diagrams of registering-balloons. He ascribes the difference for a great deal to the heating effect of the balloons, as the instruments swim in the wake of dead but heated air that follows the ascending balloon.

He rejects as a possible cause any thermal lagging of the instrument, because the double trace is most apparent in the isothermal layer, and also because it mostly occurs by day and not by night.

Receiving this number of the Quart. Journal, it just happened that I had made a synopsis of this kind of temperature-difference for the Batavian ascents, which throws another light on this question.

At Batavia the balloons are of a larger type than those used in England; also the string between balloon and instrument is much longer, measuring 30 m. and more. Moreover, it has been observed in numerous cases that up to the greatest heights the whole system of balloon-parachute-instrument often swings strongly. Accordingly any heating effect by the air in the wake of the balloon seems most improbable.

The instruments are of the pattern usual on the continent and made by Bosch (Strassburg); they are provided with clockwork. When possible the heights have been calculated separately for the ascent and the descent; thus, when the downward temperatures were found to be lower than the upward, the corresponding heights became lower, and accordingly the difference of temperature for the same calculated height in the ascent and the descent was increased. In half of the thirty ascents which up to the present have been made, the balloon was liberated 1–1½ hours before, and in the other half 1–1½ hours after sunrise. Thus, in the first cases only the latter part of the descent took place at an hour that solar radiation begins to be active.

The mean differences found are:—

Temperature Higher in the Ascent than in the Descent.

Height in km.	Before sunrise °C.	After sunrise °C.	Number of cases Before	After
1	0·0	0·4	16	14
2	0·1	0·4	18	14
3	0·4	0·0	18	16
4	0·2	1·4	18	16
5	0·2	1·5	17	15
6	0·7	2·4	16	15
7	1·0	3·0	17	12
8	1·2	3·3	15	13
9	1·3	3·2	15	12
10	2·2	4·4	15	11
11	2·7	4·6	15	11
12	3·0	4·3	15	11
13	3·4	5·0	15	10
14	3·8	3·6	13	9
15	3·3	2·9	12	9
16	3·5	2·5	6	5

The prominent fact, demonstrated by this table, is that up to 13 km. the differences before sunrise are much smaller than those after sunrise.

The synopsis teaches, that before sunrise negative values occur in all heights, especially below 7 km. In one case up to the stratosphere the difference was negative in all heights.

On the contrary, in another ascent it went up to 9·2°. After sunrise no ascent, with negative values only, occurred, and in one case the differences amounted to 11·2°.

For the stratosphere, only in eight cases a set of these differences was obtained, its height being so great in these low latitudes that only part of the balloons reach its layers. Only in one of these cases (after sunrise) the descent-temperatures in the stratosphere exceeded those of the ascent, and in another case (before sunrise) higher temperatures alternated with lower.

In the five other cases (before sunrise) the sign of the differences in and below the stratosphere were contrary. It must be borne in mind that scarcely any isothermal state prevails in the tropical stratosphere, but that the temperature increases with the height (*cf.* my letter in NATURE of March 5, p. 5).

However, in the above-mentioned case of alternating positive and negative values, isothermal condition was met with up to 23 km.

The reversal in sign of the difference, which accompanies the reversal of the temperature gradient, strongly points to a thermal lagging of the instrument. Its heavy parts, and the basket also, will lag strongly and will influence the thermograph. In the ascent the lesser the ventilation the greater the heating. Thus the influence will increase with the height, as the ventilation decreases. In the descent the ventilation in most cases was greater than in the ascent, and accordingly the negative lagging less. After sunrise the thermal lagging of the basket will be enhanced in the ascent by sun-radiation, which easily explains the fact that the differences are larger after than before sunrise.

Perhaps the English instruments, being smaller than the German, have a smaller thermal lag than the latter. Thus Mr. Dines's explanation may be applicable to the facts observed in England, and mine to those met with in Java. From them I think the following lessons may be learnt, which applies to most Continental ascents made in a similar way and with the same pattern of instruments:—

(1) The temperatures of ascent and descent should be averaged.

(2) When descent or ascent is available only, a mean correction, to be derived from a large number of corresponding cases, should be applied.

(3) The temperatures and heights taken from the publication of the International Committee, in which, in most of the cases, ascents only are given, are affected by a systematic error.

W. VAN BEMMELEN.

Batavia, March, 1914.

Cellular Structure of Emulsions.

THE same arrangement that is shown by Fig. 2, in NATURE of May 7 (p. 240), may be seen in an emulsion of Oriental finely powdered coffee suspended in milk and water. I have supposed that it is connected with a strange phenomenon which I reported in NATURE about forty years ago. Sooty rain-water, after standing for some hours, will develop clear planes of water, as much as 10 cm. long and only 1 or 2 mm. wide. These planes are most readily seen by candle light when vertical, but may develop at any inclination, and change inclination. Such a straight segregation of clean water shows that no self-attraction of the suspended solids can be the cause. In a recent point of view it looks like a liquid crystal arrangement of water expelling the powder as foreign matter, especially when we remember the habit of ice crystals in very thin plates. The question then arises, Are all these emulsion figures due to the clear liquid segregating and expelling the suspended matter?

W. M. Flinders Petrie.

MODERN FORMS OF RÖNTGEN-RAY TUBES.

In spite of many obstacles, medical technique in the application of Röntgen rays has made steady progress during recent years. But there still remain certain primary difficulties which are often a source of hindrance and confusion. The demand for a more trustworthy method of working than exists to-day is the natural outcome of wider radio-therapeutic experience, but what is required above all is an accurate means of measuring the output of the tube.

The solution of this problem clearly requires that we shall have at our disposal an apparatus capable of emitting a specific type of ray in definite quantity; and were it not for some experiments by Dr. Lilienfeld, and more recently by Mr. Coolidge, of New York, there would be little prospect of actually realising this result in practice. I shall refer to their work more in detail later.

Meanwhile, it is worth noticing that the modern X-ray tube, with all its imperfections, is a triumph of craftsmanship. It is the result of numberless costly and difficult experiments carried out by manufacturers and others to meet a demand which grows more exacting every year. The collection of historical X-ray tubes brought together some time ago by the Röntgen Society, and now on view in the Science Museum at South Kensington, contains the first bulb which embodied the chief features adopted universally up to the present time in the construction of X-ray tubes. That bulb was made by Prof. Herbert Jackson in 1896, and measures only 3 in. across. The diameter of those in use to-day is, however, usually twice or three times as great, the electrodes being heavy and the vacuum carefully adjusted.

The successful working of the apparatus depends so largely upon this last factor that decrease in pressure of the residual gas, invariably accompanying prolonged use, has to be compensated for. The devices employed for regulating the vacuum may be divided into three main classes, viz., those :—

(1) In which a few discs of mica, a piece of carbon or asbestos, etc., fixed within the bulb, offer an alternative path for the discharge, so that gas is, when necessary, liberated by the heat generated, as the electric current follows the line of least resistance.

(2) In which a fine palladium tube stopped up at one end has a small tubular extension of platinum soldered to it for sealing into the X-ray bulb. A gas flame brought near so as to heat the palladium enables hydrogen to enter by osmosis, and so lower the vacuum. All the tubes used in the X-ray treatment cubicles at the London Hospital, for instance, have these "Osmo" regulators.

(3) In which air is allowed to enter through the pores of a piece of unglazed porcelain, which is usually sealed with mercury until by a pneumatic contrivance it is momentarily uncovered.

But none of these methods is free from objections. The regulation is generally too insensitive. The tube often outlives the supply of gas from the first sort, and the others are only trustworthy in skilled hands. The mica disc regulator is shown in the diagram (Fig. 1), which otherwise is self-explanatory.

Messrs. C. H. F. Muller describe some eighteen types of tubes of this character in their recently

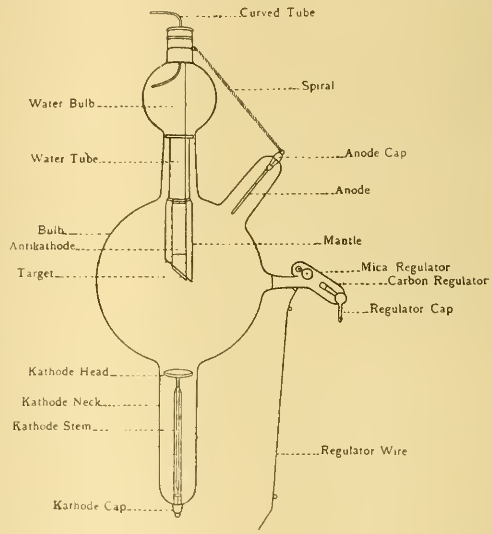

Fig. 1.—Showing the terms in common use to denote the different parts of the instrument.

published catalogue, and give precise instructions for the adjustment and use of each kind. There are in addition five coloured plates showing the appearance of X-ray bulbs in action, and a great amount of useful information besides. Fig. 2 (Muller) may be taken as representing a typical example of modern heavy discharge X-ray tube.

The cause of the disappearance of gas with prolonged use has given rise to much speculation. It has been suggested that the ions produced by the discharge are driven actually through the walls, and so escape; there is proof at least that the glass takes up a large part of the residual gas under these conditions, and that lead glass absorbs more than Jena.

Since the degree of vacuum controls the resistance of the tube, and this in turn determines the current that passes with a given potential difference between the electrodes, it is evident that the pressure of the residual gas is the chief factor which defines the type and quantity of rays to be obtained. Moreover, the kathode itself must carry a minute trace of gas to facilitate the transfer of electricity from the metal to the surrounding space. Further, the great heat often generated at the antikathode raises the temperature of the walls to such an extent that gas is set free there, and the balance of working conditions upset. A new tube, in fact, generally requires "maturing" until its vacuum when at work will keep practically constant, and yet be neither too high nor too low. This calls for much care and patience on the part of the operator. A bulb may in this way be coaxed to carry 5 milliamperes for hours at a stretch, and be of great service in "treatment." In most cases, however, the current does not exceed 2 milliamperes for that purpose. But in radiographic work the usual practice is to employ a heavy current—20 milliamperes—for a few seconds or even a fraction of a second. The length of exposure is, of course, determined by a number of considerations, but with such a large current it cannot exceed a few seconds on account of the enormous heat generated at the antikathode by the impact of electrons.

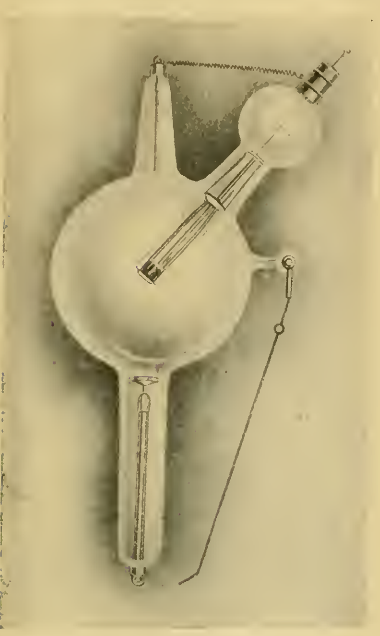

FIG. 2.—Heavy-discharge X-ray tube.

The same difficulty is met with in the treatment tubes, quite apart from the disengagement of gas, for a longer exposure has to be given now than would be necessary if more current could be carried with regularity and safety.

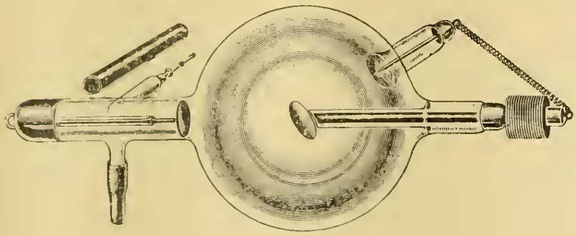

FIG. 3.—Heavy discharge radiator tube.

Under existing conditions the antikathode stem is usually made hollow, so as to enable water or air to flow in and carry off the heat, or an actual radiator may be fitted, as shown in Fig. 3 (Cossor). The osmosis regulator is also represented in the same illustration. Otherwise, even the hardest substance used as target would melt or become pitted by the impinging electrons. As an example of what occurs, the photomicrograph (Fig. 4; for which I am indebted to Dr. Rodman) of a plate of platinoid-nickel which has served as target may be of interest. In all cases except for very light work, the antikathode is made of stout copper faced with platinum-iridium or pure iridium, tantalum, etc., at the place where the kathode rays impinge upon it. The uncertain variation of vacuum, together with the development of excessive heat at the antikathode, constitute the most serious objections to the present system of working. The first difficulty especially hinders progress towards the attainment of an accurate method of measuring or describing the radiation dealt with, for it may change from day to day, or even during an exposure. But there are, in addition, many minor ailments which develop with the age of the tube. Thus a deposit comes gradually upon the inner surface of the walls. It is mainly metallic, and occludes gas; but it also provides electrified areas which disturb the normal streams of electrons. Occasionally, too, patches of bright fluorescence appear on the glass, due to specks of foreign matter sticking to the kathode. The direction of the discharge will sometimes reverse in the tube from no apparent cause. Indeed, the behaviour of a bulb is so erratic at times that a superstitious person might be excused for regarding it with distrust.

FIG. 4.—Photomicrograph of eroded target.

However, with care and experience, and in spite of many disadvantages, splendid work is being done with this super-sensitive apparatus. But it is none the less necessary to make every effort towards placing X-ray therapeutics upon an accurate quantitative basis, and to simplify the technique. With existing appliances the prospect of so doing is remote indeed.

But we are on the eve of great improvements! Dr. Lilienfeld, of Leipzig, has already constructed a Röntgen tube which is so highly exhausted that the residual gas plays no part in the working of the apparatus. The first description of this new departure was given in the *Fortschritte auf dem Gebiete der Röntgenstrahlen* for June, 1913, and more recently a further account has appeared in a later issue (Band xviii., p. 256).[1]

Dr. Lilienfeld creates an electric field in the neighbourhood of the antikathode between an aluminium tube and a white-hot wire. The working potential difference is then applied to the main electrodes and a discharge immediately passes. Since the current taken by the tube depends upon the temperature of the so-called priming device, the operation is under control.

But Mr. Coolidge[2] has simplified this design still further by placing a small spiral of tungsten at the centre of the kathode; heating this by an independent current he obtains a supply of electrons which are repelled and driven against the target with such speed as to produce copious X-rays where they strike. Thus, given a powerful induction coil and noting that the bulb is so well exhausted that 100,000 volts at its electrodes produce no discharge, the spiral is heated and the current that then passes is simply a function of the temperature. Variation of the potential difference would mean an alteration of the speed at which the electrons are driven against the target. The *quality* of the X-rays produced can therefore be varied, irrespective of their quantity. This is not possible with any other type of X-ray tube. Its importance cannot be over-rated. It places in the hands of X-ray operators an instrument of precision. Many questions are still outstanding; it is not even claimed yet that this apparatus is beyond the experimental stage. Meanwhile, however, it may be of interest to point out that the Coolidge tube has already given some remarkable results. The most successful bulb so far made measured 18 cm. in diameter, and was blown from German glass; it carried a current of from 1·7 to 36 milliamperes with the spiral heated to a temperature varying between 2010° and 2240° absolute. It was run for fifty minutes continuously on one occasion with 25 milliamperes passing. There was, of course, great heat developed in the antikathode, but the regularity of the action seems to have been unaffected. No fluorescence appeared upon the glass of this bulb, and the starting and running voltages were identical. The tube is also its own "rectifier," and may be run off an alternating circuit without any additional device to suppress one phase.

The prospect of being able to speed up the electron so much that it may give rise to a radiation with a wave-length equal to, or even shorter than, that of the Gamma ray from radium, offers great therapeutic possibilities.

It remains so far to improve the means of supplying electricity to the tube that a steady potential difference may be maintained at its electrodes. Then, since reversal seems impossible with the Coolidge system, it should be feasible to produce pencils of approximately *homogeneous* X-rays in definitely measurable *quantity* and of a *quality* expressed in terms of the coefficient of absorption in some agreed substance.

An attempt to construct a tube upon the new principle is at present being made in the physics laboratory of the Cancer Hospital, and experiments will be taken in hand there as soon as possible to test the types of ray obtainable by this means.

CHARLES E. S. PHILLIPS.

[1] A good summary is published in the *Archives of the Röntgen Ray*, for February, p. 340

[2] *Physical Review*, December, 1913.

THE SICILIAN EARTHQUAKE OF MAY 8.

THE earthquake which visited the south-east flank of Etna on May 8 is evidently one of the strongest of the local shocks which occur so frequently within the bounds of the volcano. Unlike the Messina earthquake of 1908, the shock was heralded by many slight tremors in the surrounding district, several having been felt every day since April 25. But for these warnings, the loss of life might have been far greater than it was, though more than 150 persons are reported to have been killed and about 500 injured. The villages of Linera, Passapomo, Pennisi, and Zerbati are completely ruined; Cosentini, S. Caterina, and S. Maria Vergina are half-destroyed; while about a dozen other villages from Zafferana and S. Venerina on the north to Trecastagni on the south are seriously damaged.

The epicentre of the earthquake is clearly at and near Linera. The details at present known are insufficient to determine the boundary of the meizoseismal area, but its greatest dimension can scarcely exceed two or three miles. For the same reason, nothing more is known as to the extent of the disturbed area beyond the fact that it was small considering the violence of the shock near the epicentre. Probably the disturbed area is far less than that of some of the weakest of British shocks. This alone proves how rapid was the decline in intensity from the central region. At Acireale, only four miles south of Linera, the damage to property was slight. At Catania, seventeen miles to the south, the shock was felt, and excited some alarm. These two facts—the great intensity near the epicentre and the rapid decline in strength outwards—show that the focus must have been quite close to the surface.

It is, however, in its relations with previous earthquakes in the same region and with the eruptions of the neighbouring volcano, that the interest of the earthquake chiefly lies. Two and a-half years before, on October 15, 1911, a similar, though less destructive, earthquake occurred in the immediate vicinity. The meizoseismal area in this case was a narrow band, four miles long and about a-third of a mile wide, extending from Fondo Macchia to Guardia, and passing about a mile and a-half to the north-east of Linera. On this occasion twelve persons were killed and forty-eight injured. On July 19, 1865, the same district was ruined by an earthquake, by which seventy-four persons were killed and fifty-six injured. Other shocks visited the same or neighbouring villages on July 11, 1805, and January 26, 1859; while, from 1893 to 1900, twenty-seven strong shocks were felt, six of them being of ruinous strength.

Many of these earthquakes were closely connected as regards time with Etnean eruptions. The earthquake of 1805 occurred after, and that of 1859 during, a period of activity. The earthquake of 1865 took place eighty-eight days after the conclusion of a violent eruption; and that of 1911 twenty-two days after the close of the last eruption, which began on September 10 of that year and lasted for twenty-three days. The recent shock occurred about two years and eight months after the end of the same eruption.

The same phenomena seem to characterise all the earthquakes of this district. The disturbed area is small, the intensity of the shock great in its central portion, and the isoseismal lines extremely elongated in form. In some cases the axes of the isoseismal lines are directed towards the central crater; in others (as in the earthquake of 1911) in a perpendicular direction. The small depths of the foci, their situation within the Etnean boundary, the direction of the meizoseismal bands, and the close connection of many of the earthquakes with eruptions of Etna—all these phenomena point clearly to the volcanic origin of the earthquakes, their immediate cause being probably local slips along radial and peripheral fissures.[1] C. Davison.

[1] M. Baratta, I terremoti d'Italia, 1901, pp. 829–33; A. Riccò, Boll. Soc. Sis. Ital., vol. xvi., 1912, pp. 9–38.

THE BACHELET LEVITATED RAILWAY.

THE daily Press, or rather a section of it, has been greatly excited during the past week by the exhibition of a model railway, the invention of M. Emile Bachelet, in which a metal carriage is levitated in the air above the rails in a model railway, and then flung forward with very great speed through a series of solenoids. The reporters for the daily Press have discovered new and tremendous possibilities in a scientific principle entirely new to them, but which has been perfectly well known to every electrician and physicist for the last twenty-five years.

The repulsion of a metal plate or ring by an electromagnet or coil carrying an alternating current was discovered independently by Dr. J. A. Fleming and by Prof. Elihu Thomson. In 1887 Dr. Fleming invented and described in the *Electrician* of March 25, 1887, an alternating current galvanometer, in which a copper disk suspended in the interior of a coil carrying an alternating current was repelled and deflected. On June 10, 1887, Prof. Elihu Thomson published in the *Electrician* a lecture on novel phenomena of alternating currents, in which he described the repulsion of copper disks and rings by an alternating electromagnet. Prof. Thomson's apparatus was exhibited at the Paris Exhibition in 1889, and the experiments shown by Prof. Fleming to the Royal Society of Arts in a lecture in May, 1890, and also at a Royal Society *soirée* in the same year, as well as at a Friday evening discourse at the Royal Institution in March, 1891.

Dr. Fleming expounded the whole matter with numerous striking illustrations. Heavy copper rings were made to float in the air, or were shot up into the air with great velocity. This repulsion is due to the repulsion between the currents in the magnet coil and the eddy curents set up by the alternating field in the plate or ring.

The principle was applied by Prof. Elihu Thomson in the invention of an alternating current electric motor, and it has been developed in the well-known compensated repulsion motor of Winter and Eichberg. It is also applied in several forms of rotating and recording electric meter. The phenomena known as "electromagnetic repulsion" are therefore perfectly familiar to electrical engineers, and except in the ingenious application to the support of a model railway carriage there is nothing new. Press reporters and others who have been astonished by the exhibition of this force are merely learning afresh facts which were publicly exhibited and described by Profs. Fleming and Elihu Thomson nearly a quarter of a century ago. Careful experiments and quantitative measurements will, however, be necessary before any valid opinion can be formed whether the principle admits of economical application in the propulsion of real railway trains. Nevertheless M. Bachelet deserves credit for his highly ingenious application of this well-known principle of electromagnetic repulsion.

NOTES.

Lord Lamington, G.C.M.G., G.C.I.E., has consented to be president of the Research Defence Society, in succession to the late Sir David Gill, K.C.B., F.R.S.

On the recommendation of the council and of the special committee on the Hayden award, the Academy of Natural Sciences of Philadelphia has this year conferred the memorial gold medal on Dr. Henry Fairfield Osborn, in recognition of his distinguished work in vertebrate palæontology.

At the annual meeting of the Irish Forestry Society on April 23, it was stated by Prof. Campbell that the department hoped to secure 15,000 acres for State forestry in Ireland. A grant had been obtained from the Development Commissioners of 31,430*l.*, spread over fifty-two years, for a scheme of forestry in Cork, and the department is applying for a further grant of 45,000*l.* It is thus evident that State forestry in Ireland has broken ground in earnest, and this makes it all the more remarkable that State forestry in England and Scotland should still be waiting to start.

The sixtieth general meeting of the Institution of Mining Engineers will be held in London, on Thursday, June 4, in the rooms of the Geological Society, under the presidency of Sir William E. Garforth. The following papers will be read, or taken as read:—Sinking and equipment of Blackhall Colliery for the Horden Collieries, Ltd., J. J. Prest and J. Leggat; development of the internal-combustion engine for power generation at collieries, J. Davidson; the geology of the Kent coalfield, Dr. E. A. Newell Arber. In addition, certain papers which have already appeared in the Transactions of the society will be open for discussion.

The death is reported, in his seventy-fifth year, of Mr. Newton H. Winchell, State Geologist of Minnesota from 1872 to 1900, and professor of mineralogy at the University of Minnesota from 1873 to 1900. In 1888 he founded the *American Geologist*, which he continued to edit until 1905. He was the author of "Geology of Ohio and Minnesota," "The Iron Ores of Minnesota" (in collaboration with his son, Mr. Horace V. Winchell), "Elements of Optical Mineralogy," and "The Aborigines of Minnesota." Mr. Winchell was three times elected to the presidency of the Minnesota Academy of Sciences, of which he was the founder. Since 1906 he had been archæologist to the Minnesota Historical Society.

The President of the Local Government Board has appointed a Departmental Committee "to consider the present state of the law with regard to the pollution of the air by smoke and other noxious vapours, and its administration, and to advise what steps are desirable and practicable with the view of diminishing the evils still arising from such pollution." The Committee will consist of :—The Right Hon. Russell Rea, M.P., Mr. H. Brevitt, Prof. J. B. Cohen, F.R.S., Colonel H. Hughes, C.B., Mr. J. F. MacCabe, the Right Hon. Lord Newton, Captain H. R. Sankey, Mr. B. Duncomb Sells, Mr. P. C. Simmons, Mr. E. D. Simon, Mr. W. B. Smith, Mr. H. O. Stutchbury, Mr. Christopher Turner, and Sir Aston Webb, C.B. Mr. E. A. Faunch, of the Local Government Board, will act as secretary of the Committee.

In an article published in the *Times* of May 8 attention is directed to the great practical difficulties presented by the problem of the prevention of the spread of sleeping sickness in Uganda, and especially to that of obtaining the cooperation of the natives in carrying out preventive measures. Whatever the chiefs, wishing to stand well with the administration, may profess to believe, there can be no doubt that the native equivalent of "the man in the street" has no faith at all in the assertion of European science that the tsetse-fly is responsible for the spread of the disease; he points to the indisputable fact that the fly was there long before the disease, and he asks why, amongst the many hordes of biting flies, mosquitoes and other insects, should the tsetse alone be blamed? The further fact that the disease did not appear in the country until the Pax Britannica permitted natives to make long journeys in safety, and thus enabled persons infected elsewhere to enter the country, infect the fly, and so start the deadly epidemic, lends colour to the sinister suspicion that the Europeans introduced the disease into the country in order to establish effectually their dominion over its inhabitants. The writer in the *Times* refers to the comparative freedom from natural enemies enjoyed by the adult tsetse-fly, by reason of its alertness and swiftness of flight, but he seems to have forgotten that the insect passes a not inconsiderable period of its existence as a helpless pupa, buried close to the surface of the soil, and therefore much more easily destroyed.

An account of some of the discoveries of expeditions to Peru in 1911–1912 was given by Prof. H. Bingham in Nature of March 26. A new expedition has just started for the same region. As in 1912, the expedition is under the joint auspices of Yale University and the National Geographic Society. Unlike former expeditions, it will cover a period of two years, instead of being confined to one field season. The plan of work will include the making of a topographical map of the region north-west of Cuzco, between the Apurimac and Urubamba rivers; a detailed geographical reconnaissance of the more lofty portions of the mountains, including a study of the large undescribed glaciated region; the establishment of two meteorological stations at different elevations for the taking of systematic records for two years; a study of the distribution and history of food plants of this region; the collection of data respecting the forms and distribution of vertebrates, particularly mammals and reptiles; a survey of the present Indians inhabiting this region, including a study of their dialects, the collection of anthropometric data, and the collection and study of the skeletal remains; an archæological reconnaissance of the entire area, and a continuation of the studies begun by the first expedition, looking toward a geographical interpretation of the Spanish chronicles of the era of discovery and exploration, with particular reference to the identification of ancient place names, the story of Macchu Pichu, and its connection with the history of the Incas.

The issue of the Journal of the Royal Anthropological Institute, July–December, 1913, is largely devoted to the ethnology of Africa. Sir H. H. Johnston contributes a masterly survey of the general question. One of his most important suggestions is that the cattle-keeping communities of the Central Sudan and of Bantu Africa owe much of the slight Caucasian element in their blood and almost all their culture to infiltration from ancient Egypt, rather than to influences from Galaland and Somaliland. In the same connection Prof. Seligmann's elaborate article on some aspects of the Hamitic problem in the Anglo-Egyptian Sudan deserves attention. He supports the suggestion made by Dr. J. G. Frazer in the recent edition of his "Attis, Adonis, Osiris," that the killing of the Shilluk rain-maker or divine king can best be understood in connection with the yearly renascence of vegetation.

The Huxley Memorial Lecture, by Prof. W. J. Sollas, published in the July–December, 1913, issue of the Journal of the Royal Anthropological Institute, is devoted to an account of the exploration of the Paviland Cave at the base of the limestone cliffs of Gower, looking over the waters of the Bristol Channel. It belongs to the Aurignacian period, and the hunters who found shelter there were men of large stature, members of that Crô-Magnon race which occupied during that period the greater part of habitable Europe. They possessed highly developed brains, and had acquired such simple mechanical arts as are essential to primitive man. They had little artistic ability, and have left no recognisable drawings on ivory or bone, the red stripes discovered by Abbé Breuil and Prof. Sollas in the neighbouring cave of Bacon Hole being the only attempts at mural decoration which this race is known to have left behind in Wales. They wore rude ornaments, doubtless exercised some magical arts, and they respected their dead sufficiently to provide for them a ceremonial burial. Whether the Mousterians, their predecessors, occupied this cave is doubtful, nor is it certain that they were followed here by the Solutrians or Magdalenians. Prof. Sollas has thus opened up a new and interesting chapter in the prehistoric archæology of Great Britain.

During the last two months excavations have been carried on in a brickfield to the north of Ipswich with the object of discovering and collecting flint implements of probable Lower-Middle Aurignac-Palæolithic age, which are known to occur at a well-marked "occupation level" at varying depths round the sides of the small valley in which the brickfield is situated. Mr. J. Reid Moir informs us that on April 30 digging was commenced at a spot on the south side of this valley, and a section was exposed consisting of 2 ft. of sandy surface material with 2 ft. 3 in. of undisturbed sand below it. At the base of the section the solid London Clay was met with, and on the surface of this clay, under the compact, undisturbed sand many fragments of pottery, calcined flints, and the remains of a hearth were found. A large piece of pottery was found and photographed *in situ*. The pottery was carefully removed, and has been forwarded to the British Museum, Bloomsbury, where it is being examined. It was in an extremely soft and friable condition, contains many fragments of white quartz, and is of a primitive and rudimentary kind.

The first memoir issued by the South African Institute for Medical Research is an inquiry, by Mr. G. D. Maynard, into the etiology, manifestations and prevention of pneumonia amongst natives on the Rand recruited from tropical areas (published by the institute, Johannesburg, price 5*s*.). Mr. Maynard has availed himself of modern statistical methods and finds, among other interesting results, that the attack and death-rates from pneumonia are influenced by the country of origin of the natives, that the highest attack-rates are found among the gangs which have the lowest physique, and that the prophylactic inoculations with a pneumococcus vaccine appear to reduce the incidence of pneumonia during a limited period. Mr. Maynard's results appear to show that the effect of such immunisation is transitory, the period during which some protection is afforded not exceeding four months, and that little reduction of the case mortality is attained. The paper should be read in conjunction with those of Sir Almroth Wright and his colleagues, who approach the subject from a somewhat different point of view.

We have been favoured with a separate copy of an illustrated article, by Mr. A. Gallardo, from vol. xxvi. of the *An. Mus. Nac. Hist. Nat. Buenos Aires*, on the new museum of natural history it is proposed to erect in Buenos Aires, for which a considerable amount of money has been voted already. The building, which is to comprise all the essential features of an up-to-date museum, is to be in a modification of the Louis XVI. style, and will comprise a basement, a ground-floor, and a first-floor.

Although isolated mammalian remains of Sarmatian age have been known for some time from the Crimea, it was not till 1908 that a regular deposit of these was discovered, and this, too, in the very heart of Sebastopol itself during certain municipal works. The fauna, a part of which is described by Mr. A. Borissiak, with great wealth of illustration, in the *Mém. Com. Géol. St. Pétersbourg*, ser. 2, livr. lxxxvii., 1914, appears to show indications of affinity with the Pikermi fauna on one hand, and that of the Bugti Hill and Siwaliks on the other. An interesting item is a giraffe-like ruminant, regarded as representing a new genus and species, under the name of *Achtiaria expectans*.

The fourth part of vol. viii. of Records of the Indian Museum contains seven articles, by as many writers, on the specimens of various groups of, for the most part invertebrate, animals collected during the Abor Expedition of 1911–12. Among these, it must suffice to refer to a preliminary note on certain groups of the Mollusca by Col. Godwin-Austen, who states that the collection as a whole "is one of the finest and most interesting from the eastern frontier I have ever looked over, containing as it does so many genera and new species, and so many that are quite distinct from land Mollusca at present known from the most western part of Assam." Descriptions of two new species appear in this part, and those of others are to follow.

Missionaries and pioneer explorers of equatorial Africa long ago reported the finding of wild oranges and wild lemons; if the fruits were green, they resembled small limes and lemons, but if ripe their sweet flavour caused them to be classed as oranges. The plants yielding this fruit form the subject of an investigation by Mr. W. T. Swingle and Miss Maud Kellerman, of the United States Bureau of Plant Industry, which is published in No. 5 of vol. i. of the *Journal of Agricultural Research*. It is now clear that these plants have been wrongly classed in the Asiatic genus Limonia, and are more closely related to the Citrus; it is proposed to establish a new genus for these African oranges by raising to generic rank the section Citropsis of Engler. A detailed study is given of the different species of this genus. Interesting results have been obtained as regards the grafting and hybridisation of these plants, and an investigation is being made of their possible uses as a fruit. It is probable that Citropsis will show immunity to diseases and adaptations to soil and climate not possessed by the stocks upon which citrous fruits are usually grafted.

The growing importance of the prickly pear pest in South Africa and Australia has given rise to a search for remedial measures, two of which, the one biological and the other chemical, are described in the March number of the Agricultural Journal of the

Union of South Africa. The first paper, by Dr. Ernest Warren, describes infection experiments with a species of cochineal insect (Green's *Coccus cacti*, var. *ceylonicus*) which showed that, of the two species of prickly pear common in South Africa, the long-spined *Opuntia monocantha* and the small-spined *O. tuna*, only the former succumbed to the attack of the insect, some substance probably being present in the sap of the latter which is injurious to the cochineal insect, since even a wounded surface is not attacked. The second paper, derived from the *Queenslander*, describes a method introduced by Mr. O. C. Roberts, in which treatment consists in the action of arsenious trichloride vapour, at the rate of three quarts of the compound per acre of bush. Up to the present this has only been tested on several hundred acres of land, but the results are said to be sufficiently promising to warrant much more extensive operations in the near future.

STUDENTS of palæobotany will note with pleasure a folio memoir in German on certain fossil calcareous algæ from Japan and China, by Dr. H. Yabe (Sci. Rep. Tôhoku Imp. University, Sendai, Japan, vol. i., No. 1). Only three species are described, but two represent new genera, Metasolenopora and Petrophyton, and the author's well-known care in microscopic details leads to their adequate illustration.

UNDER the title of "Les plus jeunes volcans de la France," Prof. Glangeaud, of Clermont-Ferrand, contributes a well-illustrated account of the chain of the Puys to the *Revue générale des Sciences*, 25e Année (1914), p. 50. The trachytic domes, which are more common in the Mont-d'Or region, are compared with those of the Montagne Pelée and Guadeloupe. Reyer's descriptions of those in Bohemia may provide, however, examples nearer home. A remarkable amount of modern information, including an explanation of the puzzling Puy Chopine, is compressed into this single article.

IN vol. xx. of the *Berichte der naturforschenden Gesellschaft zu Freiburg-im-Breisgau* (1913), W. Deecke discusses the frequent variation in type to be found in European sedimentary rocks of all ages, and concludes that deep marine basins and shallow waters lay side by side, and that the European area always showed, as now, an interlocking of sea and land. Continuous oceanic deposits seem wanting, and the acceptance of this view helps to account for the near association of different sedimentary facies, which other writers have ascribed to the importation of one type over another during lateral thrusting. It may be noted that the author regards the fucoids of the Alpine Flysch, not as algæ or worm-tubes (see NATURE, vol. lxxxv., p. 284), but as sponge-bodies indicative of deep water. In a later paper on "Die Bedeutung salzführender Schichten für tektonische Vorgänge," Deecke ascribes the anomalous position of some of the Alpine masses to gravitational slipping over Triassic strata, from which solution has removed sulphates and chlorides. Such solution takes place easily when the beds are lifted above the usual water-table and are exposed to free percolation, and the author asks for caution before the faulted relation of any overlying mass to its support is ascribed to overthrusting from a distant source. It will be seen that these two papers have a common philosophic aim.

THE Rev. H. V. Gill has sent us a reprint of his paper read at the last meeting of the British Association on the distribution of large earthquakes in time and space. Mr. Gill's theory is that a great mass-displacement of the crust, such as occurs during a violent earthquake, gives rise to a "wobble" or unevenness in the rotation of the earth, which is neutralised by other mass-displacements occurring either in a distant region or regions symmetrically placed along the great circle through the origin, or of displacements in the opposite direction in the neighbourhood of the origin. To test this view, he has examined the distribution of the 889 world-shaking earthquakes recorded by the seismological committee of the British Association. He finds that 674 (or three out of every four) great earthquakes occurred in groups, successive members of which were separated by a week or less, while the remaining 215 were isolated disturbances. Of the former, 163 (or 18·6 per cent. of the whole) belonged to groups of two or more earthquakes occurring at different places symmetrically situated with reference to the origin of the first earthquake of a group; 511 (or 57·1 per cent.) were members of groups occurring at or near the same place. No attempt, however, is made to show that the displacements of individual groups of the latter class occurred in opposite directions.

THE annual report of the Hampstead Scientific Society for 1913 naturally refers with gratification to the favourable reception which was accorded to the publication, "Hampstead Heath: its Geology and Natural History." The membership of the society has attained a "record figure" of 374, with a net increase of thirty for the year. The report contains brief notices of the many valuable papers which have been read to the society, and a summary of the meteorological statistics for the Hampstead Observatory for 1913. "The combination of meteorological circumstances in July was most unusual; coupled with a remarkable cloudiness of eighty-two and an extremely deficient sunshine of only 109 hours were a mean pressure of 30·087 in.—a figure some way in excess of the average—and a rainfall an eighth of an inch below the normal, falling on only eleven days." For the first time, average meteorological data are included in the report; this action marks the fact that the station has been at work for five years. From these preliminary averages it would appear that Hampstead is the coldest, rainiest, snowiest, and frostiest, as well as almost the sunniest and foggiest of the stations in the neighbourhood of London.

THE report of the Royal Prussian Meteorological Institute for the year 1913 (director, Prof. G. Hellmann) exhibits great activity in useful work, relating chiefly to land meteorology and special researches. Arrangements have been made for the preparation of an important work on the climate of Germany, and a special department has been created for the purpose. Among the researches made at the Potsdam Observatory may be mentioned the comparison of different sunshine recorders, and the investigation of unexplained differences which occasionally exist in the indications of ordinary and self-registering rain gauges. The report is accompanied, as in previous years, by several interesting scientific papers. One of these, by Dr. Hellmann, "On the determination of air temperature," bears particularly on the recent discussion on that subject in this country (Nature, April 9, p. 143). Comparisons of readings in a "Stevenson" screen with those of an aspiration thermometer showed that on a sunny day the temperature by the latter might change more than 1° C. within a minute, while the readings in the screen are not so quickly affected by sudden changes. The results seem to indicate, as was also inferred by Dr. J. Aitken, that the screen readings give trustworthy mean values for short intervals (say two to three minutes); a closer agreement than this in the *time* of observing, as Dr. Hellmann remarks, can scarcely be expected.

A new form of Gauss's principle of least constraint forms the subject of a short note by Dr. H. Brell, of Graz, in the Vienna *Sitzungsberichte*, vol. cxxii., p. 7, in which the author obtains a single formula for Appell's equations.

An addition to the numerous tables of logarithms and anti-logarithms that have been published by various writers for special purposes is the "Table auxiliaire d'Intérêts composés" of M. A. Trignart (Paris: Gauthier-Villars, 1914, price 2 francs). This table gives the various powers of the base, 1·0001, for all integral indices from 1 to 1000, for indices in "thousands" from 1000 to 100,000, and for the ten indices completing the range from 100,000 to 1,000,000. In the first two tables the anti-logarithms to this base are calculated to fifteen decimal places. Those in the third table are given to twenty significant figures. It will be observed that to all intents and purposes these anti-logarithms differ from those of the natural system of logarithms in that the fundamental base differs from unity by 1 in 10,000 instead of by an infinitesimal quantity; at the same time it would appear that a similar difference existed in the case of the original logarithms of Napier. The present table is obviously adapted to meet requirements of a special character, such as might perhaps occur in actuarial computations.

Among the reports of recent investigations at the Imperial Institute the first quarterly issue of vol. xii. (1914) of the Bulletin includes papers on the little-known economic products of Somaliland, and on the composition of monazite, which is used extensively in the manufacture of incandescent gas mantles. An illustrated article describes an important plant of rubber-testing machinery set up at the Institute for the purpose of carrying out a systematic investigation of samples of plantation Para rubber specially prepared in Ceylon in different ways, in order to secure accurate data for comparison. A note of agriculture in the Gold Coast states that the cultivation of cocoa is still being extended, and that the crop in 1913 was valued at nearly two and a half millions sterling. The interesting fact, probably not commonly known, is stated that more than one-third of the world's production of cocoa is produced under the British flag.

In part vi. of the *Verhandlungen* of the German Physical Society Dr. F. A. Lindemann shows how the simple method of dimensions may be applied to the construction of atomic models which shall have many of the properties of the actual atoms. Taking the frequency of the electronic oscillations in such an atom to depend only on the distances between the negative and positive charges, the mass of the carriers of the charges, the force between the charges at unit distance apart, and on Planck's constant h, he shows that if the frequency is proportional to the nth power of the force, it must also be proportional to the $(n-1)$th power of the mass, the $(n-2)$th power of the distance and to the $(1-2n)$th power of h. Taking n in succession equal to 0, 1, and 2, he shows how far the model will represent the behaviour of an actual atom without further hypothesis, and what additional hypotheses must be brought in to reproduce given atomic properties. In this way he arrives at the relations previously given by Balmer, Moseley, Bohr, Gehrcke, and others, as holding for the actual atoms.

The flow of sand and other fine materials through openings of various shapes and in different circumstances is not a subject which has received much attention from experimentalists, although it is of considerable practical importance. We welcome therefore the recent work of Prof. E. A. Hersam, of the University of California, on sands of various degrees of coarseness, on crushed slate, crushed shale, mustard seed, and lead shot. From Prof. Hersam's paper in the April number of the Journal of the Franklin Institute we gather that the following are his principal results. The velocity of flow is determined mainly by the size of the particles and of the opening, but is slightly diminished by angularity of the particles or by moisture on them. The specific gravity of the particles, the height of the material above the opening, and the shape of the upper contour of the material have little effect. If D is the diameter of the opening, d that of the particles, both in inches, the mean velocity of flow V in feet per second is given with sufficient accuracy for most practical purposes by the equation, $V=(D-2d)/\sqrt{D}$.

We have received a report by Prof. Ph. A. Guye on the unification of the bibliographic abbreviations in chemical memoirs which was presented at the third session of the council of the "Association internationale des Sociétés chimiques," held at the Institut Solvay at Brussels in September, 1913. The author points out the inconvenience which arises from the same periodical being represented by several different abbreviations, and suggests that a uniform system should be adopted by scientific societies and by authors of chemical works. It appears there are only two systematic methods at present in use, namely, those of the International Catalogue of Scientific Literature and of the Concilium Bibliographicum de Zürich. Neither of these lists is complete, but the author is in favour of adopting the system of the International Catalogue, which is under the control of the Regional

Bureaus of twenty-six States and of five societies, and is therefore truly international. The International Catalogue has four regulations for the abbreviation of titles: (*a*) the abbreviated title must be intelligible without a key; (*b*) in the abbreviated title the words, whether entire or abbreviated, must follow each other in the same order as in the original title; (*c*) titles of proceedings, reports, or scientific periodicals in general which are edited or published by learned societies, academies, etc., must, however, begin with the name of the place where the society resides; (*d*) in the case of other periodicals the name of the town where they are edited follows the abbreviated title. The regulations of the Consilium Bibliographicum contain the first two rules of the International Catalogue, but the names of towns are used only when necessary to avoid confusion. It would be a great convenience to readers of chemical works if a uniform system could be adopted, and it is to be hoped that Guye's suggestions will be carried out.

Engineering for May 8 gives particulars of the arrangements made at the Royal Air-craft Factory, Farnborough, for the aeroplane engine competition instituted by the British Government, and now proceeding. The engines are to be of British manufacture throughout (magneto excepted), and in view of the successful performances of British aeroplanes fitted with foreign engines, it is satisfactory to note that there has been a good entry, and that a large number of engines has actually been delivered for test. The test-house has been arranged with six test-beds and friction brakes, each contained in a separate cubicle, and supplied with a wind current of sixty miles an hour. The brakes are the latest pattern of Heenan and Froude's water dynamometer. The War Office proposes to publish a report at the conclusion of the trials.

THE new Cunard liner *Aquitania* was towed successfully from the Clydebank yard of Messrs. John Brown and Co., Ltd., to Greenock on Sunday, May 10. After her trial trips this week, she will proceed to Liverpool to be prepared for her maiden voyage to New York on May 30. *Engineering* for May 8 contains an illustrated article dealing with the propelling machinery of this ship. There are twenty-one cylindrical double-ended boilers, each having eight furnaces. The turbine machinery driving the four propeller shafts has been arranged to work on the triple system. The high-pressure ahead turbine, which, along with a high-pressure astern turbine, occupies a separate compartment on the port-wing turbine-room, receives boiler steam direct, which is passed in turn to the intermediate-pressure turbine, occupying, along with a high-pressure astern turbine, a similar compartment on the starboard wing. Two low-pressure ahead turbines on the two inner shafts receive their steam from the intermediate-pressure turbine. Some idea of the enormous size of these turbines may be obtained from the diameter of 15 ft. 4 in. over the tips of the blades of the low-pressure turbine. The combined weight of the low-pressure ahead and astern turbines on one shaft is 445 tons.

OUR ASTRONOMICAL COLUMN.

A REGISTERING MICROPHOTOMETER.—In 1912 Dr P. Paul Koch described a registering microphotometer designed by himself; the apparatus records photographically the varying intensities of a series of objects such as the lines in a spectrum or a set of interference rings and show their distance apart. The principle involved is to move the negative to be measured slowly in front of an opening through which a beam of light from a constant source is passed, and the resulting changes in the intensity of this light are recorded on a moving photographic plate. Dr. Koch now describes (Contributions from the Mount Wilson Solar Observatory, No. 77) an application of this instrument to the study of certain types of laboratory spectra, and displays in diagrams the resulting curves obtained. Thus, there are types of curves for furnace lines for different temperatures, for lines displaced by pressure, reversed lines, tube-arc lines, etc. While the observations described are stated to be only preliminary and very limited in scope, they are sufficient to indicate the usefulness of the instrument in those branches of spectroscopy in which it is desired to investigate quantitatively measures of line-intensity and structure.

VARIABLE STAR OBSERVATIONS.—No. iii. of the Publications of the Vassar College Observatory contains a most useful series of variable star observations made during the period 1901 to 1912, totalling in all 4797 observations. In the publication two points in particular have been aimed at, namely, first to reduce all magnitudes to a uniform standard, that of the Harvard photometry; and secondly, to give the original observations with the exact identification of the companion stars, in order that they may be reduced to any other desired photometric scale. In the introductory remarks, written by the present director, Caroline E. Furness, a detailed account is given of the instruments used, methods of observation employed, etc. Table I., which occupies the greater portion of the publication, gives the details of the observation of each variable; Table II. deals with some photometric observations; Table III. gives the magnitude on the Harvard photometric scale for every tenth grade of the Hagen, while the observed maxima and minima are compared with the ephemeris in Table IV.

ENHANCED MANGANESE LINES AND α ANDROMEDÆ.—The spectrum of α Andromedæ displays peculiarities which have rendered it difficult to couple it up with other stars in stellar classifications. Both the Harvard and the South Kensington classifications have indicated this star as an anomaly. The lines which are responsible for this peculiarity have now been run to earth by Mr. F. E. Baxandall, and he finds that in the main they are due to a form of manganese known as proto-manganese (Monthly Notices R.A.S., vol. 74, No. iii., p. 250). In his paper, Mr. Baxandall publishes three independent sets of measures of the stellar lines, and he states that while there is no proto manganese line which does not agree in position—within the limits of error in measurement—with an α Andromedæ line, this long succession of close agreements leaves little or no doubt that the two sets are identical. Attention is directed to the interesting fact that while in α Cygni and α Canis Majoris the enhanced lines of iron, chromium, and titanium are strongly shown, and the proto-manganese lines are comparatively weak or lacking, on the other hand, in α Andromedæ the case is the opposite. It will thus be seen that important criteria are being accumulated to help in the task of stellar classification, a former prominent case of another proto-substance being that of chromium in the spectrum of ϵ Ursæ Majoris shown at South Kensington.

THE CARNEGIE TRUST.[1]

THE Carnegie Trust for the Universities of Scotland has been in operation for twelve years, and it is now possible to draw some general conclusions as to the success which has attended its working. No other scheme for the endowment of higher education and research in this country has been planned on such a large scale as that indicated in the present report and its predecessors, and the progress of an experiment of such magnitude has been followed with interest by all who have to do with University affairs.

The financial statement for the year 1912–13 shows that the annual income of the trust amounts to rather more than 100,000*l*., and after defraying the expenses of administration there is left about 99,000*l*. as the net revenue available for distribution under the two main heads of the scheme. Half of this sum is earmarked annually for the payment of students' fees, while the other moiety is devoted (*a*) to the better equipment of the Scottish universities and colleges by the foundation of additional chairs and lectureships, and by the provision of new laboratories and permanent equipment, and (*b*) to the endowment of research. Of course, the equipment section of the expenditure also plays its part in the advancement of research work, as it furnishes places in which investigations can be carried on and also helps to provide posts for men who become directors of research in their various departments. It will be seen that the operations of the trustees are financially on a grand scale; for the funds at their disposal annually represent a sum equivalent to about 60 per cent. of the total Government grant in support of the higher educational institutions in England and Wales.

In the allocation of the funds, the trustees have been guided by two main considerations. First, they decided that their assistance to the four universities and their kindred colleges should be given under a quinquennial scheme, so that each step forward has been based upon the allocation of approximately half a million sterling. Secondly, a general rule was laid down that the trust would not hamper its income by paying salaries for new posts year by year out of the annual revenue, but instead, any new chair or lectureship is endowed fully at the start, so that its subsequent career entails no further draft upon the funds of the trustees. In this way, each chair on its foundation disappears from the books of the trust, and the next quinquennial distribution can be devoted to entirely fresh needs.

Any visitor to the Scottish universities in recent years must have been struck by the progress which has been made in the provision of new laboratories and departments of all kinds; buildings have sprung up until the older part of the fabric appears to be lost in the new. But buildings alone are of little value, and the influence of the trust is equally marked in the large increases of staff which have been rendered possible.

These, however, though they represent the major part of the trust's expenditure, are by no means the most striking monument which the trustees have raised, for their endowment of research and post-graduate study has been on an equally far-reaching scale. A system of scholarships and fellowships has been founded, which is supplemented by a series of grants in aid of research to Scottish graduates resident in Scotland; and this part of the trust's work has been of equal, if not greater, importance to the Scottish university system. Thus from the time a student enters the University to the day he leaves Scotland he finds a helping hand extended to him should he wish to grasp it.

[1] Twelfth Annual Report of the Carnegie Trust for the Universities of Scotland, 1912–13.

During his undergraduate career, he may obtain payment of his university fees; later, he may aspire to carry out researches, in which case he may apply for a scholarship or a fellowship. The research scholarships are conferred upon students on the recommendation of experts—usually the persons under whom the beginner in research will have to take his first steps in original work. Research fellowships are meant for men who have already accomplished something, and they are allocated on the merits of the work which the candidate has already published. In neither case is there any competitive examination, nor do the trustees bind themselves to furnish a fixed number of scholarships or fellowships in a given year. This is one of the most desirable features of their policy; for, as any teacher knows, an institution may turn out, say twenty first-class men in a given year, whilst in the following year only one or two may appear, so that the granting of a fixed number of scholarships per annum simply means that in some years a first-class man may not secure an appointment to a scholarship which in the following year will fall to the lot of a much inferior man owing to there being a dearth of candidates. It should be pointed out that the trustees retain all these appointments in their own hands, so that graduates of all the four universities are dealt with on equal terms. The scholarships are of the value of 100*l*. per annum, and are tenable for one year with a possibility of extension or of the holder's promotion to a fellowship; the fellowships are of the value of 150*l*. per annum, and are normally tenable for two years, though further renewals are possible.

The facts given in the report with regard to the subsequent careers of scholars and fellows go to prove that the research training they have undergone has fitted these men for the most varied appointments; and it must be remembered that the actual output of research work during the tenure of a scholarship or fellowship is not by any means the full index of the success of the scheme. Most of the men continue their investigations after they have severed their actual connection with the trust, and their later work must to some extent be placed to the credit of the trustees.

The impetus to research which has been produced by the work of the trust can be gauged from an example chosen from one science, chemistry. In the eight years 1903–11, the trust appointed in this department forty-five scholars, twenty-five fellows, and thirty-one grantees. The work of these has resulted in the publication of more than 130 original communications to scientific journals. Now, in 1912, the contributions of the whole British chemical world to the Transactions of the Chemical Society amounted to only double this number, 266, so that it is evident that the Carnegie Trust, by its encouragement of research, has indirectly in the course of eight years produced a series of results equal to half the annual output of the whole Empire at the present time. This, it must be remembered, represents only a single department of the trust's activities; for, in addition to chemistry, work is being carried out in physics, biology, medicine, economics, history, and languages.

One final point deserves note. In dealing with a machine of this magnitude, it is, of course, impossible to proceed without laying down some general rules; but the Carnegie Trustees have hitherto avoided the pitfall of too great rigidity, and the flexibility of their system is one of its most valuable features. There can be no doubt that Dr. Andrew Carnegie's experiment has resulted in brilliant success in the development of the research talent of his native country.

LAWS OF ATMOSPHERIC MOVEMENTS.[1]

THE motion of the upper layers of the atmosphere is discussed in these two papers by Dr. W. N. Shaw, recently published. It is difficult in a short space to give a clear idea of the conclusions reached, but some of the main points may be here summarised.

In the paper published by the Scottish Meteorological Society it is shown that if p denote the pressure in millibars, and θ the absolute temperature (C.), and Δp and $\Delta\theta$ the changes that occur in passing horizontally from one place to another, then the rate of increase of pressure difference in millibars per metre of height is $0{\cdot}0342\ p/\theta\ (\Delta\theta/\theta - \Delta p/p)$. It is then shown that from about 1 km. to 9 km. the values of $\Delta\theta$ and Δp have in general the same sign, so that the term in brackets is small, and hence pressure differences, *i.e.* the barometric gradient, are maintained without much alteration up to 9 km. Above 10 or 11 km. $\Delta\theta$ and Δp have in general a different sign and the magnitude of the gradient rapidly falls off. The effect upon the wind at various altitudes is then considered, and special cases where simultaneous observations over England, Scotland, and Ireland are available are taken.

In the paper published by the Royal Society of Edinburgh, Dr. Shaw gives five axioms or laws of atmospheric motion, two lemmas or postulates, and six propositions. His first law reads thus :—

"In the upper layers of the atmosphere the steady horizontal motion of the air at any level is along the horizontal section of the isobaric surfaces at that level, and the velocity is inversely proportional to the separation of the isobaric lines in the level of the section."

The whole discussion turns upon the truth of this law, and Dr. Shaw confesses that observation is at present incapable of proving or of disproving it. There can be very little doubt that it is approximately true, for except near the equator pressure differences come into existence and persist for days or even weeks. These differences could not continue even for an hour if there were not some compensating horizontal acceleration acting on the air from the low towards the high pressure, for otherwise the inevitable rule which makes the surface of a liquid horizontal would come into play, and a depression would be filled up almost as soon as it was formed. Some opposing acceleration must therefore act whenever and wherever there is a barometric gradient, and we can conceive of no other possible source of this acceleration save that given in law I. But in the upper strata there must be a certain small amount of flow outward across the isobars from low to high pressure to compensate for the inverse flow that occurs close to the earth, where frictional resistances prevent the requisite velocity along the isobars from being attained. The other laws and the two lemmas will probably be accepted with the small reservations given by the author without demur.

The propositions follow from the laws and postulates. They are of great interest, but are too long to be quoted here. It will suffice to say that Dr. Shaw finds that a current flowing east or west will be stable, but a current flowing north or south is more or less unstable, and must lose or gain air as it goes. Also his suggestion about the flow of air up or down the land slopes from the interior of the continents to the sea is very pertinent, and, to my mind, affords a better explanation of the winter anticyclone over Asia and North America than that commonly given.

AN ELECTRICAL ANALOGY OF THE ZEEMAN EFFECT.

THE discovery, announced by J. Stark in NATURE of December 4, 1913, that when hydrogen in a state of luminescence is placed in an electric field of suitable strength and direction, the spectral lines are resolved into three or more components, is evidently a fact of prime physical importance. It will place in the hands of physicists another method of investigating the internal structure of the atom, and, in conjunction with the Zeeman effect, will no doubt be of immense service in the discovery of further regularities in spectral series, and in the attempts now being made by Bohr, Nicholson, and others to explain the origin of spectra on a dynamical basis. In this connection a series of papers in the *Rendiconti della R. Accad. dei Lincei* by Garbasso, Lo Surdo, and Puccianti will be of great interest to readers of NATURE.

The effect appears to have been observed independently by Lo Surdo whilst working on the retrograde positive rays in the neighbourhood of the kathode. An account of his first observations is given in a paper read on December 21, 1913. A cylindrical tube 20 cm. long and 4 mm. in diameter was used. It carried disc electrodes which completely filled the section, and it was excited by means of an accumulator battery. In these circumstances it was found that the electric field in the Crookes dark space was of itself sufficient to produce resolution of the lines. The observations were made with a four-prism quartz spectrograph. By suitable modifications the tube was varied so that the line of sight was either along or perpendicular to the field. The two outer components are polarised with the electric vector parallel to the field, the remainder in a perpendicular plane. When observations are made along the lines of force the outer components are missing. In a later paper, using a tube 1·5 mm. in diameter, Puccianti finds that the effect can readily be seen in the well-known Hilger wave-length spectroscope with constant deviation prism. The lines of the hydrogen spectrum show an interesting series of regularities; these are displayed in the following table (after Lo Surdo). Writing the Balmer formula in the form, $1/\lambda = a - 4a/n^2$, n has the values 3, 4, etc., for the different lines.

	H	H_β	H_γ	H_δ
n	3	4	5	6
Total no. of components	3	4	5	6
Order of line in the series	1st	2nd	3rd	4th
Component with electric vector $\perp$ to the field...	1	2	3	4
Appearance of resolved lines[1]				

It is seen that the number of components in a given line is the same as the corresponding value of n in the Balmer formula, and that the number of internal components is the same as the order of the given line in the spectral series. According to the measurements of Puccianti the separation of the outer components for H_β and H_α are in the ratio 1·49, or, expressed as fractions of the corresponding wave-lengths,

$$\frac{\delta_\beta}{\lambda_\beta} \Big/ \frac{\delta_\alpha}{\lambda_\alpha} = 2{\cdot}01$$

In a paper of December 21, 1913, Garbasso discusses the matter theoretically, to arrive at the conclusion that the Thomson model atom is incapable of explaining the (earlier) observations, except by the introduction of improbable hypotheses.

[1] The components placed above have the vector parallel to the field.

RELATIONS BETWEEN THE SPECTRA AND OTHER CHARACTERISTICS OF THE STARS.*

III.

To proceed farther we must have recourse to the study of eclipsing variable stars. Methods for computing their orbits have been developed at Princeton during the last few years,[20] the main motive for the investigation being the astrophysical importance of the results. Dr. Shapley, using the methods devised by the speaker, has obtained elements for eighty-seven such systems,[21] for each one of which the density of the components may be calculated. The values here employed are those which result from the assumption that the stars present discs darkened toward the edge, like the sun, but to a still higher degree, and the principal uncertainty of the results (which in any case cannot be very serious) arises from our present ignorance of the actual degree of this darkening. For our present purpose, they may be best utilised by computing the absolute magnitudes which the brighter component of each system would have if its mass and surface brightness were equal to those of the sun, leaving outstanding the differences due to density alone.

The results for the eighty eclipsing variable the elements and spectra of which are known are plotted in Fig. 4, on the same system as in the preceding figures. The black dots represent those stars for which the photometric data are most trustworthy, the open circles those of less precision. We are once more greatly indebted to Prof. Pickering and Miss Cannon for information regarding the spectra of these stars. To the absolute magnitude 4·0 on this diagram corresponds a density 1/3 that of the sun; to 3·0, 1/11; to 2·0, 1/45; to 1·0, 1/180 of the sun's density, and so on.

FIG. 4.

This diagram bears at first sight but small resemblance to the previous ones, but a little study brings out several important things. First, though the majority of these eclipsing variables are of Class A, every class from B to K is represented, and there are eight stars of Class G or redder. Secondly, all but one of these eighty stars are less dense than the sun, though but few of them are of less than 1/100 the sun's density. Thirdly, the stars of Classes A and B are fairly similar to one another in density, the great majority having densities between 1/3 and 1/45 of the sun's; those of Class F show a compact group of high density, and an isolated star of low density; but in Classes G and K the range of density is enormously great—from nearly twice that of the sun (W Ursæ Majoris) to one-millionth of the sun's density (W Crucis, at the top of the diagram). Fourthly, among the stars of density less than 1/200 that of the sun (corresponding to about +1·om. on the diagram), only one of the seventy-one stars of Classes B to F appears, while four of the eight stars

* An address delivered before a joint meeting of the Astronomical and Astrophysical Society of America and Section A of the American Association for the Advancement of Science, at Atlanta, Georgia, December 30, 1913, with a few additions, by Prof. H. N. Russell. Continued from p. 258.

[20] *Astrophys Jour.*, vol. xxxv., p. 315, and vol. xxxvi., pp. 54, 239, 385, 1912.

[21] *Astrophys. Jour.*, vol. xxxviii., pp. 159–73, 1913.

of Classes G and K are included. We may now answer decisively, and in the affirmative, the first two questions which were put a few moments ago. Some stars actually have densities quite as low as any that might be required to explain the great brightness of the reddest giant stars; and these stars of low density show a very marked preference for the "later" spectral classes, while practically all the stars of "earlier" type are far denser.

We can answer the third question as well, and in a quantitative fashion, if we are willing to assume that the eclipsing binaries, and also the telescopic double stars, of the various spectral classes are typical of the stars of these classes as a whole. Though this may not be rigorously true, there is good reason to believe that it is not seriously in error. We find, from Fig. 4, that the fifty eclipsing stars of Class A, if they all had the sun's mass and surface brightness, but their own densities, would, on the average, be of the absolute magnitude 3·06. Now, referring to Fig. 3, we find that the mean absolute magnitude which the 115 visual double stars of Class AO there recorded would have, if they were equal in mass only to the sun, but had their own surface brightness as well as density, would be 1·07. The only difference between these two groups (if they are both typical of the stars of Class A in general) is that one has been reduced by computation to the sun's surface brightness, while the other has not. It is therefore evident that the stars of Class A must, on the average, for equal surfaces, be two magnitudes brighter than the sun. Apart from the uncertainty whether the two groups compared are exactly typical, the probable error of this determination should be less than one-tenth of a magnitude.

In similar fashion, we find that the mean absolute magnitude of fifty-two visual pairs of spectra Oe5 to B9, reduced to the sun's mass, is −0·4, while that of twelve eclipsing binaries of similar spectrum, reduced to the sun's mass, and surface brightness, is +2·8, which makes the surface brightness of an average star of Class B greater by 3·2m. than that of the sun. Again, for the stars of Class F, we get +2·6 for the mean reduced absolute magnitude of the sixty-nine visual pairs, and +3·7 for that of the nine eclipsing pairs, the difference of 1·1m. being approximately the effect of surface brightness (somewhat more uncertain here, on account of the apparently different proportion of giant stars in the two groups).

It appears, therefore, that in passing down the spectral series from B to G, the surface brightness of the stars decreases by about one magnitude from each class to the next; and we have previously found that, among the dwarf stars, the decrease in surface brightness in passing from G to M must be at least 2½ magnitudes more. All this has been shown without making any use whatever of the physical meaning of the spectra, which have simply been used as symbols in classifying the stars into groups. The results are obviously in accordance with the view that the differences of spectral type arise from differences of temperature. Indeed, they constitute new and important evidence in its favour. How well they agree with other independent lines of evidence is shown by comparing the relative surface brightness just computed with the colour-index for the various classes. Taking A as a standard, we have:—

Spectrum	B	A	F	G	K	M
Surface brightness	−1·2	0·0	+0·9	+2·0	—	+4·5 (at least)
Colour-index ...	−0·3	0·0	+0·3	+0·7	+1·2	+1·6

The computed differences in surface brightness are in all cases about three times the colour-indices, in good agreement with the theoretical ratio.

We may now estimate the density of the redder giant stars. It appears from Fig. 3 that the mean absolute magnitude of the giant stars, if reduced to the sun's mass, is +0·6 for Class G, +0·5 for Class K, and 0·0 for Classes K5 and M. The differences between these values are small, and we may well take the general mean, +0·44, as typical of the whole. This corresponds to about fifty times the sun's luminosity. Such a giant star of Class G, if of the sun's surface brightness, would have to be of about seven times the sun's radius, and of 1/350 of its density. If we assume, on the basis of the foregoing study of the dwarf stars, that the surface intensities of the giant stars of Classes K and M are respectively 1·5 and 3 magnitudes fainter than that of the sun, we find that their densities must be 1/2800 and 1/25,000 of the sun's density. The observed densities of several eclipsing variables of Classes G and K are of just the order of magnitude here found, so that there is direct observational evidence in favour of all our conclusions, except the very low density assigned to the giant stars of Class M (among which no eclipsing variables have yet been found, so that their densities cannot be directly determined). But there is nothing improbable about so low a density, for we know of at least one star—W Crucis—the density of which is still smaller.

Before leaving these diagrams we should notice that, by comparing the data of Fig. 3 with those of Figs. 1 and 2, we may obtain the average masses of the stars of the various types. Consider, for example, the stars of spectra B to B5. From Fig. 3 we see that, if these stars were reduced to the sun's mass without changing either their surface brightness or density, their mean absolute magnitude would be −0·6. But the actual mean absolute magnitude of the stars of this spectral class is −2·0 according to Campbell, or −0·8 according to Boss. Taking the mean of these determinations, we find that these stars are, on the average, 2·1 times as bright as stars of unit mass, but of the same surface brightness and density, would be, from which it follows that their average surface area must be 2·1 times that of the latter stars, and their average mass 3·0 times that of the sun. The uncertainty whether the groups of stars which we are comparing are really exactly similar is here more serious than usual; if Campbell's stars are taken as typical, the mean mass comes out seven times that of the sun. It should be noticed that the "average" mass here obtained corresponds approximately to the average of the logarithms of the individual masses, and hence to their geometrical mean, which will be somewhat smaller than their arithmetical mean, and that we are here dealing with the mass of the brighter component of each system only. For the twelve spectroscopic binaries of spectrum B, which are available for comparison, the mean mass of the brighter components is about 9, and the geometrical mean probably about 7·5, times the sun's mass. As the observational selection in this case undoubtedly favours the larger masses, there is no serious discrepancy between the two results.

Proceeding similarly for the stars of the other spectral classes, we obtain the results collected in Table VII. The observed absolute magnitudes of the stars in clusters have been taken in preference to those of the stars of directly measured parallax, for the reasons already stated, and for the giant stars the mean of the results of Boss and Campbell has been used (except for Class G, for which Boss's value alone really represents them).

TABLE VII.

Mean Masses of Bright Components of Double Stars.

Spectrum	Observed absolute mag.	Abs. mag. reduced to sun's mass	Resulting average mass
B2	−1·4	−0·6	3·0
A0	+0·5	+1·1	2·3
A5, dwarf	+1·5	+1·6	1·2
F0 ,, ...	+2·4	+2·8	1·7
F3 ,, ...	+3·3	+3·1	0·8
F8 and G0 ...	+4·8	+4·0	0·5
G5, dwarf	+5·1	+4·2	0·3
K0 ,, ...	+6·4	+5·5	0·3
K5 and M, dwarf	+8·9	+7·7	0·2
G and G5, giant	−0·2	+0·6	3·0
K0, giant ...	+0·2	+0·5	1·5
K5 and M, giant	−0·3	0·0	1·5

The general similarity in mass among the stars of such widely different characteristics is very striking. In view of the small numbers of stars in some of the groups, the differences between the individual values should not be greatly stressed, but the gradual decrease of average mass among the dwarf stars is in accordance with the results of direct measurement. The geometrical mean of the computed masses of the bright components of the eight visual binaries of spectra A to F5, the parallaxes of which have been determined with tolerable accuracy, is 1·8 times the sun's mass; for the ten similar stars of spectra F8 to K it is 0·8. The greater mass of the stars of Class B is scarcely shown by these figures, but on this matter the testimony of the spectroscopic binaries deserves much the greater weight. The important conclusion which may be drawn from Table VII. is that, although the range in mean luminosity among the various groups of stars exceeds ten-thousandfold, the range in the mean masses probably does not exceed twenty-, or at most thirty-fold.

We may now summarise the facts which have been brought to light, as follows:—

(1) The differences in brightness between the stars of different spectral classes, and between the giant and dwarf stars of the same class, do not arise (directly at least) from differences in mass. Indeed, the mean masses of the various groups of stars are extraordinarily similar.

(2) The surface brightness of the stars diminishes rapidly with increasing redness, changing by about three times the difference in colour-index, or rather more than one magnitude, from each class to the next.

(3) The mean density of the stars of Classes B and A is a little more than one-tenth that of the sun. The densities of the dwarf stars increase with increasing redness from this value through that of the sun to a limit which cannot at present be exactly defined. This increase in density, together with the diminution in surface brightness, accounts for the rapid fall in luminosity with increasing redness among these stars.

(4) The mean densities of the giant stars diminish rapidly with increasing redness, from one-tenth that of the sun for Class A to less than one twenty-thousandth that of the sun for Class M. This counteracts the change in surface brightness, and explains the approximate equality in luminosity of all these stars.

(5) The actual existence of stars of spectra G and K, the densities of which are of the order here derived, is proved by several examples among the eclipsing variables, all of which are far less dense than any one of the more numerous eclipsing stars of "early" spectral type, with the sole exception of β Lyræ.

Evolution.

These facts have evidently a decided bearing on the problem of stellar evolution, and I will ask your indulgence during the few minutes which remain for an outline of the theory of development to which it appears to me that they must inevitably lead.

Of all the propositions, more or less debatable, which may be made regarding stellar evolution, there is probably none that would command more general acceptance than this—that as a star grows older it contracts. Indeed, since contraction converts potential energy of gravitation into heat, which is transferred by radiation to cooler bodies, it appears from thermodynamic principles that the general trend of change must, in the long run, be in this direction. It is conceivable that at some particular epoch in a star's history there might be so rapid an evolution of energy—for example, of a radio-active nature—that it temporarily surpassed the loss by radiation and led to an expansion against gravity; but this would be, at most, a passing stage in its career, and it would still be true in the long run that the order of increasing density is the order of advancing evolution.

If, now, we arrange the stars which we have been studying in such an order, we must begin with the giant stars of Class M, follow the series of giant stars, in the reverse order from that in which the spectra are usually placed, up to A and B, and then, still with increasing density, though at a slower rate, proceed down the series of dwarf stars, in the usual order of the spectral classes, past the sun, to those red stars (again of Class M), which are the faintest at present known. There can be no doubt at all that this is the order of increasing density; if it is also the order of advancing age, we are led at once back to Lockyer's hypothesis that a star is hottest near the middle of its history, and that the redder stars fall into two groups, one of rising and the other of falling temperature.[22] The giant stars then represent successive stages in the heating up of a body, and must be more primitive the redder they are; the dwarf stars represent successive stages in its later cooling, and the reddest of these are the farthest advanced. We have no longer two separate series to deal with, but a single one, beginning and ending with Class M, and with Class B in the middle, all the intervening classes being represented, in inverse order, in each half of the sequence.

The great majority of the stars visible to the naked eye, except perhaps in Class F, are giants; hence for most of these stars the order of evolution is the reverse of that now generally assumed, and the terms "early" and "late" applied to the corresponding spectral types are actually misleading.

This is a revolutionary conclusion; but, so far as I can see, we are simply shut up to it, with no reasonable escape. If stars of the type of Capella, γ Andromedæ, and Antares represent later stages of development of bodies such as δ Orionis, α Virginis and Algol, we must admit that, as they grew older and lost energy, they have expanded, in the teeth of gravitation, to many times their original diameters, and have diminished many hundred-, or even thousand-fold in density. For the same reason we cannot regard the giant stars of Class K as later stages of those of Class G, or those of Class M as later stages of either of the others, unless we are ready to admit that they have expanded against gravity in a similar fashion. We may, of course, take refuge in the belief that the giant stars of the

22 Phil. Trans., vol. clxxxiv., p. 688, 1902; Proc. Roy. Soc., vol. lxv., p. 186, 1899.

various spectral classes have no genetic relations with one another—that no one class among them represents any stage in the evolution of stars like any of the others—but this is to deny the possibility of forming any general scheme of evolution at all.

We might be driven to some such counsel of despair if the scheme suggested by the observed facts should prove physically impossible; but, as a matter of fact, it is in conspicuous agreement with the conclusions which may be reached directly from elementary and very probable physical considerations.

There can be very little doubt that the stars, in general, are masses of gas, and that the great majority of them, at least, are at any given moment very approximately in stable internal equilibrium under the influence of their own gravitation, and very nearly in a steady state as regards the production and radiation of heat, but are slowly contracting on account of their loss of energy. Much has been written upon the behaviour of such a mass of gas by Lane, Ritter, and several later investigators,[23] and many of their conclusions are well established and well known. So long as the density of the gaseous mass remains so low that the ordinary "gas laws" represent its behaviour with tolerable accuracy, and so long as it remains built upon the same model (*i.e.*, so long as the density and temperature at geometrically homologous points vary proportionally to the central density or temperature), the central temperature (and hence that at any series of homologous points) will vary inversely as the radius. This is often called Lane's law. If, after the contraction, the star is built only approximately on the same model as before, this law will be approximately, but not exactly, true.

The temperature of the layers from which the bulk of the emitted radiation comes will also rise as the star contracts, but more slowly, since the increase in density will make the gas effectively opaque in a layer the thickness of which is an ever-decreasing fraction of the radius. The temperature of the outer, nearly transparent gases, in which the line absorption takes place, will be determined almost entirely by the energy density of the flux of radiation through them from the layers below—that is, by the "black-body" temperature corresponding to this radiation as observed at a distance.

As the gaseous mass slowly loses energy and contracts, its effective temperature will rise, its light will grow whiter, and its surface brightness increase, while corresponding modifications will occur in the line absorption in its spectrum. Meanwhile, its diameter and surface will diminish, and this will at least partially counteract the influence of the increased surface brightness, and may even overbalance it. It cannot therefore be stated, without further knowledge, in which direction the whole amount of light emitted by the body will change.

This process will go on until the gas reaches such a density that the departures of its behaviour from the simple laws which hold true for a perfect gas become important. Such a density will be first reached at the centre of the mass. At the high temperatures with which we are dealing, the principal departure from the simple gas laws will be that the gas becomes more difficultly compressible, so that a smaller rise in temperature than that demanded by the elementary theory will suffice to preserve equilibrium after further contraction. The rise in temperature will therefore slacken, and finally cease, first at the centre, and later in the outer layers. Further contraction will only be possible if accompanied by a fall of temperature, and the heat expended in warming the mass during the earlier stages will now be gradually transmitted to the surface and liberated by radiation, along with that generated by the contraction. During this stage, the behaviour of the mass will resemble, roughly, that of a cooling solid body, though the rate of decrease of temperature will be far slower. The diameter and surface brightness will now both diminish, and the luminosity of the mass will fall off very rapidly as its light grows redder. It will always be much less than the luminosity of the body when it reached the same temperature while growing hotter, on account of the contraction which has taken place in the interval, and this difference of luminosity will be greater the lower the temperature selected for the comparison. Sooner or later, the mass must liquefy, and then solidify (if of composition similar to the stellar atmospheres), and at the end it will be cold and dark; but these changes will not begin, except perhaps for a few minor constituents of very high boiling point, until the surface temperature has fallen far below that of the stars of Class M (about 3000° C.).

The "critical density" at which the rise of temperature will cease can only be roughly estimated. It must certainly be much greater than that of ordinary air, and (at least for substances of moderate molecular weight), considerably less than that of water. Lord Kelvin,[24] a few years ago, expressed his agreement with a statement of Prof. Perry's that "speculation on this basis of perfectly gaseous stuff ought to cease when the density of the gas at the centre of the star approaches one-tenth of the density of ordinary water in the laboratory."

It is clear from the context that this refers rather to the beginning of sensible departures from Lane's law than to the actual attainment of the maximum temperature, which would come later; and it seems probable, from the considerations already mentioned, that the maximum temperature of the surface would be attained at a somewhat higher density than the maximum central temperature.

The resemblance between the characteristics that might thus be theoretically anticipated in a mass of gas of stellar dimensions, during the course of its contraction, and the actual characteristics of the series of giant and dwarf stars of the various spectral classes is so close that it might fairly be described as identical. The compensating influences of variations in density and surface brightness, which keep all the giant stars nearly equal in luminosity, the rapid fall of brightness among the dwarf stars, and the ever-increasing difference between the two classes, with increasing redness, are all just what might be expected. More striking still is the entire agreement between the actual densities of the stars of the various sorts and those estimated for bodies in the different stages of development, on the basis of the general properties of gaseous matter. The densities found observationally for the giant stars of Classes G to M are such that Lane's law must apply to them, and they must grow hotter if they contract; that of the sun (a typical dwarf star) is so high that the reverse must almost certainly be true; and the mean density of the stars of Classes B and A (about one-ninth that of the sun, or one-sixth that of water) is just of the order of magnitude at which a contracting mass of gas might be expected to reach its highest surface temperature.

We may carry our reasoning farther. Another deduction from the elementary theory (as easily proved as Lane's law, but less generally known) is that, in two masses of perfect gas, similarly constituted and of equal radius, the temperatures at homologous points are directly proportional to their masses. As in the previous case, the effective surface temperature of the

[23] An excellent summary may be found in Emden's *Gaskugeln*.

[24] NATURE, vol. lxxv., p. 368, 1907.

more massive body will be the greater, though to a less degree than the central temperature. A large mass of gas will therefore arrive at a higher maximum temperature, upon reaching its critical density, than a small one. The highest temperatures will be attained only by the most massive bodies, and all through their career these will reach any given temperature at a lower density, on the ascent, and return to it at a higher density, on the descending scale, than a less massive body. They will therefore be of much greater luminosity, for the same temperature, than bodies of small mass if both are rising toward their maximum temperatures. On the descending side the difference will be less conspicuous. Bodies of very small mass will reach only a low temperature at maximum, which may not be sufficient to enable them to shine at all.

All this, again, is in excellent agreement with the observed facts. The hottest stars—those of Class B—are, on the average, decidedly more massive than those of any other spectral type. On the present theory, this is no mere chance, but the large masses are the necessary condition—one might almost say the cause—of the attainment of unusually high temperature. Only these stars would pass through the whole series of the spectral classes, from M to B and back again, in the course of their evolution. Less massive bodies would not reach a higher temperature than that corresponding to a spectrum of Class A; those still less massive would not get above Class F, and so on. This steady addition of stars of smaller and smaller mass, as we proceed down the spectral series, would lower the average mass of all the stars of a given spectral class with "advancing" type, in the case of the giants as well as that of the dwarfs. This change is conspicuously shown among the dwarf stars in Table VII., and faintly indicated among the giant stars. The average masses of the giant and dwarf stars appear, however, to be conspicuously different, which at first sight seems inconsistent with the theory that they represent different stages in the evolution of the same masses. But the giant stars which appear in these lists have been picked out in a way that greatly favours those of high luminosity, and hence, as we have seen, those of large mass, while this is not the case among the dwarf stars. The observed differences between them are therefore in agreement with our theory, and form an additional confirmation of it.

It is now easy, too, to understand why there is no evidence of the existence of luminous stars of mass less than one-tenth that of the sun. Smaller bodies presumably do not rise, even at maximum, to a temperature high enough to enable them to shine perceptibly (from the stellar point of view), and hence we do not see them. The fact that Jupiter and Saturn are dark, though of a density comparable with that of many of the dwarf stars, confirms this view.[25]

We may once more follow the lead of our hypothesis into a region which, so far as I know, has been previously practically untrodden by theory. It is well known that the great majority of the stars in any given region of space are fainter than the sun, and that there is a steady and rapid decrease in the number of stars per unit volume, with increasing luminosity. The dwarf stars, especially the fainter and redder ones, really greatly outnumber the giants, the preponderance of which in our catalogues arises entirely from the egregious preference given them by the inevitable method of selection by apparent brightness.

What should we expect to find theoretically? To get an answer, we must make one reasonable assumption, namely, that the number of stars, in any sufficiently large region of space, which is, at the present time, in any given stage of evolution, will be (roughly at least) proportional to the lengths of time which it takes a star to pass through the respective stages.[26] While a star is growing hotter it is large and bright, is radiating energy rapidly, and is also storing up heat in its interior; while, on account of its low density, contraction by a given percentage of its radius liberates a relatively small amount of gravitational energy. It will therefore pass through these stages with relative rapidity. Its passage through its maximum temperature will obviously be somewhat slower. During the cooling stages its surface is relatively small and its rate of radiation slow; it is dense, and a given percentage of contraction liberates a large amount of energy, and the great store of heat earlier accumulated in its interior is coming out again. It must therefore remain in these stages for very much longer intervals of time, especially in the later ones, when the rate of radiation is very small.

This reproduces, in its general outlines, just what is observed—the relative rarity of giant stars, the somewhat greater abundance of those of Class A near the maximum of temperature, and the rapidly increasing numbers of dwarf stars of smaller and smaller brightness. The well-known scarcity of stars of Class B, per unit of volume, is further accounted for if we believe, as has been already explained, that only the most massive stars reach this stage.

In this connection we will very probably be asked, What precedes or follows Class M in the proposed evolutionary series, and why do we not see stars in still earlier or later stages? With regard to the latter, it is obvious that dwarf stars still fainter than the faintest so far observed (which are of Class M) would, even if among our very nearest neighbours, be apparently fainter than the tenth magnitude. We cannot hope to find such stars until a systematic search has been made for very large proper-motions among very faint stars. The extreme redness of such stars would, unfortunately, render such a search by photographic methods less profitable than in most cases.

But a giant star of Class M, a hundred times as bright as the sun, certainly cannot spring into existence out of darkness. In its earlier stages it must have radiated a large amount of energy, though perhaps less than at present. But as the temperature of a radiating body falls below 3000° C., the energy-maximum in its spectrum moves far into the infra-red, leaving but a beggarly fraction of the whole radiation in the visible region. Stars in such stages

[25] In the foregoing presentation of the theory, to avoid interference with the progress of the main argument, no mention has been made of certain considerations which should be discussed here.

(1) It is probable that at stellar temperatures the gaseous matter is very considerably dissociated and ionised. But this will not affect its gaseous nature. For our present purpose it amounts to little more than a diminution of the mean molecular weight. This will lower the temperature corresponding to a given density and pressure, and so tend to lower the maximum attainable temperature; but as the degree of dissociation is likely to vary gradually with the temperature, it should not affect the orderly sequence of changes which form the basis of the previous arguments.

(2) It is also probable that the available potential energy of a star is not entirely gravitational, but partly, if not mainly, of radio-active or similar atomic origin. If, as in the relatively very small range accessible to experimental investigation, the rate of liberation of this energy is independent of the temperature and pressure, it would simply supply a constant annual addition to the energy derived from gravitational contraction, and the only difference in the course of events would be that a star, on cooling, would approach, not complete extinction, but a steady state, of very long duration, in which as much energy was annually radiated away as was supplied by atomic disintegration. If the rate of disintegration is increased under the extremely violent molecular collisions which must occur in the interior of a star, a great liberation of energy may occur when the interior has got hot enough, thus increasing the maxima temperature and prolonging its duration. But, even on this hypothesis, the number of the violent collisions which liberate the atomic energy would increase gradually as the temperature of the interior rose, and the general character of the evolutionary changes, including the relation of the mass and density of the body to the time of their occurrence, would not be radically altered.

It seems, therefore, probable that the previous reasoning would require no essential modification on account of either of these factors in the problem.

[26] Hertzsprung, *Zeitschrift für Wissenschaftliche Photographie*, vol. iii, p. 442, 1905.

would therefore emit much less light than they would do later, and stand a poor chance of being seen.[27] We know, as yet, very little about the colour-index and temperature of stars of those varieties of Class M (Mb and Mc) which are evidently furthest along in the spectral series, and it may well be that a star usually reaches the temperature corresponding to these stages by the time that it begins to shine at all brightly. In any case, stars in these very early stages should be of small or moderate luminosity, and rare per unit of volume, and hence very few of them would be included in our catalogues.

The great luminosity and extreme redness of the stars of Class N suggest that they belong at the beginning of the series of giant stars; but the relations of this very distinct spectral type to the others are not yet quite clear, and it would be premature to give it a definitive place in the sequence. It seems clear, however, that these stars must be in a very primitive condition, rather than in a very late one, as believed by Lockyer. The stars of Class O (Wolf-Rayet stars) are of very great average luminosity, and probably lie beyond those of Class B at the apex of the temperature scale, as Lockyer supposes. But in the absence of data concerning their masses, densities, and the like, we cannot place them definitively, except that Oe5 and Oe come almost certainly just above Be.

One further application of the theory may be very briefly mentioned. If we have a large number of contracting masses of gas endowed with various moments of momentum, more and more of them will split up into pairs as they grow denser, and the pairs latest formed will have the shortest periods. A large percentage of spectroscopic binaries, especially of short period, is therefore direct evidence of a fairly advanced state of evolution, and the occurrence of this condition among the stars of Classes B and A supports—indeed, almost by itself compels—the view that they are far removed from a primitive condition. Most of the stars which have been investigated for radial velocity are giants, and the absence of spectroscopic binaries of short period among the redder stars is in agreement with the view that they are in earlier stages of evolution.

The distribution of the visual binaries and physical pairs among the various spectral classes depends mainly upon a quite different factor, namely, the resolving power of our telescopes, which allows us to separate the closer pairs of short period only among the nearer stars, so that the systems for which orbits have been determined are nearly all dwarf stars.

I have endeavoured in the past hour to set before you the present state of knowledge concerning the real brightness, masses, densities, temperatures, and surface brightness of the stars, and to sketch the theory of stellar evolution to which the study of these things has led me. This theory is inconsistent with the generally accepted view. Its fundamental principle is identical with that of Lockyer's classification, but it differs radically from the latter in the principles according to which it assigns individual stars, and even whole classes of stars, to the series of ascending or descending temperature. (For example, Lockyer puts such conspicuously giant stars as Canopus, Capella, Arcturus, and β Cygni, and all the stars of Class N, into the descending series, and places β Hydri and δ Pavonis (which are clearly dwarf stars) in the ascending series.)

Two things have gone farthest to convince me that it may be a good approximation to the truth—the way in which it explains and coordinates characteristics of the different spectral types which previously appeared to be without connection or reason, and the way in which a number of apparent exceptions to its indications have disappeared, one by one, as more accurate information concerning spectra, orbits of double stars, and the like, became available, until only one doubtful case remains.

I have purposely made no attempt at this time to touch upon certain other interesting matters, such as the difference of the mean peculiar velocities of stars of the various spectral classes, although, with the aid of simple and very reasonable assumptions, they may be added to the list of things explainable by the new theory. My reason for this has been less for lack of time than because there is at present no definite reason, assignable from general considerations in advance, why we should expect an old star to be moving faster or slower than a younger one, while there is such a reason why we should suppose that a dense star is in a later stage of evolution than one of low density. It seems better to find out what we can about the order of evolution from data of the latter kind, and then apply our results to the study of problems of the former sort, than to attack them without such aid or by means of unproved assumptions. The assumptions that are necessary on the new theory are simple and probable enough, but they do not form an integral part of the theory, and cannot be established directly from general considerations, and so I will not discuss them now.

The new theory will not explain everything about the stars—I should be rather afraid of it if it did; for example, it leaves the phenomena of preferential motion, or "star-streaming," as puzzling as ever. I have only tried to interpret some of the facts most obviously capable of evolutionary explanation, on the fundamental assumption that the properties of matter, and the forces in operation, among the stars, are the same as those with which we are familiar in the laboratory. He would be a bold man indeed who would assert that this assumption is entirely true, but it seems clear that it should be thoroughly tried out before the existence of new forces can legitimately be postulated.

If the ideas to which you have so kindly listened to-day shall prove of any help toward removing the need for belief in unknown forces, and extending the domain of those already known, my labour will be far more than repaid; but it should not be forgotten that the real labourers have been those who, through long and weary nights, accumulated bit by bit, and, through monotonous days, prepared for the use of others the treasures of observational knowledge with which it has been my pleasurable lot to play in the comfort of my study.

I need scarcely add that, if what I have said proves of interest to any of you, your frank and unsparing criticism will be the greatest service which you can render me.

27 Russell, *Science*, N.S. Vol xxxvii, p. 646, 1913.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

Birmingham.—At its last meeting the University council passed the following resolution:—"That the council desires to record its deep sorrow at the death of Prof. Poynting, who so faithfully served the Mason College and the University for thirty-four years. During his distinguished career as professor of physics he was not only an inspiring teacher and investigator, but bore a considerable part in the development of the college and of the University. His keen interest in all that concerned the University, its staff, and its students, his genial and attractive personality, will be long and affectionately remembered; his death leaves a gap which it will be most difficult to fill."

Mr. Frank E. Huxley has resigned his lectureship in dental surgery.

Dr. L. G. Parsons has been appointed assistant to the chair of forensic medicine and toxicology.

A full-time lectureship in classics, ancient history, and archæology is being established.

Miss M. Le Bour has been appointed to undertake a special investigation in helminthology in the department of agricultural zoology.

CAMBRIDGE.—Mr. E. R. Burdon has been appointed University lecturer in forestry.

The Anthony Wilkin studentship in ethnology and archæology will be available at the end of the Easter term. Applicants should send their names, qualifications, and a statement of the research which they wish to undertake, to the Vice-Chancellor before June 1.

Mr. H. C. Haslam, of Gonville and Caius College, has been approved by the General Board of Studies for the degree of Doctor of Science.

THE governors of the South Wales and Monmouthshire University College at Cardiff have accepted the generous offer of an anonymous donor to provide funds for the erection of a great school of preventive medicine. The money value of this gift, together with that of Sir William James Thomas to erect a school for other branches of medicine in connection with the college, is estimated at 180,000*l.*

Two lectures entitled "La Catalyse et mes divers Travaux sur la Catalyse," will be given by Prof. Paul Sabatier, of the University of Toulouse, at King's College, W.C., on May 14 and 15, at 5 p.m. Special interest is attached to these lectures as the subject-matter is one with which Prof. Sabatier is particularly associated, and one from which he has obtained important results in the synthetical preparation of organic substances.

IT is announced in the issue of *Science* for May 1 that the Catholic University of America, Washington, will receive the greater part of the estate of 200,000*l.* left by the late Mr. Theodore B. Basselin, of Croghan. From the same source we learn that Mr. James Deering, in a letter addressed to the trustees of North-western University and of Wesley Hospital, announces a gift of 200,000*l.* to the hospital. It is provided that Wesley Hospital shall be a teaching hospital under Northwestern University. The gift is made in honour of the donor's father and of his sister.

PROF. SIMS WOODHEAD, in his presidential address to the Royal Microscopical Society (Jour. Roy. Microscop. Soc., 1914, part 2, p. 109), suggests that too little attention is paid in our medical schools to the education of the students in the *technical* use of the microscope. He urges that there should be sound teaching on the optical and mechanical principles on which are based the construction and use of the microscope, and that the best students, at any rate, should have some opportunity of acquiring facility in the use of the various types of substage condenser, dark-ground illumination, monochromatic illumination, methods of measurement, ultra-microscopic work, micro-spectroscopy, polarisation, and the like.

FREE vacation courses in scientific instrument-making and glass-blowing will again be held this year at the University of Leyden. The course in instrument-making will include practice with modern machine tools, such as lathes, milling machines, etc., and will extend from August 20 to August 29; it will involve the cutting of screw threads, turning spheres, copying divided discs, and grinding various hardened objects. The course on elementary and advanced glass-blowing, from August 20 to September 2, will include the manufacture of vacuum tubes, vacuum flasks, and various other forms of apparatus used in physical and chemical investigation, and the manipulation of high-vacua pumps. The director of the course is Prof. Kamerlingh Onnes, and the secretary Dr. C. A. Crommelin, to whom all communications should be addressed at the Physical Laboratory, Leyden, Holland.

THE Medical Officers of Schools Association from time to time issues pamphlets on problems connected with conditions of health in schools. The latest of these useful publications deals with "School Lighting," and is a reprint of a paper read before the association by Dr. E. H. T. Nash. The author puts the difficulties of the problem of daylight illumination, and rightly asks that the Government should either subsidise further research or conduct a thorough inquiry through the Board of Education. In the present regulations of the Board we read: "The light so far as possible should be admitted from the left side of the scholars. This rule will be found greatly to influence the planning." So far all authorities agree, but there is great diversity of opinion and practice as regards bilateral and overhead lighting, the shape of class-rooms, the relative areas to be assigned to windows. These matters have an important influence on the health of the children, the class-room efficiency, and the expenditure of public money on school buildings. As regards artificial lighting, the problem is vastly more simple, and Dr. Nash gives an instance of efficient and economic lighting by incandescent gas, the cost for a class-room being rather more than $\frac{3}{4}d.$ an hour. In this case the illumination at the desks ranged from 3·5 foot-candles to 5 foot-candles, as compared with the usually recommended minimum of 2 foot-candles. The pamphlet is illustrated with diagrams, includes an account of the discussion which followed the reading of the paper, and is published by Messrs. Churchill at 1*s.*

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 7.—Sir William Crookes, president, in the chair.—Lord **Rayleigh**: (1) Some calculations in illustration of Fourier's theorem. (2) The theory of long waves and bores.—Sir Joseph **Larmor** and J. S. B. **Larmor**: Protection from lightning and the range of protection afforded by lightning rods. On modern ionic views discharge in the atmosphere should originate at a place of maximum intensity of electric field and spread both ways from it along a line which should be roughly the line of force. The explanation of branching, zigzag, and multiple lightning discharges is to be sought on these lines. The introduction of a narrow linear conductor cannot sensibly disturb a steady field of force, and not at all if it is transverse to the field. Thus it would seem to be the top of the building itself, not of the lightning conductor, that attracts the discharge, and the function of a single rod can only be to lead it more safely away. But a number of rods distributed over the area of the roof, and effectively connected to earth by a conductor, can, by their joint action, lift the intensest part of the field from the top of the building to the region around their summits, and so obviate or much mitigate the danger of discharge from above to the building which they cover. In illustration, diagrams are given of a vertical field of force as disturbed by vertical pillars of semi-ellipsoidal form and of various breadths, or by an earthed conducting region overhead, such as might be originated by gradual discharge from a pointed rod. —Prof. A. **Schuster**: Newcomb's method of investigating periodicities and its application to Brückner's weather cycle.—E. N. Da C. **Andrade**: The flow in metals subjected to large constant stresses. The law connecting the extension with time for wires of various metals subjected to large stresses has been examined at different temperatures. The stress was kept constant throughout the flow by the device of a hyperbolic weight employed in former experiments. The different types of flow observed for different metals at room temperature are only particular cases of one general law governing the flow of all single metals, and can all be found for one metal by choosing an appropriate temperature; thus, soft iron at 450° C. behaves similarly to lead at 15° C.—G. I. **Taylor**: Eddy motion in the atmosphere. The paper contains a theoretical discussion of the function of eddies in conveying heat and momentum through a fluid. It is shown also that measurements of the temperature of the air over the Great Bank of Newfoundland made by the author last year, lead to the conclusion that eddies extend upwards over the sea to a height of at least 800 metres; and that there is no appreciable diminution in their size or intensity at this height. On the assumption of a uniform amount of eddy motion, the velocity of the wind at various heights above the ground is calculated, and shown to agree with the most recent observations carried out over Salisbury Plain.—Prof. Ernest **Wilson**: The properties of magnetically-shielded iron as affected by temperature. In a paper recently read before the Royal Society, it is shown that if stalloy in ring form is shielded from the earth's magnetism and subjected to a considerable magnetising force at atmospheric temperature, the permeability can be increased. The present experiments deal with the effect of allowing stalloy to cool down through the temperature at which it regains magnetic quality when in a shield and when under the influence of a magnetising force due to a continuous current. Two specimens have been subjected to this treatment, and in each case the maximum permeability has a value of above 10,000 when the specimen is at atmospheric temperature.

Geological Society, April 29.—Dr. A. Smith Woodward, president; and afterwards, Mr. W. Hill, vice-president, in the chair.—A. S. **Woodward**: The lower jaw of an anthropoid ape (Dryopithecus) from the Upper Miocene of Lérida (Spain). The greater part of a mandibular ramus and symphysis of *Dryopithecus fontani* is described. The specimen is the latest jaw of an anthropoid ape hitherto discovered in Europe. The relatively small size of the first molar is to be regarded as a primitive character, lost in all modern anthropoids except some Gibbons. The shape of the mandibular symphysis is remarkably primitive, with the surface of insertion for the digastric muscle nearly as large as that of the ancestral Macaques. The anterior face of the symphysis slopes directly upwards from the front edge of this insertion, as in the Macaques, some Gibbons, and very young individuals of the chimpanzee, gorilla, and orang. It thus differs from the mandibular symphysis in adult individuals of these existing apes, in which the lower portion of the slope curves backwards into a flange or shelf of bone, while the digastric insertion is reduced in extent. So far as its lower jaw is concerned, Dryopithecus is a generalised form from which modern anthropoid apes and man have diverged in two different directions.—Prof. J. W. **Gregory**: The structure of the Carlisle-Solway Basin, and the sequence of its Permian and Triassic rocks. The Carlisle-Solway basin has been generally represented as a syncline, with the Solway resting on a great thickness of Triassic rocks. A boring made near Gretna in 1794 shows, on the contrary, that Lower Carboniferous rocks crop out there at the surface. This boring shows that the basin is not a simple syncline. The evidence derived from the boring necessitates reconsideration of the Permo-Triassic sequence in north Cumberland, as to which the Geological Survey maps and memoirs are not in agreement. Arguments are given to show that the evidence for the existence of the St. Bees Sandstone at the bottom of the Abbeytown and Bowness borings is quite inconclusive, and the fact is improbable. The view adopted by the Geological Survey map that the area west and north-west of Carlisle consists of Keuper deposits, is also improbable.

MANCHESTER.

Literary and Philosophical, April 7.—Mr. F. Nicholson, president, followed by Prof. F. E. Weiss, vice-president, in the chair.—W. C. **Grummitt** and Dr. H. G. A. **Hickling**: A preliminary note on the structure of coal. It was suggested that the essential constituent of coal is a homogeneous substance, red or orange in colour when thin enough to be transparent. This material under the microscope frequently shows evidence of "flow," and was doubtless a liquid vegetable decomposition product. This, in its purest form, constitutes the "bright" layers of coal; with strongly developed "cleat" or cleavage. Vegetable structures are preserved in coal in two forms: (1) in a "carbonised" condition, as is found pure in "mother-of-coal," and is quite opaque even when less than 1 μ thick; (2) impregnated with the transparent material described above, spores being the most readily distinguishable parts preserved in this manner. The ash from the various coals consists largely of fibrous material which is clearly an incombustible residue of vegetable structure and closely resembles the ash obtained by burning wood. The spores from certain coals can be isolated by maceration with Schultz solution.

April 28.—Mr. F. Nicholson, president, in the chair. —R. F. **Gwyther**: Specification of stress. Part v., An outline of the theory of hyper-elastic stress. The author dealt with the mathematical conditions of a body from the time of exceeding the elastic limit and when approaching to the conditions of rupture.—H. P. **Walmsley** and Dr. Walter **Makower**: The photographic action of α rays. Each α particle on striking a grain of silver in a photographic film affects that grain in such a manner as to be capable of photographic development. The path of the ray is thus apparent under the microscope.

PARIS.

Academy of Sciences, May 4.—M. P. Appell in the chair.—The **President** announced the death of M. van Tieghem, perpetual secretary.—Maurice **Hamy**: The position to be given to the astronomical observatory on Mont Blanc. Various possible sites have been examined from the points of view of uninterrupted horizon, accessibility and stability, and the advantages and disadvantages of each site discussed. The best position would appear to be the Petit Flambeau (3435 metres).—Emile **Picard**: Some reflections on certain results of Henri Poincaré concerning analytical mechanics.—Pierre **Termier**: Eduard Suess, the man and his work.—C. **Guichard**: Certain special congruences of circles and spheres.—René **Baillaud**: A photographic astrolabe.—N. E. **Nörlund**: Series of faculties. —Ernest **Esclangon**: The quasi-periodic integrals of linear differential equations.—Michel **Fekete**: A lower limit of the changes of sign of a function in an interval.—N. **Lusin**: a problem of M. Baire.—Lucien **Godeaux**: Double algebraic surfaces having a finite number of points of ramification.—Louis **Roy**: Quasi-waves in three dimensions.—L. **Dunoyer** and R. W. **Wood**: Correction to our note entitled photometry of the superficial resonance of sodium vapour under the stimulation of the D lines. A correction of an error of calculation in the determination of the width of the resonance lines.—F. **Charron**: A hydrodynamical arrangement for the magnification and registration of radio-telegraphic signals. The telephonic receiver is modified so that the vibrations are concentrated on the orifice of a vertical capillary tube. A stream of gas is flowing out of the capillary tube with a velocity just below that of turbulent flow. Sounds in the telephone produce disturbances in the flow of the gas through the jet, and these can be utilised to form a record without using a Morse receiver.—H. **Bourget**, H. **Buisson**, and Ch. **Fabry**: Interferential measurements of the radial velocities and wave-lengths in the nebula of Orion. The mean radial velocity of the nebula is +15·8 kilometres a second with respect to the sun, that is, the distance between the sun and the nebula is increasing at that rate. The wave-lengths of the characteristic double ultra-violet line had been determined and found to be 3726.100 and 3728.838. These lines are not emitted by any known element.—B. **Fessenkoff**: The law of reflection of light by matt surfaces.—J. **Minguin** and R. **Bloc**: The influence of solvents on the optical activity of the camphoric esters. The optical activity of the *allo*-acids is the same in alcoholic, benzene, or toluene solutions: the *ortho*-acids give higher rotations in benzene or toluene than in alcohol.—Marcel **Delépine**: Lithium chloro-iridate and chloro-iridite.—Jacques **Bardet**: The extraction of germanium from Vichy water. Germanium had been previously detected spectroscopically in Vichy water, and an attempt was made to isolate germanium compounds from this source. The starting point was the mixture of insoluble carbonates deposited on heating the water, and 0·06 gram of germanium oxide was prepared from 100 kilograms of deposit, representing about 250,000 litres of mineral water. The method of separation is given in detail.—M. **Vasticar**: The apparatus of support of the internal acoustic region.—Michel **Cohendy** and Eugène **Wollman**: Experiments on life without micro-organisms. Aseptic growth of guinea-pigs. These experiments prove that it is possible to raise guinea-pigs under strictly aseptic conditions, development and utilisation of food being in no way prejudiced by the absence of micro-organisms.—Louis **Cruveilhier**: Treatment of blennorrhagia by the method of sensitised virus vaccines.—Auguste **Lumière** and Jean **Chevrotier**: Some new considerations concerning the culture of gonococci.—P. **Macquaire**: The amylolytic diastase of the pancreas.—L. **Cayeux**: Eastern prolongation of the ferruginous formation of the May (Calvados) synclinal.

Cape Town.

Royal Society of South Africa, April 15.—Mr. S. S. Hough in the chair.—T. **Muir**: (1) Note on a theorem of Ph. Gilbert, regarding the differentiation of a special Jacobian. (2) Note on Rosanes's functions, resembling Jacobians.—R. T. A. **Innes**: The triple stellar system ζ Virginis and Σ 1757. These two stars, although a considerable distance apart, constitute a system as they are moving through space with almost identical velocities and directions.—G. A. H. **Bedford**: A curious mosquito.—A. L. du **Toit**: The porosity of the rocks of the Karroo system. Determinations are given of the porosity of more than ninety rocks, the majority being from borehole cores. It was found with the three-fold division of the Beaufort beds the mean porosity of the Sandstone was 2·9 per cent. for the lower, 5·2 per cent. for the middle, and 5·5 per cent. for the upper division. The figures for the Transvaal phase of the Karroo were much higher. The effects of weathering in increasing the porosity are discussed and analysed.—J. R. **Sutton**: A note on the temperatures of the air observed at Mochudi. The note gives a brief account of some points of interest in the results of temperature observations by Harbor at Mochudi in the Bechuanaland Protectorate. The extremes of temperature are considerable, the greatest range so far observed being from 108° F. to 28° F. The mean maximum temperatures depend upon the sun's meridian altitude in much the same way as they do at Kimberley. The annual cold wave of the middle of July is felt at Mochudi like it is elsewhere further south.

CHEMISTRY: ANCIENT AND MODERN.

Some Fundamental Problems in Chemistry—Old and New. By Prof. E. A. Letts. Pp. xiii + 235 + plates. (London: Constable and Co., Ltd.) Price 7*s.* 6*d.* net.

THOSE chemists whose memories can carry them back for a period of about half a century will have experienced several phases in the development of the science which, at their respective periods, were regarded as marking a transition from an older to a newer chemistry. The writer of this notice began his reading when water was HO and so forth. Then came the "new notation" resulting from the proper recognition of Avogadro's law, the doubling of certain atomic weights, and the reconstruction of our formulæ. This was the "new chemistry" of that period. Next arose the more complete elaboration of the conception of constitution or structure based on valency, due to Frankland and Kekulé, and we had a yet newer chemistry—a development which was so extraordinarily prolific in the way of results that chemists were inclined to hug themselves into the belief that they had come to close quarters with the inner mechanism of molecular structure, and the very weaknesses of the theory, which had shown signs of breaking down in certain directions, afterwards became cornerstones of strength in the light of the brilliant hypothesis of van't Hoff and Le Bel, which inaugurated the then new science of stereochemistry. Moreover, about the same period when structural chemistry was undergoing these developments, attention was being more systematically concentrated upon the relationships of the chemical elements among themselves, these studies culminating in that periodic classification associated with the names of Newlands, Mendeléeff, and Lothar Meyer. From that great generalisation arose a still newer chemistry which systematised the whole treatment of the science, both theoretically and practically, and dominates our present teaching. Another "new" chemistry must be added to this record—the application of purely physical methods to the study of chemical phenomena resulting in the foundation of "physical chemistry" as a distinct subject.

All these phases are familiar to the modern student of the history of the science, and they fall into the category of what the author of the present work would term the older chemistry. Dr. Letts does not, however, deal with all these developmental epochs; the older chemistry—as distinguished from ancient chemistry—is limited by him to the discussion of the methods and results of atomic weight determinations by the older as well as by the most recent workers in this field, and to a very full consideration of the periodic law and its consequences. The reader will find no reference to those fundamental problems relating to chemical statics and dynamics which the physical chemists have formulated as the results of their studies; such familiar terms as mass action, osmotic pressure, electrolytic or ionic dissociation, stereochemistry, etc., do not appear in the index. This criticism amounts simply to the statement that the author professes to deal only with certain of the fundamental problems, and within the limits thus assigned, he handles his subject in a very lucid and suggestive way. His treatment of the periodic law, for example, to which two chapters are devoted, goes far beyond the arid description found in the ordinary textbooks and may be commended as worthy of most serious consideration by all students. Workers on the look-out for new elements may take courage from Dr. Letts's suggested classifications, according to which there remain either thirty-eight or twenty-five gaps in the periodic table now waiting to be filled up (p. 60). Another valuable feature of this section is the new "atomic volume" curve, constructed by the author from the most recent available data, and, for the first time, comprising the group of "inert" elements. As will be seen on reference to the original work, this curve differs in some important particulars from that first given to our science by Lothar Meyer in 1870, and opens up some interesting suggestions with respect to missing elements.

Although the older chemistry is treated of in the present work within the limits specified, the reader will gather from the subsequent chapters that these older workers—and happily for our science that generation has not yet become extinct—have passed on to the newer school a very goodly heritage. By the "newer chemistry" Dr. Letts understands that great body of observed facts and theoretical deductions which have been accumulated since the study of the action of the electric discharge upon highly attenuated, gaseous matter was seriously taken in hand by physicists and chemists, and since the discovery of radioactivity and the radio-active elements. How much of this newer knowledge will be passed on as canonical to future generations it would be very rash to predict. It is, however, certain that chemistry, by the discovery of unexpected phenomena, and by the utilisation of novel methods of attacking the ultimate components of matter, has now entered upon a new era in its history—a state of affairs which both students and teachers, whether of the older or newer school, must perforce take into consideration.

From this last point of view the present work presents certain special advantages which may be summed up by the statement that the author handles his subject as a chemist. The day has passed away when workers with parochial views of their science can hope to impose upon the present generation stupidly narrow limitations by "method"—to insist that the evidence based upon "purely chemical" methods is alone of weight to chemists, and that the results achieved by "purely physical" methods must be received with suspicion. But for the chemist it certainly is of importance, in view of the bewildering rapidity of the development in this newer domain, to have the results, by whatever method achieved, co-ordinated and fitted in to that older structure with which we were all familiar in the days of our own studentship. Dr. Letts may be congratulated upon having accomplished this task with conspicuous success within the compass of his brief. His historical records, which are fairly given, are as up-to-date as can reasonably be expected, and the descriptive portions are summarised at the end of the chapters with a clearness which shows that the author has a thorough grasp of his subject. Perhaps it may be urged by extreme critics that he is not sufficiently critical—that he appears to accept as established truths and without comment published statements concerning "transmutation," about which there is conflict of evidence. But the present work professes to be but a literary production, and the author, perhaps wisely in the present state of knowledge, simply sets forth the evidence and the suggested interpretations of that evidence. All who have watched the development of this "newer chemistry" have thoroughly realised the extraordinary practical difficulties which confront the experimenter at every stage. The infinitesimal quantities of material which have to be dealt with and the extreme delicacy of the methods of attacking the new problems offered by a subject which is still "in the making" are such as to give much scope for apparently conflicting evidence. The future writer of the history of chemistry will find ample matter for marvel at the results which have even now been achieved in spite of the difficulties referred to. That Dr. Letts is himself appreciative of the skill which has surmounted so many of these obstacles is apparent in many pages of the volume under consideration.

It is now a matter of ancient history that on the discovery of spectrum analysis chemistry and astronomy entered into partnership. But the new chemistry, as understood in the present work, has also widened the horizon of the science to an extent that renders necessary the consideration by chemists of problems of a cosmical order in a much more definite and concrete form than has hitherto been customary. It is obvious that questions concerning the constitution of the atom and the evolution or disintegration of matter cannot be confined within terrestrial limits. On the first of these questions the author has something to say, and in the ninth chapter will be found a succinct account of the electron theory, with reference more especially to the work of J. J. Thomson. Now it is precisely on this question of the present position of the electron theory that chemists are awaiting further light from the physical side. So far, with the exception of Sir William Ramsay's preliminary attempt, this theory cannot be said to have been brought seriously within the domain of practical chemical politics. It is not mere curiosity that prompts the chemist to ask whether the atom is to be regarded as a complex mechanism composed entirely of electrons or whether there may not be other components. Dr. Letts thus answers the question:—

"From spectroscopic and other evidence it would appear to be certain that electrons are universal constituents of atoms, but on the other hand, there appears to be no sufficient evidence for the assumption that electrons are the sole constituents of these atoms. . . . all but about one-thousandth of its mass is associated with the positive part of an atom, which would tend to show that an altogether exaggerated rôle has been attached to the electron in the constitution of matter."

This at any rate was the view held by the writer of the section on radioactivity in the Annual Reports of the Chemical Society in 1906, from whom the author takes his information.

With reference to the other question—the evolution and dissolution of matter—the reader will find in the tenth chapter a good summary of the observations and conclusions of Lockyer, as set forth in his "Inorganic Evolution" and other publications. One result of the "new chemistry" is thus to bring us back to what may be termed the presentation of the case from the astrophysical side. There is distinct evidence of this reactionary influence of the new chemistry upon the pioneering work of Lockyer now to be found in many recent treatises besides the volume under consideration, in which some twenty pages are devoted to the subject. The "disintegration" theory of radio-activity, which now holds the field, has brought into modern chemistry certain very concrete notions concerning what may be defined as down-grade evolution. It is but natural to ask with Dr. Letts (p. 190) whether the reverse or up-grade process of evolution from elements of low atomic weight to elements of higher atomic weight occurs anywhere in the cosmos. If evolution is universally true in principle some process of this order must have occurred in the past and may be occurring now. Laboratory results which are indicative of "transmutation" in the sense of degradation are becoming more and more incorporated with modern chemical doctrine, but experimental evidence of the opposite process can scarcely be considered at present conclusive. The notion of utilising the energy of degradation of radium emanation for transmutational purposes was presumably based on the expectation of degradation rather than of aggregation.

The question of the evolution of the chemical elements is an old one, and the suggestion of evolution offered by the periodic law has been taken up by many writers whose speculations are no doubt familiar to chemists. The author of the present work does not discuss any of these speculative attempts to trace the lines of descent, although he gives some very useful tables summarising existing knowledge with respect to the disintegration products of the radio-active elements. But in directing attention once again to the evidence of evolution furnished by the study of stellar spectra by that comparative method which will always be recognised as the work of Lockyer and his school, Prof. Letts does good service by reminding chemists that the newer developments of their science have enhanced the importance of astrophysical (why not astrochemical?) work to an extent quite undreamt of at the time when the spectroscope was first brought to bear upon these problems.

If any justification for undertaking the part of a critic is required on the present occasion it may be permissible to express regret that the author should have devoted so much space to reprinting long extracts from the original writings of the authorities quoted. All the books and papers referred to are easily accessible, and Dr. Letts gives evidence of being such a very clear thinker when he deals with his subject in his own way that we should much have preferred to read his own version and criticisms. This particularly applies to the last chapter, which is devoted to an account of the views of Arrhenius in his now well-known book on "Worlds in the Making" published in 1908. The direct bearing of the views set forth in that work on the fundamental problems of modern chemistry are not very obvious, and we should have been glad if Dr. Letts could have given less space to the extracts from the said book and more space to the discussion of the special reasons for including the subject in his own volume. The main contribution to purely "astrochemical" thought which must be credited to Arrhenius would appear to be the recognition of heat as an associative as well as a dissociative agency. In theories of cosmical evolution, this point may have been insufficiently realised, although the possibility of endothermic combination between certain elements under high pressure in the sun and stars cannot be generalised into a universal process for all kinds of matter without further evidence.

Enough has been said, however, to warrant the statement that the author has produced a most useful and suggestive little volume which may be profitably read by chemists of both the older and younger generations.

R. MELDOLA.

GEOLOGY AND GEOGRAPHY.

(1) *La Face de la Terre.* (Das Antlitz der Erde.) By Prof. Ed. Suess. Traduit de l'Allemand avec l'Autorisation de l'Auteur et Annoté sous la Direction de Emm. de Margerie. Tome 3. (3 Partie.) Pp. xi+957—1360. (Paris: Armand Colin, 1913.) Price 12 francs.

(2) *Traité de Géographie Physique. Climat—Hydrographie—Relief du Sol—Biogéographie.* By Prof. Emm. de Martonne. Deuxième Edition. Pp. xii+922. (Paris: Armand Colin, 1913.) Price 22 francs.

THE two volumes before us strikingly illustrate the principle that scientific geography —as distinct from mere geographical description —must be based on the deductions of geology and the physical sciences; and no less do they indicate how much geology looks to gain from the study of the present features of the earth's surface, and of terrestrial processes now going on upon it.

(1) That M. Margerie's French edition of the great work of the distinguished Austrian geologist is not a mere translation has been already pointed out in the pages of NATURE. The judicious notes, bringing the text up-to-date, with the exhaustive references to recent literature and the numerous additional illustrations, make the book an absolute necessity in every scientific library. In this third part of vol. iii., M. Margerie has reached the penultimate section of his great task, and an additional coloured plate, with eighty new illustrations in the text, give a measure of the important additions which have been made to the original work.

(2) Nor are the additions which have become necessary to the comprehensive volume of Prof. de Martonne less abundant and important. Since the first edition appeared four years ago, the author reminds us that geographical research has added largely to our knowledge—not the least striking

additions being the visits paid for the first time to both the poles within that period! No fewer than 216 pages, with four plates and fifty figures in the text, have been added to the book to bring it thoroughly up-to-date. The present edition maintains the character of the original one, as an invaluable work of reference upon the subjects of which it treats. J. W. J.

WORKS ON ECONOMICS.

(1) *The Influence of the Gold Supply on Prices and Profits.* By Sir David Barbour. Pp. xii+104. (London: Macmillan and Co., Ltd., 1913). Price 3s. 6d. net.

(2) *Social Insurance. With Special Reference to American Conditions.* By I. M. Rubinow. Pp. vii+525. (New York: Henry Holt and Co., 1913.) Price 3.00 dollars net.

(1) SIR DAVID BARBOUR'S long experience in connection with the finances of India gives great weight to his conclusions on questions of currency and of the standard of value, in which he holds a position of authority. In the present work he undertakes to show in what way the quantity of money affects prices, and what are the limitations to the theory that its influence upon them is substantial. This is a question of real importance, because variations in price exercise a "profound and subtle influence" on human affairs. "A general fall in prices sets up stresses in the social fabric which search out the weak points in the structure. A general rise in prices smooths away many difficulties, but may create others." The author puts his theory in the form that "other things being equal, the level of prices is proportionate to the quantity of money." The question arises, What are the "other things" that are required to be equal, in order that this generalisation may be supported? It is important to consider the modern system of credit, as affecting the amount and efficiency of the work money has to do. Sir D. Barbour rightly deprecates the dangerous practice, which apears to be growing, of attempting to remedy by legislation the evils that are due to a rise or fall in prices.

(2) Mr. Rubinow's work is an elaborate study of a subject which has of late years acquired great importance in England and other European countries, and an urgent plea for general adoption of a policy of social insurance in the United States of America. The expression "social insurance" is, indeed, one of comparatively recent introduction, and is used as distinctive from commercial insurance, though there is no real difference of principle between them. The difference in practice arises when voluntary insurance develops into subsidised insurance, and that again into compulsory insurance. Under these heads the author describes what has been done in Europe towards insurance against industrial accidents, against sickness, against old age, invalidity and death, and against unemployment; and necessarily devotes much attention to the history of the movement in those directions in Germany and in England. In neither country does he consider that all the branches of social insurance have been adequately developed. All leave unrelieved many exceptional cases. The relief is, in general, insufficient. The question of cost becomes a material one if this is to be remedied. Here, we think, Mr. Rubinow takes too optimistic a view. He estimates the burden of the British insurance system as between 85 and 100 million dollars, and compares it with the 160 million dollars that the United States have been (we fear, improvidently) spending for war pensions. Estimating that the wealth of that country increases annually by 5000 million dollars, after all truly wasteful expenditures, both private and public, have been allowed for, he thinks it unnecessary to discuss whether it can afford the expense of a social insurance system.

Both these works are valuable contributions to the study of economics.

OUR BOOKSHELF.

The Riddle of Mars the Planet. By C. E. Housden. Pp. xi+69+plates. (London: Longmans, Green and Co., 1914.) Price 3s. 6d. net.

THERE are many who have read with real pleasure Dr. Percival Lowell's pleasant diversions based upon his assiduous and careful observations of the planet Mars, which the magnificent equipment of his well-placed observatory have made possible. Whether they have followed him to all his conclusions is immaterial, they have admired his skill and industry, his beautiful photographs, his imagination and the charming way in which he has presented his case. Among his followers the author of the present work is one who is not content with merely following Dr. Lowell, but, being apparently of a constructive turn of mind, he has gone in considerable detail into the engineering works that are obviously required to help the water of the melting snow caps to the parts of the planet where it is wanted for the growing crops. By the use of a coloured plate or diagram on which the colour changes in different latitudes in the course of the Martian year are represented, the author develops the engineering problem of moving the water, using open canals or closed pipes where water is pumped over or to high ground. He wants for this purpose 2,500,000,000 N.H.P.; 170,000 6-ft. pipes, each 1400 miles long, with ten pumping stations of 1150 N.H.P. to each to account for part of the total power required. Oil engines are suggested, the oil being obtained from wells as on earth, but possibly sun power in the clear sky is used as in Egypt. The author goes into details in other directions which it seems unnecessary to follow, and he estimates the area requiring irrigation and producing crops twice a year by a consideration of the colour changes.

The Mechanical Engineer's Reference Book. By H. H. Suplee. Fourth edition, revised and enlarged. Pp. xii+964. (London and Philadelphia: J. B. Lippincott Company, n.d.) Price 18*s*. net.

THE first edition of this well-known book was published in 1903. Sections are included giving mathematical formulæ and tables, information on mechanics, materials, machine design, heat, air, water, fuels, steam boilers and engines, internal combustion motors, and electric power. While much of the information supplied is good, and renders the book of service to engineers, there is a considerable amount of space taken up with matter which is surely unnecessary in an engineering reference book. Some of the very elementary geometry given on p. 107 *et seq.* might be eliminated. There are few engineers who would require to consult a reference book in order to find out how to bisect a line by another line at right angles. The tables given on pp. 432 and 433 face one another, but the book has to be inverted before the second table can be read. On p. 274 there is a table giving the heights traversed by a falling body to seven significant figures. The American nomenclature in several places makes it somewhat difficult to obtain the precise meaning.

The real test of the value of an engineering reference book is the up-to-dateness of its contents, otherwise the book will be used probably for the sake of the tables of areas and circumferences of circles, logarithms, etc. The present edition is by no means up-to-date in several of its sections; those dealing with the strength and elasticity of materials and the properties of steam may be specially mentioned in this respect, where very little mention is made of the valuable developments which have taken place during the last ten years.

Outlines of Chordate Development. By Prof. W. E. Kellicott. Pp. v+471. (New York: H. Holt and Co., 1913.) Price 2.50 dollars.

PROF. W. E. KELLICOTT'S introduction to the study of chordate development begins with Amphioxus, which "affords in simple diagrammatic style, the essentials of early chordate ontogeny"; it lingers over the frog; it treats the chick more briefly, but lays emphasis on the embryonic membranes and the early stages; it ends up with the mammal, with particular reference to the early stages, the fœtal membranes and the placenta, and the development of the external form. The book is well arranged, carefully and clearly written, and effectively illustrated. We think that it might have been made more interesting and distinctive by being more definitely correlated with phylogeny and comparative anatomy; but that, of course, is a big business. The well-selected bibliographies point the way.

LETTERS TO THE EDITOR.

[*The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of* NATURE. *No notice is taken of anonymous communications.*]

Action of Radium Rays on Bakelite.

A DISC 4·2 mm. thick of the light yellow variety of transparent Bakelite was cut from a rod, polished and radiated with β and γ rays from radium. The colour of the disc darkened to a wine-red after three days, and exhibited an absorption band $\lambda=5700-6000$, which was not visible at first. The spectrum beyond $\lambda=4900$ Å.U. was also obliterated. A similar disc placed in radium emanation became also rapidly coloured. The coloration extended to a depth of 2 mm., and it could be completely removed by exposure to a temperature of 100° C. for about three hours.

In order to see whether ozone played any part in the action a Bakelite disc was exposed to the gas for six hours both alone and with radium near. Not the slightest coloration occurred. A portion of a rod was coated with paraffin wax and the radium rays caused to radiate the rod partly through the wax layer. There was no diminution in the rate of colouring under the wax. The effect, therefore, appears to be due to the direct action of β rays upon the Bakelite, for it would extend much deeper were it due to the γ rays. This new substance may prove to be a useful filter for therapeutic use, especially as it is cleanly and easy to work.

Respiratory Movements of Insects.

THE concertina-like movement observable in the abdomen in the case of wasps and bees is, I believe, the visible evidence of the act of pumping the air in and out for respiratory purposes, and a similar phenomenon may be seen in dragon-flies, except that in the latter the movement is lateral and slow, whilst in wasps and bees it is axial and rather quick. I have not noticed any such movement in other groups of the Hymenoptera, and it is apparently absent in the Diptera, except *Eristalis tenax*, the common drone-fly, which obviously mimics the hive bee and other small species. If this movement really is due to respiration can any reader say why it is so comparatively restricted in the insect world? One would have expected soft-bodied insects, such as Diptera, to exhibit it more obviously than the more chitinous species amongst the Hymenoptera. I, and probably others, should be glad of any information throwing light on this matter.

C. NICHOLSON.

MR. NICHOLSON has hit upon an interesting inquiry, and will probably not be surprised to find that it has already received a good deal of attention. The respiratory movements of insects were experimentally investigated by the late Prof. Felix Plateau, of Ghent ("Recherches Expérimentales sur les Mouvements Respiratoires des Insectes," *Mém. Acad. Roy. de Belgique*, tome xlv., 1884), who contributed a short summary of his results to Miall and Denny's "Cockroach" (pp. 159–64). Respiratory movements can be demonstrated in dipterous flies, but in them the enlarged thorax is alternately contracted in different directions by the action of two sets of muscles, which are figured in Miall and Hammond's "Harlequin Fly," (pp 100–102). Far more space than NATURE could grant would be required to discuss the mechanism of respiration in different insects. I do not recollect that any notable progress has been made with the inquiry during the last thirty years, and a new observer would find that much remains to be discovered; it is, however, indispensable that he should employ precise methods of investigation. L. C. M.

THE NUMBER AND LIGHT OF THE STARS.

THE number of stars visible to the naked eye on a clear night, in the whole sky, is roughly 5,000—a very moderate total indeed, in spite of the universal custom of using the number of the stars, in common with that of the sands of the sea, as synonymous with infinity. In all ages mankind in general has rightly preferred rather to admire and wonder at the stars than to count them. In the great problem of the structure of the sidereal universe, however, which astronomers are now attacking with much energy and success, one of the essential data is the number of stars in the different regions of the sky, classified according to their brightness or magnitude.

The telescope early revealed the fact that the stars which by reason of their superior brightness force themselves upon our unaided vision shine forth beyond a host of fainter luminaries, the number of which has never yet failed to show an increase as an augmentation of telescopic or photographic power has enabled us to pierce depths of greater and greater obscurity. These fainter stars enormously outnumber the naked-eye stars, which may be compared with an oceanic island, the tiny, outstanding peak of a great mountain growing ever broader beneath the water level.

The bright stars have been divided into six traditional classes or magnitudes, the brightest being called first magnitude stars, and the faintest visible being termed of the sixth magnitude. Pogson placed this classification on a scientific basis, so that it could be extended to telescopic stars of all degrees of faintness. On the conventional standard scale the ratio of the intensities of two stars differing in magnitude by the amount m is $10^{-0 \cdot 4 m}$. The determination of the magnitude of a star on this scale is not an easy matter, as it involves the measurement of the relative brightness of stars often differing much in luminosity.

Photographic methods have been found most suitable for the purpose; the results are rather different from those obtained by visual methods, especially for stars of different colour, since the photographic plate is more sensitive than the eye to blue rays, and less sensitive to red. Magnitudes determined by ordinary photographic methods are called "photographic magnitudes."

During the past three years the fine series of star charts obtained by the late J. Franklin-Adams has been used in the investigation of the number of stars of determined photographic magnitudes in all parts of the sky. Franklin-Adams, using a specially-designed Taylor-Cooke 10-in. lens covering a wide field, photographed the whole sky on 206 plates each 16 in. square, the scale being 20 mm. to 1°; the photographs were taken (the northern set in England, the southern in South Africa) with exposures of from two to two and a half hours, which sufficed to show stars down to the seventeenth magnitude on most of the plates. From a star of this magnitude we receive only one-millionth as much light as from a second magnitude star. On each plate the stars in twenty-five uniformly distributed sample areas have been counted and classified according to the size and greyness of their images; altogether, therefore, sample counts have been made on more than 5000 regions of the sky, at intervals of 3° apart. The areas examined were of different sizes, being chosen, in accordance with the star density in the particular region, so that about sixty stars should be counted in each. The stars could not be classified according to their photographic magnitude directly from the plates, as stars of different magnitudes might show images, identical in size and greyness, on different plates, owing to inequality of the atmospheric transparency during the exposures on the two plates. The photographic magnitudes of a selection of the stars counted on each plate needed, therefore, to be determined directly, which was done by comparing them with the stars of the North Polar Sequence, a set of stars the magnitudes of which have been given very accurately by Prof. E. C. Pickering of Harvard. Auxiliary photographs for this purpose were taken with the 30-in. reflector at Greenwich. After the application of corrections depending on their position on the Franklin-Adams plates it was then possible to classify all the stars counted, upon a true magnitude basis. This complete reduction has so far been effected for thirty out of the 206 plates counted; the results from the 750 areas for which sample counts were thus afforded have recently been published.[1]

The first point of importance which will be mentioned as one on which the evidence derived from this work is decisive is that of the relation between the condensation of the stars towards the galaxy, and their magnitude. While the very brightest stars show little regularity of distribution (to their irregular grouping, indeed, much of the beauty of the constellations is due), the fainter naked-eye stars show a distinct concentration towards the plane of the Milky Way, their density in the galactic belt of the celestial sphere being about twice that near the poles of the Milky Way; still fainter stars down to the ninth magnitude show this phenomenon in a more marked degree, the density of these stars in the galaxy being three or four times that at the galactic pole. The galactic plane is a fundamental one in modern representations of the sidereal universe, which, following Sir W. Herschel's ideas, picture the stellar system as formed of a large central cluster

[1] Chapman and Melotte: The number of stars of each photographic magnitude down to 17·0m., in different galactic latitudes. Memoirs of the R.A.S., lx., 4.

Chapman: On the total light of the stars. Monthly Notices of the R.A.S., lxxiv.

of stars in the form of an oblate spheroid, equatorially surrounded by a belt of irregular star-clouds composing the Milky Way. In connection with such a theory it is of obvious importance to know whether the condensation towards the galaxy shown by the stars of magnitudes five to nine persists for still fainter stars, and in what degree. Very different views have been held on this matter. In regard to the stars classified according to their visual magnitudes, Kapteyn concluded that the galactic condensation increases very much with diminishing brightness, giving its value for all the stars brighter than 17^m as 45. Pickering, on the contrary, found no marked change in the relative densities in the galaxy and at its poles, down to the thirteenth magnitude (the limit of his data). The counts on the Franklin-Adams plates, based on a photographic magnitude classification, lead to a similar result; the density of all the stars brighter than 17^m in the galaxy does not exceed six times that at the galactic poles, and the ratio is perhaps not more than four. Although it is possible that there may be a systematic change of colour of the stars with increasing faintness, different in different galactic latitudes, which would make results derived from counts of stars of determined *visual* magnitudes differ systematically from those based on photographic magnitudes, yet such evidence upon the point as already exists renders it probable that the galactic condensation is in either case nearly constant from the sixth to the seventeenth magnitude.

On this account the rate of increase in the number of stars per magnitude will be nearly constant all over the sky, so that this rate may conveniently be studied from a table giving the numbers of stars in the whole sky brighter than each magnitude m; this will be denoted by N_m. All the best available data have been embodied in the following table, giving N_m for values of m down to 17. The values of $\Delta_m (= \log N_{m+1}/N_m)$ are also given, as they provide a measure of the geometric ratio of increase in the number of the stars.

TABLE I.—*The Number of Stars in the Whole Sky Brighter than Magnitude m.*

m	N_m	$\log N_m$	Δ_m
2	38	1·58	
3	111	2·05	0·47
4	300	2·48	0·43
5	950	2·98	0·50
6	3,150	3·50	0·52
7	9,810	3·99	0·49
8	32,360	4·51	0·52
9	97,400	4·99	0·48
10	271,800	5·43	0·44
11	698,000	5·84	0·41
12	1,659,000	6·22	0·38
13	3,682,000	6·57	0·35
14	7,646,000	6·88	0·31
15	15,470,000	7·19	0·31
16	29,510,000	7·47	0·28
17	54,900,000	7·74	0·27

The data for the stars of magnitudes 2 to 6 are somewhat uncertain, which accounts for the irregular run of the first few values of Δ_m, but beyond this point the steady decrease in Δ_m is very noticeable. This clearly shows that modern photographic telescopes now penetrate to regions of space where the stars begin to thin out in numbers to a quite considerable extent, for it is easy to prove that if the stars were distributed uniformly throughout space, Δ_m should preserve the constant value 0·6. This assumes, what appears to be fairly correct, that any possible absorption of light in space does not materially diminish Δ_m.

From the numbers in the foregoing table, the following simple rational formula can be derived,

$$\log \frac{dN_m}{dm} = a + bm - cm^2,$$

or, in an equivalent form,

$$N_m = A \frac{1}{\sqrt{\pi}} \int_{-\infty}^{B(m-C)} e^{-x^2} dx.$$

The latter formula, which is the integral of the error curve, implies that the total number of the stars is finite, and this is now generally accepted as true; A represents this total number, while C denotes the magnitude which divides all the stars into two equal groups, those brighter being equal in number to those fainter. A, B, C can be deduced from a, b, c, which are readily obtained from the observed values of N_m, but A is not narrowly determined—its value seems to be not less than 1000 million, and probably not greater than 2000 million, so that the total number of the stars is comparable with the population of the earth (this is roughly estimated as 1600 million). The constant C is more closely determined, and is approximately 23 or 24. Stars of this magnitude could just be photographed, with many hours exposure, with the largest telescope in the world, the 60-in. reflector at the Mount Wilson observatory. There remain, therefore, beyond our present powers of exploration still fainter stars equal in number to all those which could possibly be examined at the present time.

These impressive numbers shrink into a smaller compass when the total *light* of the stars is considered. It may readily be shown that if the formula for N_m is correct, the total intensity I_m of all the stars brighter than magnitude m can be represented by an expression identical in form with that for N_m; but whereas the peak for the error curve, the integral of which represents N_m or I_m, is in the former case (C = 23 or 24) beyond the limits of the observed data, in the case of I_m it is well within these limits—in fact, half the total light of the stars comes from those brighter than about $9·5^m$. Up to this point the light received from all the stars of magnitude m to $m+1$ increases; beyond this it diminishes rapidly, the increase in the number of the faint stars, great though it is, being insufficient to counterbalance their diminished brightness. Owing to the formula for N_m giving too small a number of bright stars (a defect of little moment for most values of m, in the case of N_m, but of serious importance when the total light of the stars is under consideration), the following table has been constructed from Table I., in order to give the actually-observed light of the stars so far as magnitude 17, the formula being used only beyond this point, where it is quite sufficiently accurate for the purpose. The light is given in terms of the number of first magnitude stars of equivalent intensity. Three very bright stars are given individually.

TABLE II.—*The Equivalent Light of the Stars.*

Magnitude	Number	Equivalent number of 1st magnitude stars	Totals to magnitude *m*
−1·6	Sirius	11	—
−0·9	α Carinæ	6	—
−0·0	α Centauri	2	—
m m			
0·0–1·0	8	14	33
1·0–2·0	27	17	50
2·0–3·0	73	18	68
3·0–4·0	189	19	87
4·0–5·0	650	26	113
5·0–6·0	2,200	35	148
6·0–7·0	6,600	42	190
7·0–8·0	22,550	56	246
8·0–9·0	65,000	65	311
9·0–10·0	174,000	69	380
10·0–11·0	426,000	68	448
11·0–12·0	961,000	60	508
12·0–13·0	2,020,000	51	559
13·0–14·0	3,960,000	40	599
14·0–15·0	7,820,000	31	630
15·0–16·0	14,040,000	22	652
16·0–17·0	25,400,000	16	668
17·0–18·0	38,400,000	10	678
18·0–19·0	54,600,000	6	684
19·0–20·0	76,000,000	3	687
All stars fainters than 20^{m}·0		3	690

It appears that the total light of the stars is approximately equal to that of 700 first magnitude stars. Previous estimates of this number have greatly erred on the side of excess (more than three times the present value having been given, though these estimates should be reduced by about 20 per cent. for comparison with the present one, since they have been expressed in terms of first magnitude stars on the visual scale). The present value can scarcely be much affected by our ignorance as to the exact numbers of stars fainter than 17 *m*, as it is a fairly safe deduction from the above formulæ that the stars fainter than 15 *m* contribute less than one-eighth of the total light. Indeed, the fainter half of the stars, several hundred millions in number, account for only ¼ per cent. of the total light, about equal to that of four second magnitude stars. It may be of interest, in conclusion, to express the total light of the stars in terms of the light of the full moon and of the standard candle; using some Harvard data for the brightness of these two sources of light, it appears that the full moon is very nearly one hundred times as bright as a star of magnitude −6·1, the light of which would equal the combined light of all the stars, while light of the same intensity would be received from an ordinary 16-candle-power electric lamp at forty-five or fifty yards distance.

S. CHAPMAN.

THE STONE TECHNIQUE OF THE MAORI.[1]

THE Maori have long been famous as past masters in the art of working stone, the ornaments and implements of the beautiful nephrite ("jade") of New Zealand being especially noteworthy. It is, therefore, with peculiar pleasure that we welcome the appearance of a monograph which deals in an adequate manner with this important subject; indeed this is the only complete account we have of stone technique in Oceania. The student must not overlook, however, the beautifully-illustrated monograph on "Ancient Hawaiian Stone Implements," by W. T. Brigham (*Mem. Bernice Pauahi Bishop Museum*, vol. i., No. 4, 1902), in which many implements from New Zealand are figured.

FIG. 1.—Unfinished adze-blade of very fine-grained black aphanite, illustrating the fine symmetrical form attained under the processes of flaking (or chipping) and bruising, without any grinding whatever. The tool could be utilised as an adze if only the lower part of the blade were ground. Length 12½ in. This is also a common Hawaiian type.

The preparation of the present memoir could not have been entrusted to a more competent student, as Mr. Elsdon Best has gained a deservedly high reputation for his intimate and sympathetic knowledge of the ancient lore of the Maori, and for his acquaintance with the literature of all that pertains to New Zealand. An authoritative account is given of the native terminology for the various kinds of implements and of the stones employed for the blades, as well as of the methods for the manufacture of the ordinary stone tools, the information being culled from numerous published sources and from the natives themselves. There is a certain amount of *tapu* pertaining to the task of cutting nephrite and no woman was allowed to come near the workers, but there was no *tapu* in connection with the working of any other stone. Holes were drilled in stone by means of the cord drill, but the bow drill (with or without a mouthpiece) and the pump drill seem to have been unknown to the Maori in pre-European times. The same appears to hold good for Polynesia, though it is not easy to see how the pump drill of New Guinea could have been introduced by Europeans. Having chipped and bruised his implement into the desired form,

[1] Dominion Museum Bulletin No. 4. The Stone Implements of the Maori. By Elsdon Best. (Wellington: J. Macay, Government Printer, 1912.)

the Maori had then to smooth the surface by rubbing it on a piece of sandstone, usually in a longitudinal manner, as he had no knowledge of a rotatory stone for this purpose.

The methods of hafting the implements are described and evidence is adduced to show that, contrary to what was formerly believed, the Maori did use tools helved as axes, but they were not nearly so numerous or commonly used as were tools hafted and used as adzes.

All the available information about nephrite and the tools made from it is summarised by Mr. Best. Many legends have grown up in connection with this precious stone, for this there has been ample time, since "Polynesians, or a mixed people, must have been settled in New Zealand for at least one thousand years, and possibly for a longer period. It is also highly probable that the old-time people of these isles, who here flourished long before the immigration of *circa* 1350, were acquainted with nephrite of the South Island, and also that they worked it to some extent." The memoir is illustrated by fifty-one plates which leave nothing to be desired.

A. C. HADDON.

NOTES.

THE annual visitation of the Royal Observatory, Greenwich, will be held on Saturday, June 6.

THE Faraday lecture of the Chemical Society will be delivered by Prof. Svante Arrhenius in the theatre of the Royal Institution on Monday, May 25, upon the subject of "Electrolytic Dissociation."

DR. ROBERT CHODAT and Dr. Richard Wettstein, Ritter von Westersheim, have been elected foreign members of the Linnean Society. The council of the society has decided to award the Linnean medal at the forth coming anniversary meeting on May 25 to Prof. Otto Bütschli, of Heidelberg.

A REUTER message from Ottawa states that an Order in Council has been passed setting aside as a national park an area of ninety-five square miles situated within the railway belt of British Columbia, in the vicinity of Mount Revelstoke, on the line of the Canadian Pacific Railway. It will be known as the Revelstoke National Park.

THE death is announced, on May 15, of Miss Ida Freund, late staff lecturer at Newnham College, and author of several papers on chemical subjects, as well as of a valuable work published in 1904, entitled "The Study of Chemical Composition: an Account of its Method and Historical Development."

DR. J. C. KONINGSBERGER, director of the Botanic Gardens—'s Lands Plantentuin—Buitenzorg, Java, informs us that the new laboratory for foreign scientific visitors is now open. The laboratory is consecrated to the memory of his predecessor, the late Prof. Melchior Treub, and consequently bears the name "Treub Laboratorium." We are asked to announce that, as hitherto, the director and staff of the gardens welcome visitors, and will do all that is in their power to make a scientific voyage to Java and a stay in Buitenzorg as profitable as possible.

THE annual meeting of the British Science Guild will be held at the Mansion House to-morrow, May 22, at 4 p.m., the Right Hon. the Lord Mayor presiding. Sir Ronald Ross, K.C.B., will deliver an address, and other speakers will be the president of the guild (the Right Hon. Sir William Mather), Sir Boverton Redwood, Bart., the Right Hon. Lord Blyth, Sir William Beale, Bart., Mr. C. Bathurst, M.P., Major O'Meara, C.M.G., Mr. Alexander Siemens, and Mr. Carmichael Thomas. The dinner of the guild will be held on the same date, at 7 p.m., at the Trocadero Restaurant, under the chairmanship of Sir William Mather.

THE President of the Board of Agriculture and Fisheries has appointed a Departmental Committee to consider and report upon the effect of the present arrangements for the sale of the small-scale maps of the Ordnance Survey. The Committee consists of Sir Sydney Olivier, K.C.M.G., Permanent Secretary of the Board of Agriculture, chairman; Mr. F. Atterbury, C.B., Controller of his Majesty's Stationery Office; and Colonel C. F. Close, C.M.G., Director-General of the Ordnance Survey. Mr. J. L. Bryan, of the Board of Agriculture, will act as secretary to the Committee.

THE young of the grey seal (*Halichoerus grypus*) are stated to differ from those of all other European seals by their inability to swim until several weeks after birth; and as they are born above high-water mark on rocks and skerries in the open sea, they are peculiarly liable to destruction by those acquainted with the haunts and habits of the species. Despite the small value of the pelt of the pup and of the oil of the parent, expeditions have of late years been made to the breeding-places of these seals on the British coasts, with the result that the species is in jeopardy of imminent local extermination. To put matters on a better footing a Bill has been introduced in the House of Lords to enact an annual close time for these seals from October 1 to December 15; it recently passed the third reading in the Upper House.

AT the beginning of this year the *Biologische Versuchsanstalt* at Vienna passed into the possession of the Imperial Academy of Sciences. The institution is for the experimental investigation of organisms, especially experimental morphology and developmental physiology; also of comparative physiology and the borderlands of biophysics and biochemistry. The Academy of Sciences has appointed a committee of trustees for the institution. A limited number of tables is exempt from fees, and may be awarded by the director of the Anstalt or directors of its departments. The Austrian Ministry of Education has reserved four tables of which as a rule one is to be awarded in every department. Applications for research tables may be addressed to the director of the Anstalt, or to one of the following directors of departments:—*Botany*, W. Figdor and L. v. Portheim; *Physical Chemistry*, W. Pauli (until December 31, 1914); *Physiology*, E. Steinäch; *Zoology*, H. Przibram.

THE annual meeting of the Société Helvétique des Sciences naturelles is to be held at Berne on August

31–September 3 next. Prof. E. Fischer is the president for the year, and Dr. H. Rothenbühler is the secretary of the committee of management. The following addresses to general meetings of the society have been announced:—Dr. Bluntschli, of Zürich, on the biology and ontogeny of the primates of the New World; Prof. E. Hugi, of Berne, on the geology of the Gaster range and the Lötschberg tunnel; Prof. Kohlschütter, of Berne, on physico-chemical factors in the origin of natural forms; Prof. Noelting, of Mulhouse, on the synthesis of colouring matters; and Prof. H. Sahli, of Berne, on the influence of natural science on modern medicine. The Swiss Mathematical, Physical, Chemical, Geological, Botanical, and Zoological Societies will also hold their annual meetings at Berne on September 2. Members desirous of presenting papers at any of the meetings of sections should communicate with Prof. Fischer, Kirschenfeldstrasse, 14, Berne, before July 1.

ON Monday last a Committee of the House of Lords threw out a Bill promoted by the Glasgow Corporation under which they sought powers to make an electric tramway with a double line of rails along University Avenue, which for nearly half a mile forms the northern boundary of Glasgow University and of the Infirmary. The University opposed the Bill on the ground of magnetic disturbance and vibration, which would adversely affect the physical, botanical, and biological laboratories. Technical evidence was given in support of the opposition by Profs. Gray, Kerr, and Bower, of Glasgow University, Prof. Nuttall, of Cambridge, and by Mr. C. V. Boys and Mr. Sellon. This decision is one of the first importance for the protection of our universities from encroachments upon their amenities and the quiet which they have enjoyed; it is necessary for their welfare, and will establish a useful precedent when town councillors and other promoters are trying to force their schemes regardless of the injury which they would do.

IN the issue of the *Revue générale des Sciences* for December 30, 1909, an article by M. Ernest Solvay was published dealing with "Physical Chemistry and Psychology." In that article M. Solvay propounded ten questions which opened up numerous researches; and to encourage investigation in these directions he announced that he would devote 2000*l*. to the award of prizes for work designed to answer his questions. The theses had to be sent in by January 1, 1914, to the Institut Solvay de Physiologie in Brussels. The awards were made by a commission consisting of Prof. L. Fredericq, of Liége, Prof. J. Verschaffelt, of Brussels, and Prof. O. Dony-Hénault, of Mons, and were announced in the issue of our contemporary for April 30. The prizes were awarded as follows:—To Prof. G. Bredig, of the Technical High School, Karlsruhe, for his researches on catalysis; to M. G. De Meyer, of the Institut Solvay, for his work on muscular action; and to M. J. Boselli, of Paris, for his research on the speed of reaction in heterogeneous systems.

THE plans for the Meteorological Conference which is to be held in Edinburgh in September next are taking definite shape. A strong general committee with seventy-six members has been formed. The lamented death of Sir John Murray has left the office of president vacant. The other officers of the conference are the following: *Vice-presidents*: C. J. P. Cave, president of the Royal Meteorological Society; J. Mackay Bernard, of Dunsinnan, president of the Scottish Meteorological Society; Major-General Ruck, president of the Aeronautical Society; Dr. W. N. Shaw, director of the Meteorological Office; Dr. H. R. Mill, director of the British Rainfall Organisation; Sir William Turner, principal of Edinburgh University; the Right Hon. Robert K. Inches, Lord Provost of Edinburgh. *Treasurer*: Captain H. G. Lyons. *Hon. Secretary*: F. J. W. Whipple, Meteorological Office, South Kensington, S.W. *Convener*, Edinburgh committee: Dr. E. M. Wedderburn, 2 Glenfinlas Street, Edinburgh. The programme of the conference, which will open on Tuesday, September 8, includes general discussions on meteorological questions, such as the use of pilot balloons for forecasters and aeronauts, wireless telegraphy in relation to forecasting, the electricity of thunderstorms, and evaporation and rainfall, as well as two evening lectures, which will probably be open to the public, a reception to which the members have been invited by the Lord Provost of Edinburgh, demonstrations with sounding balloons, and an excursion to Eskdale Observatory. Further particulars may be obtained from the hon. secretary, at the Meteorological Office, South Kensington.

IN the University of California's Publications on American Archæology and Ethnology, vol. x., No. 6, Mr. P. E. Goddard contributes notes on the Chilula tribe of Indians, who up to recent times inhabited the banks of Redwood Creek, Humboldt County, California. They have now ceased to exist as a separate people, and if a full account of the tribe were possible its chief interest would be found in the deviations from the Hupa type of culture due to environmental differences, and certain transitional features. A curious discovery is that of a pond round which the girls during their adolescence ceremonies used to run in a direction contrary to the course of the sun. If the girl was able to run once round without drawing breath it was assumed that she would be a good basket-maker.

IN the April number of *Bedrock* Prof. G. Elliot Smith replies to certain criticisms tending to belittle the morphological importance of the Piltdown skull (*Eoanthropus dawsoni*). After remarking that, in spite of his relatively high brain-development, his face still retained many ape-like traits, the author goes on to observe that "the Piltdown man is the nearest approximation that has yet been discovered to the direct ancestor of the genus Homo, and all of its many varieties that made their appearance in Pleistocene and more recent times." In a later passage he adds that "it must be regarded as definitely settled, with as high a degree of probability as any question of phylogeny can be said to be settled, that the genus Eoanthropus represents the immediate ancestor of the genus Homo."

IN *Man* for May Mr. Eldon Best discusses the question of the peopling of New Zealand. He thinks it is going too far to speak of two distinct races in the island; but we have certainly the blending of two races: the fair-skinned Polynesian, with good features, and the swart, thick-lipped, flat-nosed Melanesian type. The former has hair with a slight wave in it; the hair of the latter, if allowed to grow, has the frizzy and bushy appearance of that of the Fijians. Between them is an intermediate type, the result of blending. Besides these, again, in the Urukehu strain we find a fair-haired, light-skinned type, the origin of which is still a mystery. Cannibalism, he supposes, was by no means a common custom in the Society group, whence the Maori came to the island; but it was well established in Fiji, and was probably introduced by the Maruiwi—a folk with pronounced Fijian affinities—and was thus acquired by the Polynesian Maori, or rather, was inherited by the mixed descendants of these two peoples.

THE current number of the *Quarterly Review* contains an interesting account of the family of Sadi Carnot from the pen of Mr. James Carlill. Sadi himself was a captain of engineers, and died in 1832 when only thirty-six, having published his "Reflexions sur la puissance motrice du feu" in 1824. He was the eldest son of General Lazare Carnot, the "organiser of victory" of the first Republic, and member of the Committee of Public Safety. His younger brother Hippolyte became Minister of Education in, and his nephew Sadi President of, the French Republic (1887). His uncle Feulint was almost as distinguished a soldier as his father, and three other uncles became judges, one of the Cour de Cassation. His grandfather was a distinguished notary of Nolay in Burgundy, and his grandmother a woman of great beauty. Families of ten, twelve, or fourteen members are common in his pedigree. According to the author, the family mind, which enabled the Carnots for a century and a half to supply men to fill the highest offices in the State, was the normal brain encouraged from childhood to take an active interest in everything, and invigorated by constant use.

THE fishes collected during the Duke of Mecklenburg's first expedition to Central Africa are described by Messrs. P. Pappenheim and G. A. Boulenger in vol. v., Zoologie iii., Lief. 2, of the *Wissenschaftliche Ergebnisse* of the expedition, published at Leipzig by Klinkhardt and Biermann. A new genus (Schubotzia) of cichlids and a number of new species of various groups are named. The same publishers are also issuing the scientific results of the Duke's second expedition ("Ergebnisse der Zweiten Deutschen Zentral-Africa Expedition, 1910–11," etc., etc.), of which we have received Lief. 2 of the zoological section of the first volume, dealing with the copepod and cladocerotine crustaceans.

THE whole of vol. xxv. of *Anales del Museo Nacional de Historia Natural de Buenos Aires* is devoted to the mammalian Tertiary faunas of the "Araucanian" formations of Argentina, as specially represented by those of Monte Hermoso and the Rio Negro, the monograph being illustrated by thirty-one plates and ninety-two text-figures. The author, Señor Cayetano Rovereto, records a very large number of species, some of which are described as new, and likewise names several new genera. Most, at any rate, of the forms belong to types already familiar through the works of Ameghino, Dr. W. B. Scott, and others, and it may be a question whether at least some of the generic types described as new are not based on trivial characters or on those due to immaturity.

OF late years it has been very generally accepted both in this country and on the Continent, that the name "auerochs," or "aurochs," belongs of right to the extinct wild ox, or ur (*Bos taurus, primigenius*), and not to the bison (*B. bonasus*). This, we believe, was first definitely pointed out in this country on p. 14 of a paper on the zoology of ancient Europe read by the late Prof. A. Newton before the Cambridge Philosophical Society in 1862, and published later on in the same year by Messrs. Macmillan in pamphlet form. The writer's actual words are that the ur or urus "has been so very commonly confounded by writers with the zubr, or European bison (*B. bonasus*)—the aurochs, as it is commonly, although erroneously, called in France and England, that it is not easy to make out anything with certainty with regard to it." A similar view, adopted by others of his countrymen, was subsequently expressed in Germany by the late Prof. A. Nehring, who considered that the name auerochs was gradually transferred centuries ago to the wild ox, as the latter became exterminated. Recently Dr. B. Szalay, of N.-Szeben-Hermanstadt, in an article published in vol. vi. of *Zoologische Annalen* (p. 54), controverts this view, and maintains that the term auerochs properly belongs to the bison or zubr. To discuss the merits of the question in this place is impossible, but we may quote the legends to Herberstein's sixteenth-century pictures of the wild ox and the bison, which are respectively as follows:—"Ich bin der Urus welchen die Polen Thur nennen, die Deutschen Auerox, die Nichtkenner Bison," and "Ich bin der Bison, welchen die Polen Subr nennen, die Deutschen Wysent, die Nichtkenner Urochs." Again, we have the statement by Herberstein, as summarised by Prof. A. Mertens (*Abh. Mus. Magdeburg*, vol. i., p. 7, 1906), "dass der Ur, der dort mit einheimischen Namen Thur genannt wird, bei den Deutschen Auerochs heisst."

ATTENTION was directed to the interesting excursions of the *Oberrheinischer geologischer Verein* in NATURE of May 30, 1912 (vol. lxxxix., p. 328). The *Jahresbericht* of the society for March, 1914, gives the programme of an April visit to the Vorarlberg area. The same number contains a paper on the origin of the Black Forest and the Vosges, by Paul Kessler, which will be welcomed on account of its systematic treatment of a long series of events. The thirteen sections, illustrating the region now occupied by the trough-valley of the Rhine, from the close of Devonian times to the present day, are worthy of reproduction as diagrams for class-instruction. The most mountainous condition of the region, when it resembled the present Alpine chain, is shown as resulting from the Armorican folding. Immense intrusions of igneous rocks then took place, and some of the gneisses of the Vosges and the Black Forest are now recognised as granites of Carboniferous age. While the great lowering of the Rhine-trough by down-faulting dates from Middle Oligocene times, and while this was emphasised by the Miocene uplift of its flanking walls, it is interesting to reflect that the Rhine itself played no part in the modification of the valley until it flowed for the first time northward at the opening of the Glacial epoch.

SINCE the description by Prof. Malladra, in May, 1912, of the existence of a practicable path by which the bottom of the Vesuvian crater can be reached, several observers have availed themselves of the opportunity of making investigations concerning volcanic action under these unique conditions. In the *Geologische Rundschau* (Band v., Heft 2, 1914) a very interesting account of a visit to the crater is given by Mr. Max Storz, of Munich. Among the valuable results published as the outcome of this visit, we may direct attention to the temperature observations, made by means of metallic wires with different melting points, and to the determination of the acids and bases present in the emanations. The acids found were hydrochloric and sulphurous-acid gases, and indications of the following metals were detected—lead, copper, calcium, magnesium, potassium, and sodium. Useful plans of the crater and of the bocca at its bottom are given, together with photographs which are similar in every respect to those obtained by Mr. Burlingham, three of which appeared in NATURE of February 5.

THE Californian earthquake of 1906 originated in a movement along the San Andreas fault-rift extending over a distance of 290 miles. Since that year three slight earthquakes have been traced to slips along the same fault. The first, on September 12, 1912, occurred near the south end of San Francisco Bay; the second, on October 25, 1913, to the north-west of Berkeley; the third, on January 23, 1914, in an intermediate position close to San Bruno. The epicentre of the last was determined by Mr. E. F. Davis (Bull. Seis. Soc. America, vol. iv., pp. 25–28) by means of Omori's formula for local shocks from the duration of the preliminary tremors at the Lick, Santa Clara, and Berkeley Observatories.

THE report for 1913 of the Stonyhurst College Observatory (Lancs.) has been received from Father Sidgreaves, and contains *inter alia* mean and extreme meteorological values at that important station for the last sixty-six years. The observatory has recently severed its principal connection with the Meteorological Office (as explained in the last annual report of the meteorological committee), but it still furnishes the latter body with weekly reports; the automatic recorders remain at Stonyhurst, and their continuous registrations are uninterrupted.

THE yearly report for 1913 of the *Deutsche Seewarte* (Hamburg) bears witness to the great activity of that useful institution with regard especially to (1) maritime meteorology, (2) weather telegraphy, and, generally speaking, to all matters connected with the welfare of the seafaring community. Much attention is given to the proper installation of the mariner's compass, and to the application of the theory of magnetism to navigation; these matters also engaged the earnest attention of the late Dr. v. Neumayer. During the year the number of complete sets of observations received from observers at sea exceeded three-quarters of a million. These are utilised in the preparation of monthly meteorological charts, sailing directions, and daily synoptic weather charts of the North Atlantic. The daily report has undergone several recent improvements, and it now includes small charts showing separately the changes of air-pressure during the preceding day and night by lines of equal values of these changes (isallobars); these values are fully discussed by Dr. N. Ekholm in No. lxiv. of the publications of the international council for the study of the sea (NATURE, September 18, 1913).

BOLTZMANN'S formula for entropy considered in relation to the theory of probability has recently been made the basis of many of our modern radiation theories; but objections have been raised by Einstein and others, in particular to the validity of the formula when applied to systems other than isolated systems the energy of which is constant. A short note on this question is published by Dr. Karl F. Herzfeld in the Vienna *Sitzungsberichte* for 1913 (recently received), in which the author confirms the more general formula according to which the entropy in any state is proportional to the logarithm of the number of possible cases plus a constant, but the value of this constant is not definite, as it was in the usual Boltzmann formula.

A SHORT time ago Mr. Jenkins described (*Philosophical Magazine*, vol. xxvi., p. 752) a method devised by Prof. Hicks for determining a magnetic field, in particular the horizontal component of the earth's field, by a method which reduced the measurement to that of an electric current. In the case of the earth's field a solenoid through which a measured current flows is used to reverse that field. The state of the joint field is judged by the time of oscillation of a small magnet at the centre of the solenoid. In the March number of *Terrestrial Magnetism*, Prof. Schuster describes a similar method which he has had tested at the National Physical Laboratory. It seems probable that when the coil is wound with the degree of accuracy used in current-measuring instruments, the accuracy of a determination will be at least as great as with the Kew magnetometer, and the time required will be five minutes instead of an hour.

AN electrical sterilisation process has been in successful operation at one of the milk depôts of the Liverpool City Corporation for the past six months, and a report on this process drawn up by the city bacteriologist, Prof. Beattie, was presented last month to the Health Committee of the City Corporation. The process depends upon the use of an alternating current of high potential for destroying, by shock, the bacteria contained in the milk. The sterilising apparatus consists of a long tube with copper electrodes inserted in tube-shaped depressions at suitable points, the milk being passed continuously through this tube, from a raised tank, at a predetermined rate of flow. The current used varies from 2 to 3 amperes at an E.M.F. of 3900 to 4200 volts, and each unit quantity of milk is exposed to the action of this current for such a brief period of time, that no heating effects are produced. Details of the bacteriological results are given in the report, from which it is seen that *B. coli* and the ordinary milk-souring bacteria have been invariably absent from the electrically-treated milk, and that the average percentage reduction in the number of total bacteria, over a period of fifteen days' operation of the plant, was 99·93 per cent. The electrical sterilising apparatus in use at the Earle Road Milk Depôt of the Liverpool Corporation has a capacity of 125 gallons of milk a day, and this quantity is distributed in 3000 bottles. The question of extending the plant is now being considered.

A PAPER on recording pyrometers, read by Mr. C. R. Darling at a meeting of the Faraday Society on April 22, was accompanied by a full display of the most recent types of instruments. The marked improvement which has been effected in the accuracy of these instruments was attributed by the author, and by several speakers in the subsequent discussion, to the admirable work of the National Physical Laboratory as an impartial standardising agency. Some recent advances include (1) the introduction of electric power to operate the pyrometers, either by means of relay-circuits or in place of clockwork, in such a way that the automatic control of large technical furnaces may easily be provided for; (2) arrangements whereby the same instrument may be used either with a resistance thermometer or with thermal couples; (3) automatic switches with the help of which the records from several furnaces may be recorded by the same machine.

THE Chemical Society's journal for April contains two papers by Dr. Pickard and Mr. Kenyon on the dependence of rotatory power on chemical constitution. The first paper, recalling the monographs of Sir William Perkin on magnetic rotatory power, contains a description of no fewer than seventy-three optically-active esters of the fatty series. Unlike the alcohols from which they are derived, which exhibit the simplest type of rotatory dispersion at all temperatures, the esters show marked deviations from the simple law when the temperature is raised; in certain solvents they even exhibit anomalous rotatory dispersion. The second paper includes a description of the optical properties of naphthyl methyl carbinol $C_{10}H_7.CH(OH).CH_3$. This substance obeys the simple dispersion law at temperatures above 160°, but shows anomalous rotatory dispersion in the superfused condition at temperatures below about 10°. It is suggested that the anomalous dispersion is caused by the actual presence in the superfused liquid of two of the hypothetical varieties of the naphthalene nucleus which have long been postulated by organic chemists.

THE transportation problem in Canada, and Montreal Harbour, were discussed in a paper read at the Institution of Civil Engineers on April 7 by Mr. F. W. Cowie. It appears that the farmer receives for his wheat 67 per cent. of the price paid by the consumer; the remaining 33 per cent. represents the cost of transportation, handling, and selling profits. It is important that the latter percentage should be reduced to the lowest possible figure, so that the farmer may receive the full due for his toil, and the cost of living in Great Britain may not be unduly enhanced. Montreal Harbour handled sixty million bushels of grain in 1913, and nearly a hundred million bushels of Canadian grain were shipped in the same year through Buffalo in the United States. The loss to Canadian transportation and selling organisations by reason of the latter shipments amounts to about 18,000,000 dollars. The magnificent railway systems between New York and Buffalo are the most powerful rivals of the "all Canadian" routes. Great efforts are being put forth by the Canadian Government and others interested to improve facilities and render available Canadian routes. The author is of the opinion that the advantages for future transportation should lie with the St. Lawrence route. It is believed that improvements for the storage and handling of grain in the ports of Great Britain are not advancing in measure equal to the Canadian ports.

SIX new volumes have been added to "The People's Books," which Messrs. T. C. and E. C. Jack are publishing at sixpence net each. The additions fully maintain the high standard of this excellent series, which is bringing within the reach of all readers the results of modern studies in many branches of human knowledge. Particular attention may be directed to Dr. W. E. Carnegie Dickson's little book on bacteriology, and Mr. Ford Fairford's on Canada. Dr. Dickson, in the sub-title to his volume, "Man's Microbe Friends and Foes," sufficiently describes the point of view from which he has written. He gives a brief historical summary of the growth of the science, explains the relation between health and disease, describes some of the commoner organisms which produce disease, and explains the importance of bacteria in the arts and industries. Mr. Fairford's book should prove of service to students of commercial geography, and interest general readers in an important part of the Empire.

OUR ASTRONOMICAL COLUMN.

A NEW COMET.—A Kiel telegram, dated May 17, reports the discovery of a new comet, stated to be of the fourth magnitude, by Zlaitinsky. On May 15 the comet was situated close to η Persei, while on the following day it was recorded as being half a degree north of α Persei.

A further telegram from Kiel communicates an observation by Prof. Schorr. On May 16, at 11h. 12·9m. Bergedorf mean time, the comet was of the 4th magnitude, and its position was R.A. 3h. 17m. 37s., declination +49° 51′ 7″.

TELESCOPIC METEORS.—One of the interesting contributions to the *Observatory* for May is an account by Mr. W. F. Denning of observations of telescopic meteors. Thirty years ago Mr. Denning directed attention to the importance of making combined observation of these bodies, for he and others were of the opinion that these faint shooting stars were at vastly greater distances than those visible to the naked eye, for their slowness of movement and diminutive size suggested such remoteness. While ordinary meteors rarely become visible at a greater height than about 100 miles, these telescopic objects require distances of 1000 to nearly 2000 miles to explain their appearance assuming as standard the ordinary velocity and length of flight of naked-eye meteors. From four objects Mr. Denning inferred heights of 1260 to 1820 miles, and these he states were "only examples of a class and not rarities." The whole question is interestingly summarised in this contribution, and the author describes in detail observations extending over the period 1881 to 1902, and reproduces numerous diagrams of various forms of trails observed.

A NEW PHOTOGRAPHIC CHART OF THE MOON.—In the April number of *L'Astronomie*, M. Camille Flammarion gives an account of the new photographic chart of the moon, which has recently been prepared by M. C. Le Morvan. M. Le Morvan during the last eighteen years has been associated with the production of all the plates for the great atlas of Loewy and Puiseux, and this important and unique collection of clichés, taken with the Paris equatorial coudé, provides him with a rich assortment of material. The object of the work is to provide in a more convenient form as perfect a representation of the lunar surface as is possible in every detail. The plates are reproduced in héliogravure, and are issued in two parts, each part consisting of twenty-four sections, and representing increasing and decreasing phases respectively. The publication of this chart is rendered possible by a grant of 4000 francs out of the Bonaparte funds by the Académie des Sciences. M. Le Morvan communicates also a brief account of the construction of lunar charts.

THE ROYAL SOCIETY CONVERSAZIONE.

THE annual May conversazione of the Royal Society was held on Wednesday, May 13, and was, as usual, largely attended. During the evening demonstrations were given in the meeting-room by Prof. J. P. Hill and Mr. P. Schilowsky. Prof. Hill gave a short account of the work of the Percy Sladen Expedition to Brazil, 1913, illustrated by lantern-slides of material collected and regions visited; and Mr. Schilowsky demonstrated the application of gyroscopes to locomotion on land, on sea, and in air. The gyroscope's stabilising property can be applied to unstable bodies like monorail cars or monotrack automobiles, making them stable; that property can be used for stable but oscillatory bodies like ships, submarines, flying machines, preventing their rolling movement and rendering them perfectly steady. A description of the application of the system to a two-wheeled motor-car appeared in NATURE of May 7 (p. 251). Dr. J. G. Gray exhibited gyrostats with accessories for showing the more obvious properties of the gyrostat, and a series of what may be called "animated" gyrostats. The latter consist of gyrostatic acrobats, bicycle riders, and gyrostatic motor-cars, both two-wheeled and four-wheeled. A two-wheeled car was provided with a gyrostatic "chauffeur," which stabilised the car and presided at the steering wheel. This car illustrated the action of directing and stabilising apparatus for use on torpedoes, airships, and aeroplanes. A further form of two-wheeled car demonstrated methods of stabilising and manœuvring an airship by means of forces derived from the propellers, which apply a direct push to the moving body. Dr. Gray's bicycles and motor-cars can be steered by the wireless transmission of electrical action. There were many other exhibits of objects and devices of scientific interest, and we give descriptions, from the official catalogue, of some of the most interesting grouped according to related subjects.

The Astronomer Royal: Transparencies of the Milky Way (selected from the Franklin-Adams chart). The whole sky was photographed on 206 plates by the late J. Franklin-Adams. The plates have been presented to the Royal Observatory, and the number of stars of different magnitudes from the 12th to the 17th have been determined. There are altogether fifty-five million stars on the plates, and from the sequence of the numbers for different magnitudes it is shown (S. Chapman and P. J. Melotte, Mem. R.A.S., vol. lx.), that the total number of stars in the sky is not less than 1000 millions, and cannot much exceed twice this amount, and that half the stars are brighter than the 23rd or 24th magnitude. *Mr. George H. Cobb:* A terrestrial globe, dated 1620, constructed to serve as a timepiece; supported by a gilt bronze figure of Atlas. Inside the globe is a movement of the verge type, so geared to the axial spindle that the globe revolves once in twenty-four hours.

The National Physical Laboratory (Mr. F. E. Smith): Photographic record of the variations in the horizontal intensity of the earth's magnetic field at the National Physical Laboratory. The record shows the variations in H from 1 p.m. on Saturday, April 19, to 11 a.m. on Sunday, April 20. The time scale (abscissa) is 43 cm. to the hour (7 mm. to the minute), and the intensity scale (ordinate) is 2·5 mm. for a change in H of 1γ (0·00001 c.g.s. unit). The sudden variations are principally due to the earth currents produced by the London United Electric Tramway system. These sudden changes are not in general greater than 5γ. *Mr. W. A. Douglas Rudge:* Electrification produced during the raising of a cloud of dust. During the raising of a cloud of dust by almost any method, considerable charges of electricity are produced. A charge of one sign is found upon the dust itself, and another charge of opposite sign, either upon the air, or else upon fine particles of dust which remain suspended in the air. Generally, dust of an acidic nature, such as silica or molybdic acid, give a negative charge to the air, metallic oxides and organic bases give positive charges to the air.

Dr. J. A. Fleming: An apparatus for the production of stationary vibrations on strings, loaded and unloaded. Various arrangements have been employed for the production of stationary vibrations on strings to illustrate the laws of wave motion. The apparatus exhibited consists of an electric motor having on one end of its shaft a counting mechanism, and on the other a disc to which is fixed a pin carrying the end of a rocking lever This lever has on it a hook to which a string can be attached. The other end of the string is fixed to a slide rest arrangement, by means of which any required tension can be put on the string. When the motor revolves it gives to one end of the string an irrotational motion in a circle and propagates waves along the string. By adjusting the tension these waves can be made stationary. By employing a cotton cord, either single or multiple, in various degrees, it is easy to prove the fundamental laws of wave motion along cords. By using strings loaded with glass beads the effects of reflection at loads, or the laws of vibration of loaded cords, can be shown. *Mr. W. Duddell:* Water model of the electric arc. One of the essential properties of the electric arc is that, when the current through the arc increases, the potential difference between its terminals decreases. The model exhibited consists of a mushroom valve. The pressure tending to reseat the valve is so arranged that it diminishes very rapidly as the valve lifts. In this way, when the flow of water is increased through the valve, the difference of pressure between its two sides decreases and thus represents one of the properties of the electric arc. When a steady flow is established and a column of water having a definite periodic time is connected to the valve oscillations can be set up similar to those obtained with an electric arc. Other properties of the arc discharge can also be demonstrated.

The Cambridge Scientific Instrument Co.: An aerodynamic balance. Designed for the experimental investigation of the stability of aeroplanes. The main part of the balance consists of three arms mutually at right angles, each arm being counterbalanced. These arms meet in a point at which a steel centre is fixed, and the weight of the balance is taken on this point. The vertical arm passes through the underside of a wind channel and supports the model under test. The horizontal arms are arranged respectively parallel and at right angles to the wind direction. The arrangements allow of the measurement of the forces on the model along three fixed rectangular axes, and also of the three moments about these axes for any angle of incidence of the wind on the model. *Mr. F. W. Aston:* A simple microbalance for the determination of the densities of small quantities of gases. The balance is made entirely of fused quartz, and consists of a beam of the simplest possible construction, bearing at one end a small closed bulb and at the other a solid counterpoise. The whole is supported by a knife edge working on a polished quartz plate. The system is made to balance in air at some convenient pressure, and its sensitiveness made extremely high, turning at about one-millionth of a milligram. The gas is admitted to the balance case and the pressure determined at which it causes the beam to balance in a given position. The corresponding pressure for a gas of known density (*e.g.* oxygen) is then measured, the ratio of the pressures giving the inverse ratio of the densities.

Mr. E. Leitz: A new binocular microscope. The body consists of a flat casing containing the system of prisms. At the upper end are situated two eyepieces the distance apart of which can be regulated to suit the eyes of the observer by means of a milled head which actuates two levers inside the casing. The interpupillary distance can be varied between 54 and 70 mm. The eyepiece tubes slide in guides so that dust cannot enter the prism casing. The left eyepiece tube is provided with an independent adjustment to accommodate eyes of unequal vision. All kinds of eyepieces and objectives may be used, and the instrument can be employed for the same purposes as the ordinary monocular microscope. An important feature in this microscope is the parallel eyepieces which obviate the actions of accommodation and adjustment for convergence as is necessary in binocular microscopes constructed hitherto. *Prof. A. W. Bickerton:* The polyscope. A kaleidoscope rendered so optically perfect that a hundred reflections of a point or object may be seen. The angles of one are 30°, 60°, and 90°; of the other, two angles 45° and one of 90°. They produce two classes of patterns, one suitable for textile fabrics, cretonnes, etc., the other suitable for floor cloths, tiles, etc. *The Polychromide Company (The Dover Srect Studios, Ltd.):* Instantaneous photographs on paper taken in natural colour by the polychromide system. The optical separation of the natural colour of the object photographed is accomplished by means of the Hamburger-Conrady colour separation camera, which exposes three plates simultaneously—representing the red, yellow, and blue sensations in the superposed positives on gelatino-silver emulsions, which constitute the complete colour records exhibited.

The National Physical Laboratory (Dr. W. Rosenhain and Mr. J. L. Haughton): A new reagent for etching mild steel for microscopic examination. The reagent consists of an acid solution of ferric chloride containing small proportions of chlorides of copper and tin. Iron or steel sections exposed to this solution become covered with a very thin adherent layer of copper by a process of electrochemical substitution. This film of copper is deposited upon and thus darkens the ferrite areas, leaving the pearlite areas white, this effect being the reverse of that obtained with other reagents, such as picric acid.

Prof. E. W. MacBride and Mr. H. G. Newth: Double tadpoles of the frog, and double sea-urchins. The duplicity in the frog larvæ is of varying degree, and was produced experimentally. Fertilised eggs were inverted immediately upon the completion of the first cleavage-furrow, and were kept inverted until gastrulation was complete. The duplicity in the sea-urchin larvæ consists in the development of an urchin-rudiment on both sides, or of pedicellariæ on both sides, whereas the normal larva has its rudiment on the left, its pedicellariæ on the right. *Dr. W. T. Calman: Bathynella natans,* a Crustacean of the order Anaspidacea. This minute Crustacean has hitherto been known only from a solitary specimen obtained in 1882, by Prof. Vejdovský from a well in Prague. It has recently been re-discovered in a well near Basle by M. Chappuis, by whom specimens have been sent to the British Museum (Natural History). It is a blind and otherwise degenerate member of the Anaspidacea, an ancient and primitive order of Crustacea represented by fossils in carboniferous rocks of Europe and America, and by three other recent species in Australia and Tasmania. *The Zoological Department of the British Museum (Nat. Hist.):* Cast of the "paddle" or fore limb of a humpback whale. The humpback is the species of whale which has been most hunted during the last few years in Subantarctic waters. Immense numbers of these animals have been killed annually, and it can scarcely be doubted that the number will be enormously reduced unless steps are taken to control the rate of destruction. The late Major G. E. H. Barrett-Hamilton was sent to South Georgia by the Colonial Office, at the end of 1913, in order to obtain information with regard to whales and whaling in the far south. He died during the progress of his investigations. The cast shown measures 14 ft. 6 in. in length, and illustrates one of the most striking peculiarities of the humpback, the paddles of which are exceptionally long.

Dr. H. Eltringham: Preparations showing the urticating apparatus in *Porthesia similis* (gold tail moth). The female insect has long been known to possess urticating properties similar to those of the larva. It has lately been proved that the moth deliberately collects the spicules shed by its larva, and by means of a special apparatus stores them in the anal tuft. They subsequently serve as a protection for the eggs. *Prof E. B. Poulton:* A family of *Papilio dardanus,* bred by Mr. W. A. Lamborn, near Lagos, S. Nigeria. The family was bred from a captured female of the *hippocoon* form—the black and white butterfly, which is by far the commonest female form of this species in the locality. Six previous families, bred by W. A. Lamborn from the same female form, contained *hippocoon* females and no others. This, the seventh, contains approximately equal numbers of *hippocoon* and *dionysus,* a non-mimetic female form occurring, but in very small proportions, along the tropical west coast. The facts are best explained by supposing that *hippocoon* is a Mendelian recessive, *dionysus* a dominant, and that the male parent was a heterozygote.

Dr. Vaughan Cornish: Photographs illustrative of landslides and upheavals on the Panama Canal. The photographs were taken in 1910, 1912, and 1914. That of the Culebra Cut in 1910 shows an upheaval of the solid rock of the canal bottom due to unbalanced pressure of the banks. That of the Naos I. breakwater, taken in 1912, shows the upheaval of the sea bottom at a distance from the subsiding mass of the breakwater. The photographs of the Cucuracha slide, in 1914, show the downward flow of inclined strata. The ground is broken for a height of 580 ft. above canal bottom.

Mr. Charles Dawson: Lower canine tooth of the Piltdown man (*Eoanthropus dawsoni*). This canine tooth was found on August 30, 1913, near the spot where the right mandibular ramus of Eoanthropus was discovered in 1912. As it is a lower canine of the right side, is of a new form, and has been much worn by mastication, it presumably belongs to the same jaw. It is relatively large, and is shown to have completely interlocked with the upper canine, as in the apes. *Mr. R. Eliot Steel:* Palæolithic engraving of a horse on a bone from Sherborne, Dorset. The bone is part of the rib of a horse, and was found in an old heap of débris from a quarry in the Inferior Oolite, near Sherborne. It was probably derived from a rock-shelter destroyed by quarrying. *Mr. W. N. Edwards:* "Paper coal" from the Coal Measures of Central Russia. The "paper coal" forms a bed 3–4 ft. thick, over an area of several square kilometres. It is composed exclusively of the practically unchanged cuticles of a Lepidodendroid plant, with a certain amount of carbonaceous matter. It has been suggested that the preservation of the cuticles alone was due to selective bacterial action, and Renault considers that a species of micrococcus is present.

CATALYSIS IN ORGANIC CHEMISTRY.

BY the invitation of the University of London, Prof. Paul Sabatier, of Toulouse, delivered two lectures on catalysis at King's College on May 14 and 15. On Wednesday evening, May 13, he was entertained by the Faraday Society at a complimentary dinner, at which Prof. Arrhenius and Prof. Heyn, of Berlin, were also present as guests. The two lectures were delivered in French, and were illustrated by a series of experiments in which the catalytic action of nickel, of copper, of alumina, of zinc oxide, of titanium dioxide, and of thoria were shown in actual operation. Prof. Sabatier is a whole-hearted advocate of the chemical as opposed to the physical theory of catalysis. He holds that in all cases intermediate compounds are formed, *e.g.* PtO in catalytic oxidations in presence of platinum, and NiH_2 in catalytic reductions in presence of finely divided nickel. He finds ample support for his views in the totally different effects that are often produced by catalysts which are almost identical in their physical properties. Thus formic acid vapour is decomposed wholly into hydrogen and carbon dioxide when passed over zinc oxide, but into water and carbonic oxide when passed over titanium dioxide :—

$$H_2 + CO_2 \xleftarrow{ZnO} H.CO.OH \xrightarrow{TiO_2} H_2O + CO.$$

Ethyl alcohol in like manner may be converted into aldehyde and hydrogen by finely divided copper, or into ethylene and water by alumina :—

$$H_2 + CH_3.CHO \xleftarrow{Cu} CH_3.CH_2OH \xrightarrow{Al_2O_3} H_2O + C_2H_4.$$

Different catalysts also differ very widely in their efficiency in promoting any given chemical change. Alumina can be used very effectively to convert alcohol into ethylene and water, but it becomes clogged with tarry matter which cannot be burnt off without destroying the catalytic properties of the oxide; thoria, on the other hand, becomes contaminated less readily, and can be purified by ignition without losing its activity. Again, thoria is a very useful catalyst for converting acids into ketones, *e.g.* :—

$$2CH_3.CO.OH \longrightarrow CH_3.CO.CH_3 + CO_2 + H_2O;$$

but titanium dioxide is so efficient and acts at so low a temperature that it can also be used to prepare aldehydes from mixtures of fatty acids with formic acid, and esters from acids (such as formic acid) or alcohols (such as the secondary and tertiary alcohols), which lose water so easily that it is difficult to esterify them without decomposition. On the other hand, the best catalyst for preparing ketones and other derivatives from benzoic acid is ordinary chalk. A very important catalyst is manganous oxide, which can be prepared easily and cheaply from manganous carbonate, and can be used in almost every case for the preparation of ketones in place of thoria or titanium dioxide.

Prof. Sabatier laid stress on the reversibility of catalytic actions. Thus nickel will promote dehydrogenation as well as hydrogenation, and very small differences of conditions are required to cause the reversal of actions such as those which are shown by the equations :—

$$C_2H_4O + H_2 \rightleftharpoons C_2H_6O$$
$$C_6H_6 + 3H_2 \rightleftharpoons C_6H_{12}.$$

An interesting account was given of the way in which acetylene in contact with nickel at different temperatures and in presence of varying proportions of hydrogen gives rise to complex products which are in every respect identical with natural petroleums. By varying the conditions the product can be made to resemble the four chief natural types as derived from North America, from the Caucasus, from Galicia, and from Roumania. These observations suggest a theory of the origin of petroleum that has a far higher claim to acceptance than most of those that have been put forward hitherto.

Prof. Sabatier touched only lightly on the technical applications of his new methods. The vast industry which has sprung up within the last two or three years, in this country, on the Continent, and in America, was illustrated by two small samples of oils that had been hardened by the action of hydrogen in presence of finely divided nickel; reference was also made to the fact that in the process of hardening the disagreeable taste and smell of the fish-oils are completely removed.

It is not too much to say that Prof. Sabatier has introduced a new era in organic chemistry. The advantages of catalytic methods are obvious: the catalyst will last for an indefinite period unless its activity is destroyed by overheating, which is generally fatal, or by "poisonous" impurities, such as sulphur or the halogens which quickly arrest the catalytic hydrogenation of organic compounds by nickel. The only materials required are those which are essential constituents of the products, and in almost every case the first effect of the successful introduction of catalytic methods is to bring about a great reduction in the cost of production. The rapid extension of these methods is therefore a matter of great scientific and technical importance.

T. M. L.

RECENT GEOLOGICAL WORK IN AUSTRALASIA.

THE Australian Commonwealth Bureau of Meteorology at Melbourne, in its Bulletin No. 8, publishes a memoir by Griffith Taylor on the physiography of Eastern Australia, in which it is urged that a repeated shifting of the divide between the eastern coast-streams and those running towards the Darling or the interior has occurred during Cainozoic times. The former streams have in consequence been able to lengthen themselves by captures in the region of the divide, and a very considerable reversal of drainage, assisted by the outpouring of lavas, has taken place. The author pictures the rise of eastern Australia on an earth-wave that proceeded westward from the New Zealand area. The large amount of "unreduced plateau" on the crest of the wave is well seen in E. C. Andrews's model of New England (New South Wales), which is described and illustrated by him in Proc. Royal Society N.S.W., vol. xlvi., p. 143. Andrews directs attention to the agricultural possibilities of the inland slopes of Eastern Australia.

The Bulletins of the Geological Survey of Western Australia include, in No. 50, a general account of "The Geology and Mineral Industry of Western Australia," by A. G. Maitland and A. Montgomery, which is reprinted from a cyclopædia issued in Adelaide. The preparation of authoritative essays of this nature is one of the best functions of a public survey, since the ordinary citizen cannot piece together the history of his country from detailed memoirs. From the price-list given in this bulletin, which unfortunately mentions it as in preparation, we conclude that it can be obtained for about 2*s*. A geological sketch-map is included.

The West Australian goldfields are described in Bulletins 41 (West Pilbara), 42 (East Coolgardie), 45 (North Coolgardie and East Murchison), 46 (Yilgarn and North Coolgardie, southern portion), and 47 (Kanowna). The quartz-reefs that penetrate crushed and metamorphosed conglomerates in these areas are in close relation with intrusive quartz-porphyries, and E. S. Simpson and C. G. Gibson remark (No. 42, p. 64) that at Kalgoorlie sulphur and potash were introduced with gold, silver, mercury, and tellurium, through the influence of a late igneous intrusion which may or may not have reached the surface. It is pointed out that a solution of potassium sulphide dissolves both gold and tellurium. The illustrations of thin sections of the actual ore-materials are well produced and are of considerable petrographic interest. T. Blatchford and J. T. Jutson (No. 47) give a detailed account of the sheared conglomerates of Kanowna, and R. A. Farquharson discusses (p. 58) numerous types of igneous rocks, including a quartz-fuchsite-carbonate rock. This is believed to represent a former peridotite, of which chromite and fuchsite are the only unaltered relics. The type is also described in Bulletin 43, "Petrological Contributions to the Geology of Western Australia." It is clear that the official petrologist will render important service in determining the relations of the very interesting series of intrusive rocks, among which the ores have reached the surface.

Among recent publications of the Geological Survey of South Australia, general interest attaches to L. Keith Ward's Bulletin (No. 2) on the possibility of the discovery of petroleum on Kangaroo Island and Eyre's Peninsula. The author concludes (p. 25) that the asphaltum thrown up on the beaches is brought from an unknown source by oceanic currents. "Coorongite," on the other hand (p. 15), which is not proved to be in any way connected with petroleum, appears to be still accumulating from local sources as a scum on lagoons, being left behind when a shrinkage of the water takes place. Incidentally, we learn from this inquiry that Kangaroo Island is believed to have been isolated from the mainland by a system of Cainozoic fractures.

J. E. Carne describes the somewhat fitful antimony mining industry of New South Wales (Geol. Survey N.S.W., Mineral Resources, No. 16, price 2*s*.).

The Geological Survey of Queensland in Publication No. 234 deals with the Etheridge Goldfield, near Einasleigh, where barren areas of granite, composite gneiss (p. 7), and Upper Cretaceous sandstone occur along the Copperfield River. Here again, as in Western Australia, quartz-porphyry dykes appear to have some relation to the gold-bearing quartz veins; but the latter are on the whole richer in the more permeable adjacent rocks than in the porphyries themselves (p. 13). L. C. Ball (Publication 237) describes the Mount Mulligan Coalfield, about fifty miles west of the port of Cairns on the Cape York Peninsula. The Coal Measures, lying unconformably in gently sloping synclinals on uptilted grits and slates, are associated with the Glossopteris flora, and no Mesozoic plants have been found. The field is roughly estimated to contain 84,000,000 tons of somewhat friable coal.

The Geological Survey Bulletins issued by the Department of Mines in Tasmania now number thirteen, beginning with that by W. H Twelvetrees, the Government geologist, "The Mangana Goldfield," in 1907, and extending to "The Preolenna Coal Field and the Geology of the Wynyard District," by Loftus Hills, published in 1913. They are printed, like those of Western Australia, in a convenient small octavo form, with folding maps, and are in the main devoted to mining considerations. The gold ores seem to have been deposited in the veins that accompanied intrusions of granite, and these occurred at the close of an epoch of folding between Silurian and Permo-Carboniferous times. The principal folding in Tasmania is thus probably contemporaneous with the Caledonian movements of the European area. Bulletin No. 5 contains (p. 35) an interesting correlation of the Cambrian beds of Railton with those of Britain and America, and the Government geologist regards this north-western district as adding largely to our knowledge of the Older Palæozoic rocks of Tasmania. In Bulletin 8, "The Ore-bodies of the Zeehan Field," an interesting problem is raised (p. 42) by the occurrence of a glacial conglomerate dipping under "Cambro-Ordovician" beds, but probably as an inverted layer of Permo-Carboniferous age. Bulletin 9 introduces the excellent plan followed by the Survey of New Zealand, by showing on a sketch-map the position of the area described in relation to the region as a whole. W. H. Twelvetrees, in considering the more basic and hornblendic envelope of the Scamander granite (p. 19), concludes that it is a product of differentiation rather than of assimilation. The memoir on the Tasmanite shale fields of the Mersey district (No. 11, 1912) provides a valuable review of the literature on tasmanite, which is shown to be a resinous and somewhat sulphurous shale in the Permo-Carboniferous (Glossopteris) series. The seam was formed in sea-water (p. 47), and its spore-like contents may be washed-down spores of land-plants or algæ deposited with the silt. Pp. 40–54 embody a thoughtful account of the mode of occurrence and relationships of the material, and two photographs of thin sections are appended. The Mersey district, with its range of rocks from Pre-Cambrian schists to Cainozoic basalts, is made still more interesting by the maps and sections published as a supplement to the bulletin. The Preolenna Coalfield (Bulletin 13, 1913) contains Permo-Carboniferous seams amounting in the aggregate to 6 ft. 6 in., situated under the Campbell Range some fifteen miles south-west of the north coast at Wynyard. Prospecting by diamond-bores is advised. No coal is to be expected near Wynyard (p. 71).

The Geological Survey Branch of the Department of Mines of New Zealand continues its handsome series of quarto publications. Petrographers may be disappointed with Bulletin No. 12, "The Geology of the Dun Mountain Subdivision," since the exceptionally fresh olivine-rocks of Dun Mountain have made the district famous for half a century. The bibliography on pp. 6–8 perhaps explains why little more need be written on their nature and alliances. The authors, J. M. Bell, E. Clarke, and P. Marshall, describe a new rock-species, Rodingite, on p. 31. This consists of grossularite and diallage, the percentage of silica being 40, of lime 31, and the specific gravity being as high as 3·4. The authors do not see their way towards explaining this rock either by absorption of the Maitai limestone or by differentiation in the ultrabasic mass. The main object of the present bulletin has been a review of the prospects of the associated copper ores. The mineral from which the more superficial ores are derived (p. 44) is a cupriferous pyrrhotine, containing traces of gold, silver, cobalt, and nickel. This is interestingly associated with serpentinised peridotites. The chromite in the peridotites has not been mined since 1865. Dun Mountain, a rounded mass supporting little vegetation, is figured on plate iv.

Bulletin No. 13, by P. G. Morgan, who is now director of the Survey, describes the Greymouth subdivision of North Westland, where coal-seams occur, conformably overlain by marine Eocene strata. The Pleistocene glacial gravels are worked for gold, and there is said to be a probability that the Kotuku oilfield will prove profitable on further exploration. The petroleum occurs in various Cainozoic rocks above the local Coal-Measure series, and its source is at present unknown.

Bulletin 14, by E. Clarke, is also concerned mainly with petroleum, in the New Plymouth subdivision of the Taranaki division, on the jutting promontory of the west coast of the North Island. The iron-sands that compose the Recent sand-dunes and beaches are also considered, owing to their well-known richness in magnetite and ilmenite. Bulletin 15, by J. M. Bell and C. Fraser, takes us to the Hauraki division of the North Island, where the town of Waihi, picturesquely situated, and illustrated in a folding plate, is the active centre of gold and silver mining. The ore is electrum for the most part, and the veins occur in altered Cainozoic andesites or dacites resembling the propylites of Hungary. Deposition is believed to have taken place from hot solutions, which brought up silica also, and to have been promoted by a fall of temperature near the surface (p. 179). Siliceous geyser-deposits occur in the middle of the volcanic series, and cinnabar has been found in them at Mackaytown (p. 59). The physiography of the rugged country is well described, and its irregular structure is attributed to the occurrence of epochs of denudation between those of volcanic deposition (p. 27).

R. Speight, L. Cockayne, and R. M. Laing have made an interesting study of the Mount Arrowsmith district, on the eastern slope of the Southern Alps in Canterbury (Trans. New Zealand Institute, vol. xliii., p. 315), in which the physiography described by the first named author is used by his colleagues as a basis for a report on plant-distribution. The paper, with its details of glacial sculpturing and deposition, is a good example of modern geographical inquiry into the origin of surface-forms. The rivers of Canterbury are held (p. 320) to radiate from a lost highland to the west, which has been cut away by denudation, and formed the higher part of the peneplain on which they originally flowed.

THE DEVELOPMENT AND PROPERTIES OF THE COTTON FIBRE.

THE standard accounts of the cotton fibre are curiously inaccurate. Mr. W. Scott Taggart has directed attention to some of the more glaring errors in his "Cotton Spinning" (vol. i., 1896; London: Macmillan and Co., Ltd.), as did also the present writer independently in 1905 (Khedivial Agricultural Society's Yearbook, 1905), when the cytology of the fibre was traced up to a week after the opening of the flower. Some additions to this account were outlined in my "Cotton Plant in Egypt" (London: Macmillan and Co., Ltd., 1912), and a serious attempt was then made to ascertain how and when environmental effects operated on the properties of the fibre during maturation, and also to elucidate the real nature of the infinitesimal differences which the "sixth sense" of the expert classifier of lint cotton can perceive.

(1) By pickling a complete series of bolls from flowering to maturation in 1912 we showed definitely that the first half of the maturation period is occupied in the lengthening of the lint, and in the enlargement of the capsule and seed. Thickening processes take place in the second half of the maturation period. Thus a fibre may be short, but subsequently thicken satisfactorily, or conversely. Bad weather or soil in the latter half of maturation may weaken the fibres, but cannot affect the "predetermined" length.

(2) A number of open flowers in a wide-sown pure strain were marked every day for sixty days in 1912 and allowed to ripen normally. Each sample was then combed, measured, and ginned, weighed to determine various constants, tested for breaking strain of the fibre on an automatic invention, and graded for strength; the results were examined statistically and graphically. They confirmed the developmental evidence; on shifting the breaking-strain curve backwards over thirty days' displacement, it was found to be substantially identical with the lint-length curve.

The cause of fluctuation in ginning-out-turn (ratio of lint to seed-cotton) has long been a puzzle. With this material it was traced provisionally to fluctuation in the number of lint-hairs which sprout from the seed-coat; its determination is therefore effected when the flower is about to open, which was, *a priori*, the least likely time.

Plotting breaking-strains against "strength" as determined in hand-pulling by an expert (Mr. H. C. Thomas, of Alexandria), the two were found to be completely independent; the expert unconsciously integrates breaking-strain with sectional area; samples of the same pure strain with respective breaking-strains of 12 grams and 2 grams were both graded as "SS" in a scale of seven grades. This leads on to a new definition of "fineness" in cotton fibre; it is not due primarily to differences in fibre-diameter, but to differences in the thickness of the lint cell-wall. "Weakness" of a sample is thus mainly irregularity in breaking-strain.

Determinations of fibre-weight with a micro-balance showed incidentally that an ordinary seed of Egyptian cotton bears about 10,000 fibres, and that weight is closely related to breaking-strain. The spinning into yarn introduces fresh complications, with which we have not dealt.

It should be obvious to those familiar with the subject that the discovery of this phenomenon of predetermination has shattered almost all accepted beliefs about the fibre of cotton, and has at the same time coordinated the old data afresh into a straightforward story. The practical applicability of the results is slight, since every boll passes through a different life-history, on account of the continuous fruiting of the plant.

In 1913 a series of daily pickings was made from a group of pure-strain plants growing in field-crop conditions, over a period of ninety days, with parallel records of flowering, etc. The examination of these having been delayed by unavoidable circumstances, the present note has been prepared. It should be noted that this last material is unique in the history of long-staple cotton.

These results were obtained incidentally during my tenure of the post of botanist to the Khedivial Agricultural Society, and to the Egyptian Government at the Giza Cotton Experiment Station, 1904–13.

W. LAWRENCE BALLS.

NEW ZEALAND SURVEY.[1]

THE report before us gives a full account of the work of the Department of Lands and Survey, New Zealand, for the year ending March 31, 1913. As in previous years, not only surveying, but also the direction of the magnetic observatory falls within its purview. Most of the work dealt with in the report has been undertaken in connection with cadastral requirements, and the higher grade work, which is termed "standard" survey, is in great request in town and suburban holdings, where land that could probably have been purchased sixty or seventy years ago for a mere trifle is now reported as having a value of 1200*l*. a foot. Under such conditions work of the highest precision is essential, but the new secondary triangulation is as yet available for a small part of the country only. This triangulation is the equivalent of second order triangulation, since the triangular error is kept below 6″, and is usually considerably less. This is as much as can be expected from the instrument used, a 10-in. vernier theodolite, and the Conference of Surveyors-General supported the New Zealand Survey in the opinion that a modern instrument of higher class was indispensable. A standard bar of nickel-steel 10 links long has been obtained from the Société Genevoise, Geneva, as well as a comparator from the Cambridge Instrument Company for use with it. Both of these have been examined and verified at the National Physical Laboratory. Four bases, from 5·2 to 11·5 miles in length, have been measured since 1909, but only two are as yet part of the finally accepted triangulation.

In the magnetic observatory a new set of Eschenhagen-Toepfer magnetographs were received at the end of 1912, and were installed at Amberley, thirty-four miles north of Christchurch.

Considerable assistance was given to the officers and scientific staff of the British Antarctic (*Terra Nova*) expedition, who took magnetic observations and determinations of gravity as controls to the work carried out in the Antarctic. The report also publishes ten seismograms of those recorded during the year by the Milne seismograph. Maps showing the progress of the work and extracts from Conference of the Surveyors-General of the Commonwealth of Australia, which was held at Melbourne in May, 1912, complete a report which is of much interest, and contains a record of much valuable work.

H. G. L.

[1] Report on the Survey Operations for the Year 1912–13. Department of Lands and Survey, New Zealand. By James Mackenzie, Surveyor General Pp. 77+6 maps+5 diagrams. (Wellington, 1913.)

THE ENCOURAGEMENT OF RESEARCH BY THE CARNEGIE INSTITUTION OF WASHINGTON.

THE Year Book for 1913 of the Carnegie Institution of Washington is now available. The information provided in its 336 pages shows convincingly that there has been no relaxation of effort on the part of the trustees of the institution to administer wisely the funds placed at their disposal for the encouragement of scientific research, and that the results arrived at by the men of science who have received assistance are as promising and as full of interest as in previous years.

The following list shows the amounts of the grants made for the present year and the purposes to which they are being devoted:—

	£
Administration	10,000
Publication	12,000
Division of Publications	2,000
Departments of Research	137,929
Anthropology	4,000
Embryology	5,380
Minor Grants	18,980
Index Medicus	2,500
Insurance Fund	5,000
Reserve Fund	50,000
Exhibit at Panama-Pacific International Exposition	2,000
	£249,789

The next table shows the departments of scientific investigation to which the larger grants were made by the trustees for the financial year 1912-13, and the amounts allotted from these grants by the executive committee during the year:—

	£
Department of Botanical Research	7,601
Department of Experimental Evolution	19,028
Geophysical Laboratory	15,600
Department of Historical Research	5,920
Department of Marine Biology	6,378
Department of Meridian Astrometry	5,036
Nutrition Laboratory	9,310
Division of Publications (office expenses)	1,800
Solar Observatory	33,126
Department of Terrestrial Magnetism	42,053
Researches in Anthropology	1,400
Researches in Embryology	3,000
	£150,252

The following extracts from the *résumé* of the investigations of the year included in the report of the president of the institution, Dr. R. S. Woodward, will give some indication of the work which has been initiated and encouraged:—

All the departments of research of the institution are now well-defined organisations, each of them independent of and more or less isolated from the others, and each of them devoted to a field which, while in some cases related to, does not encroach upon, the fields of others. Each of them possesses a degree of autonomy which calls for a corresponding degree of freedom in the character of their annual reports and accounts of progress.

Studies of the Salton Sea, carried on during the past seven years by the department of botanical research in collaboration with a number of contributing specialists, have been brought together during the year in a volume now in the press under the title "The Salton Sea: A Study of the Geography, the Geology, the Floristics, and the Ecology of a Desert Basin."

Among many researches carried on by the director, mention may be made of his cultivation of second and third generations of mutants arising from ovarial treatments of plants and resulting in further noteworthy morphological and physiological departures from the original parent stocks.

The work of the year in the department of experimental evolution records, among many other advances, additional contributions to the laws of human inheritance; the results of further and more conclusive studies of the transmission of traits in plants of the genera Bursa and Œnothera; and some preliminary indications of specially instructive investigations in the field of biochemistry. The director has divided his time between researches based on breeding experiments carried on at his station and studies of data bearing on human heredity collected under the auspices of the Eugenics Record Office, of which he is also the directing head.

In his annual report the director of the geophysical laboratory gives instructive accounts of the effects of pressure in the formation of minerals, of progress in the perfection of adequate appliances for calorimetric measures of minerals, of the factor of temperature in optical studies of crystals, of the results thus far obtained in volcano studies, and of the important economic investigations of the secondary enrichment of copper sulphide ores. It had been hoped that the signal success attending the studies of Kilauea a year ago might be followed up during the past year, but in this the staff has met disappointment, for the volcano has been inactive and gives no warning of renewed opportunities.

When the laboratory of the department of marine biology was established on Loggerhead Key, Dry Tortugas, Florida, now nearly ten years ago, Fort Jefferson, on an adjacent island, was an important base station of the United States Navy, and transportation to and from points on the Gulf coast was a matter of daily occurrence. In the meantime, however, this station has steadily diminished in importance, and is now virtually abandoned as a naval base. This change of conditions shifts the burden of transportation between the laboratory and the nearest port, Key West, about thirty miles distant, wholly upon the department; and the resulting increased cost and inconvenience have led the director to recommend a gradual transfer of his laboratory and activities to a more favourable site. Preliminary investigations indicate that such a site may be had in Jamaica, where health conditions and transportation facilities have been much improved in recent years, where the cost of labour and subsistence is low, and where such an international scope as best befits marine biology could be readily developed. It may be anticipated that definite plans for an advantageous change of site will be matured during the present year, and ready for submission to the board of trustees in December, 1914.

The extensive computations essential in the derivation of the great number of stellar positions observed at the temporary observatory at San Luis, Argentina, are going forward in the department of meridian astrometry at a favourable rate, so that the inclusive catalogue of precise positions for stars in both hemispheres may be expected in due time. Some instructive results of these computations, showing the stability of the San Luis meridian mark (mire), the diurnal variation of the clock corrections, and the changes of personal equation for day and night observations are given in the report. As in most lines of fruitful research, the work of this department is noteworthy for its by-products, or for contributions it is making to allied lines of inquiry. Obviously, a first requisite to a knowledge of stellar motions lies in precise determinations of stellar positions at different epochs. The so-called proper motions of stars are thus brought to light, and from these it is possible to determine also the motion of our solar system. But now comes the surprising discovery that these proper motions, hitherto supposed to be of a random character, are of a systematic nature dependent in large degree, apparently, on the stage in evolution any individual star has reached and on the group to which it belongs. A new and peculiarly fascinating field is thus opened to astronomers of all kinds, and the by-products referred to seem destined to prove not less important than its primary object in positional astronomy. The world of astronomy, however, is anxiously awaiting the attainment of this object, as is well shown by the fact that the preliminary catalogue issued by the department three years ago is already out of print.

One of the noteworthy events of the year for the department of terrestrial magnetism is the completion of the second cruise of the non-magnetic ship *Carnegie*. She arrived in New York in February last, having been continually in service since June 20, 1910. The aggregate distance traversed in her two cruises is in round numbers 100,000 miles. The corresponding distance covered by the chartered ship *Galilee*, in the Pacific Ocean during 1905–8 is 60,000 miles. Thus the total distance traversed up to date in the magnetic survey of the oceans is 160,000 miles, or about six times the circumference of the earth. Accurate magnetic data have been obtained thereby in all of the oceans between the parallels of 50° north and 50° south latitude, or near the courses usually followed by vessels. By reason of the expedition attained in deriving from these surveys the results of chief interest to mariners, it has been practicable for chart-publishing establishments to make prompt revision of defective sailing charts or to issue corrections thereto; and a distinct improvement in these aids to navigation is already noticeable in the charts issued by the leading maritime nations. In the near future it is considered that the *Carnegie* should make surveys in areas not yet covered and along some stretches already traversed where cloudy or stormy conditions have prevented the securing of adequate observations. She will at the same time cross her previous tracks as often as practicable in order to determine for such intersections the information now most needed by chart-makers, namely, the annual changes in the magnetic elements.

In the near future it is anticipated that the department will have sufficient data to permit the construction of a new set of magnetic charts, including all three magnetic elements (declination, dip, and intensity), especially for that part of the globe included between the parallels of 50° north and 50° south of the equator. It will then be practicable to study the general problem of the earth's magnetism by aid of a large mass of homogeneous data surpassing in definiteness any mass hitherto available for this purpose. In anticipation of the need of experimental facilities for studies of this problem and others closely related thereto the office and laboratory building of the department was authorised a year ago and has recently been completed.

From the date of its establishment nine years ago the solar observatory has been one of the most important of the enterprises fostered by the institution. It has called for heavy annual appropriations; it has grown with extraordinary rapidity and with equally extraordinary productivity; and it is now an organisation of which the staff of investigators, research associates and collaborators, constructors, computers, designers, mechanicians, and operators includes upwards of sixty individuals. The report of the director of the observatory has been described already (April 23, p. 201) so it need not be summarised here.

The complexity of the relations which research associates and collaborators sustain to the institution is so great as to preclude any comprehensive explanation within the limits allotted to an annual administrative report. Their work embraces a wide range of subjects, and varies in its conduct from individual independence to intimate collaboration with the departments of research and with the division of publications. During the past year more than twenty distinct fields of research have been cultivated, and a total of more than one hundred investigators have contributed to the output. Summaries of the work of associates proceeding independently are given by them in the Year Book.

THE TOTAL ECLIPSE OF 1914 IN TURKEY AND PERSIA.

ON account of the unfavourable weather prognostications for the approaching total eclipse of the sun throughout the European countries traversed by the track of totality, it seems particularly desirable that stations should be occupied beyond the Black Sea, nearer the sunset limit of eclipse, in eastern Turkey and western Persia.

The central line of the eclipse passes very nearly through Baiburt and Bitlis, just a few miles to the west of Lake Van, in the former country. In Persia it passes through Kermanshah and Khorremabad, to the south-west of Teheran, and through a point about midway between Persepolis and Dehbid, and slightly to the north-east of Shiraz, only a few miles distant from Bushire, a port in the north-east of the Persian gulf.

The desert character of a large part of this region would indicate that the probability of a cloudless afternoon sky in August is very good. Most of this region traversed by the shadow is quite elevated, some of it being as much as five or six thousand feet above sea-level; and this would, in large measure, if not entirely, compensate for the lesser altitude of the afternoon sun at local totality. Throughout the Turkish region the approximate local time of totality is 3h. 50m. p.m., the duration of total eclipse being about 120s. Throughout the Persian region the time is about 4h. 50m., with totality shortened to about 105s. As very little of the European track has a likelihood of less than 50 per cent. of cloud, it seems highly desirable that some of the observers now contemplating European location should undertake the extra journey into Turkey, at least in order to diminish, if possible, the chances of entire failure of the eclipse, such as befell astronomers in 1887, and was nearly repeated in 1896.

The region of western Persia is not especially difficult to reach by way of Batum, at the east end of the Black Sea, thence through Tiflis to Baku on the Caspian, thence to Resht on the south-west coast of the Caspian, whence Kermanshah is easy by caravan through Kazbin; or, better, first to Teheran to receive Government authority and facilities. Most of the roads of Persia would permit the use of wheeled vehicles only with difficulty. Allow four weeks from London or Paris to Teheran, and two weeks thence to Kermanshah. Camping outfit and subsistence for the most part should be taken along, as only chicken, fruits, and similar edibles can be depended on for the last stage of this journey. Roads are in part built, in part old roads and trails. From Teheran the best route is to Kum, and thence to Sultanabad and Kermanshah; also Bourodjird, quite a large town with a telegraph station, and the chief city of Luristan. Summer clouds are said to be highly improbable. From Bushire to Shiraz and Persepolis is rather more than 100 miles by caravan, the particular drawback at this season being the intense heat, which renders travel exceedingly uncomfortable, except at night. There are telegraph lines traversing this region which would make it feasible for the eclipse observer arriving early in the field to check up his longitude as well as latitude, so as to make sure of being within a few miles of the line of central eclipse. Bushire is very accessible; the steamers of the British India Company are scheduled to sail from Bombay every Thursday; from Karachi every Saturday, and are due in Bushire on Wednesday. The Bombay steamers of the P. and O. are due to arrive at Bombay on Friday, and there is direct rail connection for Karachi, and while the British India steamers are scheduled to sail from Karachi on Thursday, if the English mails are late, the steamers will be held pending their arrival. Transportation from Karachi to Bushire is approximately 15*l*.

The Turkish region is very accessible from Trebizond. The eclipse is total at Trebizond itself, the line of exact centrality intersecting the coast a few miles west of Trebizond, about midway between that port and Tereboli. While at the coast towns themselves, including Plattana, Eskiefe, and Jaueboli, the chances of clear weather are not at all good, one can, by ascending the cliffs and entering the elevated tableland of the interior, select observing stations which apparently decrease in probable cloudiness, the farther inland one goes. Of course, there are no railways; but travelling so far as Erzerum, about 150 miles south-east of Trebizond, is not particularly arduous, because it is the first section of the early caravan route through Tabriz to Teheran. Wheeled vehicles are now possible so far as Erzerum, and packages of any size and weight required by the eclipse astronomer are not prohibited.

Probably the most detailed map of this region is Richard Kiepert's "Karte von Kleinasien," on a scale of 1 : 400,000, published in 1902 by Dietrich Reimer, Berlin. The sheets which should be consulted are AVI, Tirabzon, and BVI, Erzirum. Another good map is the "Map of Eastern Turkey-in-Asia, Syria, and West Persia," published by the Royal Geographical Society, 1910, and is accompanied by notes. Consult also "Zug des Zenophon bis zum Schwarzen Meere" (Karte ii.), Entworfen von E. v. Hoffmeister, accompanying "Durch Armenien und der Zug Zenophons" (1911) and "Wandkarte des Osmanischen Reiches," von W. v. Diest and Dr. M. Groll (Gea-Verlag, Berlin W. 35, 1911); scale 1 : 1,250,000.

Erzerum itself is within the belt of totality, though not far from the north-eastern edge of it, so that totality would not last more than a very few seconds there. Besides this, Erzerum is quite likely to be cloudy; and the same might be said of Bitlis itself, which is located in a sheltered valley. But about fifteen miles west of Bitlis begins the elevated tableland of Moush, which, according to the best information I have been able to secure from those resident in Bitlis, would probably be cloudless. At the time of the eclipse, this whole region rarely experiences any rain from the latter part of June until the middle of September. The atmosphere is very clear, being only a trifle cloudy during that season, and clear skies can be depended upon, although it is extremely hot.

Officers of the Turkish customs are not inclined to cause trouble over the baggage of travellers, and it is probable that the English and American Consuls would be able to get instruments passed without examination, especially if the observer brought a letter visèd by the Turkish Consul nearest his home.

It would be highly desirable, before leaving home, to pack all parcels of instruments with especial reference to caravan travel, as otherwise repacking in Trebizond would be necessary and much delay occasioned. Two hundred pounds is too heavy, and it is better if no package exceed 150 lb., as a mule must carry two of them; the average load is about 300 lb. As a mule must have a perfectly balanced load, it is well to have the paraphernalia so divided that pairs of packages will be of the same weight. The nearer a parcel approaches a cube, the easier it is to handle, though moderately oblong packages are not particularly troublesome. Packing must, of course, be done much more thoroughly than for transit by railway and steamship, as the continued motion of a pack animal will cause screws and delicate parts of instruments to disconnect themselves. I have found nothing better for packing than granulated cork, such as Malaga grapes are packed in.

As before said, travel so far as Erzerum can be accomplished in fairly comfortable carriages, and even a rubber-tyred vehicle is possible. Baggage might go in a species of lumber wagon, or springless vehicle; but beyond Erzerum carriages would not go, except at great expense. From Trebizond to Erzerum eight days of travel should be allowed, by starting promptly every morning. From Erzerum to Bitlis would require eight or nine days; and before leaving either Trebizond or Erzerum, it is necessary to make the drivers or muleteers agree to arrive at the desired place on a certain day; then, in addition to this, the traveller must keep prodding them to see that they make their schedule. They much prefer to travel in the very early morning, starting from three to five o'clock. The journey from Erzerum to Bitlis cannot be called an easy one; but the country and its people are very interesting.

The eastern end of the plain of Moush is a day's journey from Bitlis on the route to Erzerum, and on this plain at this time of year the American residents of Bitlis usually spend two or three quiet and healthful months in camp.

To the west of Bitlis and far outside the path of totality, although in the same generally elevated region of Turkey, is Kharput, where records of cloudiness for the month of August have been kept for many years past. The average for five years gives 70 per cent. of the afternoon observations in August entirely cloudless, with not a single record of a sky totally overcast. Most of the cloudiness is of the order of 0·1 or 0·2, only occasionally an afternoon being largely overcast. These afternoon observations were taken at 2.30, and there is a slightly greater chance of cloudiness at 4.

For most of the foregoing information I am indebted to the Rev. Dr. Henry H. Riggs, of Kharput, Dr. Harrison A. Maynard, of Bitlis, Rev. Robert A. Stapleton and Dr. Edward P. Case, of Erzerum, and Rev. L. S. Crawford, of Trebizond. All are greatly interested in the coming eclipse, and are ready to assist in observing it so far as possible.

Prof. A. G. Sivaslian, of Anatolia College, Marsovan, will proceed eastward to the Trebizond region to observe the eclipse. He is an astronomer trained at the Northfield Observatory in Minnesota, and will be of great assistance to whatever party of observers he may join; also Prof. A. H. Joy, of the Syrian Protestant College at Beirut, is expecting to join the ranks of the eclipse observers, but he may go to the Crimea instead of Trebizond.

Of course, it is well known that Trebizond is very accessible. The easiest route from western Europe is *viâ* Marseilles, whence a weekly steamer of the Messagerie leaves for Trebizond without change at Constantinople or elsewhere. The same from Trieste also, by the Austrian Lloyd. From Paris the through rate by rail to Marseilles, and thence by steamer to Trebizond is about 14*l.* first class. From Constantinople steamers leave every Friday and Saturday, reaching Trebizond the following Tuesday and Wednesday mornings.

Fuller information regarding the Persian region can be obtained from the house of Messrs. Lynch Brothers in London, and concerning Armenia the standard work is by the late senior member of this firm, Mr. H. F. B. Lynch, recently published in two fine volumes by Longmans. DAVID TODD.

UNIVERSITY AND EDUCATIONAL INTELLIGENCE.

CAMBRIDGE.—The completion of the third edition of "The Golden Bough" has suggested to the many friends and admirers of Dr. J. G. Frazer that the present is a suitable time to offer him some token in recognition of his great services to learning. It is proposed that a Frazer Fund for Social Anthropology be established to make grants to travelling students of either sex, whether connected with a university or not, with a view of their investigating problems in the culture and social organisation of primitive peoples, a department of anthropology which Dr. Frazer has always been eager to promote. Contributions to the fund may be sent either direct to the secretary and treasurer, Mr. F. M. Cornford, Trinity College, Cambridge, or to the "Frazer Fund Account," Messrs. Barclay and Co., Mortlock's Bank, Cambridge.

LONDON.—Presentation Day on May 13 passed off without special incident. The Principal reported a slight falling off of examinees, particularly for matriculation. Of the 1807 candidates for degrees 900 were internal and 907 external; 1301 degrees and diplomas were granted, and the total number of internal students is now 4888. Sir Philip Magnus, M.P. for the University, in his speech after the presentation of graduates, suggested that a committee of the Senate should be appointed to consider without prejudice or bias the recommendations of the Royal Commission on University Education in London with the view of deciding which of them should be adopted with or without legislation.

MR. ALFRED E. CAMERON, Board of Agriculture scholar in entomology, of Manchester University, has taken up economic work in the United States, where he is temporarily attached to the entomological department of the New Jersey Agricultural Experiment Stations, New Brunswick, New Jersey.

MR. MALCOLM E. MACGREGOR, of Trinity College, Cambridge, has recently been appointed collaborator with the U.S. Bureau of Entomology, to join the Robert M. Thompson Pellagra Commission (formerly the Thompson-Macfadden Pellagra Commission), at Spartenburg, South Carolina, to study the possible rôle played by insects in the transmission of the disease.

WE learn from the Paris correspondent of the *Chemist and Druggist* that the council of the University of Paris has just decided to distribute 3600*l.*, being interest of a bequest by the late M. Loutreuil for the encouragement of scientific laboratories of French universities. The Chemical Institute of Nancy University is receiving 400*l.* for extension and enlargement, and Toulouse 800*l.* for the foundation of a similar establishment. Montpellier University will get 160*l.* for its biological laboratory, Rennes 320*l.* for the botanical and physical science laboratories, Lille, Clermont, and Grenoble are getting goodly sums for electrical equipment, and Paris 100*l.* for the herbarium of the Academy of Sciences.

THE Association of Teachers in Technical Institutions will hold its eighth annual conference at Liverpool during Whitsuntide, May 30–June 3. The open meetings begin on Monday, June 1, when the chairman of the Liverpool Education Committee, Councillor J. W. Alsop, will welcome the conference to Liverpool, and the president, Mr. P. Abbott, will deliver his presidential address. During the conference papers will be read by Mr. W. Hewitt, director of technical education for Liverpool, Prof. Haldane Gee, Mr. W. E. Harrison, Mr. Laurence Small, Mr. W. R. Bower, and others. Sectional meetings will be held on the afternoon of June 2, when papers of special interest to the various sections of technical education will be read. Resolutions on matters of educational and professional interest will be discussed at the various meetings.

A LIMITED number of free places at the Imperial College of Science and Technology, South Kensington, S.W., will be awarded by the London County Council for the session 1914–15. The free places will be awarded on consideration of the past records of the candidates, the recommendations of their teachers, the course of study which they intend to follow, and generally upon their fitness for advanced study in science as applied to industry. Candidates will not be required to undergo a written examination. It is possible that the free places may be extended to two or more years. Parents (or guardians) of candidates must be resident within the administrative county of London, except in the case of self-supporting candidates above twenty-one years of age on July 31, 1914, who must themselves be resident within the county. Application forms (T. 2/268) may be obtained from the Education Officer, L.C.C. Education Offices, Victoria Embankment, W.C., and must be returned not later than Saturday, May 23.

IN addition to much other matter of interest and importance, the recently published Report of the Board of Education for the year 1912–13 (Cd. 7341), contains particulars as to the main provision for full-time education in connection with the industries of the country. This has been provided in the past either by means of advanced courses known as technical institution courses at the larger technical schools, or by means of day technical classes, which, as a rule, take younger pupils and give more elementary instruction. There are twenty-six institutions giving technical institution courses, the total number of separate courses in these institutions being eighty-one in 1911–12. But of these twenty-two were courses in preparation for matriculation. Fifty-four were courses in engineering, chemistry, and subjects connected with the building, mining, textile, and leather trades. Five were purely scientific courses. The number of students taking full courses was 1246, of whom 528 were in their first year, 414 in their second year, 245 in their third year, and fifty-nine in later years of their courses. The number of day technical classes recognised in 1911–12 was in all 324, and these were held in 111 institutions. The students in attendance numbered 12,041. One hundred and fifty-four of the courses were full-time day schools, and these will in future receive aid from the State to a degree more commensurate with their importance. The report may well point out that the provision for full-time education in applied science is regrettably small in bulk compared with the industrial development of the country.

SOCIETIES AND ACADEMIES.

LONDON.

Royal Society, May 14.—Sir William Crookes, president, in the chair.—Dr. A. D. **Waller**: The various inclinations of the electrical axis of the human heart. Part IA.—The normal heart.—Effects of respiration. Continuation of previous observations (Phil. Trans., 1889, p. 169) in which the electrical effects of the human heart were first demonstrated, and the distinction made between favourable and unfavourable leads dependent upon the obliquity of the cardiac axis, and of subsequent observations (Proc. R.S., B, vol. lxxxvi., p. 507, 1913) to determine the angular value of the inclination of the electrical axis.—Dr. D. H. **Scott** and Prof. E. C. **Jeffrey**: Fossil plants showing structure from the base of the Waverley Shale of Kentucky. The specimens were collected by Prof. C. R. Eastman and Mr. Moritz Fischer, near Junction City, Boyle County, Kentucky. The nodule layer containing the plants is described by Prof. Eastman as lying at the base of the Waverley (Lower Carboniferous) and immediately above the Genessee Black Shale of Upper Devonian age. The anatomical structure is, on the whole, well preserved.—F. **Kidd**: The controlling influence of carbon dioxide in the maturation, dormancy, and germination of seeds. Part ii. The inhibitory effect of carbon dioxide on the germination of seeds previously described is dealt with in relation to temperature and oxygen supply. In relation to temperature the result obtained is unusual, the inhibitory action being more pronounced at low temperatures than at high. At 3° C. complete inhibition was obtained with 4 per cent. CO_2; at 17° C. as much as 24° C. had to be employed to obtain the same result. Varying partial pressures of oxygen also effect the inhibitory action of carbon dioxide, but to a less degree than temperature. Thus with 5 per cent. oxygen, 15 per cent. CO_2 produced inhibition; with 20 per cent. oxygen, 27 per cent. CO_2 was necessary. The author emphasises the fact that the adjustments of the moist seed by which it is enabled to continue dormant in the presence of oxygen and water, rather than those of the dry seed, are likely to have formed the central problem of seed life in nature. A low temperature and a decreased oxygen supply are often the natural conditions of a seed's environment in the soil. Correlating the results obtained in this and in a former paper, the author strongly emphasises the controlling influence of carbon dioxide in the biology of seeds. It appears that the normal resting stage of a seed is primarily a phase of narcosis.—D. **Thomson** and J. G. **Thomson**: The cultivation of human tumour tissue *in vitro*. Small portions of tissue from two human tumours, (*a*) intracystic papilloma of the ovary, and (*b*) carcinomatous lymphatic gland, have been cultivated successfully in a medium composed of fowl blood plasma + extract of embryonic chick. This proves that human tissue can be grown *in vitro* in a medium obtained entirely from a bird. This is contrary to what was previously believed, since it was considered that the tissue of a certain animal could only grow in a medium composed of the blood plasma of the same species of animal.—H. G. **Thornton** and G. **Smith**: The nutritive conditions determining the growth of certain fresh-water and soil protista. Experiments made on the growth of *Euglena viridis* in artificial media showed that, in addition to those inorganic constituents necessary for the growth of a green plant, which were supplied by Miguel's formula for growing diatoms, a certain quantity of organic material, *e.g.* infusion of hay, was necessary. In order to determine the constituent in this organic material which stimulated growth, various pure substances, such as carbohydrates, tartaric acid, saccharin, allantoin, peptone, and various amido-acids, were used in dilute solutions. Of these, only very weak solutions of amido-acids favoured a really strong growth, the most favourable substances being tyrosin and phenyl-alanine, which are very slightly soluble in water. Experiments with soil flagellates, especially *Prowazekia terricola* (Martin), showed that they could be cultivated in many solutions in which bacteria flourished, the flagellates feeding on several different kinds of bacteria. Samples of various types of soil and water were tested for the presence of bacterial-feeding flagellates, and these were found in all the samples, being most abundant in highly manured soil. The wide distribution and abundance of these soil flagellates, and their very rapid growth in the presence of bacteria, suggests that they are of importance in the economy of the soil.

Zoological Society, May 5.—Dr. Henry Woodward, vice-president, in the chair.—Surgeon G. Murray **Levick**: Manners and customs of Adélie penguins (*Pygoscelis adeliae*). The penguins were observed at the Cape Adare rookery while the author was with Scott's Antarctic Expedition. Their mating habits, the making of their "nests," hatching of the eggs, and rearing of the young were described.—R. C. **Lewis**: Two new species of tapeworms from the stomach and small intestine of a wallaby from Hermite Island, Monte Bello Islands. The parasites belong to the genus Cittotænia, having two full sets of genital glands in each proglottis.—Oldfield **Thomas**: A remarkable case of affinity between animals inhabiting Guiana, West Africa, and the Malay Archipelago. The case referred to was that of the pygmy squirrels (Nannosciurinæ), known to the natives of West Africa and the Malay Archipelago, and of which Mr. Thomas was now able to state that the Guianan *Sciurus pusillus* was also a member. It was sufficiently distinct to need generic separation (Sciurillus, gen. nov., was suggested as a name for it), but was unquestionably assignable to the Nannosciurinæ, and not to the Sciurinæ, to which all the other American, all the European, and all the Asiatic continental squirrels belonged.—H. B. **Preston**: Diagnoses of new general and species of Zonitidæ from equatorial Africa. The material on which the paper is based was recently collected from many localities in British East Africa, Uganda, and the Belgian Congo, by Messrs. A. Blayney Percival, Robin Kemp, and C. W. Woodhouse, and descriptions are given of seventy-six new species, two new varieties, and eight new genera of Zonitidæ, to which latter a number of hitherto described forms are also referred.

Mathematical Society, May 14.—Prof. A. E. H. Love, president, in the chair.—Prof. W. H. **Young** and Mrs. **Young**: The reduction of sets of intervals.—Prof. H. M. **Macdonald**: Diffraction by a straight edge.—J. **Proudman**: Diffraction of tidal waves on flat rotating sheets of water.—H. F. **Moulton**: Quadratic forms and factorisation of numbers.—F. S. **Macaulay**: The algebraic theory of modular systems.

MANCHESTER.

Literary and Philosophical, May 12.—Mr. F. Nicholson, president, in the chair.—F. R. **Lankshear**: The chemical significance of absorption spectra and a new quantitative method of measuring them. The author reviewed the history of the study of the relation between chemical constitution and absorption spectra, and the various theories as to the cause of absorption bands. He pointed out that for further progress to be achieved quantitative methods were necessary.—Dr. J. R. **Ashworth**: Note on the intrinsic field of a magnet. An experiment on the electromotive force between magnetised and unmagnetised iron in a solution, from which an argument was drawn in favour of the view that in the interior of a magnet there is an enormously strong field acting on the molecular magnets.

DUBLIN.

Royal Irish Academy, May 11.—Rev. J. P. Mahaffy, president, in the chair.—J. G. **Leathem**: Doublet distributions in potential theory. The paper discusses the formulation of the problem of irrotational liquid motion as a double-sheet problem. In connection with the hydrodynamical application it examines some aspects of doublets and doublet distributions, and the manner in which these and their fields fit into Kelvin's theory of inversion. A surface concentration of tangential doublets is also considered, and an account is given of the convergence or semi-convergence of the potential and force integrals associated with it. J. R. D. **Holtby**: Some human bones from an ancient burial ground in Dublin. The paper dealt with a collection of human bones discovered about a year ago buried deeply under the basement of the City Hall These were considered to represent inhabitants of Dublin about the twelfth to fourteenth centuries. Apart from the worn condition of the teeth, found in almost all ancient remains, the chief interest lay in the form of the bones of the lower limbs and in the impressions on them. These were such as to suggest full and frequent flexion at the hip, knee and ankle joints, such as would occur in squatting

PARIS.

Academy of Sciences, May 11.—M. P. Appell in the chair.—Ch. **Lallemand**: The question of the litre. For scientific purposes the author considers the definition of the litre as the volume of a kilogram of water at 4° C., and 76 cm. pressure should remain. The correction to a cubic decimetre is +27 millionths (0·027 gram).—Mme. **Ramart-Lucas** and A. **Haller**: Syntheses by means of sodium amide. The action of the epihalohydrins on the dialkylacetophenones. Oxypropylene-dimethylacetophenone and its derivatives. The dialkylacetophenones treated with sodium amide and epihalohydrins give substitution products in which the halogen is replaced in a normal manner, whilst with acetophenone itself only tarry reaction products are obtained.—E. **Jungfleisch** and Ph. **Landrieu**: Researches on the acid salts of the dibasic acids. Oxalates. From the experiments detailed the conclusion is drawn that acid potassium oxalate should be represented as $(K_2C_2O_4.H_2C_2O_4)$ and not as $KH.C_2O_4$. The results are analogous with those previously obtained for the acid camphorates.—Charles **Richet**: General anaphylaxy. Phosphorus poisoning and chloroform. It has been shown in a preceding note that a dog chloroformed for the first time never subsequently shows leucocytosis, but that a month later the same dog, although in perfect health, if submitted a second time to chloroform, always subsequently shows leucocytosis. It is now shown that an animal, after treatment with non-toxic doses of a phosphide, and then a month later submitted to chloroform, presents the same phenomenon. This entails a modification of the generally accepted view of the specific nature of anaphylaxy.—A. **Calmette** and V. **Grysez**: A new experimental demonstration of the existence of a generalised lymphatic stage preceding localisations in tuberculous infection It is shown that whether the tubercle bacilli enter by the eye, throat, alimentary canal, skin, or lungs, before local lesions appear, the bacilli can be proved to be present in the tracheo-bronchial, submaxillary, and mesenteric ganglia, in the spleen and blood.—H. **Parenty**: A regulator for the flow of water in streams and reservoirs with constant level. J. W. **Nicholson**: The atomic weights of the elements of nebulæ. A discussion of the results recently published by MM. Bourget, Fabry, and Buisson on the spectra of nebulæ. —A. **Buhl**: The geodesic torsion of closed contours.—N. E. **Nörlund**: Series of faculties and the methods of summation of Cesarò and Borel.—Léopold **Fejér**: The number of changes of sign of a function in an interval and its moments.—Léon **Brillouin**: The diffusion of light by a homogeneous transparent body.—André **Léauté**: The mathematical theory of the working of electric lines formed of two different trunks.—J. de **Kowalski**: The oscillating spark as an economical source of ultra-violet light.—Alexandre **Dufour**: A kathodic oscillograph.—René **Constantin**: Fluctuations of concentration in a colloidal emulsion.—André **Helbronner** and Gustave **Bernstein**: The vulcanisation of solutions of india-rubber by ultra-violet light.—Œchsner de **Coninck** and M. **Gérard**: The determination of the atomic weight of nickel. The figure 58·57 was obtained as a mean of five determinations of the amount of nickel obtained by the reduction of the hydrated oxalate in hydrogen at 270° C.—M. **Picon**: The preparation of normal pentene. Remarks on the melting and boiling points of the first terms of the true normal acetylene hydrocarbons. This hydrocarbon has been prepared by the interaction of normal propyl iodide and an ammoniacal solution of monosodium acetylene at −20° C. Its physical constants are given.—Georges **Dupont**: The synthesis of the acetylene γ-diketones. Good yields are obtained by the oxidation of the acetylene γ-glycols by chromic acid in acetic solution. Three examples of the reaction are given.—Andre **Brochet**: The catalytic hydrogenation of liquids under the influence of the common metals at moderate temperatures and pressures.—Charles **Tanret**: The plurality of the starches.—R. **Souèges**: New observations on the embryogeny of the Crucifereæ.—Paul de **Beauchamp**: The evolution and affinities of the genus Dermocystidium.—MM. **Variot** and **Fliniaux**: Tables of the comparative growth of infants raised at the breast or by the bottle during the first year of life. Contrary to current ideas, there is a very small difference between the size and weight of children raised at the breast or by the bottle, if the food in the latter case is properly made up.—Louis **Roule**: The influence exercised on the migration of salmon (*Salmo salar*) by the proportion of dissolved oxygen in the streams. On the coast of Brittany it has been noticed that the salmon select certain rivers in preference to others and for no obvious reason. Determinations of the proportions of dissolved oxygen in the river waters shows that the salmon select those in which this proportion is highest.—Rémy **Perrier** and Henri **Fisher**: The existence of spermatophores in some Opisthobranchs.—Ch. **Gravier**: The Madrepores collected by the second French Antarctic Expedition (1908–10).—A. **Malaquin** and A. **Moitié**: Experimental observations and researches on the evolutive cycle of *Aphis euonymi*, destructive to the beetroot.—R. **Fosse**: The simultaneous presence of urea and urease in the same plant.—Em. **Bourquelot** and Alex. **Ludwig**: The biochemical synthesis of β-anisylglucoside.—L. **Lematte**: The estimation of the monoamino-acids in the blood. The albumenoids and ammonia are precipitated by phosphotungstic acid, neutralised with soda and the excess of the phosphotungstic acid precipitated by calcium chloride, and excess of the latter by oxalate. The solution then contains the amino-acids, and can be determined by the formol method.—Louis **Mengaud**: The tectonic of the neighbourhood of Infiesto, Arriondas and Rivadesella (Asturia).—M. **Dalloni**: The Neocomian in the west of Algeria.

GREEK PHYSICS AND DYNAMICS.

Le Système du Monde: Histoire des Doctrines Cosmologiques de Platon à Copernic. By Prof. Pierre Duhem. Tome Premier. Pp. 512. (Paris: A. Hermann et Fils, 1913.) Price 18.50 francs.

THIS book contains a good deal more than one might expect from the title. It not only gives an account of the cosmical systems of the Greeks from Pythagoras to Ptolemy, but discusses in considerable detail the views of the different schools of the same period as to the constitution of matter, and their principles of dynamics. As was to be expected from the author's previous publications on the history of natural philosophy, he shows himself well acquainted with ancient literature, and also (with a few exceptions) with the very extensive modern literature of monographs on Greek science. The most recent editions of the classical writers are always quoted, but with one notable exception, Diels's edition of the Doxographi Græci not having been made use of.

The astronomical chapters, which fill less than half the book, do not call for any extended notice, as the subject treated in them has been dealt with in more than one book accessible to English readers, the last being Sir Thomas Heath's book on Aristarchus, published only a year ago. As to the origin of the heliocentric idea, the author follows in the main the theory of Schiaparelli, that it was really due to Herakleides, fifty years before the time of Aristarchus, and he seems unconvinced by the weighty arguments brought forward against it by subsequent writers.

The most valuable part of M. Duhem's book is undoubtedly that dealing with the physics and dynamics of the Greeks, especially of Aristotle, and it gives a very clear and thorough account of this difficult subject. While Plato's views on nature were characterised by doubts as to facts learned by perception, as the immutability which is regarded as the essence of things is not revealed thereby, Aristotle rehabilitated experience and observation, though often led astray by preconceived notions. In his dynamics the idea of mass does not enter; every moving body is necessarily subject to two forces, a power and a resistance; without a power it would not move at all, without resistance the motion would be accomplished in an instant. The velocity with which the body moves depends both on the magnitude of the power and on that of the resistance; if both are constant the resulting motion is supposed to be uniform; if the resistance decreases the velocity will increase, if the same power be employed to move resisting bodies, the velocities which it communicates to them are inversely proportional to the resisting weights.

Velocity is therefore proportional to the ratio of power to resistance, and yet, how can motion cease when they become equal? Aristotle sees this difficulty and tries to get over it by remarking that because a certain power moves a body through a certain length it does not follow that any fraction of the power will move the body through the same fraction of the length. A body falling through air or water represents to Aristotle the simplest motion we can conceive; the power is here the weight of the body, while the resistance is caused by the medium it traverses, and the velocity of the fall is proportional to the weight. On the other hand, by the fundamental principle of Aristotelian dynamics, the velocity is inversely proportional to the resistance, and Aristotle seems to admit that this resistance is proportional to the density of the medium. But he maintained that if a fall in empty space were possible (which he denies), bodies of different weight would not fall with the same velocity. "This," he says ("Physics." iv. 8, p. 216a), "is impossible, for what should then cause one body to move faster? This is necessarily the case in a medium because the body which has the greater power divides the medium more quickly, but in the void all bodies would have the same velocity, which is impossible."

The author also discusses very fully the theories prevalent after Aristotle so far as John Philoponus in the sixth century. In opposition to Aristotle, Philoponus taught that weight is something which belongs to a body and represents the downward motion it would have in empty space; the resisting medium prolongs the time of the fall, but if the resistance is diminished to zero the fall does not become instantaneous, the limit of the velocity being that with which it would fall through empty space. This doctrine, so different from that of Aristotle, was not accepted in the Middle Ages, though it was not without some influence on the views of Simplicius, who otherwise was a severe critic of Philoponus. We shall look forward with interest to M. Duhem's second volume, in which he will doubtless discuss the views of Thomas Aquinas and other philosophers of the Middle Ages, which did not always coincide completely with those of Aristotle.

J. L. E. D.

A MODIFIED ALPHABET FOR ENGLISH.

Sounds and Signs: a Criticism of the Alphabet with Suggestions for Reform. By Archer Wilde. Pp. 180. (London: Constable and Co., Ltd., 1914.) Price 4*s*. 6*d*. net.

THE main object of this book is to advocate modifications in our present alphabet, so as to make it suitable for representing English sounds. On plates facing pp. 142 and 144 the suggested alphabet is portrayed; the capitals are practically identical with the small letters, but slightly more ornate. A characteristic is that no letter projects above or below the line; nor are parts of each letter thicker or thinner than others; the character is what is termed "Doric." The uniformity in height of the letters makes it possible to bring the lines of print closer together, and so to save space. But, in the opinion of the reviewer, legibility is therebv sacrificed; Russian type, in which the general effect is that of printing in capitals, is not so quickly read by Russians as is English or French by Englishmen or Frenchmen. In the example given on p. 20, of printing in Doric capitals, the effect is to dazzle the eyes; it is not easy reading. The author is not sanguine as to the adoption of his scheme; but he opens the interesting question whether if our alphabet is to be modified, convenience is to be increased by carefully choosing the form of the letters.

He is a strong advocate of spelling reform, and looks on the proposals of the Simplified Spelling Society as good, having regard to the restrictions with which they have limited themselves, viz. no accents; no new letters; and as little change as may be, provided consistency is attained. The system of Ellis and Pitman, phonotype as it was called, narrowly escaped achieving success in the 'seventies; had Ellis's health not broken down, and had his type not been destroyed by a fire, it is not unlikely that steps might have been taken to introduce its use into schools. The type is easily read; it is also easily written, for the script hand is not difficult; and there is a saving of nearly 20 per cent. in space compared with ordinary spelling and alphabet. One of the most remarkable pieces of evidence in its favour is an account of an experiment by an Edinburgh schoolmaster, Mr. Williams, who "proved that children averaging five years of age could learn to read printed books in phonetic type in one-third or one-fourth the time in which children of six or seven years of age could, without the intervention of the phonetic system, learn to read the common 'Romanic' books; and when these younger children had been one session (between ten and eleven months) learning to read through the phonetic system, they could read books printed in the 'Romanic' type quite as well as the elder class which had been engaged during two sessions, or double the time, learning to read without the intervention of the phonetic system."

A considerable amount of space is occupied in a discussion of the English phonetic alphabet; that is, what English sounds should be characterised by separate characters. The point of view is that of a southern Englishman; it is too often forgotten that among English speakers they are in a small minority. A large majority, for instance, retain at all events some reminder of a trill at the end of the word "star," although in America, if the South be excluded, the "r" may be described as a buzz, rather than a trill.

In Mr. Wilde's vowel system different symbols are given to the "a" in "alms" and the "a" in "at," and quite correctly; the difficulty arises when it is realised that it is indifferent whether the first or second sound of the "a" be used in such words as "castle" or "dance." And this involves the question of a standard pronunciation, about which few people will agree. In the reviewer's opinion (to take the instance given), it is better to retain the one symbol "a" for both sounds, leaving it to individuals to pronounce the "a" as they are accustomed to do. Again, many English speakers make no distinction between the two sounds of "oo" in "boot" and "foot"; here, again, it would appear advisable to let one symbol represent both sounds.

This book is well written, and puts a case for a view of spelling reform which is not usually considered; if it should commend itself to the public to adopt new characters, no decision ought to be taken without attention to what Mr. Wilde has brought forward.

W. R.

THE INDIAN ORIGIN OF THE MAORI.

Who are the Maoris? By Alfred K. Newman. Pp. 303 + plates. (Christchurch, Melbourne, and London: Whitcombe and Tombs, Ltd., n.d.) Price 7*s*. 6*d*. net.

THE origin of the Polynesians has long been discussed by more or less qualified persons, and a general agreement has been arrived at. Mr. A. K. Newman takes up the problem where it had been left by Mr. Percy Smith, the author of "Hawaiki," and adduces a great deal of evidence to prove that the cradle-land of the race was northern India—a view, by the by, which has been held for some time by other students. He says, "By the word 'Maori' I mean the brown-skinned race called Polynesian by European writers. Maori was their own word, should always be used . . . The Maoris were the first people to discover the Pacific islands . . . Some writers talk of other races who inhabited these islands prior to their discovery by Maoris. I assert that there were never any people in these islands except the Maori." The Maori were, he claims, an "Aryan-Naga people"; he agrees they are dominantly Caucasian, but is convinced they have a large infusion of Mongolic blood, which they received, according to him, before their emigration, since he classes the Kolarians and Santals as Mongolic. He says, "centuries before India was invaded by Aryans there was an invasion from the north-west by Mongolic peoples called Scythians, or Turanians. These Mongols conquered the black aborigines and extended their dominion all over northern India. Their principal tribes were called Takkes or Nagas, Kolarians, and Santals." It is a pity that he gives no references in support of these wide statements. "In India the word Maori was variously spelt—Mauri, Maurea, Maori, Maoli, Mauli, Baori, Baoli, Kaori, Waori," for most of which he finds parallels in the Pacific, and he gives a large number of place- and tribal names, mainly in Bengal, which are similarly equated.

The author is evidently unaware of the linguistic researches of Father W. Schmidt, who showed in 1906 ("Die Mon-Khmer-Völker") that the Polynesian, Melanesian, and Indonesian are dialects of the Austronesian group of the Austric linguistic family, of which the Austroasiatic was the other group. The latter group includes the Munda, Khasi, Mon-Khmer and other languages. The Nagas may be "dropped colonies of Maoris," but surely allusion should have been made to the Khasis, who alone in Assam speak an Austric language.

Religion, mythology and various arts and crafts are alike impressed to bear witness to the Indian origin of the Polynesians and their migration through the East Indian Archipelago. There is certainly a great deal to be said in favour of the main thesis, and doubtless many of the facts adduced may support it, but the entire absence of references makes it impossible to gauge their value unless the reader happens to know the authorities. A number of parallels are cited which would equally prove an African or American affinity with the Maori. There is a good deal of repetition in this badly-arranged book, and there is no index.

OUR BOOKSHELF.

Marriage Ceremonies in Morocco. By Prof. E. Westermarck. Pp. xii+422. (London: Macmillan and Co., Ltd., 1914.) Price 12*s.* net.

It is to be hoped that Dr. Westermarck will one day give us a general work on the origin and development of social ceremonies. Ceremony is a sort of material complement to social ideas, an action-language embodying and expressing, if not imitating and compelling, the social will. Its roots are in the same soil as magic.

This very complete study, by the historian of human marriage, of the marriage ceremonies of the Moroccan peoples, includes a mass of detail, none of which is unimportant. The wealth of ceremonial possessed by Arab and Berber folk-custom is extraordinary. But in most cultures marriage tends to be more ceremonialised than any human happening. Even modern Germany, as Reinsberg - Düringfeld's "Hochzeitbuch" shows, is in this respect nearly the equal of Morocco. Most of these are what anthropologists ten years ago styled customs, but the formal "solemnity" of practically all social and most individual acts in semi-civilised societies has now been well established. It is the main character of the "religious" or "magical" stage of culture.

The betrothal, the negotiations about dowry or bride-price, the preparation of the trousseau, the arrival and reception of the bride, the meeting of bride and bridegroom (as a rule they have never set eyes on one another), these and other scenes are set off by continuous and minute ceremonial. The preservation of so many thousand details by oral tradition is an astounding feat of memory, which deserves the attention of psychologists.

In dealing with the ideas embodied in these ceremonies, the author refers to the magical theory advanced by the present writer in "The Mystic Rose," and to Mr. Van Gennep's theory of *rites de passage*, *rites de séparation*, and *rites d'aggregation*. But he recognises the extreme probability that they may have a mixed origin. Some may be prophylactic or purificatory, others mere expressions of emotion, others again may be positive and intended to promote welfare. The author does not aim at a general philosophy of ceremony; but the many points of view which the material and the comment suggest should lead to important conclusions.

The work is a splendid monograph, worthy of its author. A. E. Crawley.

A Text-book of Geology. By Prof. James Park. Pp. xv+598+lxx plates. (London: Charles Griffin and Co., Ltd., 1914.) Price 15*s.* net.

Prof. Park's mining researches have increased rather than lessened his interest in the wide fields of geology, and the present text-book adequately covers the range required for students of mining colleges and secondary schools. It is systematically divided into paragraphs, headed in thick type; facts are concisely stated, and the author's personality is not permitted to intrude.

Already, however, in history for college students—witness Prof. Bury's recent single volume upon Greece—there is a tendency to keep in view the philosophy of the subject as a higher stratum based upon the facts; and something of the kind may be possible in our text-books of science as time goes on. At present one would like to recommend a pupil to read no text-book, but to buy a number of the shilling volumes written by specialists on the lines and subjects that attract themselves. This, however, would not enable the student to meet the requirements of a university degree. Prof. Park is well aware of this, and has kept himself within traditional bounds. At the same time he makes good use of recent work, including even the Piltdown skull (p. 480); and his references to New Zealand and the southern hemisphere introduce a welcome series of examples. The illustrations are numerous and well chosen, though those of ammonites lead to the retention of a somewhat old classification. Formulæ might have been more freely utilised to show the composition of the rock-forming minerals, which are here rather loosely described. The absolutely essential boron would then have appeared as a constituent of tourmaline, and the rhombic pyroxenes would not have been defined merely as "variable silicates." "Titanite" (pp. 197 and 198) is not a synonym for the titanic iron-ores. The explanation of technical terms founded on Greek words is a very useful feature throughout the book.

G. A. J. C.

The West India Committee Map of the West Indies. Scale 55 miles = 1 in. Size 3 ft. 9 in. by 2 ft. 10 in. (London: George Philip and Son, Ltd., 1914.) Mounted on cloth and varnished with rollers, 10*s.* 6*d.*; on sheet, unmounted, 7*s.* 6*d.*

THE object of the West India Committee in issuing this map is to stimulate interest in the British West Indies. No attempt has been made to give the land relief and other physiographical features of the individual islands—the relative size of the islands in relation to the parts of the mainland shown making such a course impracticable. Prominence is given to railways, sea routes, cables, and other data of commercial importance. Three inset maps are provided: one shows the routes and distances between Canada and the United States and the West Indies, another a plan of the Panama Canal, and a third a graphic representation of the areas and populations of the islands.

The Origin of the World. A Book for Children. By R. McMillan. Pp. xiii+136. (London: Watts and Co., 1914.) Price 2*s.* net.

THE object of this little book is to explain, in language simple enough for an intelligent child to understand, the steps in the evolution of our planet, of plant and animal life, and of the human race. The book is written in a pleasant style which should appeal to young readers, arrest their attention, and engender a desire for fuller knowledge.

LETTERS TO THE EDITOR.

[The Editor does not hold himself responsible for opinions expressed by his correspondents. Neither can he undertake to return, or to correspond with the writers of, rejected manuscripts intended for this or any other part of NATURE. *No notice is taken of anonymous communications.]*

Temperature-Difference between the Up and Down Traces of Sounding-Balloon Diagrams.

DR. VAN BEMMELEN'S letter in NATURE of May 14 is of great interest to me, and seems to prove an appreciable amount of lag in the instruments he uses. Every thermometer must as a matter of course have a certain amount of lag, but I have not been able in the records of the English instruments to detect any sign of it, although there is a marked distinction between records obtained at night or when the sun is low, and those obtained when it is high.

In the diagram, A is the ordinary type of a night ascent, B that of a day ascent. The double trace, one made on the ascent, the other on the descent, is apparent in about every record obtained. It is not often apparent to the naked eye, and hence the diagram is an exaggerated one, but under the microscope by means of which the records are read, the traces in type A can be seen to cross each other here

and there, in type B, on the other hand, the traces are distinct throughout, but the distance between them is plainly variable, ranging often from about 1° to about 3° C. It is very seldom that differences so large as 4° C. are found. In three cases out of four type A will occur at night, and type B when the sun's altitude exceeds 10°, but now and then type B occurs at night, and seems then to indicate an actual change of temperature during the ascent.

In the English instruments the thermograph depends on the temperature of a very thin strip of German silver; this is kept stretched by a small invar tube. The expansion of the invar is nil, and therefore its temperature is of no consequence; the German silver is 0·03 mm. thick, and exposed on both sides to the air current. It is therefore very sensitive as a thermometer; certainly much more so than the Bourdon tube or ordinary metal couple.

I have always accepted the Continental records made in the winter as being free from any systematic error, but have long felt that their summer ascents show temperatures that are persistently too high.

The policy of making all ascents at a fixed time, 7 a.m. G.M.T., seems to me a most unfortunate one

Its advantage is that it is the time of the morning weather chart, and hence the results can be plotted on the chart with the knowledge that all the observations shown are simultaneous. But the objections are twofold. In many cases figures obtained at great expense have to be rejected, because they are obviously falsified by solar radiation. This must happen if the balloon does not burst, and the sun is high, whereas if the sun is near to or below the horizon it is of no consequence if the balloon does or does not burst. This gives cause for doubt also about some of the printed figures since it is not too clear in all cases as to what may be accepted and what must be rejected. Secondly, it is impossible to get the annual or the daily variation from observations at a fixed hour. The daily variation is, of course, hopeless, and not knowing the law of the daily variation, it is uncertain whether the same correction for the hour should be applied both summer and winter. The result is that the annual variation above 12 km., as shown by the English ascents, many of which were made at sunset before the international time of 7 a.m. was fixed, differs by 3° C. from the Continental value, but it is very improbable that there is any real difference. A plan has now been adopted by which the string carrying the instrument uncoils after the balloon is started, and since last winter a very much longer string has been employed in the English ascents. This avoids the difficulty of starting with a long string in rough weather, and it will be interesting to see what effect the plan will have on the records. The change of length is from 44 to 132 ft.

W. H. DINES.

May 20.

Transmission of Electric Waves Round the Bend of the Earth.

IN a paper on the transmission of electric waves round the earth's surface, read by Prof. H. M. Macdonald before the Royal Society on February 12, some conclusions are recorded which cast new light on the problem of long-distance wireless telegraphy. Prof. Macdonald's point of view is that of simple diffraction, and the paper is the latest one of a notable series of attempts by a number of eminent mathematicians. In the present paper the author reduces his formulæ to figures, and thus makes comparison with experiment easy. The most extensive quantitative experiments yet made over great ranges are those of L. W. Austin in 1910 (Bulletin Bureau of Standards, vol. vii., No. 3), and those of J. L. Hogan in 1913 (*Electrician*, August 8, 1913). From the former experiments Austin and L. Cohen deduced a formula which has been corroborated by Hogan's results. This formula may be written:—

$$i = c\epsilon^{-ax/\sqrt{\lambda}}/(\lambda x),$$

where i is the current in amperes in the receiving antenna at the distance x kilometres for the sending station, λ is the wave-length of the radiation in kilometres, a has the value 0·0015, and c, like a, is a quantity which does not depend on λ or x. This formula was deduced from daylight experiments extending over larger ranges of λ and x than those used in the table below.

By aid of this formula Prof. Macdonald's calculations can be quickly compared with the results of experiment. In the following table the first column contains the number of miles between sender and receiver, and the remaining columns contain the ratios of the effect at various distances to that at 419 miles. R_d is the ratio, calculated on the diffraction theory, between the electric fields, R_m is the ratio found by measurement between the currents in the same receiving antenna when moved to the successive distances in turn.

Miles	λ = 320 m.		λ = 625 m.		λ = 1220 m.		λ = 2560 m.		λ = 5000 m.	
	R_d	R_m	R_d	R_m	R_d	R_m	R_d	R_m	R_d	R_m
419	1	1	1	1	1	1	1	1	1	1
536	0·304	0·481	0·392	0·554	0·464	0·605	0·537	0·660	0·585	0·693
675			0·128	0·286	0·184	0·349	0·256	0·418	0·315	0·467
814					0·0764	0·218	0·128	0·282	0·178	0·336
1070							0·0392	0·148	0·0637	0·184
1257								-	0·0321	0·134

From the table it seems fair to draw the conclusion that diffraction accounts for a large proportion of the observed effects up to distances of, perhaps, 2000 miles. The proportion is much larger than has hitherto been demonstrated, and compels the admission of diffraction into the list of phenomena contributing to the practical success of wireless telegraphy.

But the Austin-Cohen formula expresses a remarkable experimental fact which is not explained, but, rather, is contradicted by the diffraction theory; namely, that for each distance there is a best wave-length. The formula indicates that this optimum wave-length is given by $4\lambda = a^2x^2$, and, consequently, that under the best condition

$$i = 4c(a\epsilon)^{-2}x^{-3} = cx^{-3} \times 2{\cdot}140 \times 10^5,$$

for rather long ranges. These equations are, broadly, borne out by the experience of wireless telegraph engineers. The equation for λ shows that as the wave-length is increased the effect at a given place first increases and then decreases. Here the theory of diffraction appears to fail, for the diffraction effect at any fixed point should increase steadily with increase of wave-length. On the other hand, the hypothesis of the refraction of electric waves in the atmosphere when it is ionised by sunlight seems more promising. For while radiation of very short wave-length is lost into space by the rays suffering too little bending, radiation of great wave-length, by being too strongly refracted, is lost in the ground between the oscillator and the receiver; and thus an optimum wave-length is easily conceivable.

Some Phenomena of Clay Suspensions.

THE interesting letters in NATURE on the cellular structure of emulsions induced me to test the behaviour of clay which I have been accumulating for some time for evaporation experiments. The clay is obtained by the usual sedimentation method, and is that fraction of the soil which does not settle in twenty-four hours in a beaker containing dilute ammonia to a depth of 8·5 cm. The suspension is then evaporated to dryness *in vacuo*.

If some of this dried clay be well shaken up with strong ammonia solution and poured into a Petri dish, the usual network, mentioned by Mr. Wager in NATURE for May 7, gradually develops. Occasionally a different pattern appears, only the angles of the network are formed, and the surface thus has a pitted appearance.

The pattern persists for a few minutes and then gradually becomes blurred. The two cases are shown in Figs. 1 and 2 respectively. In neither case are groups of cells formed. Although the structure is quite sharp to the eye, the lack of contrast makes the photographic difficulties considerable. I am indebted to Dr. H. B. Hutchinson and Mr. A. Appleyard for the photographs here reproduced.

A suspension of clay in alcohol gives the opposite effect; in this case the preliminary network does not seem to appear. Isolated groups or single cells form active centres, from which other cells grow until the surface is covered. The cells are nearly hexagonal and sharply rectilinear, and frequently measure half cm. in diameter. There is a light spot in the middle of each, and the particles can be seen flowing up at the middle and down at the sides of the cells. The pattern persists for a few seconds and then fades away, only to reappear after a short interval. This periodic reappearance is very fascinating to watch. In all probability it is caused by small air currents flowing over the surface of the liquid, disturbing the rate of evaporation.

FIG. 1.

FIG. 2.

I have occasionally noticed another very curious phenomenon in the beakers containing the clay suspension in dilute ammonia. Usually, after the lapse of a few hours, the brown coloured mixture increases in opacity from top to bottom of the liquid. In the case mentioned this graduation is broken by one or two colourless horizontal rings, which appear round the side of the beaker. Thus, there is an increase in opacity from the surface to a depth of one or two cm., until the first ring is reached. The layer immediately below seems to be less opaque than the layer immediately above the ring, but this may be purely an optical illusion. The liquid below the ring increases in opacity until the second ring is reached, when the appearance already mentioned is repeated.

This stratification will persist indefinitely. The rings remain unbroken and gradually sink, at a rate below one cm. in twenty-four hours, as the suspension slowly clears. The phenomenon seems to be quite fortuitous, and I have not been able, up to the present, to reproduce it at will.

It is possible that it may be related in some manner to those forces producing the cellular structure, and I should be glad if some reader could supply me with information or references to it.

B. A. KEEN.

Rothamsted Experimental Station, Harpenden.

THE KAISER-WILHELM INSTITUTE OF CHEMISTRY.

A DESCRIPTION of the objects of this Institute has already been given in NATURE of Feb. 23, 1911, in the report of a lecture delivered at the inauguration of the Kaiser-Wilhelm Gesellschaft by Prof. Emil Fischer on January 11 of that year.

The institute was formally opened by the Emperor on Oct. 23, 1912. It is divided into sections each of which is under the direction of specialists with a consultative committee of experts. Dr. Beckmann is director of the chemical section and is assisted by Dr. Willstätter, who is head of the organic laboratories, and Dr. O. Hahn, who is engaged upon the study of radioactive substances.

The institute is situated at Dahlem, not far from Berlin, and it forms a three-sided block consisting of three floors and a basement. The top floor is occupied by Dr. Beckmann and has accommodation for about a dozen workers, the first floor is apportioned to Dr. Willstätter, and the ground floor to Dr. Hahn. In the basement are installations for vacuum and pressure machines, electric motors and accumulators, liquid air plant and cold storage rooms. The ventilating exhausts are in a chamber under the roof where distilled water is prepared. The main buildings are shown in the accompanying illustration.

Main building, with director's and porter's houses, of the Kaiser-Wilhelm Institut, Berlin, Dahlem.

The first volume of researches issued by the institute and covering the period from April, 1912, to October, 1913, has recently been issued, and its chief contents are here summarised.

The first paper is a contribution by Dr. Beckmann on the use of various solvents,

$$(SO_3,\ SO_2(OH)Cl,\ CrO_2Cl_2,\ SO_2Cl_2),$$

for ebullioscopic determinations. He finds that many organic compounds give normal results in sulphonyl chloride; but that for one reason or another the others are unsuitable. In a second paper the same author describes a Bunsen burner of porcelain, its object being to prevent the coloration of the flame by metallic incrustations in analytical examinations, and so masking the presence of small quantities of salts. In a third paper the constant for iodine when used as a solvent in cryoscopic determinations, was estimated, the value found for a large number of metals and metallic iodides, varying between 200 and 211. As an ebullioscopic solvent iodine gave a constant of 102 to 107. Taking 105 as the mean, the formulæ for aluminium and ferric chloride were found to be Al_2I_6 and Fe_2I_6. As in the case of the cryoscopic method, the alkaline iodides gave abnormally high molecular weights.

In a further paper a new sodium lamp is described. It is so constructed that a spray of sodium hydroxide or carbonate is driven into a bunsen burner supplied at the orifice with oxygen. The spraying is produced by nickel electrodes let into the vessel near the bottom of the burner. In another paper which is in reality a continuation of the above, a method is described for spraying salt solutions by dropping the solutions on to a horizontal revolving disc, and has been utilised for obtaining a steady colour intensity in the flame. In collaboration with R. Hauslian, Beckmann has studied the molecular weight of selenium, which had been previously found to correspond to Se_2, as determined by its cryoscopic effect on iodine, whereas in methylene iodide and phosphorus it is Se_{10} and Se_8 respectively. They found that the dissociation of the molecule in iodine is not due to any thermal effect as sulphur has the molecular weight of S_8 under similar conditions, nor is there any union with the iodine.

The series of papers published by Dr. R. Willstätter begins with an account of the interesting hydrocarbon *cyclo*octatetrene which he has recently prepared.

It behaves like an ethenoid compound inasmuch as it is rapidly oxidised by permanganate; is readily reduced by hydrogen in presence of colloidal platinum to *cyclo*octane, and combines with a molecule of bromine and hydrogen bromide to form $C_8H_8Br_2$ and C_8H_9Br respectively. Moreover it cannot be nitrated either by nitric acid or benzoyl nitrate. It therefore is very unlike an aromatic compound such as benzene. Like benzene, however, it exhibits no exaltation of molecular refraction nor of dispersion for $H_\beta - H_\alpha$, but, in consequence of a higher dispersion in the violet regions, shows distinct exaltation for $H_\gamma - H_\alpha$. It shows no absorption bands but selective general absorption. The pure substance has a yellow colour, and solidifies at $-27°$ to a pale yellow crystalline mass. In another paper Willstätter and King describe the preparation of dihydronaphthalene and its reduction products with hydrogen and platinum. It behaves like benzene with an unsaturated side-chain such as styrene, $C_6H_5.CH=CH_2$, inasmuch as the partly reduced ring in dihydronaphthalene is much more rapidly reduced than the other. In this respect naphthalene is sharply distinguished from dihydronaphthalene, for in the former case no tetrahydroderivative is obtained at whatever stage the reduction is interrupted, but the decahydro-compound with larger or smaller quantities of the unaltered hydrocarbon. They still leave the formula of naphthalene an open question.

In conjunction with Wirth, Willstätter has further extended the method of exhaustive methylation which he has successfully used in the preparation of dihydrobenzene, dihydronaphthalene, *cyclo*butene, *cyclo*heptene, and *cyclo*octene, to the formation of vinylacetylene, $CH:C.CH:CH_2$, from the dibromide of butadiene. It is a gas boiling at 2–3°, and forms a greenish-yellow copper salt, and a colourless crystalline silver salt.

The memoir on chlorophyll by Willstätter and Forsén, which follows, has already been published *in extenso* in Liebig's *Annalen*, vol. ccexcvi., and is a continuation of previous work on the same subject. It is concerned with methods for introducing magnesium into the porphyrin molecule by Grignard's reaction and into other chlorophyll derivatives by heating with magnesium oxide and an alcoholic potash solution under pressure.
