1. *Extroversion of the urinary bladder.*—For a full description of this malformation we must refer to the articles BLADDER and MONSTROSITY. This malformation is known to occur more frequently in the male than in the female, and when present in the former it has occasionally given rise to a supposition of hermaphroditism, the red fungous mass formed by the mucous membrane of the protruded posterior wall of the bladder, and situated above the pubis, having been mistaken for the female vulva,—an error which has probably been the more readily committed from the uterus and seminal ducts, and sometimes also, as in an instance described by A. Fraenkel,* a part of the intestinal canal opening upon the surface of the exposed portion of bladder. In some instances of this malformation occurring in man, the external male sexual organs are very imperfectly formed, or can scarcely be said to be at all present. In other cases the scrotum is of the natural form, with the two testicles in it; and the penis is of considerable size, though almost always fissured on its upper surface from the epispadic or open state of the urethra.

An example of supposed hermaphroditic malformation briefly described by Rueffe,† which seems referable to this variety will be sufficient to illustrate it. "In the year 1519 an hermaphrodite or androgynus," he remarks, "was born at Zurich, perfectly formed from the umbilicus upwards, but having at this part a red mass of flesh, beneath which were the female genitals, and also under and in their normal situation those of the male."

2. *Adhesion of the inferior surface of the penis to the scrotum by a band of integuments.*—This state of parts has occasionally given rise to the idea of hermaphroditism, the penis being so bound down as not to admit of erection, and the urine passing in a direction downwards, so as to imitate the flow of it from the female parts.

In a boy of seven years of age regarding whom Brand ‡ was consulted, the penis was confined in this manner to the scrotum by abnormal adhesions. He had been baptized and reared as a girl, but by a slight incision the adherent organ was liberated, and the parents were convinced of the mistake that they had committed in regard to the sex of their child. The difficulty of determining the true sex of the boy was increased by the testicles not having descended into the scrotum.

Wrisberg* mentions two similar instances in persons of the respective ages of nineteen and forty-six. He relieved the adherent penis in the first case by operation.

3. *Fissure of the inferior part of the urethra, perinæum, &c.*—This species of malformation, which has perhaps more frequently than any other given rise to the idea of the person affected with it being the subject of hermaphroditism, evidently consists in an arrest of the development of the external male sexual parts.

At an early stage of the development of the embryo, the various central sexual organs are, like all the other single organs situated on the median line of the body, found to be composed of two separate and similar halves, divided from each other by a vertical fissure, which, after the originally blind extremity of the intestinal canal has opened upon the perinæum, forms a common aperture or cloaca for the intestinal canal, and also for the urinary and genital apparatus, both of which are, in their primary origin, prolongations from the lower part of that canal. After a time, (about the second month in the human embryo,) the opposite sides of this cloaca gradually approximate, and throw out two corresponding folds, which by their union constitute a septum that separates the rectum from the canal or portion of the fissure, that still remains common to the urinary and generative organs; and, in the same way, by two similar and more anterior folds, the urethra of the female, and the pelvic portion of that of the male is subsequently produced. After this in the female the process of median reunion does not proceed further, and the primary perinæal fissure remains, forming the vulva and vagina. In the male, however, the development, when normal, goes on to a greater extent, and the sides of the opening become so far united as ultimately to leave only the comparatively contracted canal of the urethra to serve as a common passage for both the internal urinary and genital organs; and the situation of the line of junction of the opposite sides of the original perinæal cleft remains still marked out in the adult, by the raphé existing in the median line of the scrotum. The two lateral parts of the female clitoris unite together into one solid body, having on its under surface a slight groove or channel, indicative of the line of conjunction of its two component parts; and the urethra is left to open at the root of this imperforated organ. In the male, on the contrary, the two primitive halves of the penis, consolidated together at an early stage along the course of their upper surfaces, come, in the progress of development, to unite inferiorly in such a manner with one another as to form a tubular prolongation of the pelvic portion of the canal of the urethra, which is gradually extended forwards along the body of the penis and ultimately through its glans.

Many of the malformations to which the

* De Organorum Generationis Deform. Rarissimâ, Berlin, 1825, with a plate.

‡ Case of a boy who had been mistaken for a girl. London, 1788.

* Comment. Med. &c. Arg. p. 534.

male genital organs are liable may be traced to stoppages in the above process of development, the character of the malformation depending upon the period of the development at which the arrest takes place, and varying consequently in degree from the existence of a cloaca or permanent primitive fissure common to the intestinal, urinary, and generative organs,* to that want of closure, to a greater or less extent in different instances, of the inferior surface of the canal of the urethra in the body of the penis, or in its glans, which is generally known under the name of *hypospadias*. When the development of the male organs is arrested, immediately after the two septa respectively separating the canals of the intestine and urethra from the original perinæal cleft are formed, and consequently when this perinæal fissure and that running along the inferior surface of the penis are still open, the external genital parts often come to present at birth, and during the continuance of life, a striking resemblance to the conformation of the external organs of the female, and the resemblance is frequently rendered greater by the coexistence of other malformations of the male organs. In these cases the imperfect and undeveloped penis is generally of small size, and, at the same time, from being imperforate, may readily be mistaken for the clitoris; the two halves of the divided scrotum have the appearance of the two labia externa; the two labia externa or nymphæ are sometimes represented by the lateral divisions of the penis forming two folds, which run backwarks along the internal surfaces of the split scrotum; and the cleft in the perinæum corresponds in situation and direction, and occasionally also in size and form, with the canal of the vagina; this cleft is generally lined also by a red mucous membrane that is kept, like the natural female parts, constantly moistened by the secretions of the follicles with which it is provided; its mucous membrane occasionally presents irregular elevations imperfectly representing the carunculæ myrtiformes; and, further, the opening of the urethra at the root of the diminutive and imperforate penis serves still more to assimilate the malformed parts to the natural conformation of the female organs. In a number of cases, however, the apparent analogy to the female parts is rendered less striking by the perinæal cleft being small or altogether absent, the urethral orifice at the root of the penis often forming the only opening leading to the internal urinary and generative parts, and the halves of the scrotum in such instances being frequently more or less perfectly united. Generally the seminal ducts, and sometimes also the ducts of Cowper's glands, are seen opening on the surface of the urethra or supposed vaginal canal, at a short distance from its external orifice.

In males malformed in the manner described, the testicles are seldom found in the divided scrotum at birth, but commonly they descend into it through the inguinal rings towards the period of puberty; and in several instances on record, in which the sex of the individual had been mistaken for that of a female, the tumours formed in the groin at that time by the organs in their descent have been erroneously regarded and treated as hernial protrusions. At the same time it occasionally happens that with the descent of the testicles, and the arrival of puberty, the diminutive penis enlarges in size, and the individual assumes more or less fully the habits and attributes of the male. In several instances on record this change has, under venereal excitation, appeared to occur suddenly, and persons formerly reputed female have thus unexpectedly found themselves provided with an erectile male penis. These various changes are occasionally postponed for a considerable period beyond the usual term of puberty.

In a few rare instances one testicle only descends through the inguinal ring, and occasionally they both remain throughout life within the abdomen, in or near the situation in which they are originally developed, imitating in this abnormal state the normal position of the same organs in many of the males among the lower animals. In a number of instances in which the testicles are thus retained within the cavity of the abdomen, they are found small and imperfectly developed, and from the want of their usual physiological influence upon the constitution, the whole physical and moral character of the malformed individual frequently presents a considerable approximation to that of the female, or, as we should perhaps more justly express it, never attains the perfection of the male, but preserves that kind of common or neutral state exhibited by the constitution of both sexes before the specific sexual characters of each are developed at the time of puberty.

Numerous curious examples of mistakes having been committed with regard to the sex of males affected with the above species of malformation have now been put on record, from the time at which Iphis, the daughter of Ligdus, king of Crete, was conceived to be changed into a man by the miraculous interference of Isis, down to the present day. Pliny, (lib. vii. chap. iv.) has noticed several cases; and in the treatise of Duval on hermaphrodites a number of additional instances are collected from Livy, Trallian, and others, some of them no doubt invested (as most of the details regarding hermaphrodites in the older authors are) in much misrepresentation and fable, but others bearing every mark of accuracy and authenticity. In more modern times the sexes of individuals have often been mistaken in consequence of this variety of malformation. Jean Chroker* relates, in apparently the most authentic manner, the case of Magdelain Mugnoz, a nun of the order of St. Dominique in the town of Ubeda, who was changed, as he supposes, into a male, seven years after having taken the vows.

* See on this malformation in the human subject (the normal form of structure in birds, &c.) Meckel on Kloakbildung in his Path. Anat. Bd. i. s. 693.

* Fax. Histor. cent. i. and Arnaud, Dissertation sur les Hermaphrodites, p. 200.

He was expelled the convent, assumed the male dress, and took the name of Francois. The sequel of the story, as told by Chruker, would seem to shew that his sexual desires became extremely strong, and he is said to have been ultimately condemned, whether justly or not, under an accusation of rape.

Portal* quotes from Tigeon the story of a person who was brought up as a female, and afterwards was considered to be suddenly changed by a surprising metamorphosis into a male, and in citing this case Dr. Hodgkin,† of London, mentions, on the authority of a friend, a recent instance of an equally sudden development of the male sex in a previously reputed female. Similar instances in which the proper sex of malformed males was unexpectedly discovered under the excitement of sexual passion at the period of puberty are mentioned by Paré, Tulpius, and others.

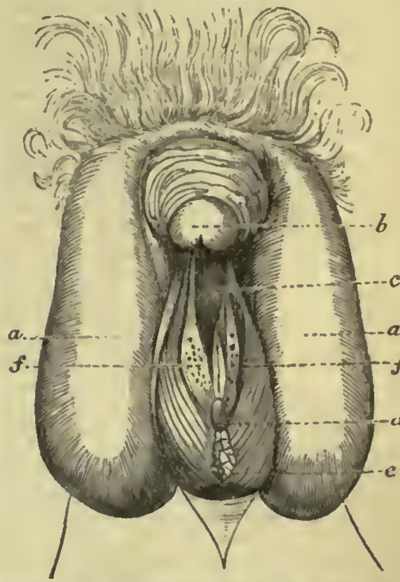
Schweikard‡ has recorded an instance of a person baptized and brought up as a female, and whose true sex was only at last disclosed by his requesting, at the age of forty-nine, permission to marry a young woman then pregnant by him. On examination it was discovered that the penis was slender and scarcely two inches long; the right testicle only had descended into the scrotum, and the urethra opened at the root of the penis, but its orifice was placed in such a manner that during micturition the urine was thrown along the groove or channel on the under surface of the penis, so as to appear to issue from its anterior extremity. The two halves of the scrotum were so far united that they left only a small oval opening between the anterior part of the raphé and the roots of the corpora cavernosa. In this opening the orifice of the urethra was situated.

Dr. Baillie§ has mentioned a case which appears to belong in all probability to the present division. The subject of it was twenty-four years of age. She had always passed in society as a woman, and came for consultation to the Nottingham Hospital on account of her menses never having appeared; a circumstance, however, that had in no way affected her health. The spurious vagina consisted of a cul-de-sac two inches in depth. The penis was of the size of the female clitoris, but there were no nymphæ. The labia were more pendulous than usual, and contained each of them a body resembling a testicle of a moderate size, with its cord. The look of the individual was remarkably masculine, with plain features, but no beard. The mammæ resembled those of a woman. The person had no desire or partiality for either sex.

Adelaide Preville, who had been married as a female, died in the Hôtel Dieu of Paris. In examining the body of this individual after death, Giraud* found that, except a perinæal cleft or false vagina consisting of a cul-de-sac placed between the bladder and rectum, nothing else resembling the female sexual apparatus could be detected, while all the organs belonging to the male sex were present

Otto† has described and represented (*fig*. 289)

Fig. 289.



a case of the present species of hermaphroditism in an individual whose history is remarkable. The person had lived ten years in the state of wedlock with three different men; but at the age of thirty-five an action of divorce was brought against her by her third husband, accusing her of being affected with some disease of the sexual parts that rendered the connubial act on his part extremely difficult and painful. After some difference of opinion between the two medical men to whose professional examination the wife was submitted, it was at last considered that she was in reality a male, and the case came at last under the investigation of the members of the Royal Medical College of Silesia, who confirmed this opinion. The imperforated penis (*b*) was one inch and a half in length; the perinæal fissure (*c*) forming the false vagina was, at the posterior part of its orifice, bounded by a distinct frænulum, but was of a size sufficient to receive the glans of the husband for an inch and a half in depth. This cavity, as well as the internal surfaces of the two lobes (*a a*) of the divided scrotum, were lined with a vascular mucous membrane. At the bottom of it the round orifice of the urethra (*d*) was seen to open; and at the same

point a hard mass could be felt, probably consisting of the prostate gland; and more upwards and outwards, nearly in the natural situation of the bulb, was seen the split urethra (c) with a row of three considerably sized openings (*f f*), which, under pressure and irritation of the genital parts, gave out several drops of a transparent mucous fluid. Otto considers these openings as the extremities of the ducts of the prostate and Cowper's glands, and of the seminal canals. The right half of the scrotum contained a small testicle about the size of that of a boy of ten years of age; the left testicle lay likewise external to the abdominal ring, and was still softer and smaller than the right. Both were furnished with spermatic cords. The general configuration of the individual was strong, muscular, and meagre; the beard was thin and soft, and the face, mammæ, thorax, pelvis, and extremities were evidently masculine.

Along with the preceding instances we are inclined to classify the case of Maria Nonzia, as detailed by Julien and Soules.* This individual was born in Corsica in 1695, was twice married as a female, and at last divorced in 1739 by her second husband, after having lived sixteen years in wedlock. The penis was two inches in length, but imperforate, and the meatus urinarius was placed at its root. Two bodies, like ordinary sized testicles, and furnished with spermatic cords, were felt in the divided scrotum; and there was a narrow false vagina or perinæal canal one inch and three lines in depth, and crossed at its upper extremity by two small traversing membraneous bridles. The character and appearance of the person were masculine; the visage was bearded; the mammæ were as fully developed as in the adult woman, but the nipples were each surrounded with hair.

So far as the preceding details go, they seem amply sufficient to justify us in considering Maria Nonzia as a malformed male; and we are still inclined to take this view of the case, notwithstanding the statement inserted in the report of Julien and Soules, that the menses were present as in other women. For not to insist upon the circumstance that the reporters do not shew that they made any minute or satisfactory inquiry into this alleged fact, and not improbably took it upon the mere word of the subject of the case, who was necessarily greatly interested in maintaining the reputed female character, it would be requisite, in any such paradoxical instance, to ascertain if the discharge actually agreed in character with the menstrual fluid, or was not pure blood, the result of an hæmorrhage from the genito-urinary passages, or from the rectum, where, as in other parts of the body, this form of disease frequently assumes a periodical type. We would be inclined to apply even still more strongly these remarks to the celebrated case of Hannah Wild, detailed by Dr. Sampson.† This person had evidently the male genital organs malformed in the manner mentioned with regard to the other cases included under the present section, and possessed all the secondary sexual peculiarities of the male; so that we can only receive with great doubt and distrust the alleged existence of the menstrual discharge, and the more so, as this is evidently stated on the report of the subject of the case alone, who, deriving a precarious subsistence from the exhibition of his malformations, had a deep interest in amplifying every circumstance that could enhance the public curiosity with respect to the reality of his hermaphroditic character.

* Observ. sur l'Hist. Nat. sur la Physique et sur la Peinture, tom. i. p. 18, with a plate.

† Ephem. Nat. Curios. Dec. i. an. iii. p. 323.

At the same time, however, it must be remarked that in some instances of spurious hermaphroditism, it is found extremely difficult or even impossible during life to determine with precision the true or predominant sex of the malformed individual; and in regard to several well-known cases on record, we find on this point the most discrepant opinions offered by different authors. Thus while Morand,* Arnaud,† and Delius‡ described Michel-Anne Drouart as a male; Guyot,§ Ferrein,‖ and Caldani¶ maintained that this person was a female; and Mertrud** regarded the individual as an example of a real hermaphrodite.

A useful lesson of caution to us against our forming too decided and dogmatic an opinion in cases in which the sexual conformation appears in any marked degree doubtful, has lately been offered in the instance of Maria-Dorothée Duriée, or, as this individual was named in the latter years of his life, Charles Durge. While Metzger†† considered this person as a specimen of that kind of equivocal sexual formation to which the designation of hermaphroditism is truly applicable, Hufeland,‡‡ Mursinna,§§ Gall, Brookes,‖‖ and others¶¶ declared the sex of Duriée to be in reality female; and Stark,*** Mertens,††† and the Members of the Faculty of Medicine at Paris ‡‡‡ were equally positive in regarding the individual as merely a malformed male. The dissection of the body of Duriée by Professor Mayer has, as we shall afterwards state more in detail, shewn the sexual conformation of this individual to consist of a true mixture of both the male and female organs.

In attempting to determine the true sex in such doubtful instances of sexual formation as those which we have been now considering, we are inclined to attribute very little weight to the nature of the sexual desires of the malformed individual, as we have already found Adelaide Preville, the dissection of whose body shewed him to be in reality a man, living for some years before death in the capacity of a wife, and the same remark might be further illustrated by a reference to Otto's and other cases.

A species of spurious hermaphroditism similar in character to that which we have just described in man, is occasionally met with in the males of our domestic quadrupeds, and has been amply illustrated, as it occurs in these animals, by Professor Gurlt in his work on Veterinary Medicine. In instances of this malformation among the animals to which we refer, the hypospadic male penis has usually been found of a tortuous and winding form and of small size. In the cases in which the fissure of the parts extends through the scrotum, a false vagina is seldom formed, as in man, for the scrotum in most quadrupeds lies too remote from the perinæum, and consequently from the normal situation of the vagina, for this purpose; but in some examples this division appears to be carried upwards into the perinæum itself, leaving a vaginal-like opening, in which the urethra terminates. The testicles, as in man, are sometimes retained within the abdomen, and in other instances descend into the scrotum. They are frequently small in size. The mamma or udder seems to be often well developed.

This variety of hermaphroditic malformation has been met with in the horse by Penchenati;* in the he-goat by Haller;† and in the ram by the same author,‡ and by Wagner,§ Wepfer,‖ Stark,¶ Gurlt,** Kauw Boerhaave,†† and A. Cooper.‡‡ We have seen an excellent specimen of this malformation in the last-mentioned animal in the museum of Dr. Handyside of Edinburgh. In this instance the internal male organs are all perfect; the large testicles are situated in the halves of the split scrotum; the penis is small and imperforate, and a furrow running along its inferior surface is continued backwards and upwards along the perinæum to within a short distance from the anus, where it leads into a canal, into which the urinary bladder and seminal ducts open. This canal is evidently formed of the dilated pelvic portion of the male urethra; its orifice is comparatively contracted, but corresponds in situation with the vulva of the female. We have seen a second similar case in the ram in the possession of Professor Dick of the Veterinary School of Edinburgh.

There is another variety of malformation of the male parts occasionally found in quadrupeds, which is allied in its nature to the preceding. In this second species all the external male sexual organs are small; the short penis lies, when not in a state of erection, upon the posterior surface of the enlarged udder, and the imperfectly developed testicles are generally retained within the abdomen; or, if they have passed out of that cavity, they are found situated in the substance of the udder. The vasa deferentia, prostate, and Cowper's glands are usually of their normal size and appearance. This imperfect hermaphroditic formation appears to be not rare among horses, several instances of it in this animal having been now described by Arnaud,* Gohier,† Volmar,‡ Pallas,§ Virey,‖ and Gurlt.¶ Anselmo** and Lecoq†† have met with this variety of malformation in the bull; and Sandford ‡‡ has described an instance in the calf which seems referable to the same head. Gurlt§§ also notices the preparation of an analogous case in the calf, as preserved in the museum at Berlin.

II. TRUE HERMAPHRODITISM.

True hermaphroditism exists as the normal type of sexual conformation in several classes of the vegetable and animal kingdom. Almost all phanerogamic plants, with the exception of those included under the class Diœcia, are furnished with both male and female reproductive organs, placed either upon the same flower, or, as in the Linnæan class Monœcia, upon different flowers in the same individual. In the class Polygamia various exceptional genera are included, that present indiscriminately upon the same individual, or upon different individuals of the same species, male, female, and hermaphrodite flowers, and which thus form a kind of connecting link between the general hermaphroditic form of phanerogamic vegetables, and the unisexual type of the monœcious flowers, and the diœcious plants.

From anormalities in developement, these normal conditions of the sexual type in the different members of the vegetable kingdom are occasionally observed to be changed. Thus, among the Diœcia, individual plants are sometimes, in consequence of a true malformation, observed to assume an hermaphroditic type of structure; or, on the other hand, in hermaphroditic plants more or fewer flowers are occa-

sionally found unisexual, in consequence of the arrested developement of one order of their sexual organs; and again, though still more rarely, from an excess of evolution, a double set of male parts, or a double set of stamens, is seen developed on some of the individual flowers.

In the animal kingdom we find instances of a perfect hermaphroditic structure as the normal form of the sexual type in the Trematodes and Cestoides among the Entozoa, in the abranchial Annelida, in the Planaria, and in many of the Mollusca, particularly in the Pteropoda, and in several families among the Gasteropoda. In some of these animals that are thus naturally hermaphroditic, the fecundation of the female organs of the bisexual individual is accomplished by its own male organs; but in others, although the anatomical structure is strictly hermaphroditic, yet the union of two, or, as sometimes happens, of more individuals is necessary to complete the sexual act; and during it the female organs of each are respectively impregnated by the male organs of the other.

In the Nematodes and Acanthocephali among the Entozoa, and in the Cephalopoda and Pectinibranchiate Gasteropoda among the Mollusca, as well as in all symmetrically formed animals, or, in other words, in those whose bodies are composed of an union of two similar halves, as in Insects, and the Arachnida, Crustacea, and Vertebrata, the male and female organs of reproduction are placed each upon a different individual of the species, constituting the basis of distinction between the two sexes. In such animals a mixture of more or fewer of the reproductive organs of the two sexes upon the same individual appears occasionally as a result of abnormal formation; but the male and female organs that coexist in these cases are seldom or never so anatomically perfect as to enable the malformed being to exercise the proper physiological function of either or of both of the two sexes. This form of true hermaphroditism or abnormal mixture upon the same individual of the organs of the two sexes in the higher animals, has been termed *unnatural* or *monstrous*, in opposition to the natural hermaphroditism which exists as the normal type of sexual structure in some of the lower orders of animals, and in phanerogamic plants. The malformation itself is observed to differ greatly, both in nature and degree, in different cases, varying from the presence or superaddition of a single organ only of the opposite or non-predominant sex, up to the development and co-existence of almost all the several parts of the two sexes upon the same individual. In describing the malformation, we shall classify its various and diversified forms under the three general orders pointed out in our table, including, 1st, *lateral*; 2dly, *transverse*; and 3dly, *double* or *vertical hermaphroditism*.

A. *Lateral hermaphroditism.* — According to the opinion of many physiologists of the present day, the two lateral symmetrical halves of the body, and even the two halves of all its single mesial organs, are originally developed in a great degree independently of one another. Granting this point in the doctrine of eccentric developement, we can easily conceive how, in the same embryo, an ovary might be formed on one Wolffian body, and a testicle on the other; or, in other words, how female organs might be developed on one side, and male organs on the other. It is the existence of such an unsymmetrical type of sexual structure upon the two opposite sides of the body of the same individual, that constitutes the distinctive characteristic of lateral hermaphroditism.

Instances of this species of true hermaphroditic malformation have been observed in many different classes of animals, as well as in the human subject.

Individual examples are sometimes observed among insects, particularly among the Lepidoptera, in which all the different parts of the two sides or lateral halves of the body are formed after opposite sexual types. We shall afterwards have occasion to notice different examples of this form of lateral hermaphroditism as seen in the general conformation of the body, but may here state that in two or three instances such malformed insects have been carefully dissected, and found to present, in the anatomical structure of their sexual organs, a mixture of the organs of the male and female.

In a *Melitæa didymus* described by Klug,* the general external characters were those of the male, but the left eye, palpus, and antenna, and the left sexual fang, were smaller than in individuals belonging to this sex; and the left antenna was annulated with white and yellow at the apex, while the right was of one colour. On dissection, the various male sexual parts were present, and they had appended to them a free female ovary situated upon the left, and united to no other organ.

In a *Gastrophaga quercifolia* dissected by Schultz, and described by Rudolphi,† the left side appeared externally male, and the right female, with a distinct line of separation throughout the whole body. On dissection, Schultz discovered an ovarium upon the right side, and two testes upon the left. The oviduct of the ovary joined the canal of the vasa deferentia about two inches before its termination; and the spermatheca was connected with the common evacuating duct. The two testicles on the left side were placed one behind the other, and connected by a thin vessel. The spermatic duct belonging to one of the testicles immediately received, as in the Lepidoptera, the spiral vessel; further beyond, and on the opposite side, a second vessel, which appeared to consist of the rudimental spermatic duct of the other testicle, opened into it. The oviduct of the ovary joined the canal of the vasa deferentia about two inches before its termination in the penis, and a female spermatheca was connected with the common distended evacuating duct.‡

* Froriep's Notizen, vol. x. p. 183.

‡ See also drawings of the body and genital organs of an hermaphrodite *Sphinx populi* in Fischer's Oryctographie du Gouvernement de Moscou (Moscow, 1830.)

A well-marked example of lateral hermaphroditism among the Crustacea has been recorded by Dr. Nicholls.* In a lobster (*Astacus marinus*) he found on the right side of the body a female sexual aperture in its normal situation at the root of the third leg, and connected with a regularly formed oviduct, full of ova. On the left side of the animal there was a male sexual aperture placed, as usual, at the root of the fifth leg, and connected internally with an equally perfect testicle and spermatic cord. The general external conformation of the animal corresponded with its internal sexual structure, the right lateral half of the body presenting all the secondary characters and peculiarities of the female, and the left all those of the male; so that if split from head to tail, (to use Dr. Nicholls' mode of expression,) the animal would have been perfectly female on the right side, and perfectly male on the left.

The investigations of Sir E. Home† led physiologists some years ago to believe that among Fishes lateral hermaphroditism constituted the natural type of sexual formation in the genera Myxine and Petromyzon; but the later and more accurate observations of Rathké‡ have shewn that these species are strictly bisexual, and that the opposite opinion had arisen from the kidneys of the female having been mistaken for the male testicles. Various instances, however, are on record of fishes, known to be normally bisexual, presenting from abnormal developement a lateral hermaphroditic structure, or a roe on one side, and a milt on the other. Such an hermaphroditic malformation has been met with in the genera *Salmo*,§ *Gadus*,|| and *Cyprinus*,¶ and in the *Merlangus vulgaris*,** *Acipenser huso*,†† and *Esox lucius*.‡‡

Of lateral hermaphroditism in Birds, we have one instance recorded by Bechstein,* in a chicken that had a testicle on the right side of the body, and an imperfect reniform ovary on the left. The external appearance of the bird presented a mixture of the characters of the two sexes.

Rudolphi has referred to a second and more ancient example of lateral hermaphroditism in the hen, mentioned by Heide.† The case, entitled by the author "galli qui putabatur hermaphroditus anatome rudis," is so imperfectly detailed as not to be entitled to much attention.

We have ourselves been fortunate enough to meet with two domestic fowls that presented in their sexual organization examples of lateral hermaphroditism. In the first of these cases (*fig.* 290) the female sexual organs were placed on the left side of the body, and the ovary (*a*) and oviduct (*b*) were in all respects apparently naturally formed. On the right side, a male vas deferens (*d*), of about half the normal length,

‡ Bemerkungen ueber den Innern Bau der Pricke, s. 119. See also additional observations by the same author in Müller's Archiv fur Anatomie, &c. for 1836. Heft. ii. s. 171. The older error of Cavolini, who supposed that he had detected two ovaries and two testicles in the *Perca marina* and *Labrus channa*, (Sulla Generazione dei Peschi et dei Granchi, Nap. 1787,) had been previously shewn by Rudolphi to depend upon his having mistaken undeveloped portions of the ovaries for testicles. ran up from the cloaca to opposite the origin of the iliac vessels (*c*), and during this part of its course was bent into those short transverse zig-zag folds which characterise the structure of this part in the common cock. (See article Aves, vol. i. p. 354.) When it reached the middle third of the kidney (*d d*), it lost this particular form, became membranous (*e*), and after proceeding upwards for about an inch, in the common course of the canal, at last disappeared. The convoluted or contorted portion ran over a space of about two and a half inches, and if unrolled would have extended three or four times that length. Its canal was about the usual size of the same part in the perfect cock, and perhaps at some parts even more dilated. Its cavity was filled with a whitish seminal-looking albuminous fluid, which at first prevented a mercurial injection from readily passing through it. There was not any apparent vestige of a testicle. The fowl that was the subject of this malformation possessed in an imperfect degree the plumage, comb, spurs, and general appearance of the cock, and when young was considered to be a male until the time it commenced to lay eggs, which it did very constantly, except during the moulting season, up to the time of its death. Its eggs were remarked to be very large. They had repeatedly been tried to be hatched, but always without success. The bird itself was never known to incubate. It was peculiar in its habits in so far that in the barn-yard it did not associate with the other poultry, and at night roosted separately from them. It crowed regularly, especially in the morning, and often attempted copulation with the hens.

In the second case, the ovaries and oviduct on the left side of the body were, as in the former example, natural in themselves; but in the mesometry of the oviduct, a tube of the size of the male vas deferens was found. This tube, like the normal vas deferens, was thrown into the distinctive angular folds. It ran for about an inch and a half through the upper portion of the mesometry, was blind at either extremity, and admitted of being injected with quicksilver. On the right side, there was also a male vas deferens, marked with the characteristic angular folds. The contorted portion of this canal only stretched in this instance to about an inch above the cloaca; but the folds were even stronger than in the first case, and the tube itself was rather more dilated. Above or anterior to this convoluted part, the tube became straight and membraneous, and ran up in this form for about two inches in its usual track over the abdominal surface of the kidney; but there was not at its upper extremity any trace of a testicle. This bird presented during life, in a very slight degree only, the appearance of a cock, its comb and spurs being even less developed than in the previous case. It shewed the same solitary habits in the poultry-yard. It layed eggs regularly. On three different occasions I had a number of them submitted to incubation, but in none of them was a chick produced.

In the Quadruped, Schlump* has mentioned an instance of lateral hermaphroditic malformation. In a young calf he found on the left side, under the kidney, a small testicle having attached to it a vas deferens, which was connected with the peritonæum towards the abdominal ring of the same side, and there became lost in the cellular texture of the part. An ovary and Fallopian tube, with an uterus consisting of a single horn only, were connected to the right side of the loins by a ligament. The neck of the uterus lost itself in the cellular substance beneath the rectum, and there was no vagina. The external organs were male, but imperfectly formed. The udder occupied the place of the scrotum.

In the human subject several different instances of sexual malformation have now been met with referable to the head of lateral hermaphroditism. In these cases, along with a testicle on one side, and an ovary on the other, there has generally co-existed a more or less perfectly formed uterus. The external parts have differed in their sexual characters, in some instances being female, in others male, and in others again of a neutral or indeterminate type.

In man, and in the higher quadrupeds, we have not unfrequently exhibited to us a slight tendency to this unsymmetrical type of sexual structure constituting true lateral hermaphroditism in the testicle of one side only descending, whilst the other, in consequence of imperfect development, remains within the inguinal ring. In the single unsymmetrical ovary of most female birds and some fishes,† we see a still nearer approach to the state; and it is worthy of remark, that among birds at least, the single ovary is always placed upon the left side. In lateral hermaphrodites in the human subject, the left side also appears to be that on which we most frequently meet with the female type of the sexual organs. We shall divide the following cases according to the particular sides which were respectively male and female in them.

1. *Ovary on left side, and testes on the right.*— *a.* M. Sue met, in 1746, with an instance of lateral hermaphroditism in the human subject, in a young person of thirteen or fourteen years of age, whose case was the subject of a Thesis sustained by M. Morand.‡ Of the interual

* Archiv. fuer die Thierheilkunde, Bd. ii. Hft. ii. s. 204.

† In the early embryo of birds, the ovaries are originally double, as pointed out by Emmert, (see Reil's Archiv for 1811;) and as was previously known to Wolff and Hochsteller, (Anat. Phil. tom. i. p. 349.)

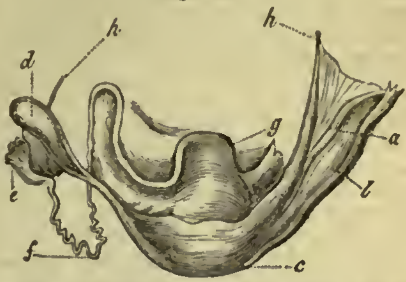
‡ De Hermaphroditis, Paris, 1749. This, according to Arnaud, (p. 323,) is the same case of lateral hermaphroditism with that described by Lecat. If so, the latter author, (probably from drawing his description from memory, and not, as Morand seems to have done, from the parts placed before him,) has stated that along with the testicle and vas deferens on the one side, there existed a vesicula seminalis, and that both sides were provided with round ligaments, the one on the male side forming probably one of the two tubes described by Morand as arising from the testicle.

genital organs, there existed on the *left* side a very distinct ovary, a round ligament which ran outwards to the groin of the same side, and a well-formed Fallopian tube with its usual fimbriated extremity. The other extremity of the Fallopian tube terminated in the fundus of the uterus, which occupied its usual situation between the bladder and rectum. On the *right* side, again, there was a slender elongated testicle, which had moved forwards to the corresponding inguinal canal, but had not proceeded so far as to pass out of the abdominal cavity. On the superior part of the testicle was a body resembling the epididymis, and the testicle itself sent off two tubes, which afterwards united into one immediately before their insertion into the uterus. The *external* genital organs were those of a hypospadic male, and during life the person had been always looked upon as belonging to the male sex. The perinæal canal or vagina terminated, between the scrotum and root of the imperforate penis, in a very small opening, which was common to it and to the meatus urinarius.

b. In 1754,* a young person of about eighteen years of age died in the Hôtel Dieu of Paris; and in dissecting his body, the anatomist, Varole, found the reproductive organs malformed in the following manner. On the *right* side the scrotum contained a testicle, and the vas deferens arising from it opened, not as usual into the neck, but into the middle of the external border of the corresponding vesicula seminalis. On the *left* side the scrotum was empty; and internally on this side there were found an ovary, a Fallopian tube with its fimbriated extremity, a small oval uterus without a neck and somewhat flattened, and a broad and round ligament, the last of which ran outwards, and was lost in the cellular tissue of the left half of the scrotum. The vesicula seminalis on the right, and the imperfect uterus on the left side, communicated by a canal of an inch and a half in length. The external organs were male; but the penis was very small, had no corpus spongiosum, and was imperforate for half an inch at its anterior extremity. The mammæ were as large as in women of the same age. The individual had been regarded during life as a male.

c. In 1825 the late Professor Rudolphi† detailed to the Academy of Sciences at Berlin the case of an infant who was reported to have died seven days after birth, and whose sexual organs exhibited the following interesting instance of lateral hermaphroditic conformation. On the left side were discovered an ovary (*fig*. 291, *a*), without a distinct broad ligament,

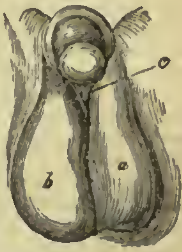
Fig. 291.



Uterus (c) turned downwards and forwards to show its posterior surface and connections, &c.

and a Fallopian tube (*b*), which communicated with the superior and left portion of an uterus (*c*). The left side of the scrotum (*fig*. 292, *a*), was empty; the right (*b*) contained a testicle (*fig*. 291, *d*) furnished with an epididymis (*e*) and tortuous vas deferens (*f*). Below the uterus there was a hard flattened ovoid body (*fig*. 291, *g*, and *fig*. 293, *b*), which, when divided was found to consist of a cavity with thick parietes, and was considered by Rudolphi as the prostate gland in a rudimentary state.

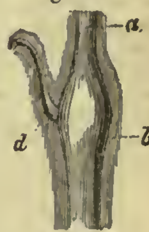
Fig. 292.



External organs.

The mouth of the uterus (*fig*. 293, *a*) terminated below in the parietes of this ovoid body, and on the right the vas deferens (*d*) penetrated into its substance, but without opening into its cavity. At the inferior part of the uterus there was a true vagina (*fig*. 293, *c*), which terminated in a cul-de-sac. The anus, rectum, and other organs were natural. The external sexual parts were male, but the penis was divided inferiorly (*fig*. 292, *c*). The testicle and ovary were supplied with the two usual spermatic arteries (*fig*. 291, *h h*).

Fig. 293.



Os uteri, vagina, prostate, and vas deferens.

d. Under the present section of lateral hermaphroditism, we may also, according to Mayer's report, include the celebrated case of Marie Derrier, or Charles Doerge.* This person was baptised and brought up as a female, but at forty years of age was persuaded to change his name and dress to those of a man. We have already alluded to the great diversity of opinion which was entertained by the medical men of

Meckel (Reil's Archiv. Bd. xi. s. 322,) considers Morand's and Lecat's as two different cases, and points out that what is described as the male side in the one, was the female in the other, and *vice versa*. It is, perhaps, not unworthy of remark, that in the coloured plate accompanying the translation of Morand's case by Gautier, the male and female sides have been reversed from an error in the engraving; and this circumstance may have contributed to mislead Lecat in his description, provided he happened to look to this notice of the case.

Europe in regard to the true sex of this individual. Even the different parts of his body were at one time referred to the male type, and at another time, and by other persons, to the female. The pelvis was the only part that was generally considered as decidedly female, yet the inspection of the body after death by Professor Mayer shewed that even in this respect all were in error.

Of the female sexual organs there existed an uterus, vagina, two Fallopian tubes, and an ovary ; and of the male, a testicle, and prostate gland and penis. The uterus was placed in its normal situation between the urinary bladder and rectum, but with its fundus directed in some degree to the left. The organ was extremely narrow, and two and a half inches in length. The cavity of its cervix presented on its inner surface some slight folds, but would scarcely admit a quill ; the cavity of its fundus was nearly half an inch across. The small canals of two Fallopian tubes opened into the fundus uteri. Their abdominal extremities were shut, but the corpora fimbriata were present. Near the extremity of the right Fallopian tube, which was four inches and four lines in length, a small flattened almond-shaped body was placed, which on examination proved to be distinctly a testicle. It was completely enveloped in peritonæum, and received a cord composed of muscular fibres, and of a spermatic vein and artery. Its internal structure was yellow and filamentous, like that of the testicle, and its seminiferous tubes could be easily separated. The left Fallopian tube was an inch shorter than the right; and a little outside and behind its abdominal extremity another small flattened body was found inclosed in the peritonæum. It resembled an ovary rather than a testicle. Its tissue was composed of small granules conglomerated together. The penis was two inches and nine lines in length, and was for the greater part concealed underneath the mons veneris. During life it was capable of erection, and was then elongated to more than three inches. The prepuce covered only half the glans. There was not any corpus spongiosum. A fossa or groove, representing an urethral canal divided inferiorly, ran along the under surface of the penis. The two folds of skin forming the sides of the groove separated from each other posteriorly, and might be compared to nymphæ. Towards the root of the penis, by uniting inferiorly with a puckering of the skin of the labia majora or divided halves of the scrotum, they formed a circular orifice not larger than a quill, having some bodies, supposed to be vestiges of the carunculæ myrtiformes, at its lower edge, and leading to a short vestibule, or common canal, into which the urethra, surrounded by a firm but small prostate, entered from above, and the vagina, encircled at its entrance by a vascular ring of varicose veins, opened from below. The vagina was two inches and eight lines in length, and only ten lines at its greatest breadth. Its inner surface was somewhat wrinkled anteriorly, but smooth behind. It terminated above in a kind of spongy isthmus representing the blind orifice of the uterus, and from four to six lines in length. The diameters and form of the pelvis were, on dissection, found to be most evidently masculine.

The general character of Doerge was a mixture of the male and female type. When between twenty and thirty, he had been examined by different medical men in Germany, France, and England, and, as we have already mentioned, the most contradictory opinions were offered upon his real sex. The breasts were not much developed, and there was no distinct mammary glandular structure. His stature was small (five feet). As he had advanced in age, his voice had become more firm and grave, and a slight trace of beard had appeared; but his head and face presented the aspect of that of an old woman. His neck was short, and the thyroid cartilage did not project much : his chest was fat and full. During the last few years of his life he was subject to epistaxis and hæmorrhoids, but did not present any trace of sanguineous discharge from the genital organs,—a phenomenon which was alleged to have manifested itself three times during his twentieth year.

The right hemispheres of the cerebrum and cerebellum, particularly that of the latter, were smaller and less developed than the left, and the left side of the occiput was externally more prominent than the right. He is stated by Professor Mayer to have shewn a certain predilection for females, without, however, feeling any sexual desire.

2. *Testicle on the left, and ovary on the right side.*—An instance of malformation of the reproductive organs minutely described by Maret,* and which is in all its more essential anatomical points an example of lateral hermaphroditism, may be included under this head.

a. The subject of the case (Hubert Jean Pierre) died in the hospital at Dijon in 1767, at the age of seventeen. On the left side a perfect testicle was discovered with its usual spermatic vessels, vas deferens, and vesicula seminalis, all occupying the natural situation in which they are placed in the male adult. The vesicula seminalis contained a fluid of the colour and consistence of semen. On the *right* side an oblong cystic tumour was found lying in the iliac fossa, and stretching outwards into the inguinal region. On opening it a quantity of reddish limpid fluid escaped, and then the solid contents of the tumour were seen to consist of a somewhat flattened body, that gave off from the upper part from its right side a short Fallopian tube; and at the fimbriated extremity of this tube an ovary of the natural size, consistence, and figure, was situated. The roundish shaped body to which the tube was attached was about an inch and a half in its greatest, and an inch in its smallest diameter. It contained in its centre a small cavity continuous with that of the tube,—a circumstance, which, along with the structure of its walls, left little doubt that the body itself was an imperfectly formed uterus. No other opening except that of the tube could be traced into its cavity. Its external surface

* Mém. de l'Acad. de Dijon, t. ii. p. 157.

was attached to the ovary by a kind of ligament. On this same side of the body (the right) there existed also a vesicula seminalis, but smaller and more shrivelled than that on the left. It gave off a vas deferens, which became gradually smaller as it was traced backwards, and at last disappeared altogether without being connected with any structure resembling a testicle. In regard to the external organs of generation, the penis was four inches long and imperforate, but in all other respects perfectly formed. It possessed a corpus spongiosum, which does not exist in the female clitoris. On raising the penis, it was observed to cover a large fissure, the sides of which resembled the labia of a female. In the left labium or left half of the scrotum the testicle already alluded to was placed, but there was none in the right. When the labia were separated, two red spongy bodies were seen, resembling the nymphæ in appearance, and seemingly consisting of the sides of the split urethra. Between these bodies and at their upper part, the urethra opened as in the female; while below there was a very narrow aperture covered by a semilunar membrane, and presenting on one side of its entrance a small excrescence somewhat resembling in figure a caruncula myrtiformis. This orifice led into a membranous canal or cul-de-sac an inch in depth, and half an inch in diameter. On the lower part of this canal the verumontanum and orifices of the seminal ducts of both sides were discovered.

During life Pierre had been considered a male, but was not known to have shown any partiality for the female sex. His countenance was more delicate than what we ordinarily see in the male sex. There was no beard on the face; the larynx was not enlarged as in man; and the mammæ, each of which was furnished with a very large areola, were of a moderate size and roundish form. The configuration of the lower part of the body was more decidedly masculine, and there was none of that enlargement of the buttocks and projection of the thighs, from the increased width of the pelvis, which is observable in young females.

In this case we have on the *left* side of the body male sexual organs, consisting of a perfect testicle, vas deferens, and vesicula seminalis. On the *right* side, again, we have a female ovary and Fallopian tube with a rudimentary uterus, together with an imperfect male vesicula seminalis and vas deferens.

Arnaud mentions a very imperfect form of lateral hermaphroditism as having been recognised by M. Boudou, surgeon to the Hôtel-Dieu of Paris, on the person of a monk who died in that hospital in 1726. The external genital parts were those of a hypospadic male. In one of the halves of the scrotum a testicle was found; the other was empty. The seminal canals and vesiculæ seminales on the side on which the perfect testicle existed were natural in their course and situation. Those of the opposite side lost themselves between the bladder and rectum in a small body, which, in M. Boudou's opinion, was a shrunk uterus.*

Among the preceding cases of lateral hermaphroditism in the human subject, there are four in which the left side, and one only in which the right was the female. In the last instance quoted from Boudou the respective sides on which the male and female organs were placed are not stated by Arnaud.

B. *Transverse hermaphroditism.*—In the variety of hermaphroditic malformation which we have last considered, we have found upon the same individual the reproductive organs of one side disagreeing in their sexual type from those of the other. In the present division we have a similar sexual antagonism following a different direction; for supposing the internal sexual apparatus to be divided from the external by a transverse line, we have, in transverse hermaphroditism, on each side of this partition, organs of an opposite sexual type: in other words, the organs of reproduction (in the more correct sense of the word) or the internal sexual organs do not, in the present species of hermaphroditism, correspond in type with the organs of copulation, or the external sexual parts,—a circumstance the occasional occurrence of which tends to shew that these two portions of the generative apparatus are in some degree independent of one another in their normal development and existence, and consequently also in their abnormal formations.

Transverse hermaphroditism varies in its character according to the relative positions occupied by the co-existing male and female organs; the external organs, or all those exterior to the supposed transverse line, being sometimes female, and the internal male, and *vice versâ*.

1. *Transverse hermaphroditism with the external sexual organs of the female type.*—In the cases included under this division, the external genital organs consist of a clitoris, vagina, and uterus; the uterus is often rudimentary, and sometimes altogether absent and replaced by the male vesiculæ seminales. The male internal organs are the testicles, generally small and imperfectly developed, and placed either within or without the abdomen, with vasa deferentia terminating in the uterus and vagina.

This variety of sexual malformation has been repeatedly observed among our domestic quadrupeds, particularly among black cattle. Mr. John Hunter, in an essay read before the Royal Society in 1779, and published in their Transactions,† and in his Observations on the Animal Economy, shewed that, (as had been long known among agriculturists,) when among black cattle the cow brings forth twin calves, one of them a male, and the other apparently a female, the male is a perfect bull calf, but the female, while it has all the external marks of a cow-calf, as the teats and udder, is still, with a few exceptions, imperfectly formed in its

* Arnaud, loc. cit. p. 283.

† Vol. lxix.

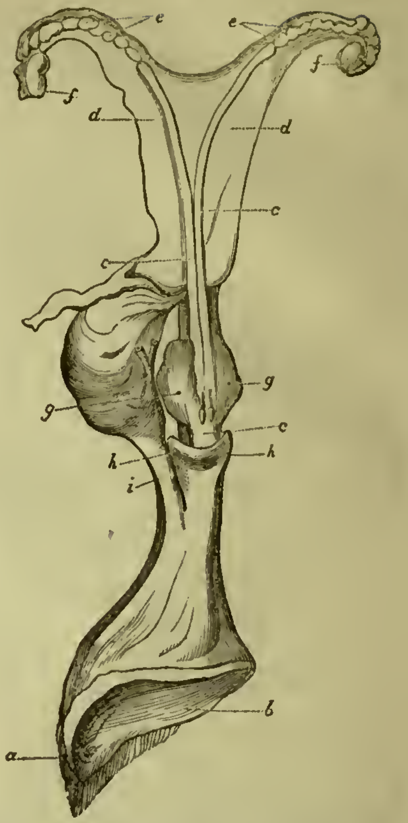
internal sexual organs, and very generally presents a mixture of the organs of the two sexes in various degrees. Such hermaphroditic twin cattle have long been distinguisbed in this country under the name of *free-martins.* In some exceptional cases only have they been observed capable of breeding; and generally they shew no sexual desire for the bull, or the bull for them. In appearance they resemble the ox or spayed heifer, and have a similar, or still greater disposition to become fat under the use of good food.

In the paper to which we have referred, Mr. Hunter has described the dissection of three free-martins: and one of these seems to belong to our present division of female transverse hermaphroditism. The clitoris and external parts appear to have been strictly of the female type, and there was a small udder with four teats. The vagina terminated in a blind end a little beyond the opening of the urethra, and from this point the vagina and uterus were impervious. The uterus at its superior part divided into two horns, and at the terminations of these horns, not ovaria, but bodies resembling the male testicles were found. These bodies had not a perfect internal structure like that of testicles, but resembled these organs in so far that, 1st, they were nearly as large as the male testes, and much larger than the female ovaries; 2nd, they were supplied with tortuous spermatic arteries like those of the bull or rigdil; and 3d, cremaster muscles passed up to them, as in rigdils, from the abdominal rings. There were two small vesiculæ seminales placed behind between the bladder and uterus, with their ducts opening into the vagina. Nothing, according to Mr. Hunter, similar to the vasa deferentia was present; but Gurlt is inclined to believe that the parts which Mr. Hunter has described as the horns of the uterus were really the deferent vessels.

Professor Gurlt* has himself given, from a preparation in the Museum of the Berlin Veterinary School, the accompanying sketch of the malformed sexual organs of a five-year old free-martin, (*fig.* 294,) which presents to us an illustration of Mr. Hunter's supposed mistake, at the same time that it affords a well-marked example of transverse hermaphroditism. The detail of the anatomical peculiarities of the case has been unfortunately omitted by the author, but from the short explanations appended to the drawing, it appears that the clitoris (*a*) and external pudenda (*b*) were perfectly feminine, and that the vagina, short and funnel-shaped, terminated at its superior contracted extremity in two vasa deferentia (c c c), which were carried upwards in a duplicature of peritonæum (*d d*) resembling the broad ligament, until they joined the unrolled and lengthened epididymes (*e e*) of two small testicles (*f f*) placed in the position of the ovaries. Near the junction of the vagina and vasa deferentia bodies resembling the male vesiculæ seminales

* Lehrbuch der Pathol. Anat. d. Saug. Th. Bd. ii. S. 186.

Fig. 294.



(*g g*) and Cowper's glands (*h h*) were situated, and the urethral canal (*i*) opened into the vagina and was shorter than it usually is in the cow.

We have found upon a free-martin cow a state of the sexual apparatus very much resembling that figured in the above case by Professor Gurlt. The two vasa deferentia, as they ran in the duplicature of the peritonæum, had very much the appearance and shape of an imperfectly developed uterus. The vesiculæ seminales were large; the vasa deferentia were quite impervious throughout their whole course; and the bodies placed at their abdominal extremities were large, but of so indeterminate a structure as not to enable us to pronounce them to be either true testicles or ovaries.

M. Geoffroy St. Hilaire published in 1834 a very distinct case of an hermaphroditic goat which had two male testicles and epididymes with a two-horned uterus and female external parts.* M. Isidore St. Hilaire† mentions a nearly analogous case in the same animal, and quotes a third from Bomare which was observed upon a deer.‡

* Nouv. Ann. du Museum d'Hist. Nat. t. ii. p. 141.

† Histoire des Anomalies, t. ii. p. 128.

‡ Journ. de Phys. t. vi. p. 501.

To the present division of transverse hermaphroditic malformation with external female and internal male organs, we may probably also refer the case of the hermaphrodite dog detailed by Sir E. Home,* and three instances in the sheep described by Ruysch,† Herholdt,‡ and Gurlt.§ In all these instances imperfectly developed testicles were situated either within the abdomen or without it upon the udder, at the same time that the external parts exhibited in a more or less marked degree the peculiarities of the female sex; the vagina was, however, narrower, and the clitoris more developed than in the perfectly formed female; and in the dog mentioned by Home, this latter organ was very large, being three quarters of an inch long, and half an inch broad, but still it could not properly be considered as an imperfect penis, since the bone, which forms the distinguishing mark of that organ in the dog, was wanting.

Few well-marked instances of transverse hermaphroditism with external female organs have been hitherto described as observed in the human subject, unless we regard as an approach to it the numerous cases, already referred to, of spurious hermaphroditic malformation in the male from hypospadic division of the urethra, scrotum, and perinæum.

a. In his essay on hermaphroditism, however, Steghlehner‖ has detailed at great length the particulars of a case belonging to the present variety, which he met with on the body of a woman who died of phthisis at the age of twenty-three. The external sexual organs were all of the female type and in general well formed, though the clitoris and nymphæ were perhaps smaller than natural, and the orificium vaginæ was rather contracted and half shut up by a hymen. The fossa navicularis was very distinct, and the vagina normally situated, but extremely short and narrow. Its internal surface presented an appearance of transverse and longitudinal rugæ, but its upper extremity formed a blind sac, and no traces could be found beyond it of the uterus, nor indeed any vestiges whatever of the other internal female organs, the ovaries and Fallopian tubes. On more minute examination a testicle with its spermatic cord was found in each inguinal region, placed outside the external ring, and surrounded with their cremaster muscles and vaginal coats. The testicles were flaccid and small, but their internal structure and that of their epididymes was natural; and the slender pervious vasa deferentia arising from them entered the abdomen, descended into the pelvis, and were joined behind the urinary bladder by two vesiculæ seminales of considerable size. Their common ejaculatory ducts opened into the vagina. The form of the thorax and pelvis, and of the body in general, was feminine; and the mammæ and nipples were well developed, but the larynx was rather more protuberant than in females, and the voice approached in tone to that of a man. There had never been any menstrual discharge, but the periodical molimina indicative of its appearance were said to have been observed regularly. There were some hæmorrhoidal tumours situated around the anus.

b. If possible a still more perfect example of the present variety of transverse hermaphroditism in the human subject has lately been observed at Naples. The malformation occurred in the person of an individual Maria E. Arsano, who died at the age of eighty in one of the pauper charities at Naples, and who had passed through life as a female and been married as such. No suspicion of the malformation existed during life, and it was only at first accidentally discovered in preparing the dead body for demonstration in the anatomical theatre of Professor Ricco, who afterwards carefully dissected the malformed parts in company with Professors Sorrentino and Grosetti. We have taken the following account and sketches from Ricco's published description of the case.*

The external organs of generation were those of the female in their natural or normal state, consisting of the mons veneris with a scanty quantity of hair (*fig.* 295, *a*); of the labia ex-

Fig. 295.

terna (*fig.* 295 & 296, *b b*) naturally formed, and the nymphæ (*fig.* 295 & 296, *d d*); of the clitoris (*fig.* 295 & 296, *c*), which was perfectly imperforate, and of the ordinary size of the same organ in the adult female; of the orifice of the urethra (*fig.* 295 & 296, *e*) situated below the clitoris; and of the os vaginæ (*fig.* 295 & 296, *f*), which was of the usual size and diameter. Altogether the aperture of the vulva was natural. The canal of the urethra was of the usual length, as seen at *u* in the section

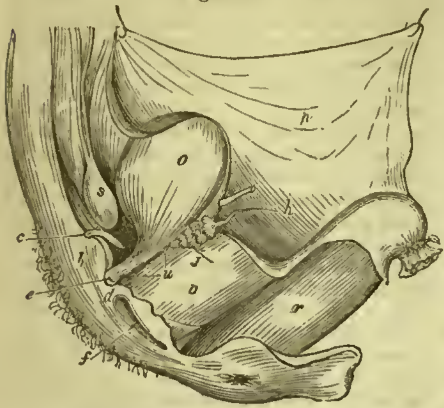
of the pelvis represented in *fig.* 296, in which *s* marks the divided symphysis pubis, and *p* the

Fig. 296.



peritonæum. The os vaginæ shewed no vestiges of the membrane of the hymen, or, in other words, was without carunculæ myrtiformes. The canal of the vagina *(fig.* 296, *v)* was about two inches long, but without rugæ, and it terminated internally in a completely blind extremity or cul-de-sac. The uterus was entirely wanting, as were also the Fallopian tubes and uterine ligaments.

The internal organs of reproduction were, on the other hand, completely male. The two testicles *(fig.* 295, *g g)* were situated in the region of the pubis, and were scarcely clear of the inguinal rings. They were of the usual ovoid figure, and natural in size. They had internally the structure of the tubuli seminiferi, but it was not well developed. The spermatic cords were quite normal both in regard to their composition and the origin and course of their bloodvessels. The right spermatic artery *(fig.* 295, *l)* arose, as usual, from the renal, and the corresponding vein (*m*), after forming the pampiniform plexus (*k*), opened into the vena cava inferior; while on the left side the artery (*l*) arose from the aorta, and the vein (*m*) terminated in the left emulgent. The epididymes of the testes were also of the usual vermiform figure, and the corresponding vasa deferentia *(fig.* 295 & 296 *h h)* coursed towards their vesiculæ seminales *(fig.* 296, *j)*, and terminated in an attenuated membranous expansion without any external aperture or ducti ejaculatorii. The vesiculæ seminales (see the left one *j* in *fig.* 296) were placed between the urinary bladder (*o*) and rectum (*r*); they were smaller and more shrunk than those of the adult male, though certainly they preserved their naturally oblong form. Their internal hollow or tubular structure was indistinct. The prostate gland was not present. The urinary bladder (*o*) and ureters (*n n*), the rectum (*r*), and the other intestinal viscera, with the abdominal bloodvessels (*s*, the aorta, *t*, the vena cava, *fig.* 295) seem to have been all quite natural.

The head of the above individual was of the usual size, the neck long, and the stature ordinary. The periphery of the thorax was so expanded as almost to equal that of the male, notwithstanding the presence of well pronounced mammæ. The face, although entirely free from hair, had yet neither the expression of that of a female nor of a male, but shewed more of that mixed character which is seen in the eunuch. The pelvis was altogether that of a male in its form and dimensions, and the limbs were perfectly masculine. According to information collected after death, the voice was deep, and the temperament strong and firm. Though there was never any menstruation, yet, from being constantly employed in domestic occupation, the mental character was feminine, and the married state had been willingly entered into.

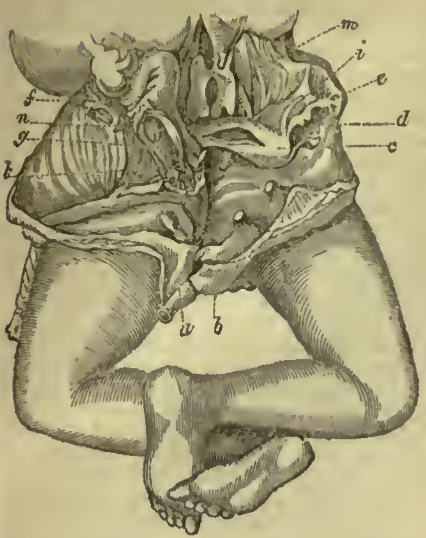
2. *Transverse hermaphroditism with the external sexual organs of the male type.*—The male organs that are present consist of the penis, which is provided with a regular formed prepuce, glans, corpora cavernosa, and corpus spongiosum, with the urethra perforating it, and of the prostate gland, verumontanum, &c. The co-existing female organs are the ovaries, the Fallopian tubes with their infundibula, and the uterus.

We are not aware of any recorded instances of this variety of hermaphroditic malformation among the lower animals. We have already, under the head of spurious hermaphroditism in the female from enlargement of the clitoris, &c., mentioned several cases, in which, from excessive developement, the external organs in women had assumed some of the characters of the corresponding parts in man; but the two following cases described by Professors Eschricht of Copenhagen, and Bouillaud of Paris, present instances of malformation in which the more exterior sexual organs were all formed upon the male, and the internal upon the female type.

a. The subject of the case described by Eschricht* was a twin child that died very shortly after birth, and in whom the external sexual organs were of the male type, and the internal female. The penis *(fig.* 297, *a)* and scrotum (*b*) were well developed, but the usual raphé seen upon the latter was absent. The urethral canal of the glans and body of the penis was pervious throughout, and admitted of a sound being easily passed into the bladder. The glans was remarkably thin and slender. The prepuce could be easily pushed back. No testicles could be felt in the scrotum, and internally there was an uterus with Fallopian tubes and ovaries. The uterus (*c*) was about an inch in length, and had the general form presented by this organ in female infants. It contained a cavity marked with rugæ, but had no orifice inferiorly, nor any vagina attached to it. Its blind or imperforate neck was firmly attached to the posterior walls of the urinary bladder (*g*), while its fundus was directed very obliquely downwards and over to the left side. From the left side of the fundus of the uterus a twisted Fallopian tube (*d*) proceeded, having

* Müller's Archiv fuer Anatomie, &c. 1836, Heft ii.

Fig. 297.



well developed fimbriæ (*e*) at its abdominal extremity, and the broad ligament or fold of peritonæum along which it ran contained an oblong soft body (*i*), (which Eschricht considered as distinctly an ovary,) and a round ligament that took its course through the inguinal canal of the same side. On the right side an ovary (*k*) and Fallopian tube (*f*) were likewise discovered, but they were displaced and separated from the body of the uterus. The ovary lay in the iliac region, and above it and towards its outer side was placed the fimbriated extremity of the corresponding Fallopian tube. The tube presented towards this extremity a vesicular swelling of the size of a small pea, which admitted of being inflated and filled with quicksilver through a small opening between the fimbriæ. Below this it was impervious, and apparently diverged off into two prolongations, one of which (the round ligament) passed down into the inguinal canal, and the other crossed over with a fold of peritonæum to where the rectum and urinary bladder were preternaturally connected together. Professor Jacobson suggested that this latter part was a rudiment of the right half or horn of the uterus. It may perhaps, however, be more properly regarded as the commencement of the right Fallopian tube, and in this case it would, if continued onwards, have been joined to the neck of the uterus,—an arrangement which would be quite in accordance with the usual deep and displaced origin of one of the tubes in instances of congenital obliquity of the uterus.

The child was malformed in other respects also. The anus was imperforate, and the rectum (*n*) opened into the urinary bladder, which was very contracted. The kidneys (*m*) were irregularly formed, and lay near the promontory of the sacrum. There was an accessory spleen, and the formation of the heart and large vessels was abnormal. The other twin child was well formed and lived.

b. The case of transverse hermaphroditism observed by Bouillaud* was even still better marked than that of Eschricht. Valmont, the individual who was the subject of it, died in one of the hospitals of Paris of the epidemic cholera. He was a hatter by trade, and had been married as a male. No further particulars of his history or habits could be obtained. The following was found by MM. Manec and Bouillaud to be the state of the external and internal sexual organs.

Externally there was a penis (*fig*. 298) of a

Fig. 298.

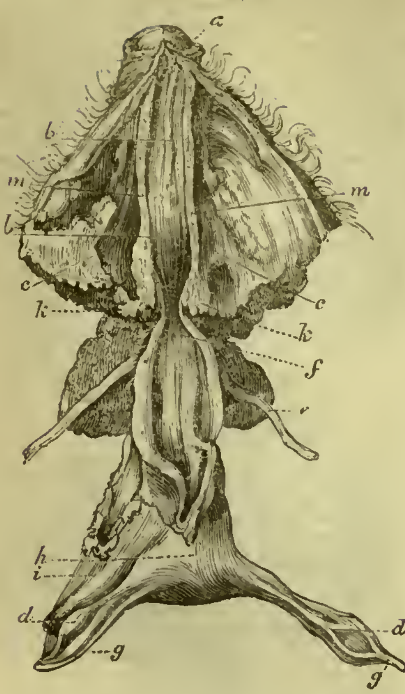
medium size, terminating in a regularly formed glans (*a*), and furnished with a prepuce (*b*).

The urethra (*fig*. 299, *b b*) opened on the inferior side of the glans (*fig*. 298 & 299, *a*). In its course from this point backwards to the bladder, it perfectly resembled the urethra of the male, and was surrounded at its origin by a well-formed prostate gland (*fig*. 299, *k k*). Cowper's glands were also present (*fig*. 298, *d*). The verumontanum or caput gallinaginis was distinct, as well as the orifices of the prostatic follicles; but the usual openings of the seminal canals could not be found. The corpus spongiosum urethræ (*fig*. 298, *g*) and the corpora cavernosa (*fig*. 299, *m m*) were as well developed as in the perfect male subject. The scrotum was small, and did not contain any testicles; it presented on its middle a line or raphé extending from the prepuce to the anus, and which was harder and better marked than it usually is upon male subjects. The various muscles of the male perinæum (*fig*. 298, *c c*) were present, and very perfectly formed. The constrictores urinæ muscles (*e*) were particularly long and thick.

In the cavity of the pelvis two ovaries (*fig*. 299, *d d*), similar in form and structure, according to M. Manec, to those of a girl of fifteen or sixteen years of age, or (to adopt

* Journ. Hebdom. de Méd., tom. x. p. 466. "Exposition Raisonnée d'un cas de nouvelle et singulière variété d'hermaphrodisme observée chez l'homme."

Fig. 299.



M. Bouillaud's statement) two bodies in some sort fibrous, and perhaps intermediate in their structure between ovaries and testicles, were found along with two Fallopian tubes (*fig.* 299, *g g*), having each a fimbriated extremity at one end, and opening by the other into the cavity of an uterus (*h*) which occupied the usual situation of that organ in the female, and opened inferiorly into a kind of vagina (*e*). The internal surface of the uterus showed the usual arborescent wrinkles of this organ in the unimpregnated state; the os tincæ was regularly formed; the vagina was about two inches long, and of a middle size, and presented internally numerous ridges, such as are met with in virgins. This canal, when opposite the neck of the bladder at *f*, became much contracted, and was continued downwards in the form of a small tube to the membraneous portion of the urethra, into which it entered by a narrow orifice. The broad ligaments of the uterus were normally formed; the round ligaments passed through the inguinal canal accompanied each by an artery larger than that of the corresponding one in the female sex.

The external appearance and form of Valmont are described by M. Bouillaud as having been intermediate between those of the male and female sex. The stature was short; the mammary glands and nipples were well developed; the face was bearded; but the general physiognomy was still delicate. The body was fat; the hands and feet were small; the pelvis was shallow; and the haunches were wider than in a well-formed man.

C. *Double or vertical hermaphroditism.*—In the two divisions or orders of true hermaphroditism which have been already considered, we have seen re-united upon the body of the same individual more or fewer of the organs of the two sexes, but so arranged as not necessarily at least to present the occurrence of actual duplicity in any of the corresponding male and female parts. In both lateral and transverse hermaphroditism the type of the sexual apparatus is in fact *single* in so far that it consists, in almost all cases, in the presence at one part of an organ or organs differing in sexual type from those that are present at other parts, without there necessarily co-existing at any one point the two corresponding male and female organs. In the present or third variety, however, of true hermaphroditism, we come to a tendency to actual sexual duplicity, in the co-existence of two or more of the analogous organs of the two sexes upon the same side, or in the same vertical line of the body. For, supposing we viewed, either from before or behind, the reproductive organs belonging to the two sexes all stretched out upon the same erect plane, so that their corresponding organs should be exactly superimposed upon one another,—as the two female ovaries upon the two male testicles, the Fallopian tubes upon the vasa deferentia, the uterus upon the vesiculæ seminales and prostate gland, &c.,—we should find in vertical or double hermaphroditism more or fewer of those analogous organs of the two sexes that were thus placed upon one another, and that consequently lay in the same vertical line, or upon the same side of the body, co-existing together at the same time upon the same individual.

Double, vertical, or complex hermaphroditism differs much in variety and degree in different cases, from the imperfect repetition of two only of the corresponding organs of the male and female upon the same body, to the reunion or co-existence of almost all the genital organs of both sexes upon one individual.

For the purpose of contrasting and collecting together as much as possible the more analogous cases, we shall arrange the instances of double hermaphroditism under three genera or divisions; the *first* including cases in which there co-existed a female uterus and male vesiculæ seminales, with a general female type; the *second*, those in which a female *uterus*, occasionally provided with Fallopian tubes, was added to an organization that was in other respects essentially male; and the *third* comprehending all examples in which ovaries and testicles are alleged to have been repeated together upon one or both sides of the body. Other divisions of double hermaphroditism may become necessary under the accumulation of new varieties of cases, but we believe it will be possible to arrange all the instances hitherto recorded under one or other of the above divisions. In classifying and describing these instances we shall in the meanwhile offer no observations on the probable anatomical mistakes that have been committed in the examination of individual cases. We reserve this important subject for special consideration under a separate head, where we shall endeavour to shew the numerous sources of error with which the observation of individual examples and varieties of complex hermaphroditism is beset.

1. *Male vesiculæ seminales, &c. superadded to organs of a female sexual type.*—In this first genus of double hermaphroditism we find two female ovaries, or bodies resembling ovaries, and an imperfect uterus co-existing with two male vesiculæ seminales, which are occasionally accompanied also with rudiments of the vasa deferentia. One of the free-martins described by Mr. Hunter* is referable to this variety of double hermaphroditism. The external genital organs and mammæ resembled those of the cow, but were smaller in size. The vagina, beyond the opening of the urethra into it, was, with the uterus itself, impervious. The imperfect uterus divided into two horns, at the end of which were the ovaria. On each side of the uterus there was an interrupted vas deferens broken off in several places; and between the bladder and vagina these vasa deferentia terminated in two vesiculæ seminales. The ducts from the vesiculæ and the vasa deferentia opened into the vagina. In this instance we have all the female organs present, but imperfect in their development; and at the same time there is superadded to them a tubular structure, formed, according to Mr. Hunter's opinion, of the male vesiculæ seminales and vasa deferentia.

We have met with a free-martin cow, in which upon dissection we found an arrangement of sexual parts very similar to that described in the preceding case. The uterus, however, though small, was pervious for a distance of some inches above the vagina; and at the abdominal end of each blind Fallopian tube there was a dilated sac of considerable size lined by peritonæum, and opening into the abdominal cavity by a small orifice. These sacs we considered as abortive attempts at the formation of the fimbriated extremities. The imperfect bodies which we considered as testicles were placed near the cavities which we mention, in the situation of the ovaries. They were small in size, and of an oblong shape. On a section being made of them, they shewed internally a kind of dense homogeneous yellow tissue, dotted or crossed with strongly marked white lines. The vasa deferentia could be traced along each side of the uterus in the form of broken dense cords. The vesiculæ seminales were large and partially hollow, and near them on each side there was an oblong body of considerable size, having the appearance of Cowper's glands. The tubes from them, and from the vesiculæ seminales, opened near the os tincæ into a vagina of nearly the usual size.

2. *An imperfect female uterus, &c. superadded to a sexual organization essentially male.*—In the cases included under this second division of double hermaphroditism there exist a male testicle, or testicles, vasa deferentia, and vesiculæ seminales, along with a female uterus. The uterus occupies its normal situation between the bladder and rectum. It is sometimes defectively developed, and of a membranous structure; and occasionally it is not provided with Fallopian tubes, or, in the quadruped, with cornua. The cavity of the uterus communicates with a vagina that either opens in its usual situation externally, or, as happens more frequently, joins the male urethra. In some cases the vagina is wanting, and the uterus opens directly into the canal of the urethra.

Several cases of sexual malformation in the ram, goat, and dog referable to this variety of double hermaphroditism have been described by different authors; and various analogous instances have now also been observed in the human subject.

In a lamb described and delineated by Mr. Thomas,* all the external parts were male, but the scrotum was divided or hypospadic. Internally there were two perfect male testicles in the situation of the ovaries, with their epididymes, vasa deferentia, and vesiculæ seminales; and a well-formed two-horned uterus furnished with its usual ligaments, and with Fallopian tubes that ran up and terminated in a tortuous convoluted manner upon the testicles. The body of the uterus possessed the common rugose structure, but the horns were lined by a smooth membrane without their usual glandular bodies internally. At the anterior extremity of the fundus uteri, a thick semilunar valve, which seemed to correspond to the os tincæ, passed across and hardly allowed a fine probe to be entered over its upper edge. The vagina scarcely existed, and formed only a short smooth pouch terminating below in a cul-de-sac. The male vesiculæ seminales and vasa deferentia entered the male urethra in their normal situation at the caput gallinaginis.

Gurlt† has described and delineated the sexual parts of a goat in which all the internal male genital organs, with the exception of Cowper's glands, were found (*fig.* 300). There was also present an uterus (*c*) provided with long but narrow and curved cornua (*f f*), that accompanied the vasa deferentia and testicles through the abdominal rings, and ended blind at the epididymes. The testicles lay externally upon the udder, which was of considerable size. The scrotum was absent; the penis (*g*) was short, tortuous, and imperforate; and there was a fissure in the perinæum into which the urethra (*h*) opened.

Stellati‡ has recorded an analogous case in the same animal. The male sexual organs

* See An. Econ. p. 64. Mr. Well's free-martin.

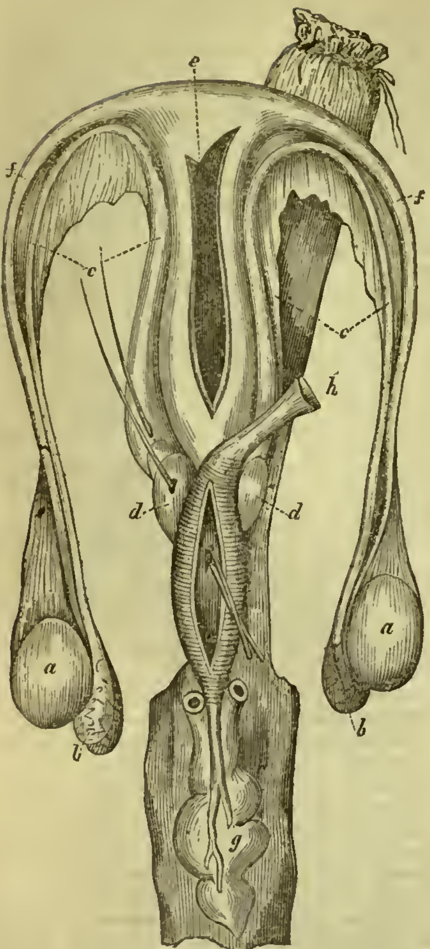
Fig. 300.



a a, the testicles; *b b*, epididymes; *c c*, vasa deferentia; *d d*, vesiculæ seminales.

were not entirely complete, and there were superadded to them a female vagina and an imperfectly developed uterus, the Fallopian tubes of which ran towards the inguinal rings, and terminated with them upon the epididymes of the testicles.

Another instance of hermaphroditic malformation in the goat, detailed at great length by Meckel,* seems also in its principal points justly referable to the present division of cases, although there was at the same time a tendency, in the unequal size of the two cornua uteri, &c., to a degree of lateral hermaphroditism.

Professor Mayer, of Bonn,† has detailed at length the dissection of three hermaphroditic goats, in all of which the conformation of the sexual parts resembled in its more essential parts the preceding cases of Thomas and Gurlt. In all the three instances there were found two male testicles with their epididymes, vasa deferentia, and vesiculæ seminales; and at the same time there was present a well-marked female two-horned uterus, with a vagina opening into the urethra. In the first case the large hollow cornua uteri terminated in blind extremities, and there were only very short impervious rudiments of the Fallopian tubes. In the second case, at the extremity of the right horn of the uterus, a blind appendicula was situated, formed by a vestige (according to Mayer) of the Fallopian tube; and from this a ligament was sent off to the corresponding testicle; a similar ligament, but no appendicula, existed on the left side. In the third case both Fallopian tubes were present, and each ended in a bursa formed by the lamina of the peritonæum, and partly surrounding the testicle and epididymes. In two of the instances the ejaculatory ducts seem to have opened into the urethra near the point at which the vagina terminated in it; and in one of the cases they opened into the canal of the vagina itself before it joined that of the urethra. All the external organs were male, but malformed in so far that the penis was short, and in two of the cases somewhat twisted; and the scrotum was either small or wanting.

The same author* has described the dissection of a dog, the sexual organs of which exhibited a similar variety of hermaphroditic malformation. The Fallopian tubes were pervious throughout in this instance, and at their further extremities opened upon the neighbouring cellular tissue. The body of the two-horned uterus was very small. On compressing the epididymes and vasa deferentia, a fluid resembling semen issued from the openings of the latter into the urethra. The external sexual parts were those of a hypospadic male.

Several cases of hermaphroditic malformation in the human subject, similar in their anatomical characters to the preceding, have been described by Columbus, Harvey, Petit, Ackermann, and Mayer.

a. In a person with external hypospadic male organs, Columbus† found two bodies like testicles in the situation of the ovaries, and larger in size than the latter female organs naturally are. From each of these testiform bodies two sets of tubes arose, one of which, like the male vasa deferentia, passed on to the root of the penis and opened into the urethra; while the other, like the female Fallopian tubes, were inserted into an uterus. The prostate gland was absent.

b. Harvey‡ has mentioned a very small hermaphroditic embryo, on which he found a two-horned uterus with two testicles of a very

† De Re Anat. lib. xv.

‡ De Gen. Anim. Exerc. lxix. p. 304.

small size, and, near the diminutive penis, some traces of a prostate gland.

c. The observation of M. Petit,* of Namur, is still more complete. On the body of a soldier, aged twenty-two, who died of his wounds, and whose external organs appear to have presented no deviation from the male type except in the absence of the testicles from the scrotum, these bodies, with male vasa deferentia, vesiculæ seminales, and a prostate, were found to co-exist with female Fallopian tubes, and an uterus that was attached to the neck of the urinary bladder, and opened into the urethra between this neck and the prostate. The form of this imperfect uterus, M. Petit remarks, merited for it rather the name of a vagina than of an uterus, and it resembled more this organ in the female quadruped than in women. From the body of the uterus, at three inches from its entrance into the urethra, two Fallopian tubes arose. These tubes were perforated, and were three inches and a half long; their abdominal extremities were not loose and provided with fimbriæ, but were attached to a small soft body on each side, occupying nearly the natural situation of the ovaries, but having the substance or structure of the testicles, and provided with an epididymis and vas deferens. The vasa deferentia were each seven inches and a half long, and were attached to two long and rather slender vesiculæ seminales placed alongside of the uterus. The vesiculæ opened into the urethra by two ducts.

In a note appended to this case, M. Petit states that he had been consulted by a man who rendered blood by the penis regularly every month, without pain or any troublesome symptom. Perhaps, adds M. Petit, this man had also a concealed uterus. We have been informed, on credible authority, of two similar cases, the one in a young unmarried man of seventeen years of age, and the other in a person who had been married for several years without his wife having had any children. In both of these cases the discharge was in very considerable quantity, and perfectly regular in its monthly occurrence. Did it consist in a periodical hæmorrhage from the urinary bladder or passages only? or was it, as M. Petit seems to suppose in his instance, of a true menstrual character, and produced by the reproductive organs of the female existing internally, and communicating with the bladder or urethra?

d. Professor Ackermann,† of Jena, published in 1805 the following interesting case of the present variety of hermaphroditic malformation. It occurred in an infant that lived about six weeks after birth. On dissection, two testicles were found; one of them had descended into the scrotum or labium; the other had advanced no further than the groin. Both were perfectly formed, and had their usual appendages complete. In the natural situation of the female uterus, there was found a hollow pyriform organ, which, from its locality and connections, was supposed to be an uterus, though its coats were finer and thinner, and its cavity greater than naturally belongs to that viscus. Duplicatures of peritonæum, resembling the ligamenta lata, connected this imperfect uterus with the sides of the pelvis, and its cavity opened into a kind of short vagina, which soon united with the urethra, and formed one common canal with it (*vagina urethralis*). The vasa deferentia ran from the testicles towards the superior angles of the uterus, and penetrated into its substance at the points where the Fallopian tubes are usually placed. Without opening here, however, they passed onwards under the internal mucous-like membrane of the uterus and vagina, and at length terminated, by very small orifices, in the vagina urethralis. Immediately previous to entering the ligamenta lata, each vas deferens formed a number of convolutions, conglomerated into a mass resembling a vesicula seminalis.

e. Steghlener* has described at great length the case of an infant that survived only for half an hour after birth, and upon whose body he found perfect external male organs (*fig.* 301, *a b*), and internally two small elongated testicles (*c c*), with their epididymes (*g g*), the convolutions of their vasa deferentia (*b b*)

Fig. 301.

* Hist. de l'Acad. Roy. des Sc. for 1720, p. 38.
† Infantis androgyni historia et iconographia, Edinb. Med. and Surg. Journ. vol. iii. p. 202.

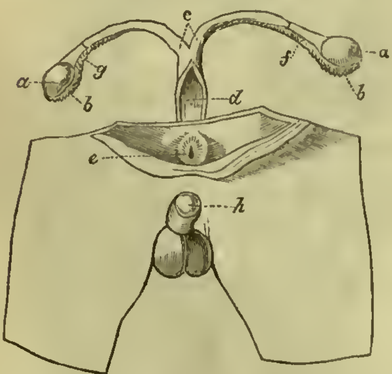
* De Hermaphr. Nat. p. 104.

distinctly marked. Between the rectum and bladder there was placed a very large pear-shaped bag or pouch (*f*), with firm, coriaceous, but not thick walls, and distended with fluid. This bag or imperfect cystoid uterus terminated inferiorly by a narrow neck, in a vagina that opened into the urethra, in the situation of the verumontanum, and was there dilated into a large bag or ampulla, occupying exactly the site of the prostate gland, and resembling this organ also in its form and position. The internal membrane of the uterus was collected at its neck into numerous valvular-like folds, and that of the vagina had also a rugous or plicated arrangement. From the fundus of the large sac of the uterus, and not from its angles, but from near its middle, two impervious solid ducts (Fallopian tubes, or rather vasa deferentia,) arose, and after a somewhat flexuous course reached the testicle (*c c*) lying in the superior part of the iliac fossæ. These ducts had attached to them at one or two points a number of small reddish nodules (*b b*), consisting, according to Steghlener, of glandular granules, and described by Ackermann in his case as vesiculæ seminales. The canal of the urethra was obliterated for a short distance towards the fossa navicularis, and the urinary bladder (*j*) and uterus (*i i*) were extremely distended, and the left kidney (*m*) was vesicular.

Mayer, in the work already referred to,* has described and delineated the following five cases of the present species of hermaphroditic malformation in the human subject, all of which he had himself met with and dissected.

f. In a fœtus of the fourth month, and affected with omphalocele and extroversion of the urinary bladder, he found male testicles (*fig.* 302,

Fig. 302.

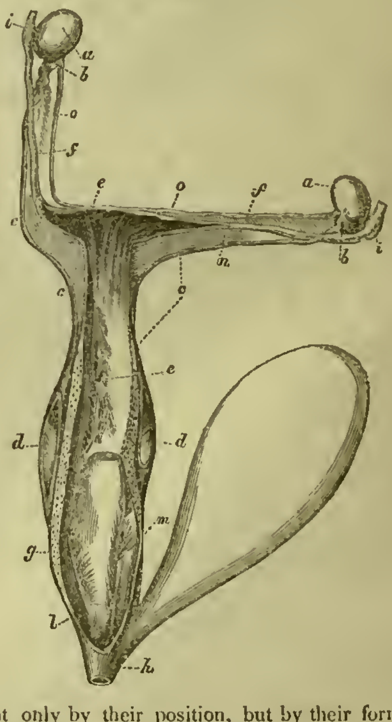


a a) with their epididymes (*b b*), and a two-horned uterus (*c*) terminating in a vagina (*d*), that opened into the posterior part of the urinary bladder (*e*). From the left testicle a contorted vas deferens (*f*) arose, and ran down to the vagina; the right vas deferens (*g*) was shorter, and became thread-like, and disappeared near the corresponding cornu of the uterus. A rudiment only of the left male vesicula seminalis was observable. The external organs were male; the glans penis (*h*) was imperforate.

g. In another fœtus of the sixth month,* there existed a perfect set of internal and external male sexual organs, viz., testicles, epididymes, vasa deferentia, and vesiculæ seminales, with a prostate gland and a normally formed penis and scrotum. But besides these, there was also present an imperfect female uterus, the body of which divided into two cornua, the right longer and incurvated, the left shorter and sacciform. The neck of the uterus was marked internally by its usual arborescent appearance; and it opened into a vagina that terminated in the urethra near the exit of the latter from the urinary bladder.

h. In a third case† of hermaphroditic malformation in an infant who died of convulsions when six months old, Mayer found the following blending of the organs of the two sexes. Of the internal male genital organs there were present two bodies at the inguinal rings that were evidently testicles, (*fig.* 303, *a, a*) as was proved

Fig. 303.



not only by their position, but by their form, coverings, connections, and internal structure, ("their substance," says Mayer, "being evidently composed of yellow canals"); their epididymes (*b b*) were also distinctly developed, and each of them sent off a vas deferens (*c c*), which

* Icones, p. 8. tab. ii. fig. 5.

† Icones, p. 9, tab. iii. fig. 1 and 2.

was furnished with a corresponding multilocular vesicula seminalis (*d d*). Of the internal female sexual organs there were found a perfectly developed uterus (*e e*), with its broad (*n n*) and round (*o o*) ligaments naturally formed and placed, and provided with two Fallopian tubes (*f f*) that followed the course of the testicles through the inguinal canals, and a vagina (*g*) which opened into the urethra (*h*) near its external orifice. The ejaculatory ducts of the male vesiculæ seminales opened into this vagina at *l* and *m*. The internal surface of the vagina was already beginning to present the appearance of its usual rugæ. The cavity of the uterus was triangular, and exhibited on the internal part of the cervix its characteristic plicated or arborescent structure. The Fallopian tubes were, at their uterine orifices, of a large caliber; their cavity afterwards became suddenly contracted, and then again dilated, and terminated at their ulterior extremities, where they lay in contact with the testicles at the external inguinal rings, in blind sacs (*i i*), without any very distinct appearance of fimbriæ. The external genital parts in this very interesting case were of a doubtful nature, being referable either to those of a hypospadic male, or of a female with a large clitoris, but without nymphæ, the meatus urinarius being in its normal situation, but leading behind to the cavities of both the urinary bladder and uterus. The circle of the pelvic bones was large.

i. The two other instances described by Mayer occurred in adult subjects, and the malformation in both of them differed from that found in the cases just now cited in this, that there was only one testicle present along with the imperfect uterus.

The subject of one of these cases* was a person who died at the age of eighteen, and whose external sexual organs were those of a hypospadic male, with a narrow perinæal canal or fissure. On dissection this perinæal canal was found to communicate anteriorly with the urethra, and posteriorly with a vagina of two inches and nine lines in length, and five or six lines in caliber. The anterior and posterior column of rugæ belonging to the vagina was only slightly marked. Its canal led to a large dilated uterus, the superior part of which was unfortunately cut away with some diseased viscera before the genital organs were examined; but, from the portion left, this organ seemed to resemble the uterus of quadrupeds in its oblong form, and in the thinness of its walls, which were composed of a cavernous fibro-vascular texture, and full of lacunæ. The usual arborescent appearance of the internal surface of the os uteri was very perfectly marked. Besides these female organs, there was a well-formed male prostate gland at the neck of the bladder; and behind the abdominal ring of the right side, a small roundish body, similar in form and texture to the testicle, and having the cremaster muscle adhering to its membranous involucrum. There were no traces of any similar organ on the left side. On both sides some portions of a canal were seen, but whether they were the remains of the vasa deferentia or Fallopian tubes was not ascertained on account of the previous mutilation of the uterus. On each side of the neck of the uterus there was placed a vesicula seminalis, provided with an ejaculatory duct that opened into the orifice of the vagina. The dimensions of the pelvis approached much nearer to those of the female than those of the male. In the secondary sexual characters of the individual, the female type was further recognised in the want of prominence in the larynx, in the slender form of the neck, and (according to Professor Mayer) in the rounded shape also of the heart, the smallness of the lungs, the oblong shape of the stomach, the large size of the liver, the narrowness of the forehead, and the conformation of the brain; while the individual approximated, on the other hand, to the male in the length and position of the inferior extremities, in the breadth of the thorax, the undeveloped state of the mammæ and the hairy condition of their papillæ, and in the existence of a slender beard upon the chin and cheeks.

j. In the second adult subject (a person of eighty years of age) Mayer* found, on the left side of the cavity of the abdomen, and near the inguinal ring, a small oval body exhibiting imperfectly in its internal structure the tubular texture of the male testicle, and having an appendix resembling the epididymis attached to it. From this testicle arose a vas deferens, which was joined in its course by a vesicula seminalis, and ended in an ejaculatory duct. On the opposite or right side a vesicula seminalis, having no continuous cavity, was present; but no vestige of a corresponding testicle, vas deferens, or ejaculatory duct could be discovered. The prostate gland was present, and regularly formed. In the cavity of the pelvis an uterus was found with parietes of moderate thickness, and of the usual cavernous texture; its cervix was marked internally with the appearance of the natural arborescent rugæ. Inferiorly it opened into a narrow membranous vagina, that received the right ejaculatory duct, then passed through the body of the prostate, and latterly joined the canal of the urethra. The fundus of the uterus could not be examined, as it had been removed in a previous stage of the dissection. The external parts were male and naturally formed, with the exception of the penis, which was shorter than usual, and had the canal of the urethra fissured inferiorly, and the meatus urinarius situated at its root. The individual was during life regarded as a male, but had all along remained in a state of celibacy. The general appearance of the face and body was that of an imperfectly marked male, but the pelvis was broad like that of a female.

3. *Co-existence of female ovaries and male testicles.*—This third division of complex or double hermaphroditism includes all those cases in which a male testicle and female ovary exist together either upon one side only, or upon

* Icones, p. 11. tab. iii. fig. 3 and 4.

* Icones, p. 15, tab. iv. fig. 1 and 2.

both sides of the body. With this arrangement, other malformations by duplicity of the sexual organs are generally combined; but these are so various in their character as not easily to admit of any useful generalization. In considering this third division of complex hermaphroditism, we shall mention, *first*, the cases in which *two* testicles and *one* ovary are stated to have co-existed; and *secondly*, those in which there have been supposed to be present *two* testicles and *two* ovaries.

Two testicles and one ovary.—The two dissections that we have previously detailed of lateral hermaphroditic insects, (see *Lateral Hermaphroditism*, p. 696,) shew that in these two cases this variety of sexual duplicity existed. It appears to have been observed also in two instances of hermaphroditic malformation in the quadruped, the histories of which have been described by Mascagni and Mayer.

In a bull, nine years of age, and which was provided with the usual external organs of the male, Mascagni found internally, on dissection, a prostrate gland and two perfect vesiculæ seminales, vasa deferentia, epididymes, and testicles. The testicles and epididymes were injected with mercury through the vasa deferentia. In addition there was discovered near the left testicle, and connected to it by peritonæum and bloodvessels, a body having the structure of the female ovary; and, in its normal situation, there existed a distended double uterus, containing from fifteen to sixteen pounds of a clear fluid. This uterus was furnished with two Fallopian tubes at its upper part, and terminated inferiorly in a vagina, which opened by a small orifice into the male urethra.*

In a goat dissected by Mayer,† he found two testes with their epididymes fully developed, and vasa deferentia and vesiculæ seminales. One of the testes was placed without and the other still remained within the abdominal cavity. At the same time there were present a large female vagina communicating with the urethra, and a double-horned uterus provided with two Fallopian tubes. One of these tubes terminated in a blind canal, but the other had placed at its abdominal extremity several vesicles, resembling, according to Mayer, Graafian vesicles, or an imperfect ovary. The vesiculæ seminales and (through regurgitation by the urethra and ejaculatory ducts) the cavities of the vagina and uterus, were filled with about four ounces of a whitish fluid, having the colour and odour of male semen. This fluid could not be found by the microscope to contain any seminal animalcules, but only simple and double Monades (*Monades termones et guttulas*). Bergmann, however, is alleged to have found it, on analysis, to contain the same chemical principle that characterizes human male semen.

Two testicles and two ovaries.—Various instances have now been published in which this sexual duplicity has been supposed to exist among cattle and other domestic quadrupeds, as well as in the human subject.

One of the free-martins* described by Mr. Hunter comes under this variety. In the case referred to, in the situation of the ovaries "were placed," to use Mr. Hunter's words, "both the ovaria and testicles,"—or, as Sir Everard Home, in alluding to this case, more justly expresses it, "an appearance like both testicles and ovaria was met with close together."† The two contiguous bodies were nearly of the same size, being each about as large as a small nutmeg. There were no Fallopian tubes running to the ovaries, but a horn of an imperfect uterus passed on to them on each side along the broad ligament. Pervious vasa deferentia were found; they did not, however, reach up completely to the testicle on either side, or form epididymes. The vesiculæ seminales were present, and much smaller than in the perfect bull. The external parts appear to have been those of the cow, but smaller than natural. The vagina passed on, as in the cow, to the opening of the urethra, and, after having received it and the orifices of the seminal ducts, it began to contract into a small canal, which ran upwards through the uterus to the place of division of that organ into its two horns.

Velpeau,‡ in his work on Midwifery, mentions that in an embryo calf, he had "found reunited the testicles and ovaries, the vasa deferentia, and uterus."

In an hermaphroditic foal-ass, Mr. Hunter§ found both what he considered to be two ovaries placed in the natural situation of these bodies, and two testicles lying in the inguinal rings in a process or theca of peritonæum similar to the tunica vaginalis communis in the male ass. No vasa deferentia or Fallopian tubes could be detected; but there was a double-horned uterus present, and from its broad ligaments, (to the edges of which the cornua uteri and ovaries were attached,) there passed down on either side into the inguinal rings a part similar to the round ligament in the female. The horns and fundus of the uterus were pervious; but its body and cervix, and the canal of the vagina from above the opening of the urethra into it, were imperforate. The external parts were similar to those of the female ass; but the clitoris, which was placed within the entrance of the vagina, was much larger than that of a perfectly formed female; it measured about five inches. The animal had two nipples.

Scriba has given an account‖ of an hermaphroditic sheep, in which two large testicles are stated to have been found in the scrotum, at the same time that there existed, in their normal situation, two moderately sized ovaries, and a small uterus furnished with two apparently closed Fallopian tubes. The external sexual parts appear to have been those of a

‖ Schriften der Gesellschaft Naturforschender Freude zu Berlin, Bd. x. s. 367.

malformed male, the penis being short and impervious, the scrotum divided, and the urethra opening into a contracted perinæal fissure resembling the female vulva. This animal had often attempted connection with the female sheep.

Borkhausen* has described a very similar case in the same species of animal. Each half of the divided scrotum contained a testicle which was regularly formed, but greater in size than usual, and furnished with a large spermatic artery. The pelvis contained a normal uterus, which was smaller, however, than natural; it was provided with its usual ligaments. The Fallopian tubes were present but imperforate, and the two ovaries were full of vesicles and inclosed in a strong membrane. The vagina was natural and opened as in the female. Behind the divided scrotum the rudiment of an udder with four teats (instead of two) was situated. The male penis was also present, but diminutive and short; its erectores muscles were small, and the prostate gland indistinct. The urethra was single as it left the bladder, but it afterwards divided into two canals, the wider of which opened into the female vagina and vulva, and the narrower ran through the male penis. The urine passed in a full stream through the former canal, and only by drops through the latter. The animal is alleged to have attempted coition in both ways.

In 1829, an account of an hermaphroditic goat was published at Naples, which is said to have been provided with both female ovaries and male testicles.† The two ovaries occupied their usual situation; no Fallopian tubes were found; but there were present a double-horned uterus with blind cornua, and a vagina which opened externally, as in the female. In the neighbourhood of the ovaries, and more external than them, two small testicles were discovered, having two vasa deferentia arising from them. The vasa deferentia ran downwards to two corresponding vesiculæ seminales, that were placed alongside of the uterus. In the lower angle of the external pudenda, a body, resembling in length the male penis more than the female clitoris, was situated: it was, as we have already had frequently occasion to mention in regard to the penis in malformed male quadrupeds, of a very tortuous or convoluted form.

We have had an opportunity of examining an excellent preserved specimen of double hermaphroditism in the sow, referable to the present section, which was met with some years ago by Dr. Knox, and we have his permission to state here the following particulars of the case.

Among the internal female organs there is present a natural well-formed double uterus, provided with broad ligaments and two hollow cornua, each about six or seven inches in length. The fimbriated extremities are not distinctly marked, the female tubes appearing to end blind at their upper terminations, as they have often been observed to do in similar cases. The os uteri opens inferiorly into a vagina, which seems normal in its structure. At a short distance from the upper extremity of each horn of the uterus, two bodies of considerable magnitude are seen lying in close juxta-position. The smaller of these two bodies is on either side about the size and shape of a large almond; and though internally of an indeterminate amorphous structure, they are considered by Dr. Knox as answering to the two ovaries. The two larger bodies, which are placed *between* the supposed ovaries and the upper extremities of the cornua uteri, are most distinctly testicles, as shewn by their numerous tortuous seminiferous tubes, which have been successfully filled with a mercurial injection. They are of the full size of the organ in the adult male. The seminiferous tubes of each testicle terminate in a vas deferens, which was injected from them; and the two vasa deferentia run downwards through the ligamenta lata of the uterus, and terminate inferiorly in the upper part of the vagina, thus following the course of those natural canals in the female sow that we shall afterwards have occasion to allude to at greater length under the name of Gaertner's ducts, and which Dr Knox, from the evidence of the present case, believes to be in reality typical of the male vasa deferentia. There is no trace of vesiculæ seminales. Externally the vagina opened along with the urethra upon the perinæum, at a point lower than natural in the well-formed female. The clitoris in situation and size was nearly normal.

The animal at the time of death was fourteen months old; it was ferocious in its habits; and it had been in vain tried to be fattened. It had repeatedly shewn strong male propensities, and at the season of heat its vagina is said to have presented the usual injected appearance observed in the female sow.

Dr. Harlan of Philadelphia* has lately described a still more perfect instance of double hermaphroditism than any of the preceding, which he met with in the body of a gibbon or orang outang, from the Island of Borneo (*Simia concolor*). This animal died of tubercular disease in Philadelphia in 1826, when it was considered to be under two years of age. Dr. Harlan gives the following account of its sexual formation. The penis (*fig.* 304, *a*) was about one inch in length, and subject to erections; it terminated in an imperforate glans; and a deep groove on its inferior surface served as a rudimentary urethra. This groove extended about two-thirds of the length of the penis, the remaining portion being covered with a thin articular diaphanous membrane, which extended also across the vulva (*b*), and closed the external orifice of the vagina. The vagina was rather large, and displayed transverse striæ. Traces of the nymphæ and labia externa were visible. The meatus urinarius opened beneath the pubis into the vagina, but the urine must have been directed along the groove of the penis by the

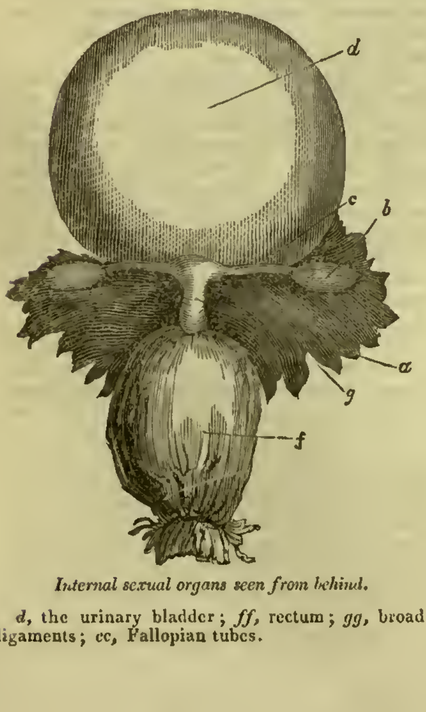
membrane obstructing the orifice of the vulva. The os tincæ was surrounded by small globular glands. The orifice and neck of the uterus admitted a large probe into the cavity of that organ, which appeared perfect with all its appendages. The round and broad ligaments, together with well-developed ovaries (*fig.* 305, *b b*), were all found in situ. The scrotum

Fig. 305.



Internal sexual organs seen from behind.

d, the urinary bladder; *ff*, rectum; *gg*, broad ligaments; *cc*, Fallopian tubes.

(*fig.* 304, *c*) was divided, and consisted of a sac on each side of the labia externa, at the base of the penis, covered with hair. The testicles (*fig.* 304, *d d*) lay beneath the skin of the groin about two inches from the symphysis pubis, obliquely outwards and upwards: they appeared to be perfectly formed with the epididymis (*f f*), &c. The most accurate examination could not discover vesiculæ seminales; but an opening into the vagina, above the meatus urinarius, appeared to be the orifice of the vas deferens. In all other respects the male and female organs of generation were in this animal as completely perfected as could have been anticipated in so young an individual, and resembled those of other individuals of a similar age.

Two imperfect instances are on record of the co-existence of male testicles and female ovaries in the human subject.

a. The first of these cases is detailed by Schrell.* It occurred in an infant who died when nine months old. All the internal and external male organs were present and perfectly formed, with the exception of the prepuce of the penis, which seemed divided in front and rolled up. At the root of the large penis, was a small vulva or aperture capable of admitting a pea, and provided with bodies having an appearance of labia and nymphæ. This vulva led into a vagina that penetrated through the symphysis pubis, and terminated in a nipple-like body or imperfect uterus, to which, structures having a resemblance to the Fallopian tubes and ovaries were attached.

b. The other and still more doubtful case of the alleged existence of both testicles and ovaries in the human subject, was first published by Beclard.† The case was met with by M. Laumonier of Rouen, who injected and dissected the sexual parts, and deposited them in a dried state, along with a wax model representing them in their more recent condition, in the Museum of the School of Medicine at Paris. In the wax model two female ovaries with an uterus, vagina, external vulva, and large imperforate clitoris, are seen combined with two male testicles, the vasa deferentia of which terminate in the uterus at the place at which the round ligaments are normally situated; these ligaments themselves are wanting. The preparation of the dried sexual parts is far from being equally satisfactory, and, in its present imperfect condition at least, does not bear out by any means the complete double hermaphroditic structure delineated in the model.

III. HERMAPHRODITISM AS MANIFESTED IN THE GENERAL CONFORMATION OF THE BODY, AND IN THE SECONDARY SEXUAL CHARACTERS.

In the preceding observations we have principally confined ourselves to the description of hermaphroditic malformations as seen in the resemblance in appearance and structure of the

* Schenk's Medic. Chirurg. Archiv. Bd. i. s.

† Bullet. de la Fac. de Méd. 1815, p. 284; or, Dict. des Sc. Méd. xxi. p. 111.

external genital parts of one sex to those of the other, and in the different degrees and varieties of reunion or co existence of the reproductive organs of the two sexes upon the body of the same individual. Hermaphroditism, however, may appear not only in what are termed the *primary* sexual parts or characters, or, in other words, in the organs more immediately subservient to copulation and reproduction, but it may present itself also in the *secondary* sexual characters, or in those distinctive peculiarities of the sexes that are found in other individual parts and functions of the economy, as well as in the system at large. We have occasionally an opportunity of observing some tendency to an hermaphroditic type in the general system, without there being any very marked corresponding anormality in the sexual organs themselves, but it rarely happens that there exists any hermaphroditic malformation of the primary organs of generation, without there being connected with it more or less of an hermaphroditic type in the secondary sexual characters; and this circumstance often offers us, in individual doubtful cases, a new and perplexing source of fallacy in our attempts to determine the true or predominating sex of the malformed individual. Before, however, describing that variety of hermaphroditism which manifests itself in the general system and in the secondary sexual peculiarities, it will be necessary, in order to understand its nature and origin, to premise a few remarks on the dependence and relation of these secondary characters upon the normal and abnormal conditions of the primary sexual organs.

That the various secondary sexual peculiarities which become developed at the term of puberty are intimately dependent upon the changes that take place at the same period in the organism of the female ovaries and male testicles, seems proved by various considerations, particularly by the effect produced by original defective development and acquired disease in these parts, and by the total removal of them from the body by operation. In considering this point we shall speak first of the effects of the states of the ovaries upon the female constitution, and shall then consider those of the testicles upon the male.

When the usual development of the ovaries at the term of puberty does not take place, the secondary sexual characters which are naturally evolved in the female at that period do not present themselves; and this deficiency sometimes occasions an approach in various points to the male formation. Thus in a case recorded by Dr. Pears,* of a female who died of a pectoral affection at the age of twenty-nine, the ovaries on dissection were found rudimentary and indistinct, and the uterus and Fallopian tubes were present, but as little developed as before puberty. This individual had never menstruated nor shewed any signs, either mental or corporeal, of puberty. The mammæ and nipples were as little developed as those of the male subject. She had ceased to grow at ten years of age, and attained only the height of four feet six inches.

* Phil. Trans. for 1805, p. 225.

In another analogous instance observed by Renauldin,* scarcely any rudiments of the ovaries existed, and the body of the uterus was absent, but the external genital female organs were well formed. The individual who was the subject of this defective sexual development had never menstruated; the mammæ were not evolved; in stature she did not exceed three and a half French feet; and her intellect was imperfectly developed.

In reference to these and other similar instances that might be quoted,† it may be argued that they do not afford any direct evidence of the evolution of the sexual characters of the female depending upon that of the ovaries, as the arrestment in the development of both may be owing to some common cause which gives rise at the same time to the deficiency in the development of the genital organs, and to the stoppage of the evolution of the body in general. That the imperfection, however, in the organism of the ovaries may have acted in such cases as the more immediate cause or precedent of the imperfection or non-appearance of the secondary characters of the sex, seems to be rendered not improbable, in regard to some, if not to all the instances alluded to, by the fact that the removal of these organs before the period of puberty, as is seen in spayed female animals, entails, upon the individuals so treated, the same neutral state of the general organization as was observed in the above instances; or, in other words, we have direct evidence that the alleged effect is capable of being produced by the alleged cause; and further, when in cases of operation or disease after the period of puberty, both ovaries have happened to be destroyed, and their influence upon the system consequently lost, the distinctive secondary characteristics of the female have been observed also to disappear in a greater or less degree.

Thus in the well-known case recorded by Mr. Pott,‡ the catamenia became suppressed, the mammæ disappeared, and the body became thinner and more masculine, in a healthy and stout young woman of twenty-three years of age, whose two ovaries formed hernial tumours at the inguinal rings, and were, in consequence of their incapacitating the patient from work, both removed by operation.

Many facts seem to show that the act of menstruation most probably depends upon some periodical changes in the ovaries, if not, as Dr. Lee§ supposes, in the Graafian vesicles of these organs; and when the function becomes suddenly and permanently stopped in a

* Seances de l'Acad. Roy. de Méd. 28 Fevrier 1826, and Medical Repository for 1826, p. 78.

† Davis, in his Principles and Practice of Obstetric Medicine, p. 513, refers to several instances in point. We may mention that Dr. Haighton found that after the Fallopian tubes were divided in rabbits, the ovaries became gradually atrophied, and the sexual feelings were lost. Phil. Trans. for 1797, p. 173.

‡ Surgical Works, vol. iii. p. 329.

§ Article OVARY in Cyclo. of Pract. Med.

woman at the middle period of life, without any indications of the catamenial fluid being merely mechanically retained, we may perhaps suspect with reasonable probability the existence of a diseased state which has destroyed either successively or simultaneously the functions of both ovaries. In such a case the distinctive secondary peculiarities of the female sex come to give place to those of the male. Thus Vaulevier mentions an instance in which menstruation suddenly ceased in a young and apparently healthy woman; no general or local disease followed; but soon afterwards a perfect beard began to grow upon her face.* Again, in women who have passed the period of their menstrual and child-bearing life, and in whom consequently the functions and often the healthy structure of the ovaries are lost or destroyed, we have frequently an opportunity of observing a similar tendency towards an assumption of some of the peculiarities of the male; an increase of hair often appears upon the face, the mammæ diminish in size, the voice becomes stronger and deeper toned, the elegance of the female form and contour of body is lost, and frequently the mind exhibits a more determined and masculine cast. Women, both young and aged, with this tendency to the male character, are repeatedly alluded to by the Roman authors under the name of *viragines;* and Hippocrates† has left us the description of two well-marked instances.

Among the females of the lower animals a similar approach to the male character in the general system not unfrequently shows itself as an effect both of disease and malformation of the sexual organs, and also in consequence of the cessation of the powers of reproduction in the course of advanced age. Female deer are sometimes observed to become provided at puberty with the horns of the stag,‡ and such animals are generally observed to be barren,* probably in consequence either of a congenital or acquired morbid condition of their ovaries or other reproductive organs. In old age, also, after the term of their reproductive life has ceased, female deer sometimes acquire the horns of the male in a more or less perfect degree;† and Burdach alleges that roes sometimes become provided with short horns when they are kept from the male during the rutting season, and at the same time furnished with abundant nourishment.‡ Mehliss§ alludes to two cases in which a virilescent type was shewn principally in the hair of the female deer. In one of these instances the hair of the head, neck, and abdomen, the shape of the ears and extremities, and the odour of the animal, gave it the closest resemblance to the male, and it followed the other females as if urged by sexual desire.

This kind of acquired hermaphroditism in aged females has, however, been more frequently and carefully attended to as it occurs in Birds than as met with among the Mammalia, the change to virilescence in the former being more marked and striking than in the latter, owing to the great difference which generally exists between the plumage of the male and female.‖ When old female birds live for any considerable period after their ovaries have ceased to produce eggs, they are usually observed to assume gradually more or less of the plumage and voice, and sometimes the habits also of the male of their own species. This curious fact, first pointed out by Aristotle¶ in relation to the domestic fowl, has now been seen to occur in a number of other species of birds, but particularly among the Gallinaceæ. It has been in modern times remarked in the common fowl *(Phasianus gallus)* by Tucker, Butler, and Jameson; in the common pheasant *(P. colchicus)* by Hunter and Isidore St. Hilaire; in the golden pheasant *(P. pictus)* by Blumenbach and St. Hilaire; in the silver pheasant *(P. nychemerus)* by Bechstein and St. Hilaire; in the turkey *(Meleagris)* by Bechstein; in the pea-hen *(Pavo)* by Hunter and Jameson; and in the partridge *(Tetrao perdrix)* by Montagu and Yarrell. Among the Cursores it is mentioned as having occurred in the bustard *(Otis)* by Tiedemann, and in the American pelican *(Platalea aiaia)* by Catesby. In the order Palmipedæ it has been observed by Tiedemann and Rumball in the

‖ It occurs also more frequently among birds than among mammalia, from the former possessing only a single ovary.

¶ "Gallinæ, cum vicerint gallos, concurrunt maresque imitandi subagitare conantur. Attollitur etiam crista ipsis, simul et clunes (uropygium); adeo ut jam non facile diagnoscantur an fœminæ sint. Quibusdam etiam calcaria parva surriguntur." Hist. Animal. lib. ix. cap. 36.

domestic and wild duck *(Anas boscha)*. Among the Scansores it has been seen in the cuckoo *(Cuculus canorus)* by Payraudeau; and among the Passeres in the cotinga *(Ampelis)* by Dufresne; in the chaffinch *(Fringilla)* and *rougequeue (Motacilla)* by Prevost; and in the bunting *(Emberiza paradisæa* and *longicauda)* by Blumenbach.

This change of plumage in old female birds commences, according to M. Isidore St. Hilaire,* much sooner in some instances than in others; it may only begin to show itself several years after the bird has ceased to lay, though depending more or less directly upon this phenomenon, and sometimes it commences immediately after it. The change may be effected in a single season, though in general it is not complete for some years. When it is perfected, the female may display not only the variety of colours, but also the brilliancy of the male plumage, which it sometimes resembles even in its ornamental appendages, as in the acquisition of spurs, and, in the domestic fowls, of the comb and wattles of the cock. The voice of the bird is also very generally changed. Its female habits and instinct are likewise often lost; and, in some instances, it has been seen to assume in a great degree those of the male, and has even been observed to attempt coition with other females of its own species † In most of the female birds that have undergone this change, the ovary has been found entirely or partially degenerated, though in a few cases the morbid alteration is not very marked, eggs having even been present in the organ in one or two instances. In general, however, it is greatly diminished in size, or has become altogether atrophied; but the perfection of the change in the plumage does not seem to bear any direct ratio with the degree of morbid alteration and atrophy in the ovary.

That the changes towards the male type, described as occasionally occurring in old female birds, is directly dependent, not upon their age, but upon the state of the ovaries in them, seems still further proved by similar changes being sometimes observed in these females long previous to the natural cessation of the powers of reproduction, in consequence of their ovaries having become wasted or destroyed by disease. Greve,‡ in his Fragments of Comparative Anatomy and Physiology, states that hens whose ovaries are scirrhous crow sometimes like cocks, acquire tail-feathers resembling those of the male, and become furnished with large spurs. The same author mentions also the case of a duck, which, from being previously healthy, suddenly acquired the voice of the male, and on dissection its ovary was found hard, cartilaginous, and in part ossified.

Mr. Yarrell, in a paper read before the Royal Society in 1827,* has stated that in a number of instances he had observed young female pheasants with plumage more or less resembling the male, and in all of them he found on dissection the ovaries in a very morbid state, and the oviduct diseased throughout its whole length, with its canal obliterated at its upper part. He also shews that a similar effect upon the secondary sexual characters of the female bird is produced by the artificial division and removal of a small portion of their oviduct in the operation of making capons of female poultry; and he states that his investigations have led him to believe that in all animals bearing external characters indicative of the sex, these characters will undergo a change and exhibit an appearance intermediate between the perfect male and female, wherever the system is deprived of the influence of the true sexual organs, whether from original malformation, acquired disease, or artificial obliteration.†

From the frequency with which castration is performed, the effects of the testicles in evolving the general sexual peculiarities of the male have been more accurately ascertained than those of the ovaries upon the female constitution. These effects vary according to the age at which the removal of the testicles takes place. When an animal is castrated some time before it has reached the term of puberty, the distinctive characters of the male are in general never developed; and the total absence of these characters, together with the softness and relaxation of their tissues, the contour of their form, the tone of their voice, and their want of masculine energy and vigour, assimilate them more in appearance and habits to the female than to the male type. If the testicles are removed nearer the period of puberty, or at any time after that term has occurred, and

* Edinburgh Journ. of Philosoph. Science, (1826) p. 308.

† Rumball, in Home's Comparative Anatomy, vol. iii. p. 330, states having observed an old duck which had assumed the male plumage, attempt sexnal connection with another female. This may perhaps enable us to understand tho reputed cases of hermaphroditism in women, who, as related by Mollerus (Tract. de Hermaphr. cap. ii.) and Blancard, (Collect. Medico-Phys. cent. iii. obs. 80,) after having themselves borne children became addicted to intercourse with other females. Of coorse we cannot give our credence to tho alleged successful issue of such intercourse.

Trans. for 1827, p. 268, with a drawing of the diseased ovaries, &c.

when the various male sexual peculiarities have been already developed, the effect is seldom so striking; the sexual instincts of the animal, and the energy of character which these instincts impart, are certainly more or less completely destroyed, and the tone of the voice is sometimes changed to that of puberty; but the general male characteristics of form, such as the beard in man, and the horns in the Ruminantia, most commonly continue to grow. In animals, such as the stag, which possess deciduous horns, the removal of the testicles during the rutting season causes the existing horns to be permanent; and if the operation is performed in an adult animal when out of heat, no new horns in general appear.* In the ox, the effect of castration upon the growth of the horns, even when performed before the time of puberty, is quite remarkable; for instead of having their development altogether stopped, or their size at least diminished by the operation, as occurs in the ram and stag, the volume of these appendages is even increased by the operation, the horns of the ox being generally larger but less strong than those of the entire bull. Castration in the boar causes, according to Greve,† the tusks to remain small, and prevents altogether the replacement of the teeth. This author also states that the same operation on the horse prevents the full development of the neck, renders the teeth smaller and slower in their growth, increases the growth of the hair, and the size of the horny protuberances on the inside of the legs. The prostate gland, he further alleges, as well as the vesiculæ seminales, become augmented as much as a third in their volume in consequence of the operation.‡

The removal of the testicles both before and after the period of puberty commonly gives rise to another singular effect,—to an increased deposition of fat over the body, as has already been mentioned in the article Adipose Tissue, and from this circumstance the general form of the body, and in man that of the mammæ, is sometimes modified in a degree that increases the resemblance to the opposite sex. In the sterile of both sexes in the human subject an unusual corpulency is not uncommon, and the same state is often met with in old persons, and particularly in females, after the period of their child-bearing life is past.

The nature of the effects produced by the existence and functional activity of the testicles and ovaries upon the development of the secondary sexual characters of the male and female, may be further illustrated by what occurs in the season of heat to animals such as the deer, sheep, birds, &c. that have periodical returns of the sexual propensity. At these periods all the distinctive general characters of the sexes become much more prominently developed, in conjunction with, and apparently in consequence of, the changes which have been ascertained by observation to occur at that time in the relative size and activity of the internal organs of generation. Thus with the return of the season of sexual instinct the dorsal crests and cutaneous ear-lobes of tritons enlarge; in Batrachian Reptiles the spongy inflations of the thumbs become increased in size; the various species of singing birds reacquire their vocal powers; and some, as the cuckoo and quail, appear capable of exercising their voice only at this period of the year. At the pairing season also the plumage of birds becomes brighter in tint, and in some instances is in other respects considerably changed, as in the male ruff *(Tringa pugnax)*, who then reassumes the tuft of feathers upon his head and neck, and the red tubercles upon his face that had fallen off during the moulting, and thus left him more nearly allied in appearance to the female during the winter. In reference to this subject, it appears to us interesting to remark, that in certain birds, as in the different species of the genus Fringilla, the male presents in winter a plumage very similar to that of the female,* and in the present inquiry it is important to connect this fact with the very diminutive size and inactive condition of the testicles of these birds at that season. (See Aves.)

From the remarks that we have now made upon the influence of the ovaries and testicles in developing the general sexual peculiarities of the female and male, it will be easy to conceive that when, in cases of malformation of the external genital organs giving rise to the idea of hermaphroditism, there is at the same time, as sometimes happens, a simultaneous want of development in the internal organs of reproduction, particularly in the ovaries and testicles, the general physical and moral peculiarities distinctive of the sex of the individual may be equally deficient, or have a tendency even to approach in more or fewer of their points to those of the opposite sexual type. In this way we may, it is obvious, have *general* or constitutional hermaphroditic characters, if they may be so termed, added to those already existing in the *special* organs of generation, and rendering more difficult and complicated the determination of the true sex of the malformed individual. Some cases of spurious hermaphroditism in the male published by Sir E. Home† may serve to illustrate this remark.

A marine soldier, aged twenty-three, was admitted a patient into the Royal Naval Hospital at Plymouth. He had been there only a few days, when a suspicion arose of his being a woman, which induced Sir Everard to examine into the circumstances. He proved to have no beard; his breasts were fully as large as those of a woman at that age; he was inclined to be corpulent; his skin was uncommonly soft for a man; his hands were fat and short, and his thighs and legs very much like those of a woman: the quantity of fat upon

† Comp. Anat. vol. iii. p. 320.

the os pubis resembled the mons veneris; and in addition he was weak in his intellect, and deficient in bodily strength. The external genital organs shewed him to be a male, but the penis was unusually small, as well as short, and not liable to erections; the testicles were not larger in size than they commonly are in the fœtal state; and he had never felt any passion for the opposite sex.

The following cases by the same author strongly illustrate this subject.* In a family of three children residing near Modbury in Devonshire, the second, a daughter, was a well-formed female, the eldest and youngest were both malformed males. The eldest was thirteen years of age. His mons veneris was loaded with fat; no penis could be said to be present, but there was a præputium a sixth of an inch long, and under it the meatus urinarius, but no vagina. There was an imperfect scrotum with a smooth surface, there being no raphé in the middle, but, in its place, an indented line; it contained two testicles, of the size that they are met with in the fœtus. His breasts were as large as those of a fat woman. He was four feet high, and of an uncommon bulk, his body round the waist being equal to that of a fat man, and his thighs and legs in proportion. He was very dull and heavy, and almost an idiot, but could walk and talk; he began to walk when a year and a half old. The younger brother was six years old, and uncommonly fat and large for his age. He was more an idiot than the other, not having sense enough to learn to walk although his limbs were not defective.

A case in a similar manner confirmatory of the preceding remarks is mentioned by Itard de Riez.† A young man, aged twenty-three, had no testes in the scrotum, a very small penis, not capable of erection, and a divided scrotum. He was in stature below the middle size. His skin was soft, smooth, and entirely free from hair, the place of the beard being supplied by a slight down. The voice was hoarse; the muscles were not well marked; the form of the chest resembled that of the female, and the pelvis was extremely broad and large. The intellectual faculties were very dull, and the sexual appetite was entirely wanting.

Renauldin, also, in the same work,‡ has recorded another case in point. In a soldier of twenty-four years of age, whose genital organs were extremely undeveloped, his penis being only of the size of a small tubercle, and his testicles not larger than small nuts, the pelvis was broad; the chest narrow; the face and body in general were not covered with hair, with the exception of a small quantity upon the pubis; the voice was feminine, and the mammary glands were as perfectly developed as in the adult female. The body of this individual was rather lean than otherwise. The mammæ had begun to enlarge when his body attained to its full stature at sixteen years of age. He had all the habits and sexual desires of the male sex.

† Mémoires de la Société Méd. d'Emulation, tom. iii. p. 293-5.

‡ Tom. i. p. 241.

In quadrupeds as in man, when the testicles or ovaries are imperfectly formed, the secondary sexual peculiarities are frequently so defectively evolved as to offer a kind of hermaphroditic or neutral type in the general configuration and characters of the animal. Thus, the free-martin does not present an exact analogy in form either with the bull or cow, but exhibits a set of characters intermediate between both, and more nearly resembling those of the ox and of the spayed heifer. In size it resembles the castrated male and spayed female, being considerably larger than either the bull or the cow, and having horns very similar to those of the ox. Its bellow is similar to that of the ox, being more analogous to that of the cow than of the bull. Its flesh, like that of the ox and spayed heifer, is generally much finer in its fibre than the flesh of either the bull or cow, and is supposed to exceed even that of the ox and heifer in delicacy of flavour.*

The consideration of the various facts that we have now stated inclines us to believe that the natural history characters of any species of animal are certainly not to be sought for solely either in the system of the male or in that of the female; but, as Mr. Hunter pointed out, they are to be found in those properties that are common to both sexes, and which we have occasionally seen combined together by nature upon the bodies of an unnatural hermaphrodite; or evolved from the interference of art, upon a castrated male or spayed female. In assuming at the age of puberty the distinctive secondary peculiarities of his sex, the male, as far as regards these secondary peculiarities, evidently passes into a higher degree of development than the female, and leaves her more in possession of those characters that are common to the young of both sexes, and which he himself never loses, when his testicles are early removed. These and other facts connected with the evolution of both the primary and secondary peculiarities of the sexes further appear to us to shew that, physiologically at least, we ought to consider the male type of organization to be the more perfect as respects the individual, and the female the more perfect as respects the species. Hence we find that, when females are malformed in the sexual parts so as to resemble the male, the malformation is almost always one of excessive development, as enlargement of the clitoris, union of the labia, &c.; and, on the other hand, when the male organs are malformed in such a manner as to simulate the female, the abnormal appearance is generally capable of being traced to a defect of development, such as the want of closure of the perinæal fissure, and of the inferior part of the urethra, diminutive size of the penis, retention

* Hunter's Obs. on the An. Econ. p. 60.

of the testicles in the abdomen, &c. In the same way, when the female assumes the secondary characters of the male, it is either, first, when by original malformation its own ovaries and sexual organs are so defective in structure as not to be capable of taking a part in the function of reproduction, and of exercising that influence over the general organization which this faculty imparts to them; or, secondly, when in the course of age the ovaries have ceased to be capable of performing the action allotted to them in the reproductive process. In both of these cases we observe the powers of the female organization, now that its capabilities of performing its particular office in the continuation of the species are wanting or lost, expend themselves in perfecting its own individual system, and hence the animal gradually assumes more or fewer of those secondary sexual characters that belong to the male.

We do not consider it subversive of the preceding view to qualify it with the two following admissions,—1st, that, owing to the energies of the female system being so strongly and constantly directed towards the reproductive organs, and the accomplishment of those important functions which these organs have to perform in the economy of the species, the general characters of the species may be developed in her body in a degree *less* than they otherwise would be, or than actually constitutes the proper standard of the species; and, 2dly, in consequence of the peculiarities of the sexual functions of the female, some of the individual organs of her system, as the mammæ, are evolved in a degree *greater* than is consonant with the standard characters of the species. At the same time we would here remark that the occasional enlarged condition of the mammæ in hermaphrodites in whom the male sexual type of structure predominates, (as in the examples of spurious male hermaphrodites that have been quoted from Sir E. Home, and in other instances mentioned by Renauldin, Julien, Petit, Rullier, and others in the human subject, as well as in numerous cases among hermaphrodite quadrupeds,) would almost seem to shew that the full development of the mammary glands is a character proper to the species in general, rather than one peculiar to the female system alone. In males, also, who are perfect in their reproductive organs and functions, the mammæ are sometimes observed to be developed in so complete a manner as to be capable of secreting milk, forming what may be regarded as one of the slightest approaches towards hermaphroditic malformation in the male organization;* and the mammæ of the infants of both sexes not unfrequently contain a lactiform fluid at birth.

In some instances of hermaphroditic malformation the total form and configuration of the body have been alleged to present not only a general tendency towards the physical secondary characters of the opposite sex, or to exhibit in a permanent state the neutral condition existing before puberty, but different individual parts of it have been occasionally conceived to be developed after a different sexual type. Thus, for instance, we have already mentioned in regard to Hubert Jean Pierre, that the upper half of the body of this individual seemed formed after the female, and the lower half after the male type, the larynx and mammæ being quite feminine, the face shewing no appearance of beard, and the arms being delicate and finely rounded, while the pelvis was narrow, and the thighs were marked and angled as in man. In a case described by Schneider,* the reverse held true, the bust being male with a strong beard and large thorax, and the pelvis being large and distinctly female. A more mixed combination of the secondary sexual characters has been already described as existing in the cases detailed by Ricco, Mayer, Arnaud, Bouillaud, &c.

One side of the body has been sometimes observed to be apparently formed in one or more of its parts on a sexual type different from that of the same parts on the opposite side. Girald, in his Topography of Ireland,† mentions a reputed female, who had the right side of the face bearded like that of a man, and the left smooth like that of a woman. Mr. King ‡ has described an interesting instance of hermaphroditic malformation in an individual whose general character was masculine, but with the pelvis large and wide; the left testicle only had descended into the groin, and the mamma of this side was small comparatively to that of the opposite or right side.

In a hind mentioned by Mr. Hay,§ and which, he believed, had never produced any young, one of the ovaries on dissection after death was found to be scirrhous. The animal had one horn resembling that of a three years-old stag on the same side with the diseased ovary; there was no horn on the opposite side. Bomare‖ has given a similar case in the same

* The secretion of milk in the mammary glands of the male is occasionally observed amongst our domestic quadrupeds. animal, where a single horn was present, situated also on the same side with the diseased and degenerated ovary; and Russell* states, as the result of his experiments on castration in the deer, that when he removed one testicle only from the animal, the horn on the opposite side was the more completely developed of the two. Azara † observed in two birds the right side of the tail to possess the characters of the male, and the left those of the female.

In the hermaphroditic lobster previously alluded to as described by Nicholls, the general external configuration of the body was, like that of the sexual organs, perfectly female on one side, and perfectly male on the other.

It is principally, however, among hermaphroditic insects that a difference of sexual type in the general conformation of the opposite sides of the body, and of its individual parts, has been observed; and this malformation is the more striking and easy of observation in this class of animals, on account of the great differences in colour, size, and form respectively presented by the antennæ, wings, and other parts of the body of the males and females of the same species.

Lateral hermaphroditism of the body in Insects has been most frequently observed by Entomologists amongst the class Lepidoptera. It has now been remarked in the following species:— in the *Argynnis paphia*, *Lycæna alexis*, *Saturnia pyri*, *Endromis versicolor*, and *Harpya vinula* (Ochsenheimer); in the *Gastrophaga medicaginis* and *Lycæna adonis* (Rudolphi); in the *Liparis dispar* (Schaefer, Ochsenheimer, and Rudolphi); in the *Saturnia Carpini* (Capieux, Ochsenheimer, and Rudolphi); in the *Gastrophaga quercifolia* (Hettlinger and Rudolphi); in the *Gastrophaga pini* (Scopoli); in the *Gastrophaga cratægi* (Esper); in the *Sphinx convolvuli* (Ernst); *Sphinx populi* (Fischer and Westwood); *Papilio polycaon* (Macleay); *Polyommatus alexis* (Entomolog. Mag. vol. iii. p. 304); *Bombyx castrensis* (Duval); in the *Argynnis paphia* (Allis); in the *Vanessa atalanta* (Schrank and Germar); and in the *Vanessa antiopha* and *Deilephila euphorbiæ* (Germar). Klug and Germar have recorded two instances of it among the Coleoptera, the former in the *Lucanus cervus*, and the latter in the *Melolontha vulgaris*; and Mr. Westwood mentions a third case in the large water-beetle *(Dyticus marginalis)*, as contained in Mr. Hope's collection, and has seen a fourth in the stag-beetle *(Lucanus cervus)*.

Out of twenty-nine recorded cases of lateral hermaphroditism in Insects, in which the sexual characters of each side are distinctly specified, we find that in seventeen instances the right side was male, and in twelve female. Burmeister alleges that in by far the majority of cases the right side is male, and the left female,—a statement in which Meckel coincides, while Westwood maintains the reverse. The cases we have ourselves collected are certainly numerically in favour of the former opinion, but the data are as yet so few, and the difference so trifling, as not to warrant us to come to any decided conclusion on this point.

In some instances we find among insects an imperfect lateral hermaphroditism consisting of some parts of one side, as of one or more of the wings, palpi, or antennæ being formed according to a different sexual type from the same parts of the opposite side, and from the general body of the animal. Thus in the Melitœa described and dissected by Klug (see *Lateral Hermaphroditism)* the general form of the insect was male, but the left eye, palpus, antenna, and left sexual fang were smaller than in individuals belonging to this sex; the left antenna was annulated with white and yellow at the apex, while the right was of one colour; the general form of the abdomen was male but somewhat thick, and the wings were all equal and male.

In a *Pontia duplidice* mentioned by Rudolphi, and which in its general external characters was female, the right anterior wing was formed after the male type, and the sexual organs also resembled those of the male.

Ochsenheimer mentions one *Gastrophaga quercus* with the body, and the antennæ and wings on the left side female, and the right wings male; and a second with the body and the right side female, and the left side and two antennæ male, the latter being brown and pectinated.

In this imperfect variety of lateral hermaphroditism, the malformed wing, antenna, or palpus is sometimes formed after one sexual type and coloured after another. In a male *Melitæa phœbe* noticed by Germar, the right wings and antenna were female in regard to size, but male in respect to colouring and markings. In a female *Deilephila galii*, he found the left antenna and palpus of the small size of the male, but agreeing in colouring and markings with the corresponding female parts on the right side. In a *Pontia cardamines*, which was male in all its other characters, Ochsenheimer observed the right superior wing marked as in the female, and he mentions another individual of the same species which had a female form with some male colours.

In another variety of insect hermaphroditism the sexual difference is sometimes, as we have already noticed in regard to the human subject, expressed not by a lateral, but by a longitudinal sexual antagonism, or, in other words, the anterior and posterior parts of the body are formed after the two opposite sexual types. Thus in a *Saturnia carpini* described by Ochsenheimer, the antennæ were male, the superior wings male in form, but coloured as in the female, and the posterior wings, with the exception of a reddish brown spot upon the left, were, with the body and other parts, female.

Lastly, in a third variety of external hermaphroditic conformation in Insects, we find the characters of the two sexes mixed up and crossed in different irregular combinations upon the body of the same individual. In a *Gastrophaga castrensis* described by Rudolphi, and where the male type predominated, with a tendency,

* Economy of Nature in Glandular Diseases.
† Kob's Dissert. de Mutatione Sexus, p. 19.

however, in all parts to the female form, the right antenna and the wings on the opposite or left side were distinctly female, while the left antenna and right wings were entirely male, the latter being only somewhat larger than in male insects, and the colours brighter than in the female. In a *Bombyx castrensis* alluded to by Westwood, the wings on the right side, and the antennæ and abdomen of the left, were those of a male, while the left wing, right antennæ, and right side of the abdomen were those of a female.

GENERAL SUMMARY WITH REGARD TO THE NATURE OF HERMAPHRODITIC MALFORMATIONS.

1. *Of the varieties of spurious hermaphroditism.*—On some of these varieties it is unnecessary for us to dwell here. The first species of spurious male hermaphroditism, or that arising from extroversion of the urinary bladder, is elaborately discussed elsewhere (see BLADDER); and two others, namely, the second female species consisting of prolapsus of the uterus, and the second male consisting of an adhesion of the penis to the scrotum, seem both referable to the head rather of disease than of original malformation. This latter indeed appears in all probability only an effect or result of adhesive inflammatory action in the affected parts during embryonic or fœtal life. Both of the two remaining forms of spurious hermaphroditism,—viz. those consisting of hypospadic fissure of the urethra, scrotum, and perinæum in the male, and of abnormal magnitude of the clitoris in the female,—seem readily explicable upon the doctrine of arrestment and anormality in the development of the malformed parts.

We have already described at sufficient length the process of development of the different copulative organs, and have shewn that those various degrees of hypospadic malformation which constitute the common form of spurious hermaphroditism in the male, may be traced to arrestment of this process at various periods or stages of its progress. And we may here remark that the earlier this arrestment occurs, the distinction of the true sexual type of the malformed organs will always be the less marked, because the younger the embryo, and, on a similar principle, the lower we descend in the scale of animal existence, we find the differences between the organs of the two sexes proportionally the less pronounced, until at last we arrive at that primitive type in which these organs present altogether a common, neutral, or indeterminate character.

We have also already shewn that at a certain early stage of the development of the female organs, the female clitoris holds the same, or nearly the same relatively larger size to the whole embryo as the penis of the male, and that so far we may consider the occasional occurrence of spurious hermaphroditism from magnitude of the clitoris, and its resemblance in this respect to the male organ, as a permanent condition of a type of embryonic structure that is normally of a temporary or transitory existence only. But besides this permanence of the embryonic type of the clitoris, we must farther, in all the more complete instances of spurious female hermaphroditism, admit an excess of development in the malformed external sexual parts, and more particularly in the line of the median reunion of the two primitive lateral halves or divisions of these parts. In this way the vagina (a remnant in the female of the primitive perinæal cleft or fissure) is often in such cases more or less contracted and closed, so much so indeed in some instances as to leave only, as in the male, a small canal common to the genital and urinary passages. If the median junction is extended still farther, this canal comes also to imitate the male urethra in this respect, that it is united or shut up *below* in such a way as to be carried onward to a greater or less length, and in a more or less perfect condition along the under surface of the enlarged clitoris; and occasionally the male type of structure is still more completely repeated in the female organization by the median reunion of the two labia, giving the appearance of the united scrotum and closed perinæum of the opposite sex.

If we divide the whole sexual apparatus of the male and female into three corresponding transverse spheres or segments,—the first or deep parts including the testicles and ovaries, the second or median comprehending the male seminal canals and prostate gland, and the female oviducts and uterus, and the third or external embracing the copulating organs of the two sexes,—we shall find that, relatively speaking, the deep and the external spheres are naturally most developed in the male economy, while the median, comprising the uterus, (the principal and most active organ in the female reproductive system,) is developed in the greatest degree in that sex. In malformed females presenting a spurious hermaphroditic character, this important portion of the female sexual organization is, in general, either itself in some respects malformed, or, from the structure of the other parts of the sexual apparatus being imperfect, its specific importance in the economy is cancelled, and therefore the energy of development takes the same direction as in the male, being expended upon the more complete evolution of the organs of the external and deep spheres. Hence the greater size of the clitoris, and the greater development which we have just now pointed out, in the median line of reunion of the external sexual parts; and hence also the occasional though rare occurrence, in the same cases, of the descent of the ovaries through the inguinal rings into the labia,—an anomaly that certainly consists in a true excess of development, and which we cannot but regard as interesting, both in this respect, and as affording a new point of analogy between these organs themselves and the male testicles.

There is another and equally interesting point of view in which we may look upon this subject. Not only are the forms of spurious hermaphroditism which we have been considering, capable of being traced backward to certain transitory types of sexual structure in the embryos of those animal species in which the malformations in question occur, but they may be shewn also to present in their abnormal states repetitions of some of the normal and permanent conditions of the sexual organs in various species of animal beings placed lower in the scale of life. Thus the occasionally imperforate penis of the male hermaphrodite has been supposed to have an analogue in the naturally solid penis of some of the species of the genera *Doridium* and *Hyalæa*.* Its more or less grooved or hypospadic condition is similar to the natural type of the same part in some hermaphrodite Mollusca, as in the *Planorbis* and *Murex*:† in its occasional diminutive size it approaches the general smallness of the partially fissured penis of most birds and reptiles; and we find it in the Rodentia and Marsupiata tied down by a short prepuce in a way analogous to what is seen in some cases of severe hypospadias. In the sloth (*Bradypus tridactylus*) the penis is small and grooved in its lower surface, and has the urethra opening at its base;‡ and in several of the male Rodentia the scrotum is also cleft, and has its two opposed surfaces smooth, humid, and free of hair, as in most cases of hypospadic hermaphroditism in man. In Ophidian and in most Saurian Reptiles, the male seminal ducts open at once externally, as in some male hermaphrodites, at the root of the fissured penis.

The fact of the testicle some time remaining, in cases of hermaphrodite formation in the human subject, within the cavity of the abdomen, presents to us in a permanent state their original but changeable position in the early fœtus, and at the same time affords a repetition of their normal situation, in almost all the lower tribes of animals, and in the Cetacea, Amphibia, Edentata, and some Pachydermata, as the Cape Marmot (*Hyrax*) and Elephant, among the Mammalia.

The malformed clitoris in instances of spurious hermaphroditism assumes also, in its abnormal state, types of structure that we find as the normal condition of the organ in various inferior animals. Thus in female Cetacea and Rodentia, and in the animals included in Cuvier's order of Carnassiers, but more particularly among the Quadrumana, the clitoris retains as its permanent normal type that relatively larger size which we observe in the early fœtus, and in female hermaphrodites in the human subject: and further, as is sometimes seen in such malformed individuals, the clitoris becomes partially traversed by the urethra, as in the Ostrich, Emu,§ and Anteater;‖ and in the Loris (as we have noticed in a preceding page) and Maki, it is completely enclosed, like that of the male, in the body of the organ, forming a continuous and perfect canal through it.

We may here further observe, (though the illustrations should more properly belong to the next section,) that in cases of true hermaphroditism also in man and quadrupeds, as well as in the above spurious varieties, there may be often traced in some portions of the abnormal structures a sexual type bearing a greater or less analogy to the corresponding parts of those inferior animals that are naturally androgynous. Thus, in instances of true hermaphroditism, the orifices of the sexual ducts or passages occasionally open into a common cavity, as is normally the case in some species of *Doridium*, *Helix*, and other Mollusca; or the female oviducts or Fallopian tubes, and the male vasa deferentia, run closely alongside of each other without any communication between their canals, as in the *Alypsia* and most Gasteropoda. Indeed the occasional co-existence even of both testicles and ovaries in individuals among the higher animals would be only a repetition of, or retrogression to, the normal sexual type of those genera of animals that we have just named, and of the Planaria, Cestoidea, and other natural hermaphrodites.

In this way we see, that, (as in many other monstrosities,) the several varieties of malformation in the sexual organs occurring in spurious human hermaphroditism do not consist of the substitution of an entirely new and anomalous type of structure, but are only repetitions of certain types of the same organs that are to be met with both in the human fœtus and in the inferior orders of animal beings. The investigation of the whole subject shews us in reference to the sexual organs, what is equally true in regard to all the other organs of the body,—that their different stages of development in the embryos of man and of the higher orders of animals correspond to different stages of their development in the series of animal beings taken as a whole; so that here, as elsewhere, the facts of Comparative Anatomy are reproduced in those of Embryology, and both are repeated to us by nature on a magnified scale in the anatomy of the malformations of the part,—a circumstance amply testifying to the intimate relations which subsist between Comparative Anatomy, the anatomy of Embryonic Development, and that of Monstrosities. Indeed proportionally as our knowledge of malformations has increased, it has shewn us only the more strongly that the laws of formation and malformation,—of normal and abnormal development, are the same, or at least that they differ much more in degree than in essence, and that the study of each is calculated reciprocally to illustrate and to be illustrated by the study of the other.

2. *Nature of true hermaphroditic malformations.*—Of the nature of local malformations by duplicity, we at present possess much less precise knowledge than of those of simple defect or simple excess of development; but there are certain facts ascertained with regard

e formation of the sexual organs, which to th[e]nable us to make an approach at least to may e[x]e ideas of the character and origin of accurat[e] normalities that constitute the several those a[b] of true hermaphroditism. These facts varieties the interesting subject of the unity of relate to which is manifested in the correspond- structure and female reproductive organs of the ing male an[d] and of other species of bisexual human subject, animals. Greek, Roman, and Ara-

By several of the Gr... ...ctive organiza- bian physiologists,* the respe... ...ed as in tions of the two sexes were consider... ...be some degree typical of one another, the fema[le] being regarded as an inverted male, with the testicles and penis turned inwards to form the ovaries and uterus. This doctrine of analogy between the male and female sexual organs has, with various modifications, been very generally admitted by modern physiologists, and in some of its bearings it has been made, more particularly of late years, the subject of considerable discussion. The testicles are still regarded as organs which correspond with the ovaries in their original situation, in their vascular and nervous connections, and in their relative sexual functions. The recent progress of the anatomy of the development of the embryo has also shewn that the two organs correspond in their primitive origin. It is now well ascertained that the large masses occupying each side of the abdomen of the embryo at an early stage of development, and which Rathke has named the Wolffian bodies after their illustrious discoverer, form, in Birds and Mammalia at least, the primordial matrices upon which the urinary and genital organs are developed. On the inner side of each of these matrices a small body is early developed, which seems to become afterwards either a testicle or an ovary, according to the particular ulterior sexual type which the embryo assumes.

In further following up the analogy of structure between the organs of the two sexes, the vasa deferentia of the male are generally compared to the Fallopian tubes of the female, the scrotum to the external labia, the body of the penis to the clitoris, and its corpus spongiosum, or, according to others, its prepuce, is regarded as corresponding in type with the female nymphæ. A considerable difference of opinion, however, still prevails as to the prototype of the female uterus in the male system. Some anatomists, as Burdach, Steghlener, and Blainville, regard the uterus and male vesiculæ seminales as corresponding parts; while others, as Meckel, Carus, Schmidt, Ackermann, and Serres, compare the uterus to the male prostate. A sufficient number of facts seems still wanting to determine the accuracy and justness of either of these analogies. There are instances of malformation on record which appear to favour both opinions, and there are other cases which almost incline us to believe that the vesiculæ seminales correspond to the fundus or body of the uterus in the human subject, and to the cornua uteri in quadrupeds; while the prostate represents in the male structure the lower portion or cervix of the same organ. The phenomena of the development of the reproductive organs in the embryo will, when more fully investigated, probably serve to clear up this question.

M. Geoffroy St. Hilaire has propounded views of the analogy of the male and female organs in some respects different from the above. He divides the uterus of the human subject into the body and the upper part or fundus, the latter corresponding to what constitutes the cornua uteri in the human embryo, and in adult quadrupeds. Further, believing that in the determination of all analogies in type and structure between different organs, the origin and course of the bloodvessels supplying the part ought to be our principal criterion, he has been led, by the study of the distribution of the branches of the hypogastric arteries, to consider the body of the uterus and the vesiculæ seminales as repetitions of each other in the two sexes; and, contrary to the opinion of most anatomists, he conceives that the male vasa deferentia strictly correspond with the fundus or cornua uteri, and that the epididymis represents a coiled-up Fallopian tube, or in other words that the Fallopian tube is an unrolled epididymis. M St. Hilaire has offered the following table to shew what he conceives to be analogous organs in the two sexes:—*

In the male.		*In the female.*
Testicle	=	Ovary
Epididymis	=	Fallopian tube
Vas deferens.	=	Cornu of the uterus.
Vesicula seminalis	=	Body of the uterus
Sheath of the penis	=	Vagina
Penis	=	Clitoris

In tracing out the analogies between the male and female parts, the mode in which we ought to consider the female vagina has given rise to some diversity of opinion. From the above table it appears that M. St. Hilaire considers it to be represented in the male organization by the sheath of the penis, but we are certainly inclined to view it in a different light, and to regard it as a part in so far peculiar to the female, that it consists of a permanent condition of that urino-genital perinæal fissure that we have already described as existing at a certain period in the embryos of both sexes, and which is latterly shut up in the male, or, speaking more accurately, it is contracted into what forms the pelvic portion of the male urethra.

If this were a fit opportunity for following out the consideration of the unity of type between the male and female reproductive organs, it would be easy to shew the justness of those greater analogies that we have mentioned, by pointing out other numerous minor, but still strong points of correspondence manifested in

* Phil. Anat. tom. i. (1822,) p. 471.

the abnormal conditions and localities of the ovaries and testicles in the higher animals, and in their conformity of structure in some of the lower. Thus among Insects, in the genus *Libellula* the long cylindrical testes of the males correspond with the long-shaped ovaries of the females; in the *Locusta* and *Gryllotalpa*, there are ramose bunched testicles with analogous fasciculated ovaries; in the *Lamellicornia* we find compound radiating and united testes, with similar radiating and united ovaries; and sometimes, as in the genera *Melolontha* and *Trichius*, the number of the single bodies in the testicles corresponds with the number of the oviducts.*

We have already, when considering spurious hermaphroditism in the female, mentioned several facts illustrative of the analogical peculiarities in structure between the male penis and female clitoris in some species of animals; and Burmeister,† who regards the ovipositors and stings of female insects as corresponding to the clitoris in the female Vertebrata, has pointed out a remarkable conformity of structural type between its valves and those of the penis of the male of the same species.

Some organs that are, as far as regards their functions, peculiar and essential to one sex only, are nevertheless found to be repeated in the opposite sex in the form of an analogous rudimentary type of structure. Thus, in the male we may observe the unity of sexual structure maintained in the presence of the rudiments of the mammary gland, which is *functionally* an organ of the female system only. In the human subject, and in animals whose females have pectoral mammæ, these organs occupy the same position in the male; while in those species of quadrupeds in which they are placed in the inguinal region, we find them in the corresponding males forming the scrotum or bags for containing the testicles. Hence, as we have already seen, the testicles, in cases of malformation in these animals, are often laid upon or imbedded in the udder. In the same way in the Marsupiata, the bone which the female has for supporting the marsupium is repeated in the organization of the male, although in the latter we cannot conceive it to serve any possible use.‡

In the female also we observe in some points a similar disposition to the rudimentary repetition of parts that are essential or peculiar only to the male organization, as in the repetition in the clitoris of some female Rodentia, of the penis-bone of the male, and in the formation of rudimentary forms of those processes of peritonæum which constitute the tunicæ vaginales. We are ourselves inclined also to regard the common crescentic form of the hymen of the human female in the same light,§ and to consider it merely as an abortive attempt at that closure of the perinæal fissure which we have already described as effected at an early period in the male embryo—an opinion in which we conceive we are borne out both by the history of the development and the study of the malformations of the external sexual parts in the female.

M. Isidore St. Hilaire read, in 1833, to the French Academy a memoir,* in which, following up the doctrine of his father with regard to the determination and distinction of the type of parts by the particular vessels distributed to them, he endeavoured to shew some new points of analogy between the male and female organs, and to develop new views with regard to the origin and particular varieties of hermaphroditic malformations. With Burdach, he divides the whole reproductive apparatus of either sex into three transverse spheres and into six portions or segments in all, or three on each side, viz., 1 and 2, the deep organs, including the male testicles and female ovaries; 2 and 3, the middle organs, or male prostate and vesiculæ seminales, and female uterus; 3 and 4, the external organs, comprehending the penis and scrotum of the male, and the clitoris and vulva of the female. Each of these portions or segments is, M. St. Hilaire points out, supplied by an arterial trunk peculiar to itself, and the corresponding organs of the male and female by corresponding arterial branches, as the deep organs of both sexes by the two spermatics, the middle by branches of the two hypogastrics, and the external by some other hypogastric branches, and by the external pudics. This circumstance, he conceives, renders all the segments in a certain degree independent of the others, both as regards their development and existence, and allows of the occasional evolution of any one or more of them on a type of sexual structure, different from that upon which the others are formed in the same individual.

Though assuredly we cannot subscribe to the speculations of the elder St. Hilaire, that the development in the embryo of male testicles or female ovaries, and consequently the whole determination of the sex, is originally regulated by the mere relative angle at which the first two branches of the spermatic arteries come off, and the kind of course which they follow,† (more particularly as it is admitted by most physiologists that the bloodvessels grow, not from their larger trunks or branches towards their smaller, but from their capillary extremities towards their larger branches,) yet we believe that the doctrine of the comparative independence of the different segments of the

§ Burdach (Phys. § 137,) considers the small cutaneous fold situated at the orifices of the vasa deferentia, and Stiebel the membrane placed at the extremity of the urethra (Meckel's Archiv. für Physiol. Bd. viii. s. 207,) as the analogue in the male for the female hymen.

* Arch. Gén. de Méd. (1833) tom. i. p. 306.

† Anat. Phil. tom. i. p. 359. . . "L'ordre de variations des sexes tient à la position d'un artère. . . Le plus ou le moins d'ecartement des deux branches spermatiques motive effectivement cette preference. Que les deux branches de l'artère spermatique descendent parallelement et de compagnie, cette circonstance, je le repete, cette circonstance donne le sexe male; qu'elles s'ecartent à leur point de partage, nous avons le sexe femelle."

reproductive organs pointed out by the son is in its general principles correct. At the same time we would here remark that we conceive the doctrine would have been founded more on truth if the influence of the nervous branches supplying the different reproductive organs had been taken into account along with that of their arterial vessels, because, as we shall point out when speaking of the causes of hermaphroditism, there appears to be some connection between the state of the nervous system and the degree or condition of sexual development.

The consideration of the preceding analogies in structure between the male and female organs is interesting in itself, and, as far as relates to our present subject, important in this respect, that it enables us in some degree to understand how it happens that, without any actual monstrous *duplicity*, we should sometimes find, in an organization essentially male, one or more of the genital organs absent and replaced by an imperfect or neutral organ, or by the corresponding organ of the opposite sex, and *vice versa ;* inasmuch as it shews us that the moulds in which the analogous organs of the two sexes are formed are originally the same. Hence there is no difficulty in conceiving that, in the body of the same individual, the primitive structural elements of these parts should occasionally, in one or more points or segments, take on, in the process of development, a different sexual type from that which they assume at other points. Indeed some physiologists, as we shall immediately see, deny that the most complete hermaphroditic malformations ever consist of anything except such a want of conformity between the sexual type of different portions of the reproductive apparatus.

If each of the six segments (and we believe that their number might be shewn to be really greater than this,) is thus an independent centre of development in the formation of the sexual apparatus, and is consequently liable also in abnormal cases to have its own particular malformations, and to assume, either alone or along with some of the other segments, a sexual type different from the remainder, it is evident that we may have as many varieties of true hermaphroditism, without any real duplicity, as it is possible to conceive differences of arrangements among these six segments. Again, however, one or more of these segments may preserve from a development its original indeterminate or neutral sexual type, while the others are variously formed either upon one or upon both sexual types; or one or more of the segments may, by a true malformation by duplicity, have evolved within them the corresponding organs of the two sexes; and if we consider the different arrangements of double and single sexual parts that might thus occur in the six separate segments, we may gain some idea of the great diversities of structure in the sexual parts that are liable to be met with in instances of true hermaphroditism.

The above forms, as it appears to us, the most sound and rational solution of the nature and origin of many forms of true hermaphroditism which physiological science is capable of affording, upon our present limited knowledge of the laws of development; and its application to the explanation of the different varieties of lateral, transverse, and vertical hermaphroditism is so obvious as only to be required to be alluded to. It offers to us, however, no insight into the probable origin of those varieties of double hermaphroditism in which there is an actual co-existence upon one or upon both sides of the body, or, in other words, in the same segment of the sexual apparatus, of both the corresponding male and female organs. We can only refer all such instances to the laws which regulate the occasional production of *local* duplicities in different other organs of single bodies, and at the same time confess our present ignorance of what these laws are. We know that various individual muscles, nerves, &c. are not unfrequently found double, and that in the internal organs of the body examples of duplicity in individual viscera are occasionally, though rarely, observed in the heart, tongue, trachea, œsophagus, intestinal canal, &c. In the several organs composing the reproductive apparatus, instances of similar duplicity would seem to be even more common than among any other of the viscera. Examples of *three* mammæ upon the same person are mentioned by Bartholin,* Borelli,† Lanzoni,‡ Drejer,§ Robert,|| Petrequin,¶ and others;** and cases in which the number of these organs was increased to *four* have been recorded by Faber,†† Gardeux,‡‡ Cabroli,§§ Lamy,|||| Tiedemann,¶¶ Champion,*** Sinclair,††† R. Lee,‡‡‡ and Moore.§§§ An instance in which *five* mammæ even existed upon the same woman is reported to have been seen by Gorré.|||||| Valentin¶¶¶ and Gunther**** have recorded supposed cases of duplicity in the male penis; and Arnaud†††† has related an example of an analogous malformation in the female clitoris. on each side; and Hunter* alludes to the occasional occurrence of an imperfect supernumerary vas deferens. In 1833 a case of a double human uterus, furnished with four Fallopian tubes and four ovaries, was shewn by Professor Moureau to the Academie de Médecine.† Blasius‡ dissected the body of a man on whom he detected the co-existence of three testicles; the additional testicle was of the natural form and size, and was furnished with a spermatic artery and vein that joined in the usual manner the aorta and vena cava; it lay in the right side of the scrotum. Arnaud found, on dissection, three testicles in a dog; the third was placed in the abdomen, and of the natural consistence, figure, and size; it was furnished with a vas deferens.§ Other instances of triple and quadruple testicles of a more doubtful character, inasmuch as the observations made during life were not confirmed by dissection after death, are related by Voigtel,‖ Sibbern,¶ Brown,** Rennes,†† and others.‡‡ Scharff§§ even gives an alleged case of a man with five testicles, three of which are stated to have been well formed, while the other two were much smaller than natural. And, lastly, Loder‖‖ is said to have exhibited to the Gœttingen Academy drawings taken from the body of a male infant, on whom *all* the sexual apparatus existed double, there being two penes, a double scrotum, and urinary bladder, and, as it was supposed, four testicles.

In all the preceding instances the local duplicity of the particular reproductive and other organs adverted to existed independently of any duplicity in the body in general, or in any other individual parts of it. And if we once admit, (what the preceding instances will scarcely allow us to deny,) that there may occur a duplicity of some of the male sexual organs in a male, or of some of the female sexual organs in a female, it is certainly easy to go one step farther, and admit that the double organ or organs may, however rarely, be formed in other instances upon an opposite sexual type. Indeed all our knowledge of the unity of structure and development between the various analogous male and female reproductive organs, as well as the fact of the occasional replacement of an organ of the one sex by that of the other in cases in which the sexual type is entirely single (as seen in instances of lateral hermaphroditism), would lead us *à priori* to suppose that, if a local duplicity in any of the sexual organs was liable to occur, this duplicity would sometimes shew itself in the double organs assuming opposite sexual characters, and thus constituting some of those varieties of double or vertical hermaphroditism that we have already had occasion to describe.

In the preceding observations we have proceeded upon the opinion commonly received by physiologists, of the fundamental unity of sex among all individuals belonging to the higher orders of animals; or, to express it otherwise, we have assumed that each individual is, when normally formed, originally furnished with elemental parts capable of forming one set of sexual organs only. We do not here stop to inquire whether this single sexual type is, in all embryos, originally female, as maintained by Rosenmüller, Meckel, Blainville, Grant, and others; or, of a neutral or intermediate character, as supposed by the St. Hilaires, Serres, Ackermann, Home, &c., and as we are certainly ourselves inclined to believe it.* On this subject, however, a physiological doctrine of a different kind has been brought forward by Dr. Knox, and this doctrine is so intimately connected with the question of the nature and origin of true hermaphrodites, that we must here briefly consider it.

Dr. Knox,† in conformity with some more general views which he entertains on transcendental anatomy, is inclined to regard the type of the genital organs in man and the higher animals, as in the embryo, originally hermaphroditic, or as comprising elementary yet distinct parts, out of which both sets of sexual organs could be formed; and he believes that, owing to particular but unknown circumstances, either the one or the other only of these sets of elements comes to be evolved in the normal course of development. In those abnormal cases, again, in which, as in instances of double hermaphroditism, more or fewer of both sets of genital organs are present upon the same individual, he maintains that this is not to be considered as a malformation by duplicity, but is only a permanent condition of the original double sexual type, and is attributable to the simultaneous development to a

* Meckel (De Duplicitate Monstrosa, p. 14), and Andral (Anat. Path. tom. i. p. 101) assume it, after Haller, as a fact, that a much larger proportion of monsters belong to the female than to the male sex; and while they attribute this circumstance to the genital organs in these beings retaining, from the general defect of development, their *original female* sexual character, they at the same time consider this circumstance to be strongly corroborative of this particular doctrine. Isid. St. Hilaire has shewn (Hist. des Anomal. t. iii. p. 387) that the supposed fact itself does not hold true in respect to some genera of monsters, and is even reversed in others; and he doubts if it be of such a degree of generality in respect to monsters in general as to merit to be raised into a teratological law. If the views of Meckel were correct, we should certainly expect at least that spurious hermaphroditism, where the development of the sexual parts is commonly abnormal from *defect*, should be much more frequent in the female than in the male. The list, however, of recorded cases of it in the latter is, we believe, more than double the number of it in the former.
† Brewster's Edinburgh Journal of Science, vol. ii. p. 322.

greater or less extent both of the male and female sets of sexual elements.

This doctrine of the original but temporary double sexed character of all embryos derives, perhaps, its principal support from a source to which Dr. Knox does not advert,—we mean the existence of this as the normal and permanent sexual type in most plants and in many of the lower orders of animals. But this argument by analogy certainly cannot by any means be considered as a sufficient basis for the establishment of so broad and important a generalization in philosophical anatomy. Dr. Knox himself seems to have been induced to adopt the idea principally because it afforded (when once assumed as a fact) a simple and elegant solution, upon the laws of development, of the occasional occurrence of cases of true hermaphroditism; and in doing so, he appears to have proceeded upon the mode in which most such physiological hypotheses have been made, viz. by drawing his premises from his deductions instead of his deductions from his premises. In the present state, however, of anatomical and physiological knowledge, Dr. Knox's hypothesis, however ingenious in itself, is one which we cannot subscribe to; for first, it is totally opposed to all the facts which have been ascertained, and all the direct observations which have been made by Rathke, Meckel, Müller, Valentin, and other modern anatomists upon the sexual structure of the embryos of the higher animals in their earliest state; and, secondly, if we were to admit it merely as a probable hypothesis, it is still even in this respect equally as incapable as the old doctrine of sexual unity, of explaining all the cases of malformation by duplicity of the genital organs; for, as we have already shewn, there are some apparently well-authenticated instances of the existence of three or four testicles upon the same man, or three or four ovaries upon the same woman; and in reference to all such cases we would, if we proceeded upon the same data and the same line of argument as those adopted by Dr. Knox, be obliged to suppose that the original sexual type is not, as he imagines, double only as respects the two sexes, but double even as respects each sex, and that all embryos had originally not simply the elements of two, but those of three or four testicles and ovaries. In explaining such cases as those to which we allude, Dr. Knox, on his own doctrine, must of necessity admit the existence of a malformation by duplicity of the sexual organs in question; and if we grant this in regard to these instances, it is surely unnecessary to invent a particular and gratuitous hypothesis for the explanation of the analogous anatomical anormalities observed in hermaphroditism. At present we must, we believe, merely consider the occurrence of anomalous duplicity of the sexual organs, and of various other individual parts of the body, as so many simple empirical facts, of which we cannot, in the existing state of our knowledge, give any satisfactory explanation, or, in other words, which we cannot reduce to any more simple or general fact; though from the success which has attended the labours of many modern investigators in this particular department of anatomy, it seems to us not irrational to hope that ere long we may be enabled to gain much new light upon the question of double hermaphroditism and the whole subject of malformation by duplicity.

ANATOMICAL DEGREE OF SEXUAL DUPLICITY IN HERMAPHRODITISM.

Though the cases which we have brought forward do not present any instances of such perfect hermaphrodites in the human subject or in quadrupeds as those which are represented upon the ancient Greek statues and medals,* or that have been described and delineated by Lycosthenes, Paré, Schenkius, and the older authors on monstrosities, they yet present to us a sufficient number of instances in which, in accordance with the definition we have previously given of true hermaphroditism, there actually co-existed upon the body of the same individual more or fewer of the genital organs both of the male and female.

From the relations and size of the bony pelvis, and the fact of the penis and clitoris being repetitions only in situation and structure and organic connections of each other in the two sexes, it is useless perhaps to expect that we should ever find in any one case all the parts of both sexes present at the same time. For since the male penis is only a magnified condition of the female clitoris, and since both of these organs are connected by the same anatomical relations to the same part of the pelvis, it would almost require some duplicity in the pelvic bones themselves to admit of the simultaneous presence of both; and in no authentic case has any approach to their co-existence upon the same individual been observed.

Various authors who have written upon the subject of hermaphroditism have gone so far as to endeavour to refer all instances of it to some one or other of those varieties that we have described under the name of *spurious*. Thus, dogmatizing in a spirit of unphilosophical scepticism, Parsons† and Hill‡ have endeavoured to shew that all reputed hermaphrodites are only malformed females having a preternatural development of the clitoris, and in some instances with the ovaries descended into the labia. Others, on the contrary, as

* See Winckelman, Hist. de l'Art, t. i. p. 364; and Caylus, Recueil d'Antiquités, t. iii; Heinrich, Commentatio quâ Hermaphroditorum artis antiquæ operibus illustrium, origines et causæ explicantur. Hamburg, 1805. Blumenbach, in his Specimen Hist. Nat. Antiq. artis (Goetting, 1808), mentions and figures (pl. i. f. 5, p. 15), a small ancient silver cast or impression of a case of hypospadias of the male genital parts, which he supposes to have formed a votive offering from some individual malformed in the manner represented.

† Enquiry into the nature of Hermaphrodites, p. 145. We would particularly point out the cases quoted by Dr. Parsons at p. 14, 26, 30, 88, 95, 130, &c. of his able essay as directly contradictory of his own doctrine, or as instances of hermaphroditic appearances in persons not of the female but of the male sex.

‡ Review of the Philosophical Transactions.

Professors Osiander* and Feiler,† maintain with equal inaccuracy that every supposed instance of hermaphroditism is referable to a hypospadic state of the penis and scrotum, in persons that are in other respects essentially male.

Various physiologists, again, while they admit the occurrence of all the different varieties of spurious hermaphroditism, are inclined to deny that any such combinations of male and female organs upon the same body as those which constitute our several varieties of true hermaphroditism, are ever observed to occur in the human subject, or among the higher classes of animals.‡ In despite of the recent accumulation of new and authentic cases, Professor Müller of Berlin is, in particular, in his excellent treatise on the development of the genital organs, published in 1830,§ still inclined to coincide in a great degree in this opinion. This distinguished physiologist does not indeed, as some have done, doubt in any degree the authenticity of the recorded cases, and even goes so far as to admit the occasional occurrence of a combination of male and female organs upon the same individual, when that combination does not (as in lateral and transverse hermaphroditism) imply a true sexual duplicity or repetition of any of the corresponding male and female parts; but he doubts altogether the probability of our third division of double or complex hermaphroditism, and conceives that in the examination of the cases referable to that section a sufficient degree of attention has not been directed to the accurate anatomical distinction of the particular parts supposed to exist, from others with which it is possible to confound them. We shall here, therefore, shortly inquire into some of the principal sources of fallacy which are apt to mislead the incautious observer in the examination of such instances as those to which we allude; and in doing so we shall consider the various sources of error in an order conformable with those divisions of double hermaphroditism that we have previously adopted,—speaking of the mistakes which may be committed in judging of the supposed co-existence, 1st, of a female uterus, and male vesiculæ seminales and vasa deferentia; 2d, of a female uterus and male testicles, &c.; 3d, of both testicles and ovaries.

1. *Fallacies in judging of the addition of male seminal ducts to a female type of sexual organs.*—That form of sexual duplicity which we have formerly described as consisting in the supposed superaddition of male vesiculæ seminales and vasa deferentia to an organization in other respects female, appears to have been hitherto observed principally, or indeed only among the Ruminantia, and has in particular been repeatedly found in free-martin cows. In judging of the reality of this variety of hermaphroditic malformation in any given case, there is one source of fallacy that requires to be particularly guarded against, and the consideration of which may probably go far to explain away most of the recorded examples of the malformation. In the female sexual parts of some Ruminantia and Pachydermata,* but particularly in the domestic cow and sow, Dr. Gaertner of Copenhagen pointed out in 1822† the existence of two canals or ducts which have since that time been generally described under his name. On each side of the body, one of these ducts arises in the vicinity of the ovary, or near the fimbriated extremity of the Fallopian tube, runs down first in the duplicature of the broad ligament, and afterwards in the substance of the parietes of the uterus and vagina, to near the meatus urinarius, and there opens into the vaginal cavity. Each duct communicates with several small glands, follicles, or cysts that are scattered along its course, and which perhaps may not be improperly described as diverticula from the ducts themselves. Now when we consider the relations of those imperfect ducts and cysts that are occasionally observed in the free-martin cow, situated along each side of the defectively developed uterus, and which Mr. Hunter has described as male vasa deferentia and vesiculæ seminales, it seems to us not at all improbable that these supposed male organs are only in reality the ducts of Gaertner, with their accompanying follicles or cysts generally perhaps existing in a morbidly developed and dilated condition. They seem at least to correspond much in their origin, course, and position with the canals and cysts discovered by Gaertner; and certainly in the present state of our knowledge it would appear more reasonable to refer them to this *normal* portion of the female structure, than to regard them, until we have more decided evidence on the subject, as *abnormal* male organs, and as affording, in consequence, an example of sexual duplicity.

In the course of the preceding pages we have had occasion to allude to cases in the human subject, and in the dog and sheep, in which vasa deferentia were stated to have existed in the same individual along with Fallopian tubes. Whether, in any of these instances, the supposed male seminal ducts were merely canals analogous to those described by Gaertner in the cow and sow, we shall not take it upon us to determine, but in connection with this inquiry it is interesting to remark that Malpighi, who seems to have been well acquainted with the existence of the ducts in the

cow, has suggested that they may also exist in a more obscurely developed state in the human female, and may perhaps be identified with the ramous lacunæ described by De Graaf, Bartholin, Riolan, &c.

A. C. Baudelocque has, in a case published in the Rêvue Médicale for March 1826, described a human uterus which contained in its parietes a canal coming from the right Fallopian tube, and opening upon the internal surface of the cervix uteri; and Moureau and Gardien seem to have met with a second (?) similar instance.*

Before leaving this subject of the probable source of fallacy which we have to guard against in confounding the ducts of Gaertner with the male seminal canals, it is necessary also to observe, that some anatomists† are now inclined to consider these canals as the permanent remains of the ducts of those Wolffian bodies which we shall presently have occasion to allude to more at length, as forming a temporary type of structure in the sexual development of the early embryo; and certainly the two appear to accord in most points with respect to their situation and course. If, however, it happens that further and more accurate observations prove the two to be different, then the possible permanent state of the ducts of the Wolffian bodies must be looked upon as affording another source of error, by which we may deceive ourselves in judging of sexual duplicity from the supposed superaddition of male seminal canals to a female sexual apparatus.

2. *Fallacies in the supposed co-existence of a female uterus with testicles and other organs of a male sexual type.*—We have, in a previous part of this communication, adduced about twenty different instances in the human subject, and in the quadruped, in which a female uterus, or both an uterus and Fallopian tubes were described as having been found upon the bodies of individuals that were in other respects essentially males.

In reference to some of these instances it has been doubted whether the sexual organization of the malformed animal was not *entirely* male, the supposed and generally imperfect uterus being conceived to be formed either by a morbid dilatation and unfolding of the substance of the male prostate gland, or by an abnormal union and development of the vesiculæ seminales. Thus, in the case detailed by Ackermann, the only male sexual organ that was entirely deficient was the prostate, and the only reputed female organ which was present was an imperfect cystiform uterus differing greatly in structure from the form of this organ in the infant, and having, as in the normal state of the prostate, the vasa deferentia penetrating through its substance without opening into its cavity, and ultimately terminating along with it in the posterior part of the urethra. In the analogous instance quoted in a preceding page from Steghlener, a similar arrangement of parts was observed; and in that case there was, in the enlarged ureters and renal infundibula, sufficient evidence (as we shall afterwards point out when speaking of the probable causes of hermaphroditism) of a distending power having acted upon the whole internal surface of the urinary and genital organs, and with so great a force (we may in the meantime allow) as to be capable of producing such a morbid dilatation and unfolding of the substance of the prostate as the doctrine alluded to requires. Such an effect would be the more liable to be produced if we can suppose this latter organ to have been disposed, by original tenuity of its coats, or by morbid softening or other diseased states of its tissues, to yield more easily to the dilating power, than any of the other surfaces to which it happened to be applied. At the same time, however, we confess that we conceive it unphilosophical to endeavour to account for *all* the cases which we have previously quoted of the addition of a female uterus to a male type of sexual organization upon this mechanical principle, or to attempt to explain away, in the mode we have just referred to, the evidence which these cases afford of the occasional occurrence of this combination as a true form of sexual duplicity. For even granting that the instances given by Ackermann and Steghlener, and perhaps one or two other cases, are not at all satisfactory in regard to the reputed existence of such a variety of sexual duplicity, and allowing, what seems indeed not at all improbable, that the supposed very imperfect uterus in these examples was merely an organ formed by a dilatation of the prostate and seminal ducts, there is still a sufficient abundance of cases left to which this explanation cannot possibly apply.

Thus, in the person dissected by Petit, the imperfect uterus was furnished with two perforate Fallopian tubes of three and a half inches in length, and at the same time it is distinctly stated that not only the prostate gland, but the vesiculæ seminales and vasa deferentia were also present. The vasa deferentia, between their origin from the testicles and their urethral termination, were each above seven inches long, and they entered the urethra by two apertures that were quite distinct and separate from the orifice of the uterus, which opened into the urethral canal at a point placed between the neck of the bladder and the prostate. In this case we cannot suppose that the uterus and Fallopian tubes were formed at the expense of the prostate gland or male seminal ducts, as they and all the other male organs were present; and consequently we can only consider the female organs as a *superaddition* to, and not a *transformation* of the male structures; or, in other words, we must look upon the above as an instance of duplicity in a part of the sexual apparatus.

The same reasoning and remarks might be shewn, if it were necessary, to apply in a greater

* Medical Repository for 1826, p. 571.

† As Jacobson of Copenhagen in Journal de l'Institut, t. ii. p. 160; and Die Okenschen Koerper, &c. Copenhagen, 1830.

or less degree to the other analogous examples in the human subject given by Harvey and Professor Mayer,* as well as to the hermaphroditic sheep described by Thomas, and the different cases in the goat mentioned and delineated by Gurlt and Mayer. In all these latter cases in the quadruped, the male organization appears to have been perfectly developed, the testicles, epididymes, vasa deferentia, and vesiculæ seminales being present in all of them; and in Thomas's sheep the superadded female uterus shewed internally the usual characteristic rugose structure, while its cornua terminated in two long Fallopian tubes. In Gurlt's goat case all the internal male sexual organs were found, with the exception of Cowper's glands; and yet we cannot suppose that these glands could have been transformed and moulded out into that distinct and hollow uterus with its two very long curved cornua, which the reporter has represented as being present; not to mention the total want of any collateral evidence in this and in the other cases to which we have just now referred, of any dilating power having acted upon the genital or urinary organs in the embryo.

3. *Fallacies in the supposed co-existence of testicles and ovaries.*—In several of those instances in which there has been supposed to be a co-existence of both testicles and ovaries upon the same side or sides of the body, it seems highly probable that there has been a fallacy in the observation, owing to a want of knowledge of some anatomical circumstances that are liable to lead us into error in making an examination of such a case.

We have previously had occasion to allude to the existence in the fœtal state of the Wolffian bodies, which are placed one along each side of the spine, and occupy at an early period in the embryo a great part of the cavity of the trunk. These bodies, as is now well known from the investigations of Rathke, Meckel, Müller, Burdach, and others, form in Mammalia and Birds at least, and equally so in both sexes, the primordial matrices of the genital and urinary organs (see article OVUM), and in the natural course of development altogether disappear in man and in the quadruped during the earlier periods of development, leaving no vestige of their presence in the extra-uterine animal.

This particular fœtal type of structure, like every other temporary type of the embryo, may, from an impediment or arrest in the natural course of the changes occurring in the development of the body in general, or of the genital organs in particular, become, we have every reason to believe, occasionally permanent in one or more of its parts, and thus by its presence in the animal lead us to suppose that a rudimentary testicle exists in an otherwise well-marked female, or, on the other hand, that an ovary exists in an otherwise well-marked male. Both of these mistakes will be the more apt to be committed if the original excretory duct of the Wolffian body remains, for it may give the appearance of the addition of a vas deferens to the supposed testicle, or of a Fallopian tube to the supposed ovary.

The error, also, of confounding a permanent Wolffian body with the testicle will be the more liable to occur, in consequence of the former body being naturally composed of an accumulation of convoluted diverticula which might be readily mistaken by an incautious observer for the seminiferous ducts of the latter.

There is certainly strong cause for doubting whether, in some of the cases that we have cited of the supposed co-existence of testicles and ovaries upon the same sides, the unremoved Wolffian bodies and their ducts had not either been mistaken for testicles and vasa deferentia, while the sexual organization was otherwise truly female, or for ovaries and Fallopian tubes, while the type of structure was in other respects strictly that of the male. This remark may perhaps with confidence be applied, for example, to the case of the free-martin described by Mr. Hunter; and in this and in most other similar instances the supposed testicles and ovaries have not been at all examined with any thing like sufficient anatomical accuracy. At the same time, however, it appears to us impossible to explain away all the recorded cases of the supposed co-existence of testicles and ovaries upon this principle. In reference to this point we would particularly observe that the consideration of the *relative position* occupied by the reputed testicles and ovaries may perhaps afford us an useful guide in cases of doubt. In some of the instances that have been previously cited, the relative situation of the supposed testicles and ovaries was exactly such as the Wolffian bodies are known to bear to these parts. In other instances, however, as in the ape described by Dr. Harlan, the relative situation in which the testicles and ovaries were found, was that which they occupy in the perfectly formed male and female; and in such a case as this it would surely be over-sceptical, and at the same time in opposition to all that we yet know of the history of the Wolffian bodies, to suppose that these bodies had imitated the testicles so far as to move out of their original locality and travel downwards through the inguinal rings. At the same time we must recollect that in this case the distinctive anatomical structure both of the testicles and ovaries seems to have been satisfactorily made out, in so far that the former are described as "perfectly formed," and the latter as having "minute ova visible in them." "The male and female organs of generation," Dr. Harlan adds, "were as completely perfected as could have been anticipated in so young an individual, and resembled those of other individuals of a similar age." Now if we once admit in this, or in any one other particular instance, that the evidence of the co-existence of testicles and ovaries is satisfactory, then certainly we may in any equivocal case be entitled to doubt until we have some more sufficient criterion for distinction pointed out, whether the dubious double bodies that we may meet with be a

* See his second case in the fœtus and those of the two adults in a preceding page.

rudimentary testicle or ovary conjoined with an imperfect Wolffian body, or really a true instance of the presence of both testicles and ovaries upon the body of the same individual.

PHYSIOLOGICAL DEGREE OF SEXUAL PERFECTION IN HERMAPHRODITES.

Among those lower tribes of animals, such as the Abranchial Annelida, Pteropoda, &c. that are naturally hermaphrodite, every individual is in itself a perfect representation of the species to which it belongs. In the higher orders, however, in which the distinction and separation of the sexes comes to be marked, each individual being either solely male or solely female, can, as has often been remarked, be regarded only as representing one-half of its entire species. In most instances of hermaphroditism among these more perfect animals, the malformed being does not even attain to this degree of perfection, but is in general so defectively constituted as not to have the proper physiological characters and attributes of either sex. In cases of spurious hermaphroditism it would appear that sometimes, though the copulative or external sexual parts are greatly and variously malformed, the internal or proper reproductive organs are developed with sufficient perfection to enable them to perform the functions belonging to them. We have very little proof, however, that in any instances of what we have described as true hermaphroditism, the apparatus of either sex is even formed with such anatomical perfection as to empower the malformed being to bear a successful part in the reproductive function. Indeed in all, or in almost all cases belonging to this last order of hermaphroditism, the individual who is the subject of the malformation may, with much more than poetical truth, be described both anatomically and physiologically, as, in the words of Ovid,

> Concretus sexu, sed non perfectus utroque,
> Ambiguo venere, neutro potiundus amore.

There is on record one remarkable instance of apparent exception to this general observation, a notice of which we have reserved for this place on account of the want of any such precise knowledge of the true anatomical peculiarities of the case as might enable us to refer it to the section which it ought to occupy in our classification. The case to which we allude was described by Dr. Hendy of New York, in a letter dated from Lisbon in 1807, and the subject of it was a Portuguese, twenty-eight years old, of a tall and slender but masculine figure.* "The penis and testicles," to adopt the words of Dr. Hendy's own narrative, "with their common covering the scrotum, are in the usual situation, of the form and appearance, and very nearly of the size of those of an adult. The præputium covers the glans completely, and admits of being partially retracted. On the introduction of a probe, the male urethra appeared to be pervious about a third of its length, beyond which the resistance to its passage was insuperable by any ordinary justifiable force. There is a tendency to the growth of a beard, which is kept short by clipping with scissors. The female parts do not differ from those of the more perfect sex, except in the size of the labia, which are not so prominent, and also that the whole of the external organs appear to be situated nearer the rectum, and are not surrounded with the usual quantity of hair. The thighs do not possess the tapering fulness common to the exquisitely formed female; the ossa ilii are less expanded, and the breasts are very small. In voice and manners the female predominates. She menstruates regularly, was twice pregnant, and miscarried in the third and fifth months of gestation. During copulation the penis becomes erect. There has never existed an inclination for commerce with the female under any circumstances of excitement of the venereal passion." In the preceding case, (if we may confidently trust to the account given of it,) we have ample proof of the existence of the internal female sexual organs in the circumstances of menstruation and impregnation taking place; and at the same time there appears considerable evidence for believing that some of the male organs were present. For even if we were to argue that the bodies present in the scrotum or united labia might be ovaries and not testicles, and that the supposed semi-perforate penis was only an enlarged clitoris, still the masculine figure of the individual, the imperfect beard, the narrowness of the pelvis, and the form of the lower extremities would tend to indicate the probable existence of the rudiments of some male organs; and if we go so far as to admit this, we must further allow the present to be an instance of hermaphroditism, in which *one* of the sets of sexual organs was capable of assuming their appropriate physiological part in the process of reproduction, though perhaps unable, if we may judge from abortion having twice occurred, of ultimately perfecting that process.

The preceding remarks upon the functional reproductive powers of reputed true hermaphrodites have been meant to apply only to the supposed perfection of *one* order of their sexual organs. It becomes a still more interesting question whether it ever occurs that in any abnormal hermaphrodite among the more perfect tribes of animals, both kinds of sexual parts may be found in so perfectly developed a state as to enable the individual to complete the sexual act within its own body; or, in other words, to impregnate and be impregnated by itself. Though we have assuredly no positive proof to furnish* that a hermaphrodite so physiologically perfect has ever yet been observed, and should very strongly doubt its occurrence

* New York Medical Repository, vol. xii. p. 86.

* We do not certainly feel entitled to place among the category of correct observations either the alleged case given by Linneus (Mangetus' Bibliotheca Chirurg. lib. iv.) of a sow with perfect male organs on one side, and a womb containing several fœtuses on the opposite; or that mentioned by Faber (Hernandez' Nov. Plant. Anim. Mexic. Histor. p. 547) and quoted by Haller and Rudolphi, of the co-existence, in a rat, of ovaries and a uterus with nine fœtuses, along with complete male organs.

from the almost universal imperfection, in an anatomical point of view, of the malformed organs, yet we have, on the other hand, no very rational ground, except that of the experience of all observers up to the present date, for denying entirely and unconditionally the utter possibility of it. And perhaps we should look upon this possibility with a less degree of scepticism when we consider that a double hermaphroditism exists as the normal sexual condition of some of the lower tribes of animated beings, and at the same time take into account the fact of the more or less direct communication which has been generally found to exist between the female uterus and the male passages, in cases of lateral and of complex hermaphroditism in the human subject and in quadrupeds.

In one of the cases of hermaphroditism in the goat, previously quoted from Mayer, and where there were present two male testicles, epididymes, vasa deferentia, and vesiculæ seminales, and a female vagina, uterus and Fallopian tubes, with a body at the abdominal extremity of one of these tubes that was supposed by Mayer to resemble a collection of Graafian vesicles, the male vasa deferentia opened into the female vagina; and its cavity with that of the uterus, and of all the male sexual canals, was distended with a whitish fluid of the odour and colour of male semen, and containing, according to Bergmann, the chemical principle proper to that secretion. It is not, therefore, altogether without some appearance of foundation in fact, that Mayer has added to the history of this case the following problematical remark: "Fuit ergo revera hermaphroditus semetipsum fœcundare studens."*

In a similar strain Dr. Harlan has added to the account that he has given of the very complete case of hermaphroditism already mentioned as met with in the Borneo ourang-outang, the following observations and queries. "Admitting," he remarks, "what in reality appeared to be the fact, that all the essential organs of both sexes were present in this individual, had the subject lived to adult age, most interesting results might have been elicited. Could not the animal have been impregnated by a male individual, by rupturing the membrane closing the vulva? or by masturbation, might not the animal have impregnated itself? by this means exciting the testicles to discharge their seminal liquor into its own vagina. The imperfection of the urethra most probably would have prevented the animal from ejecting the semen into the vagina of another individual."†

It has been sometimes urged as an argument conclusively illustrative of the fact of a double hermaphrodite impregnating itself, that in the hermaphrodite *Gastrophaga pini* described by Scopoli,‡ the insect is stated to have been seen to advance its penis and copulate with its own female organs; and afterwards, we are informed, the female side laid eggs from which young caterpillars were produced. Before, however, admitting this case to present an incontrovertible instance of absolute hermaphroditism, with the functions of the two sets of sexual organs existing in a perfect condition upon the same individual, it is necessary to recollect a possible source of fallacy in this circumstance, that female Gastrophagi have been observed to lay fertile eggs, although they had not had previously any connection with the male, as remarked by Professor Baster* in one instance in a female *Gastrophaga quercifolia*, and in another in the *Gastrophaga pini* by Suckow.† The same fact is further alleged to have been observed in some few instances by Pallas, Treviranus, Bernouilli, and others,‡ in regard to individuals belonging to some other of the higher orders of insects and animals, as in the *Limnæus auricularis*§ and *Helix vivipara*‖ among Mollusca, thus bringing them in this respect into analogy with the Aphides and Cyprides.

CAUSES OF HERMAPHRODITIC MALFORMATION.

As yet we possess very little accurate knowledge either in respect to the mode in which the determining causes of hermaphroditic malformation act, or the nature of these causes themselves.

Most of the varieties of spurious hermaphroditism may, as we have just explained, be traced to an arrest in the development of the sexual organs at one or other period of their evolution, in consequence of which some of those types of structure in these parts which were intended to be temporary and transitory only, are rendered fixed or permanent in their character. Our knowledge of the more immediate causes of such arrested development in these and in other individual parts and organs of the body, is as yet extremely limited, and for the discussion of it we must refer to another part of the present work, (see article MONSTROSITIES). We may, however, in reference to the particular forms of arrested development observed in hermaphroditism, remark that in consequence of the great influence which, as we have already pointed out, is exercised by morbid states of the ovaries and testicles, in retarding or preventing the evolution of the sexual apparatus and characters after birth, it has been suggested with considerable probability by Meckel¶ and Isidore St. Hilaire,** that in their ultimate analysis certain cases of hermaphroditic malformation may be traced in the course of their causation to morbid influences exercised in the early embryo, at a period more or less near to conception, upon the ovaries or testicles, or upon those organs of a neuter or yet undetermined sex which afterwards assume the structure of one or other of

these bodies. Further, the effects which this supposed morbid influence exercises directly upon the embryonic ovaries and testicles, and indirectly through them, upon the rest of the genital apparatus, and consequently the modifications of sexual structure which it produces, may possibly be much varied according to its extent, duration, and nature, and according to the particular period of development at which it comes into action. It is evident that this explanation of hermaphroditism can only refer to the varieties of the malformation which consist of an imperfection or deficiency in the development, and cannot apply to those instances in which there is a superaddition of sexual organs. If, however, we can once satisfy ourselves that any set of cases whatever are traceable to a morbid action affecting the testicles or ovaries of the early embryo, our investigations into the causes of these cases will necessarily be much simplified, for our inquiries would be reduced from a vague and indefinite search after the production of a number of anomalies of structure affecting several different organs at the same time, to an attempt to trace out the nature of those morbid conditions to which the embryonic testicles and ovaries were subject, and which were capable of so far changing the structure and action of these organs as to give rise to the effects in question. Of the diseased states, however, to which the reproductive and other organs of the system are liable during the progress of their early development, we at present know little or nothing, although in the investigation of this subject a key, we believe, may possibly be yet found to the explanation of many of those malformations to which different parts of the body are subject.

Osiander* and Duges† have suggested that the variety of spurious hermaphroditism which consists of a division of the perinæum in the male, may be produced *mechanically* in the embryo by the præternatural accumulation of fluid in the urinary canal, on account of an imperforate state of the urethra, and the consequent distension and ultimate rupture of the urethra, &c. From cases published by Sandifort, Howship, Billard, and many others, we are now fully aware of the fact that all the urinary canals of the fœtus in utero are occasionally found morbidly distended with a fluid, which, according to the interesting observations of Dr. Robert Lee,‡ would appear to possess the more characteristic qualities of urine. We have dissected one case in which the dilated fœtal bladder was as large as an orange, and have seen in the Anatomical Museum of Dr. William Hunter at Glasgow the preparation of another instance in which the bladder of a full-grown fœtus was dilated to the size of that of the adult subject. In one case mentioned by Dr. Merriman, the distended organ contained half a pint of urine,* and in another detailed by Mr. Fearn it was capable of containing as much as two quarts of fluid.†

It is not impossible that the causes in question,—namely, the obliteration of the urethra and the consequent distention of all the urinary passages, and probably also of the sexual canals communicating with these passages,—may occasionally produce in the male embryo a re-opening of the perinæal fissure, giving thus to the external parts the appearance of a female vulva, and perhaps at the same time may lead to the retention and imperfect development of the testicles by the distention of their ducts, and the unusual compression to which these organs may be subjected. Indeed we have satisfactory evidence, in a few instances, that such a cause may have been in operation, by our detecting the other acknowledged effects of the urinary accumulation in question,—such as preternaturally dilated ureters, and a cystic form of the infundibula of the kidneys, as in a case of hermaphroditism given by Mayer, in a human fœtus,‡ in the kid described by Haller,§ and in the child whose case we have already quoted from Steghlener. (See *transverse hermaphroditism.)*

At the same time the total absence of these collateral proofs in most other cases of hypospadias, our knowledge of the fact that the perinæal aperture is in some cases never shut, and the difficulty of conceiving the possibility of its being re-opened when once it is firmly closed, are perhaps sufficient to shew that the cause or causes alluded to produce in but few if any instances the effect here attributed to them.

We deem it not uninteresting to point out in this place, under the question of the origin of hermaphroditic malformations, a circumstance which has struck us in considering one or two of the cases in which the sexual apparatus of one side of the body was more imperfectly developed than that of other, viz. that the opposite side of the encephalon was at the same time defectively formed. Thus in the case of Charles Durge, on the right side of whose body there was a well-formed testicle, and on the left an imperfect ovary, the right hemispheres of the cerebrum and cerebellum, but particularly of the latter, were found by Professor Mayer to be smaller and less developed than the left, and the left side of the occiput was externally more prominent than the right. The same author, in the account of his case of hermaphroditism in a person of eighteen years of age, which we have previously quoted,|| and where there was an imperfect testicle, &c. on the right side, but no trace of testicle or ovary in the left, incidentally mentions that the right side of the cranium was somewhat prominent,—"dextra pars cranii paullulo prominet," in correspon-

dence, there is every reason to believe, with a slight predominance in size in the hemispheres of the encephalon of the same side. In adducing these two cases we do not wish to draw any inference with regard to the relation of causation between the size and development of the encephalic mass and the determination of the sex, but would merely point out the facts themselves in the meantime, for the purpose of drawing attention to the subject in the observation of any future similar instances that may happen to occur.

In connection with the question of the causes of hermaphroditism, it is interesting to remark that in some instances malformations of the genital organs giving rise to appearances of hermaphroditism have been observed both to be *hereditary* in particular families, and in other cases to occur among several of the children of the same parents. Thus Heuremann* mentions an example of a family the females of which had for several generations given birth to males who were all affected with hypospadias; and Lecat† alleges that a degree of hypospadias is not uncommon among families in Normandy. In Rust's Magazine an instance is related of a degree of hypospadias existing in a father and son.‡ Baum,§ in his essay on congenital fissures of the urethra, has referred to two instances of the existence of hypospadias in brothers of the same family, the first mentioned by Walrecht,|| and the second by Gockel.¶ Sir Everard Home** found two cases of hypospadias in two children belonging to the same parents. Kauw Boerhaave†† mentions an example of four hypospadiac brothers, and Lepechin another instance of three.‡‡ Naegele has reported a case in which two male twins were both hypospadic,§§ and Katsky |||| and Saviard ¶¶ have mentioned similar instances.

We have already, when treating of transverse hermaphroditism, alluded to another fact long and extensively known among our agriculturists, but first prominently brought before the notice of physiologists by Mr. Hunter, that the free-martin cow, or the cow that is born a co-twin with a male, is generally barren and has its sexual organs more or less defectively developed or hermaphroditically formed.*** In three different instances Mr. Hunter confirmed the fact of the anomalous sexual development of such animals by dissection; and Scarpa* and Gurlt† have published some additional observations and cases. We have lately had an opportunity of dissecting the sexual parts of two adult free-martins, and found them, as already detailed, formed after an abnormal and imperfect sexual type; and our friend Dr. Allen Thomson made some years ago a similar observation upon a free-martin twin fœtal calf. Cases, however, exceptional to the general fact of the sterility and imperfect sexual conformation of the free-martin twin cow are not unfrequently met with. Mr. Hunter found the sexual organs of a free-martin calf that died when about a month old apparently naturally constituted. He speaks also of having heard of some free-martins that were so perfectly formed in their sexual parts as to be capable of breeding; and different instances of their fecundity have been published by Dr. Moulson and others‡ since the time that Mr. Hunter directed attention to this subject. In some pretty extensive inquiries which we have made in regard to this point among the agriculturists of the Lothians, we have learned only of two instances in which free-martins proved capable of propagating, and such cases seem to be always looked upon as forming exceptions to the general rule.

We are not aware that among other uniparous domestic animals, as the goat, mare, &c, when a female is born a co-twin with a male, this female is sterile, and has its sexual organs hermaphroditically formed, as in the free-martin cow; and we are sufficiently assured that no such law holds with regard to twins of opposite sexes among sheep. Sir Everard Home, in his essay on monstrous formations, § mentions that in warm countries nurses and midwives have a prejudice that such women as have been born twins with males seldom breed; and we have found the same prejudice existing to a considerable degree among the lower orders in Scotland. Mr. Cribb,|| of Cambridge, published in 1823 a short paper in order to refute this notion as far as regarded the human subject. He refers to the histories of seven women who had been born co-twins with males. Six of these had children, and the remaining seventh subject alone had been married for several years without any issue. We have ourselves made a series of extensive inquiries of the same nature

*** From the Romans employing the female noun *taura* to signify a barren cow, it has been ingeniously conjectured that they were not unacquainted with the free-martin. Thus Columella de Re Rustica, lib. vi. chap. 22, speaks of "*tauræ* which occupy the place of fertile cows;" and Varro in like manner (lib. ii cap. 5.) states that "the cow which is barren is called *taura*" (quæ sterilis est, *taura* vocatur). There is no evidence, however, that they were acquainted with the particular circumstances relative to birth under which free-martins are produced.

as those published by Mr. Cribb, and have obtained authentic information regarding forty-two adult married females who had been born as twins with males. Of these, thirty-six were mothers of families, and six had no children, though all of them had been married for a number of years. Two of the females who have families were each born as a triplet with two males.* In the Medical Repository for 1827 (p. 350) an anonymous author has mentioned an instance of quadruplets consisting of three boys and a girl, who were all reared: the female afterwards became herself the mother of triplets. Limited as the data to which we here allude confessedly are, they are still amply sufficient to show that in by far the majority of cases the females of twins of opposite sexes are in the human subject actually fertile, and, as some of the cases we have collected show, they are occasionally unusually prolific.

On the other hand, however, it may be considered by some that the same data rather tend in a slight degree, as far as they go, to support the popular prejudice of the infecundity in a number of cases of the female twin, and her analogy in this respect with the free-martin cow; for out of the forty-two instances which we have mentioned, we find six in which the woman has had no children, though living in wedlock for a number of years, or one out of seven of the marriages of such women has proved an unproductive one,—a proportion, we believe, considerably above the average of unproductive marriages in society in general, or among women of any other class. But perhaps, before drawing any very decided conclusion with regard to this point, a more extended foundation of data would be requisite than any we have hitherto been able to adduce, as it is perfectly possible that *our* having met with six exceptional cases may be a mere matter of coincidence.

As to the cause of the malformation and consequent infecundity of the organs of generation in the free-martin cow, we will not venture to offer any conjecture in explanation of it. It appears to us to be one of the strangest facts in the whole range of teratological science, that the twin existence in utero of a male along with a female should entail upon the latter so great a degree of malformation in its sexual organs, *and in its sexual organs only*. The circumstance becomes only the more inexplicable when we consider this physiological law to be confined principally or entirely to the cow, and certainly not to hold with regard to sheep, or perhaps any other uniparous animal.

The curiosity of the fact also becomes heightened and increased when we recollect that when the cow or any other uniparous animal has twins both of the same sex, as two males or two females, these animals are always both perfectly formed in their sexual organization, and both capable of propagating. In the course of making the preceding inquiries after females born co-twins with males in the human subject, we have had a very great number of cases of purely female and purely male twins mentioned to us, who had grown up and become married, and in only two or three instances at most have we heard of an unproductive marriage among such persons.

Further, we may, in conclusion, remark that among the long list of individual cases of hermaphroditism in the human subject that we have had occasion to cite, we find only one instance, (Eschricht's case of transverse hermaphroditism,) in which the malformed being is stated to have been a twin. Katsky, however, Naegele, and Saviard have each, as before stated, mentioned a case in which both twins were hermaphroditically formed in their sexual organs.

* Notes of the histories of these cases individually were read to a meeting of the Royal Physical Society of Edinburgh in the beginning of 1837.

HERMAPHRODITISM IN DOUBLE MONSTERS.

One of the most curious facts in the history of double monsters is the great rarity of an opposite or hermaphroditic sexual type in their two component bodies, the genital organs of both bodies being almost always either both female or both male.

Physiological science affords us at present no satisfactory clue to the explanation of this singular circumstance. From two cases of double monstrous embryos observed in the egg of the domestic fowl by Wolff* and Baer,† and from a similar case met with in the egg of the goose by Dr. Allen Thomson, it appears certain that double monsters sometimes originate upon a single yolk, probably in consequence of the existence of two cicatriculæ upon this yolk,‡ or of two germinal points (or two of the vesicles of Purkinje and Wagner) upon a single cicatricula. In such a case the two bodies of the double monster are so early and intimately united together as to form, almost from the commencement of development, a single system; and therefore the fact of the uniformity of their sexual character is the less remarkable. But in other instances when the double monster originates (as from the phenomena of incubation in double-yolked eggs we know to be frequently the case,) on two separate yolks or in two separate embryos becoming fused or united together, at a more advanced stage of development, it appears more extraordinary that the sexes of the two conjoined fœtuses should be so constantly uniform as they seem to be in monsters perfectly double. This uniformity only becomes the more singular when we reflect that twin children are not at all unfrequently of opposite sexes.§

* Nov. Comment. Acad. Petropolit. tom. xiv. p. 456.

† Meckel's Archiv. für Physiologie, &c. for 1827, p. 576.

‡ We have in our possession a preparation, taken from a duck's egg, in which two full-grown fœtuses are developed on opposite sides of a *single* yolk of the common size.

§ In the Edinburgh Lying-in Hospital forty-six cases of twins occurred from 1823 to 1836, both years inclusive. In seventeen of these cases the two children were both females; in sixteen both males; and in the remaining thirteen instances one child was male and the other female. We know of

The fact itself, however we may explain it, of the comparatively extreme rarity of both male and female sexual organs upon double monsters seems sufficiently established by various careful investigations made into the subject. Thus out of forty-two perfectly double monsters which Haller* was able to collect at the time at which he wrote, there were only two that were supposed to be of double sex, or, in other words, that had one body male, and the other female. Among double-headed monsters with single lower extremities, he found an hermaphroditic type more common, and adduces three examples of it.

In re-investigating this matter, the late Professor Meckel† could discover among the numerous class of monsters with perfectly double bodies united anteriorly or laterally by the thorax and abdomen, only one very doubtful case of exception to the above general fact. In the class of double monsters united in the region of the pelvis he mentions two exceptional cases from Valentin‡ and Hasenest;§ of double-headed monsters with single bodies, he quotes three similar cases from Lemery,|| Bacher,¶ and Bilsius;** and of monsters with a single head and double body he adduces two cases from Brissæus†† and Condamine,‡‡ in which in a like manner one body of the monster was supposed to have female, and the other male sexual organs. Several of these cases, however, certainly rest upon too doubtful authority and insufficient observation.

Isidore St. Hilaire has still further extended the data on which the above general fact is founded, by shewing that the same uniformity of sex holds good with respect to double parasitical monsters,§§ and even in monstrosities double by inclusion. Thus out of this last interesting class of double monsters, he alludes|||| to ten distinct cases in which the sex of the included being was ascertained. In six out of these ten cases the including and included body were both male; and in the other four they were both female.

On the whole, therefore, we must consider as founded on a proper induction from the existing data, the axiom of Meckel,—"Sexuum diversorum indicia in eodem organismo, quantumvis duplicitate peccet, non dari, sed unum tantum observari."¶¶ But while all the data hitherto collected with regard to this subject would seem to point it thus out as one of the most constant and best ascertained laws in teratology, still we are not altogether disposed to consider it with Zeviani* and Lesauvage† as subject to no exceptions whatever. In the study of monstrosities, as in the study of other departments of medical science, we find many general, but no universal laws.

(James Y. Simpson.)

HERNIA (in morbid anatomy). The protrusion of any viscus from the cavity in which it ought naturally to be contained is termed a hernia, and thus the apparent escape of any part from any of the great cavities of the body may seem to constitute the disease: still, however, as the real existence of cerebral or thoracic ruptures rests upon very doubtful authority and is extremely questionable, and as abdominal protrusions are unfortunately equally palpable and frequent, the application of the term is usually limited to them. To this frequency many causes seem to contribute. In the walls of the abdomen there are three remarkable natural openings, or perhaps it would be more correct to say, there are three situations so weak and unprotected that they easily yield and permit the escape of any viscus that may be directed against them with even a moderate degree of force: these are, the umbilicus, through which during fœtal life the umbilical cord passes; the inguinal canal, which allows the passage of the spermatic cord in the male, and the round ligament of the uterus in the female; and the crural ring, which transmits the great bloodvessels to the thigh and lower extremity. The nature of the walls too, which are principally composed of muscle, and the condition of the viscera within, loose, liable to change of size and situation, and subject to irregular pressure by the contractions of these muscular walls, dispose to the occurrence of the disease in any of these situations, where the resistance to such pressure is but feeble. Hence herniæ are most frequently met with at one of the places already mentioned,—the umbilicus and the inguinal and femoral canals. But there are other situations* at which protrusions may possibly take place, although fortunately they are infrequent, such as, at the side of the ensiform cartilage, at the obturator foramen, at the sacro-ischiatic notch, and between the vagina and rectum in the female. It is also evident that if the muscles or tendons of the diaphragm are wounded, some portions of the contents of the abdomen may escape, thus constituting the varieties of ventral and phrenic herniæ. Accordingly the forms of this disease have been arranged and named from the different places at which they occur,—an arrangement of the greatest practical importance; for as the structure, the size, and shape of each aperture must exert a peculiar influence on the condition of the protruded viscus, on its liability to become incarcerated, on the possibility of its being returned, on the steps to be adopted for this purpose, and above all on the safety and success of an operation should such be necessary, a knowledge of each of these in connexion with hernia is absolutely indispensable.

Besides this division of hernia as to situation, there is another of very considerable importance derived from the nature of the viscus displaced: thus in abdominal ruptures the contents of the tumour may be intestine alone, in which case it is called *enterocele;* or omentum alone, the *epiplocele*; or both these may be engaged, constituting the *entero-epiplocele.* There is not a viscus in the abdomen or pelvis, excepting perhaps only the pancreas and kidneys, that has not at one time or another formed the contents of a rupture. The stomach has been partially displaced through the diaphragm, or pushed through the walls of the abdomen: the duodenum has formed part of a ventral or umbilical hernia: the jejunum or ileum are very likely to be protruded in any situation: the omentum is often displaced, particularly in inguinal herniæ at the left side: the large intestines from being more fixed are not so frequently thrust out, yet the cœcum and colon are but too often found among the contents of a rupture. I have seen a large portion of the liver in an umbilical hernia of the infant: Verdier† relates numerous cases of herniæ of the urinary bladder; and Pott‡ mentions one which renders it nearly certain that the ovaria in females may suffer in a similar manner. However, the natural situation of any viscus within the abdomen is but an uncertain criterion by which to judge of the contents of a hernia in its vicinity. The strangest displacements have been observed occasionally in the examination of this disease: thus the sigmoid flexure of the colon has been protruded at the right side, and the cœcum and valve of the ileum at the left. In all large and old herniæ the parts are dragged out of their proper situations,

* Sur plusieurs hernies singulières. Garengeot, Mémoires de l'Academie Royale de Chir. tom. iii. p. 336. Paris edit. in 15 vols. 1771.

‡ Pott's Works, by Earle, vol. ii. p. 210.

and their appearances on dissection and relative positions are often such as no one from anatomical knowledge alone could ever have suspected to be possible.

In all forms of abdominal hernia excepting those only which immediately supervene on penetrating wounds, the contents of the rupture are lodged within a pouch or bag termed the *hernial sac*, which is formed of the peritoneum. This membrane lines the entire cavity so perfectly and completely that nothing can pass out from it without the membrane also participating in the derangement and being pushed out before the displaced viscus. Once formed, this sac is rarely capable of being replaced or returned into the cavity of the abdomen; never unless the hernia is small and recent, and "the cellular substance accompanying it and the spermatic cord through the ring has not lost its natural elasticity and contractility."* Many surgeons have doubted the possibility of such an occurrence at any period,† but the fact has been demonstrated by dissection, and still more forcibly by the circumstance of the hernia having been thus strangulated within the abdomen when the sac has been returned along with it. However, as I have said, the sac when once formed is rarely capable of being replaced, nor does it long remain in this abnormal situation without undergoing some change in its pathological condition—a change which it is not always easy satisfactorily to explain. In small herniæ that have recently come down, the structure of the sac differs in nothing from that of the abdominal peritoneum; and if the rupture is not reduced or kept up by a truss, it will probably increase in size without any remarkable alteration of tissue, for the membrane is extremely distensible, and will accommodate itself to any quantity of contents. But, if the hernia is carefully kept up, there can be no doubt that the sac will gradually contract and seem to rise up and approach the opening through which it originally passed, so that, although its cavity is never completely obliterated, it is palpably diminished in size, and incapable of receiving and retaining the same quantity of contents it originally held. Sometimes in old and neglected herniæ the sac *seems* to become so thin that the peristaltic motion of the intestines within it has been clearly perceived: this most frequently occurs in umbilical hernia, and is one of the reasons why this form of rupture was supposed not to have been enveloped in a sac at all. Again, on the contrary, in old herniæ also, and particularly where bandages have been worn to support or compress the tumour, it *seems* to become very thick, strong, and tense, and is said to have been met with as tough and as thick as cartilage. But in the great majority of instances these changes are rather apparent than real, and though doubtless the structure of the sac is no longer exactly that which it possessed before protrusion, the alteration is not so great as some writers have supposed. It was the opinion of Scarpa that an old hernial sac is in reality but slightly if at all thickened, and that the apparent thickening is caused by the condensation of the cellular tissue external to and around it. And here I may remark that differences of opinion as to the altered structure of the sac may have arisen from a difference of accuracy and minuteness in examination, either during the progress of an operation or after death. We shall find hereafter that the normal anatomy of the parts connected with hernia is largely indebted to the knife of the anatomist for the shapes of the different openings, the division and enumeration of the different layers of fascia, and many other points; but in the morbid anatomy of the disease the same patient investigation and the same accuracy of description has not been so uniformly observed, and hence our knowledge of the latter part of the subject as compared with the former is by no means so defined and exact.

Where a rupture has been a long time down, it is not probable that the intestine shall thus remain in an abnormal situation without occasionally suffering from inflammation, and hence adhesions between it and the sac are by no means unfrequently formed: the same effect may be produced by accidental violence, or from the latter cause the sac may be ruptured and its contents left lying under the usual coverings independent of the peritoneum. This is another of the cases in which a hernia has been supposed to exist without the investment of a sac.

The peritoneal aperture leading from the cavity of the abdomen into that of the rupture is narrow, and is called the neck of the sac: its dimensions as to length, however, vary with circumstances. As long as the communication is open and free between the two cavities, all that portion of peritoneum which is placed between them and corresponds to the canal through which the rupture has passed, may be termed the neck, and thus in inguinal hernia may be an inch, and in crural half an inch in length. But when the protruded parts are strangulated, the little circle only around which the compression directly operates is more properly entitled to the appellation, and its extent is seldom greater than two lines. When the neck of the sac of a *very recent* hernia is viewed from the cavity of the abdomen, the peritoneum in its vicinity is seen thrown into slight folds or plaits, which appear to be prolonged downwards into the tumour; but on slitting open the neck, I have never seen this appearance within it, the membrane there being smooth, rather whiter and more opaque, and evidently thicker and more unyielding than elsewhere. If such a hernia in the living subject has been reduced and kept up by a truss, the neck gradually contracts under the pressure, and its diameter with respect to that of the ring through which it has passed is altered to a degree that is of the greatest importance in the event of another protrusion, for it will be shewn hereafter that such a diminution of size greatly predisposes to the occurrence of strangulation. It is also possible

* Scarpa on Hernia, translated by Wishart, p. 68.
† See Louis, Mém. de l'Acad. Roy. de Chir. tom. ii. p. 486.

that the neck shall be so contracted that in the new occurrence of hernia an additional portion of peritoneum may be detruded, and then the sac must present the shape of an hour-glass, narrow in the centre and broad at either end: sometimes two, three, or more of these successive protrusions take place, and then the sac is divided into so many sacculi with incomplete intercepts or partitions between them. Or one portion of peritoneum may be forced within another, so that the intestine is actually included within a double sac. This last is a curious and very uncommon occurrence. On the other hand the neck of a hernial sac may suffer distension. In very old ruptures that have become irreducible or from any other cause been long down, the neck of the sac sometimes becomes wonderfully dilated, and the portion of intestine immediately passing through it scarcely subjected to the slightest pressure.

There is one form of hernia, the chief peculiarity of which lies in the nature of its peritoneal investment, for, correctly speaking, it possesses no proper sac. It is the hernia congenita,* a species of rupture which occurs in very young infants, and sometimes, under peculiar circumstances, in persons of a more advanced age also.

During the early periods of fœtal existence the testes do not occupy that situation which they possess in after life. They are placed within the abdomen, above the pelvis, which at this time is so small and imperfectly developed that many of the viscera lodged within it afterwards, seem now to lie within the belly. They are just below the kidneys, in front of the psoas muscle at each side, and possess, like other viscera, an investiture of peritoneum, which is afterwards to be the tunica vaginalis testis. About the sixth month, or perhaps the seventh or even later, (for it observes no exact rule in this respect,) the testis begins to descend, not gliding behind the peritoneum, but preserving its own investing coat until it comes to the internal abdominal ring, where it pushes a process of peritoneum out before it, just as an intestine would do in the production of a hernial sac. This is afterwards to become the tunica vaginalis scroti. The testicle then passes on through the inguinal canal, through the external ring,† and finally drops into the scrotum. After some time the canal of communication with the cavity of the abdomen begins to contract and close, and if the usual process goes on healthily and without interruption, very shortly a complete obliteration takes place, and the testis is separated from the abdomen perfectly and for ever. The time at which this is accomplished is extremely uncertain: sometimes it is perfect at birth; in other cases the canal is more or less open, and then, if the infant cries or struggles, a portion of the contents of the abdomen is protruded into the cavity of the tunica vaginalis, and the hernia congenita is formed. If any part of the above-mentioned process is interrupted or postponed, it will occasion some variety. Thus the tunica vaginalis may not exhibit its usual disposition to close and become obliterated at its neck, and then for a length of time the patient is exposed to all the inconvenience and hazard of the descent of a hernia: sometimes the testicle does not come down until a much later period, a circumstance that is often occasioned by the gland contracting adhesions with some adjacent viscus in its passage, and may be attended with the additional inconvenience of drawing down such viscus along with it. The surgeon should also be aware of the possibility of the protrusion of another portion of peritoneum into the open tunica vaginalis, and thus a mixed case may arise of a congenital containing within it a proper sacculated hernia.

The congenital rupture, then, has no proper sac, but is lodged within the tunica vaginalis in close apposition with the testis · hence many of its peculiarities can be explained. It is obviously the only kind of hernia in which an adhesion can exist between the testicle and the protruded viscus, and it is also evident that the testis does not bear the same relation to the protruded viscus in this that it does in cases of ordinary rupture. Here it is higher up, and seems to be more mixed and identified with the other contents; the entire tumour is more even and firm, the protruded parts are less easily felt and distinguished; and Hesselbach states that when strangulation is present, the sac is every where equally tense, and the testis cannot be felt at all. In very young infants a small quantity of fluid is often present along with the intestine in the tunica vaginalis: it disappears when the child is placed in the recumbent position, and does not add to the difficulty or importance of the case. It has been stated that the tunica vaginalis has a natural tendency to become closed at its neck, and therefore is it more likely to thicken and diminish in capacity in this situation so as to form a band round the protruded viscus. Pott* was of opinion that congenital hernia was more subject to be constricted at the neck of the sac than any other: Wilmer stated that out of five cases of congenital hernia on which he operated, three were strangulated at the neck of the sac; and Sandifort and others maintained the same doctrine. Scarpa† thought that every displaced portion of peritoneum possessed the same tendency to contraction, and advanced it as a reason why stricture in the neck of a hernial sac should be more frequent in all kinds of hernia than is generally supposed. It is not easy to place implicit reliance on this latter opinion, because the neck of the common hernial sac when once formed is never again completely closed; but with respect to congenital hernia the observation appears to be equally correct and important.

Scarpa‡ describes a form of hernia which may

† Page 131.

‡ Op. citat. p. 205 et seq.

under certain circumstances of imperfect or careless examination appear to be devoid of a proper sac, formed by a descent of the peritoneum. This occurs at the right groin, is always large, and is formed by a protrusion of the cœcum with the appendix vermiformis and the beginning of the colon. The cœcum is placed in the right ileo-lumbar region, and a portion of it does not possess a peritoneal covering, but lies absolutely *without* the great abdominal membranous sac: when therefore these parts are protruded, a portion of the cœcum and the beginning of the colon will be found included and contained in the hernial sac, while another portion of the same intestines will be necessarily without the sac, and lying denuded in the cellular substance which accompanies the descent of the peritoneum in the hernia. If this tumour is opened into by an incision carried too much towards its external side, the cœcum and colon will be exposed lying outside of the peritoneum, and apparently devoid of a hernial sac; but if cut into precisely in the middle or a little towards the inner side, under the cremaster muscle and the subjacent cellular tissue, the true hernial sac will be found, formed of the peritoneum. Within this will be seen "the greater portion of the cœcum with the appendix vermiformis, and likewise the membranous folds and bridles which seem to be detached from the hernial sac to be inserted into these intestines, the smaller portion of which will be without the sac, in the same manner as when these viscera occupied the ileo-lumbar region." This form of rupture I have never seen, and must therefore refer the reader to Scarpa's work, wherein he will find the peculiarity most satisfactorily explained.

But in the arrangement of herniæ, that division is most practically interesting which has reference to the condition or state of the intestine or other protruded viscus, and the disease is then described as being reducible, or irreducible, or strangulated.

1. A hernia is said to be reducible when it either retires spontaneously on the patient assuming the recumbent posture, or can be replaced without difficulty to the operator or future inconvenience to the patient beyond that resulting from the employment of measures adapted to retain it within the cavity. This condition supposes that the relation (particularly as to size) between the hernia and the aperture through which it had escaped has not undergone any alteration.

2. It is irreducible when there is such a change in the structure, situation, or other condition of the protruded viscus as to render it impossible to be returned, although the aperture through which it passed may offer no impediment. There is another case in which a hernia has been considered irreducible, namely, when it would be impolitic or unwise to attempt the reduction, supposing it to be perfectly practicable.

3. A hernia is strangulated when the relation as to size between the protruded viscus and the aperture through which it has passed is so altered as not only to prevent reduction, but to cause such a degree of compression at the aperture as will interrupt the circulation through the escaped viscus, and endanger its vitality. This condition has been supposed to exist in two different forms, strangulation by inflammation and by "engouement,"* or as Scarpa terms them, "the acute and chronic;"† but this division only has reference to the severity of the symptoms and to the rapidity or slowness of their progress, for although an intestine may be in a state of obstruction which will, if unrelieved, proceed to strangulation, yet the latter state cannot be said to have arrived until the return of the venous blood from it is actually impeded. The protruded viscus is then in a situation precisely similar to that of a limb round which a cord had been tied with sufficient tightness to interrupt the circulation and threaten to induce mortification.

These different conditions will be best understood by tracing a rupture through each of them in succession.

A person may be suspected to have a reducible hernia when, after the application of some force calculated violently to compress all the viscera of the abdomen, an indolent tumour appears proceeding from some of those places where the walls of the abdomen are known to be weakest and least resisting. And the suspicion is increased if the tumour is elastic, if it sounds clearly on gentle percussion, and becomes suddenly puffed up and swelled, as if by air blown into it, when the patient coughs, sneezes, or performs any of those actions which forcibly agitate the abdominal parietes. The reducible hernia becomes smaller or perhaps disappears altogether when the patient lies down: it appears of its full size when he stands erect; if neglected, it has a constant tendency to increase, which it does sometimes by degrees, slowly and almost imperceptibly, but more frequently by sudden additions to its bulk, which are formed by new protrusions. In this form of the disease the qualities of the viscus engaged within the sac, as to form, size, and structure, may be considered as unchanged: within the abdomen, however, the fold of mesentery which supports the protruded intestine is constantly more elongated than it naturally should be, and likewise thicker and more loaded with fat. It is also marked with dilated and tortuous veins.

Although thus displaced, the viscus is still capable of performing its part in the function of digestion, and as long as the contents of the bowel pass fairly and uninterruptedly through it, there can be little or no danger; but it is not difficult to conceive how a gut so circumstanced may occasion great inconvenience. The peristaltic motion must be more or less impaired; the passage of the contents may be delayed, and hence will arise nausea, colicky pains, eructations, and those other dyspeptic symptoms from which even the most favoured patients do not escape. These irregularities

* Goursaud, Mém. de l'Acad. Roy. de Chir. tom. ii. p. 382.

† Op. cit. p. 290.

again can scarcely exist for any length of time without producing some inflammation, and thence it follows that it is rare to meet with an old hernia in which adhesions have not formed either between the intestine and the sac, or between the convolutions of the protruded viscera, circumstances that must render it impossible to replace the hernia, or supposing it replaced by force, will be likely to occasion incarcerations within the cavity of the abdomen itself. These adhesions, as discovered either during operation, or by dissection after death, are of different degrees of closeness, firmness, and tenacity, and have been arranged under three classes, the gelatinous, the membranous, and the fleshy.

"The gelatinous adhesion, a very general consequence of the adhesive inflammation which attacks membranous parts placed in mutual contact, is only formed by a certain quantity of coagulable lymph, effused from the surface of the inflamed parts, which coagulating assumes sometimes the appearance of a vesicular reddish substance stained with blood, sometimes of threads or whitish membranes easily separable from the parts between which they are interposed and which they unite together, without any abrasion or laceration being produced by the separation, on the surface of the parts agglutinated together."* This kind of adhesion being the result of *recent* inflammation can rarely be met with in operations performed for the relief of strangulated hernia, for the condition of a viscus so engaged is that in which such an effusion would be unlikely, if not impossible. Its vessels are loaded and congested with venous blood: there is effusion of serum to a greater or less quantity, as is seen in every instance of obstructed venous circulation; and if there is recent lymph, it must be owing to the fortuitous circumstance of the viscus having been inflamed immediately before it became strangulated. In a vast number of cases operated on, I have seen but one instance of the existence of this soft adhesion, and in that the hernia was not strangulated: it was a case (such as is related by Pott) of inflammation affecting the intestines generally, in which those within the hernial sac, of course, participated.

The membranous and fleshy adhesions are the results of former attacks of inflammation, and are exactly similar to those attachments so frequently met with between serous surfaces in other situations. When the opposed surfaces lie motionless and undisturbed, their connexion is firm and fleshy, and hence this kind of adhesion is seen at the neck of the sac, between the omentum and the sac, and occasionally between the intestine and the testicle in congenital hernia; whilst between the convolutions of the intestine itself, or between it and the sac, any union that exists is more generally loose and membranous.

Besides adhesion, there are many other causes that may render a hernia irreducible, one of the most prominent of which is the patient's neglect in leaving the hernia down, and the alterations in shape and structure that thence ensue. In such case, the parts within the tumour, as the mesentery and omentum, have room to increase, whilst at the mouth of the sac they remain constricted and of their natural size, though condensed and solidified in structure. This happens particularly with the omentum, which becomes hard, very dense, and compact, and not unfrequently resembles a fibrous structure covered by a fine smooth membrane, and then there is within the sac a tumour actually much larger than the aperture it would have to pass, and through which no force could be capable of pushing it.

It may happen that the part of the omentum which is below the stricture shall remain loose and expanded, and enjoy its natural structure, whilst that which is lodged within the neck of the sac is compressed and hardened, in which case the hernia will probably prove irreducible.

It sometimes happens that scirrhus of the intestine renders a hernia irreducible. Such a malignant alteration of structure is by no means frequent in the intestinal tube—certainly far less so than in the omentum, but the possibility of the occurrence is proved by a case under my own immediate superintendence. The patient had a large hernia which he had been able occasionally to reduce, but which was usually left down. On a sudden he was attacked with symptoms of strangulation, small quick pulse, tenderness of the abdomen, acute pain in the tumour, constipation, general low fever and fœcal vomiting. The operation was performed, and the cause of the symptoms found not to have been in the situation of the neck of the sac, which was more than commonly open and free, but in a scirrhus of one of the lesser intestines.*

The form of hernia already noticed as being apparently devoid of a sac has been mentioned by Pott† as one peculiarly difficult of reduction. "They have consisted of the cœcum with its appendicula and a portion of the colon. Nor," continues this distinguished surgeon, "will the size, disposition, and irregular figure of this part of the intestinal canal appear upon due consideration a very improbable cause of the difficulty or impossibility of reduction by the hand only."

The last circumstance to be considered as rendering a rupture irreducible is the absolute size of the tumour and the quantity of viscera it contains. It is amazing to what extent the contents of the abdomen may be protruded from it, and the patient nevertheless enjoy a state of health that might be called good, so far as the annoyance of such a tumour could warrant the expression. Every surgeon must have heard of herniæ in which all the loose intestines were protruded, and in fact every thing that could with any degree of probability be supposed to have been capable of being pushed from the cavity of the abdomen. I

* Scarpa, p. 180.

* The preparation of this interesting case is in the Museum of the Medico-Chirurgical School, Park Street, Dublin.

† Pott, op. cit. p. 24.

have seen and dissected a case of this description in which the tumour during life reached to within two inches of the knee, and obliged the unfortunate subject of it (who was a lamplighter) to wear a petticoat instead of breeches. Similar instances are not very unfrequent, and it is obvious that an attempt at reduction here would be injudicious even if it was practicable. It is the nature of all hollow structures in the body, whether cavities or vessels, to accommodate their size and capacity to the quantity of their contents, and the cavity of the abdomen will, under such circumstances, become so contracted as to be either incapable of immediately receiving the protruded viscera again, or else the sudden distension will excite peritoneal inflammation—an evil greater than the existence of the hernia. These latter, however, cannot be regarded as permanently irreducible, for Arnaud, Le Dran, and Iley have succeeded in gradually restoring them by means of a bandage shaped like a bag, which being laced in front admitted of being tightened still as the tumour diminished.

The last and most fearful condition of a rupture is its state of strangulation, in which the protruded viscus, no longer capable of being returned to its former situation within the abdomen, no longer fit for the performance of its functions, is banded and bound down at its neck in such wise as to interrupt and impair the circulation through it. In order properly to understand this part of the subject, it will be necessary to consider it under three heads:—1. the causes that seem to produce the strangulation; 2. its effect on the structures within the hernial sac; 3. its effect on the viscera within the cavity of the abdomen.

1. Of the three natural apertures at which abdominal herniæ commonly occur, one, the umbilicus, is unquestionably seated within tendon, and so circumstanced that any contraction of any muscle connected with it, whether spasmodic or permanent, must rather expand the opening than contract it. Another, the crural ring or canal, is composed of tendon and of bone, and so constructed that although certain positions of the trunk or inferior extremity might possibly diminish its size, no muscular action can exert any influence over it. The third, the inguinal canal, is of greater length and more complicated in its construction, and it is a question whether the same pathological condition can be predicated of it, or whether strangulation does not here occasionally occur in consequence of muscular action alone.* Sir A. Cooper seems to acknowledge the possibility of a spasmodic stricture at the internal ring, the strangulation then being effected by a compression exercised by the inferior edge of the internal oblique and transversalis muscles.† Guthrie speaks of herniæ being frequently strangulated by passing between the fibres of the internal oblique, which are separated at the inferior and external border of the muscle above the origin of the cremaster.* Scarpa says that "towards the side, at about eight lines distance from the apex of the ring, the lower muscular fibres of the internal oblique muscle separate from each other to allow the spermatic cord to pass between them:"† and again, "the small sac or rudiment of the hernia, not unlike a thimble, when it makes its first appearance under the fleshy margin of the transverse, rests immediately on the anterior surface of the spermatic cord; it then extends and passes in the middle of the separation formed by the divarication of the inferior fleshy fibres of the internal oblique and of the principal origin of the cremaster muscle."‡ It must, however, be conceded that Scarpa did not attribute the strangulation of any form of inguinal hernia to a contraction of these muscular fibres. Now, although it is almost presumptuous to differ from authorities of so high a class, yet I cannot agree either with the opinion that herniæ are liable to a spasmodic constriction, or with the descriptive anatomy on which such an opinion might be founded.

In about one subject out of every three or four there certainly is a slight divarication or separation of fibres of the external oblique muscle, or rather there is a cellular connexion between the origin of the cremaster muscle and the inferior fibres of the oblique, which is easily separable by the knife; but the question is, does the spermatic cord in the natural condition, or the hernia in its course to the external ring, pass through or between these fibres? I believe they do not. I have dissected numerous cases of hernia without observing such a disposition of parts, and I think that if either the spermatic cord or the hernia took such a course, the protrusion must then come to lie in front of the cremaster muscle—a position that has not been hitherto observed. When a hernia is found at the groin, the tendon of the external oblique is somewhat stretched and arched forwards above Poupart's ligament in front of the inguinal canal: the fascia transversalis may be stretched also, and the epigastric artery pulled out of its place and made to approach the linea alba; but the muscles arising from Poupart's ligament, the internal oblique and transversalis, remain unchanged, and if ever strangulation is effected through their operation it is in the manner suggested by Sir A. Cooper. But it is more simple and perhaps more scientific to place muscular contraction out of the question altogether. The phenomena of strangulation exhibit nothing like the irregularities of spasm: there is no sudden exacerbation, no succeeding relaxation—no alternation of suffering and relief, no assuagement of symptom from medicines decidedly antispasmodic; the disease once established goes on with an uninterrupted and certain progression that will not admit of explanation by a cause so irregular as spasm.

But it is unnecessary to resort to an explanation which might prove so practically dan-

* See the anatomy of inguinal and femoral hernia in a future part of this article.
† Cooper on Hernia, p. 21.

* Guthrie.
† Scarpa, op. cit. p. 27.
‡ Ibid. p. 50.

gerous, because the existence of strangulation with all its fearful sequelæ may be proved, in situations and under circumstances where the influence of spasm or of muscular action is obviously impossible. Thus intestines have been found strangulated within the cavity of the abdomen itself, as when a fold of intestine has passed through an accidental opening in the mesentery or the omentum, or when artificial bands or nooses have been formed by lymph, the products of former inflammation. Scarpa relates a very interesting case in which he found that the appendix vermiformis surrounded in the manner of a ring and strangulated a long loop of the ileum just before its insertion into the colon.

If it be conceded that the natural openings at which abdominal herniæ occur are composed either of tendon or of tendon and of bone, and therefore are not subject to accidental variations of size from irregular muscular action, it would seem on a *prima facie* view that wherever any substance had passed out it ought to be able to return, provided an equal degree of force is employed with that which originally caused the displacement. And this actually does take place, for the hernia returns spontaneously or is easily reduced as long as the original proportion between the size of the protruded part and that of the aperture remains unaltered. Again, as long as this relation is maintained, the circulation through and from the protruded viscus will continue equable and healthy, but an intestine from its structure and its functions is extremely liable to a change of size, and when that happens, the proportion no longer exists, and the hernia begins to become incarcerated. If not relieved, the protruded viscus continues to swell, and is thus made to form an acute angle at the spot where it escaped, which tightens the ring of intestine immediately at the neck of the sac: the return of the venous blood is thus prevented; the swelling then increases until not even gas can pass through, and then strangulation is complete. In this way a number of circumstances connected with hernia can be explained. If the ring is small, a very trifling change of size in the protruded part will be sufficient to cause strangulation: hence crural hernia is more liable than inguinal, and very recent ruptures in which the ring is of its natural size than those of long standing, in which that aperture is probably enlarged. Persons who are formed with large rings, and thus possess an hereditary disposition to hernia, are less liable to strangulation: this may explain Pott's remark that "if the hernia be of the intestinal kind merely, and the portion of the gut be small, the risk is the greater, strangulation being more likely to happen in this case;" for assuredly if the ring is so small as to permit only the escape of a knuckle of intestine, a very trifling change in the latter will be sufficient to establish a disproportion between them. Again, if a hernia has come down, and been reduced, and kept up until the neck of the sac has been diminished in size, and if afterwards a protrusion takes place, a very trifling alteration in this latter will render it incapable of return, and explain why such herniæ are so frequently strangulated at the neck of the sac. Hence it appears that a straitness or tightness at one of the rings may be a predisposing cause of strangulation, that is, may be a reason why one hernia should become sooner strangulated than another, but the immediate or efficient cause is a change in the condition of the viscus itself. Thus when a loop of intestine is gangrened, and its contents have escaped totally or partially into the sac, the hernia often returns spontaneously, the parts in the immediate neighbourhood of the ring remaining unaltered. Also if such a hernia is the subject of operation, there is no necessity for dilating the seat of the stricture: indeed Louis forbids the practice lest some essential point of adhesion should be destroyed. "Dilatation," says he, "is only recommended in order to facilitate the reduction of the strictured parts. In the gangrened intestine there is no reduction to make, and there is no longer strangulation, the opening in the intestines having removed the disproportion that had existed between the diameter of the ring and the volume which the parts had acquired; and the free passage of the excrement which the sphacelus has permitted removes every symptom that depends on the strangulation."* In like manner may be understood why omental herniæ are less liable to become strangulated, because this structure is not subject to any sudden change of shape or increase of volume: when it does occur, the progress of the disease is more slow, and the symptoms are said to be less severe.

The division of herniæ into the incarcerated and strangulated, or into the acute and chronic forms of strangulation, however practically valuable if it inculcates a different mode of treatment for these affections, is yet pathologically incorrect if it supposes any analogy between them and the acute and chronic species of inflammation. An incarcerated hernia is not strangulated; it is really in a condition resembling irreducibility. I have before stated that in large and old herniæ the neck of the sac generally becomes enlarged, and of course such a change of dimensions in the protruded viscera as is necessary to cause their strangulation will be proportionally less likely to occur. But hard and unwholesome and indigestible substances may gain admission into some of them and lodge there, for it must be recollected that the process of digestion cannot be very favorably carried on in intestines thus protruded, placed in positions that will render it necessary that their contents must ascend against the influence of their own gravity, and deprived of the salutary pressure exercised by the walls of the abdomen on the viscera within it. If such a lodgment is formed, it will be the cause of future accumulation, and may occasion a determination of blood to the part or even inflammation within it, thus gradually increasing its volume and leading it to a state that must end in strangulation. Undoubtedly, if the dura-

* Mém. de l'Acad. Roy. de Chir. tom. viii. p. 45.

tion of such a case is reckoned from the first occurrence of symptoms, which at that period are only those of indigestion, it will be an example of a very chronic case of strangulated hernia; but these two stages of the disease ought to be distinguished, for the treatment that would be judicious in the one might be injurious or destructive in the other. The incarceration of a hernia does not, moreover, necessarily involve its eventual strangulation, and this constitutes a vast difficulty in the case, for on the one hand few surgeons will advise an operation until there is an obvious and decided necessity for it, and on the other it is quite possible in a case of this description that the symptoms shall never be urgent, and yet the intestine be found in a state of actual sphacelus. I have seen a patient operated on in whom the hernia had been down and the bowels constipated for eighteen days. The intestine was completely mortified.

That strangulation which is most rapidly formed is the most severe in its symptoms and the most dangerous in its consequences, but between these extremes there is every possible degree of intensity. A hernia has been gangrened in eight hours after protrusion. Mr. Pott frequently mentions a single day as causing a most important difference in the case, and I have found an intestine sphacelated on the day following the first occurrence of the disease; however, in general the case is not so quickly decided, although every moment of its duration is pregnant with danger. The change that is effected in the strangulated viscus next demands attention. Its altered condition has been always spoken of under the name of inflammation,* not from want of a perfect and accurate knowledge of its pathology, but probably from the term appearing convenient and being hastily adopted by one writer from another. Yet as it is not inflammation, the name is incorrect, and perhaps it has been injurious in leading practitioners to attempt a mitigation of the inflammation in the tumour, instead of the more obvious indication, a diminution of its size. The volume of a strangulated intestine is always increased. In small herniæ (which in this respect can be more accurately examined) the intestine, on the sac being divided, starts up and swells out as if relieved from a compressive force. It always contains air, and if cut into, a small portion of dark-coloured serum will generally escape. Its colour, which is manifestly occasioned by an accumulation of venous blood, is at first of a reddish tint of purple, soon however changing to a coffee brown, and there is always more or less of serum within the sac, as in every other case of venous congestion. If unrelieved, dark and fibrous spots appear which are truly specks of mortification; they very soon separate and allow a discharge into the sac of a quantity of putrid fæces and horribly fetid gas. This done, the intestine either remains collapsed within the sac, or retires spontaneously into the abdomen.

In the meantime the parts covering the hernia become inflamed; in the first instance probably from sympathy with the deeper structures, afterwards obviously as an effort of nature to get rid of the putrid and sphacelated matter underneath. In the early stages the local symptoms are seldom very severe: the tumour is scarcely painful, and will permit reiterated attempts at the reduction of the hernia, and endure considerable pressure, whilst the abdomen may not be touched without intense suffering. In a little time, however, it becomes tense and tender to the touch, red, œdematous, and pitting under the finger, which leaves a white impression for a moment after it has been withdrawn. In fact, it is erysipelatous inflammation attacking the coverings of the hernia, and its approach is often accelerated by handling the tumour or by repeated injudicious attempts to reduce it. This (if the patient lives sufficiently long) always terminates by the formation of one or more sloughs, on the separation of which the putrid coverings are thrown off, and the contents of the bowels being evacuated, the patient's life may be saved, but with the inconvenience and danger of an artificial anus at the groin. It is seldom that the efforts of nature are thus capable of procuring relief, the contents of the rupture being generally sphacelated, and incurable mischief effected within the abdomen long before its external coverings shew any disposition to burst spontaneously. I think the condition of the sac has some influence on this external inflammation. In all cases it undergoes a less injurious alteration of structure than the intestine contained within it, and is often found comparatively sound while the latter is in a state approaching to sphacelus. The superiority of its vascular organization, its containing a greater quantity of blood, and moreover the volume of air always contained within the bowel, will explain this pathological difference; but the sac itself sometimes suffers from congestion to a greater or less extent, and this, of course, in proportion to the degree of constriction fixed upon its neck. An old hernial sac, the neck of which is thickened and accustomed to its new position, and which is itself probably one of the chief causes of the stricture, will be less likely to suffer from an interrupted circulation than a recent protrusion just forced out through a narrow undilated ring. It is in this latter case that the external structures ought to be the soonest engaged, and it has been in recent and acute cases of hernia that I have seen the earliest examples of superficial inflammation.

3. Such, during the progress of a hernia, is the condition of the parts more locally engaged;

* "The inflammation that takes place in strangulated hernia is different from almost every other species: in most cases it is produced by an unusual quantity of blood sent by the arteries of the part, which become enlarged; but still the blood returns freely to the heart, and the colour of the inflamed part is that of arterial blood; whilst in hernia the inflammation is caused by a stop being put to the return of the blood through the veins, which produces a great accumulation of this fluid, and a change of its colour from the arterial to the venous hue." Cooper on Hernia, p. 20.

but a far more serious because a more fatal process is going forward within the abdomen. It must be recollected that a gangrene of the intestine when out of the abdominal cavity is not necessarily fatal; that the gut may die and putrefy, and be thrown off by the results of external inflammation and sloughing, and yet the patient live for many years with an artificial anus, or even have the natural passage *per anum* restored again. Numberless cases of artificial anus have thus occurred, not one of which could have been saved if the sloughing of the intestine was inevitably mortal. But soon after the strangulation is effected, either from the pressure on the viscus, which may be supposed to have a material influence, or from the mechanical obstruction to the passage of the fæces, inflammation is established within the cavity, commencing probably at the strictured spot, and spreading thence with great rapidity. The part of the peritoneum most engaged is that which covers the line of intestine interposed between the stricture and the stomach; the least, that which invests the walls of the cavity. This inflammation may be in part salutary, for it occasionally causes an adhesion of the intestine at the neighbourhood of the ring so firm that it cannot be removed therefrom, and thus provides for the occurrence of an artificial anus subsequently without the danger of any internal effusion; but unless the stricture is relieved at this time, and a check thus given to the progress of the disease, the intestines become matted with lymph, effusions are poured out of a similar nature to those that occur in other forms of peritonitis, and the patient dies—not of the gangrene of the protruded intestine, but of the peritoneal inflammation within.

On opening the body of a person who has thus died, the intestines above the stricture are found inflamed, of a red or pink colour, greatly distended with flatus and perhaps with fæcal matters; below the stricture they are inflamed also, but remarkably diminished in size. There is always an effusion of lymph to a greater or less extent glueing the convolutions of the bowels together, and there is often on the surface of the peritoneum not covered with lymph, a dark appearance as if blood was ecchymosed beneath it. Effusions are also constantly met with, sometimes apparently of pure pus, diffused, particularly throughout the spaces formed by the apposition of the convoluted intestines, sometimes more abundant, and consisting of serum mixed with lymph in loose and floating flakes; and occasionally a more gelatinous substance is observed very much resembling the jelly-like material that surrounds frog-spawn in stagnant ponds. I have never met the existence of gangrene within the abdomen in any case of death from strangulated hernia.

The line of intestine, then, within the abdomen, and the loop within the sac, are differently circumstanced. Above the stricture there is active inflammation exactly such as might occur idiopathically, presenting the same morbid appearances, and accompanied by a similar train of symptoms: below, there is a state of venous congestion in which the vessels endeavour to relieve themselves by pouring out a serous effusion, and in which gangrene supervenes with a rapidity proportioned to the tightness of the constriction. Between these, and immediately under the stricture, it is white, pale, and bloodless all round for the space of two or three lines, and appears to be diminished in size more than it really is on account of the great enlargement immediately above and below. The condition of this strictured ring of intestine is of the utmost importance in the progress of the case, for it is not uncommon for it to ulcerate or to slough under the influence of the continued pressure. I have seen an operation admirably performed, and the intestine returned under apparently favourable circumstances, yet the patient sink and die in the course of a few hours: a small hole existed in the constricted spot, through which fæcal matter had escaped and become diffused within the cavity. In another instance, from the anxiety of an operator to inspect the condition of this spot previous to the return of a hernia, the intestine in the act of being drawn out tore almost as easily as a wetted rag.

It will not be difficult to connect the symptoms of this disease with the morbid alterations just described. When a hernia is about to become strangulated, the earliest symptom is in general pain, at first referred to the seat of the stricture, but soon becoming diffused over the abdomen, when the chief suffering is often seated in the region of the navel. The belly then becomes hard and tense, at first rather contracted, but subsequently swollen and tympanitic: it is exquisitely tender to the touch, cannot endure the slightest pressure, and in some cases even the contact of the bed-clothes is intolerable. The patient lies in bed with his legs drawn up, and if possible his shoulders bent forward on the trunk; he cannot without excessive torture endeavour to move himself in any direction, and a moment in the sitting posture is not to be endured. Of course when the whole canal of the intestine is constricted, there must be constipation of the bowels; yet cases have been mentioned in which, though all the other symptoms of strangulated hernia were present, the discharges from the bowels have not ceased,—a circumstance that has been explained by the supposition that only a portion of the circumference of the intestine was engaged. I believe, however, that most of these cases were delusive, and that when the alvine discharges have continued to a very late period, the case was one of incarceration in which peritoneal inflammation may not be established for a long time or perhaps at all; or else the practitioner was deceived by some of those discharges from the line of intestine below the stricture which are so frequently brought away by the administration of enemata. The explanation of the symptom is too mechanical, particularly when it is recollected that idiopathic inflammation of the peritoneum will generally (although not always) produce the same effect, and that it is as regular, as constant, and as complete in omental as in intestinal ruptures. At a very early period of the case the stomach becomes engaged, and there is vomiting, at first in large quantity until the contents of the stomach are evacuated; it is then less, dark-coloured, and excessively bitter; and finally a substance is discharged having the appearance and fetor of the feculent contents of the great intestines. Considering the structure and functions of the valve of the ileum, it appears curious how an anti-peristaltic motion could be so completely established as to permit of actual fœcal vomiting, and the fact (if it is a fact) cannot be explained except by supposing the action of all the constituent structures of the intestine so deranged that the influence of the valve is altogether lost. But it is more than doubtful whether this material is really feculent, although it is difficult from its sensible qualities to consider it in any other point of view; for I have frequently seen this vomiting in cases where the herniæ were formed of loops of the lesser intestines, and therefore when the contents of those beyond the iliac valve could not have been thrown off; and in every case it is difficult from the examination of the discharge to determine its nature with accuracy. After the stomach has been emptied of its natural contents, the act of vomiting assumes a very peculiar character: strictly speaking, it is not vomiting or retching, nor is it hiccup, but a slight convulsive effort like a gulp, which brings up without much effort the quantity of a single mouthful at a time. The forehead is now bedewed with a cold and clammy sweat; the countenance presents a remarkable expression of agony and anxiety; and the pulse is small, quick, hard, and vibrating, as is the case in all internal inflammations of vital parts.

After some further time (and the period is very variable) the characters of the disease undergo a fearful alteration. Mortification attacks the incarcerated viscus, and in most instances *seems* to bring the result of the case to a very speedy issue. The tumour now loses its tense feel, and becomes soft, flabby, and perhaps emphysematous: in some instances it retires altogether. The belly also may become soft, and in general there is a discharge per anum of dark-coloured and abominably offensive fæces. This evacuation leads the patient into the encouragement of false hopes, for he may have seen his surgeon endeavouring to procure stools during the progress of the case, and combining this circumstance with the removal of the pain and the comparative ease he so suddenly experiences, he fancies so favourable a change to be the harbinger of recovery. But the delusion lasts not long. The pulse becomes low, weak, and faltering: often it intermits irregularly. The countenance is sunken, and assumes an appearance that cannot be described, but is known by medical practitioners as the "facies Hippocratica." The eye has a suffused and glassy look, and there is a certain wildness of expression very characteristic. The forehead is bedewed with a cold and clammy sweat; the extremities become cold; the sensorium is affected with the low muttering delirium, and death soon finishes the picture.

These symptoms have been laid down as indicative of mortification having taken place, probably because the protruded viscus has generally been found in that state; and from habit many practitioners have on their appearance in cases of purely idiopathic peritonitis decided on the presence of gangrene, and the hopelessness of recovery. Such cases are hopeless, and patients have died, but not of mortification, for although these symptoms are present in most cases of fatal peritonitis, yet dissection after death very rarely exhibits gangrene in that disease, and perhaps for this reason, that the functions of the abdominal viscera are too important to life for a patient to struggle sufficiently long with their inflammation to permit of mortification being established. Whilst the inflammation is very active, and the serous membrane dry, or lymph only secreted on its surface, then is the pain intense, and the first order of symptoms developed: but when effusion has taken place, and the vessels are relieved by the pouring forth of serum or sero-purulent fluid, the pain abates, and the symptoms are those of extreme debility. In confirmation of this remark it may be observed that, when a patient dies from any sudden effusion into the peritoneal cavity, whether from a ruptured intestine, or gall-bladder, or bloodvessel, or from any other source, the symptoms from the very commencement are those of debility and collapse—the same sunken and anxious look, the same feeble and fluttering pulse, and the same kind of universal sinking of the entire system.

However, although the symptoms may be very formidable, the state of the patient is not altogether hopeless. Art may still accomplish a great deal, and even the operations of nature alone and unassisted may succeed in prolonging life, although under circumstances that render life scarcely desirable. When the hernia has proceeded to gangrene and the patient still lives, the skin of the tumour assumes a very dark red and livid colour, and then becomes black in spots. The cuticle separates and peels off in patches, and some one or other of the sphacelated parts giving way, a profuse discharge bursts forth, of a horribly offensive nature. In the same way may the surgeon's interference prove serviceable. It is related by Petit, that travelling once, he met in the outhouse of an inn an unfortunate being thrown on a heap of straw in a corner to die. He immediately recognized the smell of a gangrened hernia, and proceeded to give the poor fellow all the relief within his power. He made an incision, allowed the feculent matter to escape, cleared away the gangrenous and putrid parts, and having ordered a poultice left him to his fate. On his return he found him able to move about and perform active service within the stable, and even free from the disagreeable accompaniment of an artificial anus at the groin. This is a most gratifying piece of successful surgery, but it is not one that is very frequently realised. In order to the possibility of an artificial anus being formed, the patient and the hernia must be placed under circumstances so very peculiar that it will be easily perceived how unlikely it is that they should be united and combined in one individual.

1. Although the protruded viscus has become sphacelated, the inflammation within the abdomen must not have reached such a height as to preclude the possibility of recovery.

2. Adhesions must be established between the bowel and the peritoneum either at or immediately above the neck of the sac, so that when the stricture is free and the enormous alvine accumulation allowed to escape, it will be impossible for the gut to withdraw itself within the cavity or be removed from the external aperture.

And in order that the annoyance of the artificial anus should be subsequently removed, it is necessary that the intestine and the peritoneum to which it is adherent should retire into the abdomen, and that the angle between the two intestinal tubes should be diminished or removed.

1. If the first of these conditions is indispensable, it follows that the chance of recovery with artificial anus is inversely as the acuteness of the symptoms and the rapidity of their progress. As it is the inflammation of the intestines that destroys the patient, it is pretty evident that after it has reached a given point, no operation performed on the hernia and no evacuation of the contents of the bowels can arrest its progress, or cause the absorption of the lymph, or of the sero-purulent fluid that has been effused into the peritoneal cavity. In operating on the living subject within twenty-three hours after the first appearance of the hernia, I have found the intestine sphacelated: in this case, when the stricture was divided, the discharge from the intestines within the abdomen was trifling in quantity, and in order to relieve the patient, I was obliged to introduce a gum-elastic tube for a considerable way into the superior fragment of the bowel. He died on the subsequent day, and on examining the body the front of the intestines seemed to be one mass of plastic lymph, which obliterated every appearance of convolution, and must have glued together the bowels in such a manner as to prevent the possibility of a peristaltic motion. In a case so aggravated no hope could be entertained from the establishment of an artificial outlet. It can now be easily imagined how persons of a very advanced age,* and in whom the symptoms of strangulation are mild and chronic, recover with artificial anus, in short that such a consummation is most to be expected in the cases to which the name "incarcerated" has been applied, whereas in most instances of "strangulated" hernia its occurrence is unlikely, and in many altogether impossible.

2. The second great requisite for the establishment of an artificial anus is, that adhesion shall take place between the bowel and the peritoneum, either at or immediately above the neck of the sac, so that when the stricture is free and the alvine discharges allowed to escape, it will be impossible for the gut to withdraw itself within the cavity, or be removed from the external aperture. This adhesion has, I think, been generally supposed to occur "during the inflammation which precedes the gangrene,"* but is nevertheless probably always not only subsequent to it, but to the separation of the unsound and sphacelated parts; and the attachment is, not between the contiguous and opposing smooth surfaces of the serous membrane, but between the divided edges of the sound portions of the tube remaining after the slough has been thrown off, and the part of the neck of the sac adjacent to them. I have operated on a great number of gangrened herniæ, and never found such an adhesion to have previously existed, neither have I ever met with it on dissection, and I cannot conceive the possibility of a spontaneous return after sphacelus (an event that but too frequently occurs) if the parts were thus attached together. Assuredly if such adhesions were formed at so early a period, they ought to be much more frequently found, and they would be amongst the most calamitous complications that could attend a hernia; for they would offer an almost invincible obstacle to its reduction, or supposing the bowel to have been pushed up by force, such a sharp angular fold would be formed as must prevent the passage of its contents and create an internal strangulation. Nor is the consideration of this fact practically unimportant, if it leads us to adopt every possible precaution that may conduce to the undisturbed progress of this adhesive process, and at the same time warns us not to be too sanguine in our expectations. I have (as I have said) operated on a vast number of cases of gangrened hernia, not one of which recovered with artificial anus: some, the great majority, perished, as has been remarked, in consequence of the inflammation within the abdomen having reached an incurable height; some others sank exhausted and died, the system being apparently worn out and incapable of a recuperative effort: others still, from a retraction of the divided end of the bowel and the escape of its contents into the cavity; and one, from a cause which, as it has not been mentioned by any pathological writer, may be noticed here. On the spontaneous separation of the sphacelated bowel, a frightful and incontrollable hemorrhage took place, some of which flowed into the peritoneal cavity, and was found after death diffused through the convolutions of the intestines.

When a case has been so fortunate as to permit of the formation of an artificial anus, after the mortified parts and putrid sloughs have been removed a cavity is seen, generally irregular and puckered at its edge, leading down to and communicating with the injured

* See Louis' Memoir on hernia followed by gangrene. Mém. de l'Acad. Roy. v. 3.

* Scarpa on hernia, p. 323. See also Travers on wounded intestines. "Dans les hernies, ces adhérences *précèdent* la destruction des parties, et elles previennent le plus souvent l'epanchement des matières dans le ventre."—Dupuytren, Leçons Orales, tom. ii. p. 197.

intestine, from which the fæcal discharge is constantly trickling, and as there is often a sufficient space for a portion of this to lodge and remain, it may prove a source of troublesome and dangerous ulcerations. In a short time the mucous membrane becomes everted and protrudes, often, if neglected, to the extent of several inches: it is a true prolapsus of the membrane, not very unlike the prolapsus ani in appearance. At the bottom of the cavity already mentioned, are the orifices of the intestines, the superior of which is the larger, as it is from it the discharge proceeds, whilst the inferior is small and so contracted as frequently to be discovered with difficulty. The partition between the orifices is formed by the juxtaposition and adhesion of the sides of the intestine: it is termed the "eperon" by Dupuytren, and is larger and more obvious when a portion of the bowel has been completely removed so as to divide the tube into two parts, smaller when only a knuckle has been pinched up and gangrened without engaging the entire circumference. To this "eperon" and double partition the mesentery is attached, and the functions of this membranous ligament are said to exert a very important influence on the progress and after-consequences of artificial anus.

Not only is the superior portion of the intestine (that which is in relation with the stomach) larger, but its extremity being fixed by the new adhesions, the progress of its contents is greatly facilitated, and according to Dupuytren actually accelerated as to time. The inferior or rectal portion, not performing its functions, becomes diminished in calibre, and contains a white, pulpy, albuminous material, which is sometimes discharged by stool, but may remain undecomposed within it for months or even years. The contracted condition of this portion of the gut is of the highest importance to be attended to in all instances where a recovery is possible or likely to be attempted. This disposition of all hollow structures in the body to accommodate themselves to the bulk or quantity of their contents has been already noticed, and to obviate the inconveniences likely to arise from such diminution, the older surgeons* strongly recommended the use of enemata, in order, amongst other advantages, to preserve the intestine in a sufficient state of distension.

The progress and termination of a case such as has been under consideration may be extremely variable. The aperture may be situated in the lesser intestine so high up or so near the stomach that the space to be traversed by the aliments and their period of detention are shortened: their digestion is then incomplete and nutrition so far impaired that the patient sinks gradually, and dies from the effects of inanition; or a permanent artificial anus may be established without a hope or a chance of the natural passage ever being restored; and this seemed at one time to have been the great object of surgical practice in these cases, for we find M. Littre, a celebrated French surgeon, actually tying up the lower portion of the gut when he could find it, as if to preclude for ever a possibility of the continuity of the tube being restored. This is a most deplorable condition, yet have patients endured the annoyance of a permanent discharge at the groin for a great length of time; and in the Museum of the School in Park Street, there is a preparation taken from a man who had thus existed for upwards of ten years. There is a curious instance mentioned by Louis in which something resembling the regular action of a sphincter was clearly observable, and although the discharge of the fæces was involuntary, yet it was periodical, and the gut once evacuated remained closed until a new accumulation took place. This person, of course, was comparatively free from that constant trickling of fæces which is the patient's chief annoyance, and which, if not palliated by some ingenious contrivance, absolutely renders his life loathsome.

The natural passage of the fæces has been restored. This is so desirable, so fortunate a consummation, and its practicability so clearly established by the circumstance of its being occasionally accomplished solely by the operations of nature, that it can be no matter of surprise if surgeons have laboured to attain it and diligently observed the entire process. An intestine of which a portion has sloughed away is placed in a very different condition from one that has been simply wounded. When an entire loop of bowel has been removed, the two portions within the abdomen passing down to the neck of the sac lie more or less parallel to each other, or approach by a very acute angle: they are in the same degree perpendicular to the ring, and between them is that double partition termed "eperon" or buttress by Dupuytren, and the "promontory" by Scarpa. Now as the intestines are fixed and fastened in this position, the canal can never again become continuous *in directum*, and therefore any material that passes from the upper into the lower portion must do so by going round this intervening promontory. Even when only a small fold or knuckle has been lost, although the complete continuity of the tube is not destroyed, and the partition is less evident and prominent, still an angle must inevitably be formed of sufficient acuteness materially to impede the progress of the fæces. In neither case, then, can the wounded edge of one portion of the intestine come to be applied to that of the other, nor can adhesion or union by the first intention ever be accomplished between them. In lieu of this, however, the edges of the intestine become united with the peritoneum opposed to them, which must of necessity be the neck of the sac, and then if the external wound can be healed, a membranous pouch or bag is interposed between them, of a funnel-shape, and which serves as a medium of communication and of conveyance for the fæcal matters from one portion of the tube into the other.

Reflecting on this pathological condition of parts, it will not be very difficult to explain some of the varieties observed in cases of artificial anus. The chief obstruction to the re-establishment of the canal is the intervention of the promontory.

* See Louis' Memoir, loc. citat.

If it is so large or otherwise so circumstanced as entirely to impede communication, and if in this condition it is neglected, the discharge must take place at the groin, and the disease is permanent. Such, I believe, is the history of most of those unhappy beings who have borne about them for years this loathsome and disgusting affliction, until relieved by a death that could not have proved unwelcome. In a vast number of cases the projection is not so great, and although it may impede and delay, it does not altogether prevent the passage of fæces from one portion of the tube to the other: then as the external wound contracts, the neck of the sac forms into a membranous funnel or canal of communication, and the fæces begin to pass. The wound then heals, in some instances leaving a small fistulous opening through which a limpid, straw-coloured, but fetid fluid constantly distils, whilst in others a perfect and complete cicatrix is formed. But we must recollect what happens in this seemingly perfect cure before we can fully appreciate the entire nature of the case, and the degree of danger that always overhangs it. It is evident that the viscus must (at least at first) be firmly fixed at the situation of the cicatrix; that it no longer enjoys any freedom of motion, and that it forms an angle more or less acute at the place of adhesion. It is also probable that the diameters of the two portions of intestine do not correspond. Hence the process of digestion is impaired, the patient must study every article of food he consumes, and the slightest indiscretion is followed by colicky pains, flatulence, and tormina of the bowels; often there is nausea, vomiting, loss of appetite, and a dragging sensation at the stomach, this latter symptom being explained by the omentum having formed a part of the protrusion, and become adherent at the new-formed cicatrix. It often happens that the scar gives way, and a fæcal discharge takes place again, the groin thus alternately healing up and bursting out anew. This is more likely to occur in cases where the very small fistulous canal has remained, and therefore many surgeons have regarded this event as more fortunate than where the cicatrization has been complete; for the course of the fistula serves as a guide to direct the bursting of the accumulation externally, whereas if, as sometimes happens, the intestine should give way internally, its contents are then poured out into the peritoneal cavity, and the result must be inevitably fatal.

The most curious circumstance connected with the healing of an artificial anus is, that the position of the united intestines and the intervening infundibulum or funnel behind the cicatrix is not permanent. "It is," says Scarpa,* "a certain fact confirmed by a very great number of observations, that after the separation of the gangrene the two sound segments of intestine retire gradually beyond the ring towards the cavity of the abdomen, notwithstanding the adhesion which they have contracted with the neck of the sac, whether this is caused by the tonic and retractile action of the intestine itself and of the mesentery, or rather by the puckering of the cellular substance, which unites the hernial sac to the abdominal parietes within the ring. And this phenomenon is likewise constant and evident even in herniæ not gangrenous, but merely complicated with fleshy adhesions to the neck of the sac, and therefore irreducible. In these herniæ, the immediate cause of strangulation being removed, the intestine, together with the hernial sac, gradually rises up towards the ring, and at last is concealed behind it." The same fact has been observed by Dupuytren,* who attributed it to the continued action of the mesentery on the intestine. Many individuals who had been cured of artificial anus without operation returned to the Hôtel Dieu at very remote periods, and died of diseases having no relation to the original complaint. The parts were curiously and carefully examined, and the intestine, instead of being fixed to the walls of the belly, was found free and floating within the cavity. There could be no doubt of the identity of the individuals, and moreover a fibrous cord was seen extended from the point of the wall of the abdomen which corresponded with the former artificial anus, to the intestine. This cord, some lines in diameter and some inches in length, thicker at its extremities than in the middle, covered by peritoneum, and formed entirely by a cellular and fibrous tissue without any cavity, was evidently produced by the progressive elongation of the cellular membrane that had united the intestine to the wall of the abdomen; and the cause which had occasioned this elongation was nothing else than the traction exercised by the mesentery on the intestine in the different motions of the body during life.

Having now endeavoured to describe generally the circumstances or conditions under which protrusions of the abdominal viscera may exist, I proceed to consider the peculiarities that arise from situation, premising that it is not my intention to enter very minutely into the descriptive anatomy of those several situations in their normal or healthy states, but only in reference to and in connexion with the existence of the disease under consideration.

Inguinal hernia.—When a viscus is protruded through one or both of the apertures termed rings, situated at the anterior and inferior part of the abdomen, near the fold of the groin, but above Poupart's ligament, the hernia is termed inguinal. It may exist, therefore, in three different conditions. 1. Where the intestine has been pushed through the internal ring only, and is lodged in the inguinal canal: it then appears as a small, round, firm, and moderately elastic tumour. 2. Where it has passed through the internal ring, through the inguinal canal, through the external ring, and dropping down into the scrotum of the male or the labium pudendi of the female, appears as a larger and more yielding tumour, of a pyramidal shape, the apex of the pyramid being directed towards the anterior superior spinous

* Scarpa, op. citat. p. 313.

* Leçons Orales, tom. ii. p. 207.

process of the ilium. As these are but different stages of the same disease, both come under the appellation of hernia by the oblique descent. But, 3, when the viscus has been forced through the parietes immediately behind the external ring, and passes out through that natural aperture only, it is then for obvious reasons termed the hernia by direct descent; and although the external characters of the tumour are not always such as to point out the peculiar nature of this protrusion, yet the relative position of the intestine with respect to adjacent parts must be somewhat different in these several cases, a difference that will be found to be of some practical importance.

The peritoneal sac, as viewed internally in the direction of the iliac and inguinal regions, is described by Scarpa as being divided into two great depressions at each side, the medium of partition being the ligament into which the umbilical artery of the fœtus had degenerated, together with the fold of peritoneum raised by that ligament. Of these fossæ the superior or external is the larger and deeper; it is that within which the intestines are collected when strongly compressed by the abdominal muscles and by the diaphragm in any violent exertion; and from it inguinal hernia is most frequently protruded, as the ligament and duplicature of the peritoneum prevent the compressed viscera lodged in this fossa from removing out of it to descend into the pelvis. The situation of the umbilical artery varies considerably: sometimes it is close upon the internal border of the internal ring, in other subjects at the distance of half an inch from it, or even more; but it is always at the pubic side of the epigastric vessels. Thus, in its direction upwards and inwards towards the umbilicus it crosses obliquely behind the inguinal canal: all herniæ, therefore, by the oblique descent pass out from the external or superior abdominal fossa, while those by the direct are in relation to and are protruded from the inferior or internal. Independent of this configuration there is nothing in the peritoneal cavity as viewed from within, to determine the occurrence of hernia at one place rather than at another. The membrane is in all parts equally smooth and polished, equally strong,* tense, and resisting. This, however, is not the case with respect to the muscular and tendinous walls of the abdomen, which vary very considerably in density and strength in different situations, and in these qualities dissection shews that the hypogastric or inguinal regions are the most deficient and therefore most disposed to permit of the occurrence of hernia.

In prosecuting the dissection from within (which is by far the most satisfactory manner), the peritoneum may be detached by the fingers or by the handle of the knife in consequence of the laxity of the cellular tissue connecting it to the adjacent external structures. The fascia transversalis then comes into view, and in it the aperture termed the internal ring, through which the spermatic cord in the male, and the round ligament in the female are transmitted. This aponeurosis varies in density and thickness in different individuals: it is continuous with the fascia iliaca, and is connected with the posterior edge of Poupart's ligament: it is denser and stronger externally, and becomes weaker and more cellular as it approaches the mesial line. Where the internal oblique is muscular, the connexion between it and the fascia transversalis is extremely lax, cellular, and easily separable; but after it becomes tendinous, the union is much more intimate, and the fibres of the one can scarcely be distinguished from those of the other unless by the difference of their direction. In most subjects the internal ring is very indistinct, its size, shape, and direction being in general determined rather by the knife of the anatomist than by nature. So far as the fascia is concerned, the external inferior border of the ring is its strongest part, but its internal edge *seems to be the stronger* as it is supported by the epigastric vessels, and sometimes by the remnant of the umbilical artery. Its size is about an inch in length, half an inch in breadth; its shape oval; and the direction of its longest diameter perpendicular or slightly inclining from above downwards and outwards.

The position of the epigastric artery with respect to the neck of the sac at once points out whether a hernia is by the direct descent or not, for it marks the internal or pubic boundary of the internal ring. This vessel is occasionally irregular in its origin, but in its normal or usual state it comes off from the external iliac before it has reached Poupart's ligament, and consequently in that position it lies behind the bag of the peritoneum, which it passes by forming an arch, the concavity of which is directed upwards. It then appears in front, between the fascia transversalis and the peritoneum, but more closely attached to the former, with which it remains when the membrane is torn away. The vas deferens is seen coming from the pelvis obliquely upwards and outwards until it reaches the spermatic artery, which, having descended from above, nearly in a perpendicular direction, meets the vas deferens at rather an acute angle, the former being to the outside and nearly in front of the latter. These vessels having passed the fascia transversalis disappear by arching round the epigastric artery and entering the inguinal canal, and they define the inferior margin of the internal ring. The remainder of its border is not so very distinctly marked, partly in consequence of a very delicate fascia which is given off from it and passes down a short way on the spermatic cord, where it becomes indistinct and is lost; and partly because the transversalis muscle lying before it renders the view obscure. The internal border of the internal ring is always (as stated by Sir A. Cooper) midway between the anterior superior spinous process of the ilium and the symphysis pubis.

When a protruded viscus, then, is passing

* The strength of the peritoneum is proved by a curious experiment of Scarpa's. He stretched a large circle of this membrane recently taken from the dead body, on a hoop like a drum, and found it capable of supporting a weight of fifteen pounds without being ruptured.

through this ring, it has the epigastric artery to its internal or pubic side, and generally the vessels of the cord behind it; but a variety sometimes occurs, for the hernia may protrude exactly at the spot where the spermatic artery and vas deferens meet each other at an angle, and separate these vessels from each other, leaving the artery rather to the outside and in front, the vas deferens still occupying its usual situation behind. After the hernia has passed the fascia transversalis, it is still behind the fibres of the internal oblique and transversalis muscles, and has to pass a few lines (the distance varying in different subjects) before it reaches the posterior surface of the tendon of the external oblique. On prosecuting this dissection further by detaching the fascia transversalis from the transversalis muscle in a direction downwards and outwards, the intestine will be found to have entered a canal of an inch and a quarter to an inch and a half in length, its direction being obliquely downwards and inwards to the external ring. This is termed the inguinal canal, and is thus formed. Poupart's ligament, whether it be considered as a portion of the tendon of the external oblique or not, is powerfully strong and thick: to it the fascia transversalis is firmly adherent behind, and the thinner and more expanded fibres of the tendon of the external oblique before. Between these, then, a sheath is formed in which the hernia is lodged, having in front the tendon of the external oblique, and also covered by the cremaster muscle, particularly that part of it which has its origin from Poupart's ligament. Behind it is the fascia transversalis, and more internally or nearer the pubis the conjoined tendon of the internal oblique and transversalis, and below is Poupart's ligament. Above, it is crossed obliquely by the inferior margin of the internal oblique and transversalis. These muscles have a fleshy origin from the external third of Poupart's ligament, from which they pass in an arched form to be inserted by a common tendon into the crest of the pubis. Under this arch the viscus slips and thus places itself anterior to the conjoined tendon before passing through the external ring and becoming a scrotal hernia.

Anatomists have not agreed in their descriptions of the internal oblique muscle, although a correct and accurate knowledge of the situation of it and of the transversalis in the neighbourhood of the rings is indispensable to the right understanding of hernia. According to Sir A. Cooper* and Lawrence,† the upper part only of the internal ring is shut up by these muscles, leaving the lower unprotected, and consequently, according to this view of the subject, *a hernia on entering the inguinal canal* should have them above it. Cloquet‡ states that the inferior border of the transversalis passes on a level with the superior, opening internally, but the edge of the internal oblique is lower down, covers the spermatic cord in the inguinal canal, and passes over it to be inserted into the pubis at the point where *it escapes from the inferior opening of the canal*, that is, the external ring. Scarpa* gives a different description still, where he says, "towards the side at about eight lines distance from the apex of the ring, the lower muscular fibres of the internal oblique muscle separate from each other to allow the spermatic cord to pass between them;" and Guthrie† considers the occasional passage of a hernia through the fibres of this muscle, and its compression by them, to be no unfrequent cause of strangulation. It is not easy to reconcile these conflicting authorities, which in themselves demonstrate the fact that the inferior border of this muscle exhibits some varieties in its relation to the inguinal canal and internal ring according to the extent of its origin from Poupart's ligament. When a hernia is present, I have always seen it arched over the neck of the sac, and although I would by no means assert that a rupture never takes its course between these muscular fibres, yet I have not met with an instance, and as I have observed elsewhere, I imagine such an occurrence would create a deviation from the usual relative anatomy of the cremaster muscle with respect to the hernial sac.—See Abdomen.

The inguinal canal terminates in front at the external ring, which is formed by a separation of the fibres of the external oblique muscle as it passes inwards and downwards to be inserted into the pubis. Almost immediately after the muscle has become tendinous, a disposition to this separation is observable, and a kind of split is formed in the tendon, the edges of which are, however, pretty firmly held in their relative positions by fibres passing closely and irregularly across from one to the other. These fibres have been called the intercolumnar fascia. Besides these there is a very remarkable arrangement of tendinous fibres seeming to arise from Poupart's ligament, and thence radiating in an arched form (the convexity of the arch looking towards the pubis) to form a strong interlacement with the fibres of the external oblique.‡ Independent of these adventitious bands the tendon itself, as it approaches the crural arch and the pubis, seems to become thicker and stronger; and (as has been remarked by Scarpa) in the dead body after the integuments are removed and the parts left for some time exposed, the lower portion of the aponeurosis appears opaque and dense, while the part above the umbilicus preserves its transparency, and allows the fleshy fibres of the subjacent muscle to be seen through it. The separation above alluded to being effected, the tendon is divided into two portions, termed the pillars of the ring: the anterior or internal is broader and flatter, and runs to be inserted into the pubis of the opposite side, and the ligamentous substance that covers the front of this bone. The

† Anatomy of Hernia.
‡ Sometimes termed Camper's fascia, from its being so admirably delineated in the "Icones."

inferior or external is rounder and more firm, and attached to the external part of the crest or tuberosity of the pubis. A triangular aperture is thus formed of about an inch or an inch and a quarter in length, the base of which, nearly half an inch across, is situated at the pubis, from which it tapers gradually off in a direction upwards and outwards. For a neat demonstration of this aperture we must also be largely indebted to the knife of the anatomist, its edges being obscured by a fascia* which comes off from them, and passing down on the cord is generally of sufficient density to admit of being traced as far as the tunica vaginalis testis. This ring is never well developed in the female, it then being smaller, rather of an oval figure, and from its deficiency of size appearing to be nearer the pubis than in the male: even in subjects of the latter sex the size of this opening exhibits considerable variety. When a hernia has descended through it, the shape and direction of the external ring are altered: the inferior pillar is still more flattened and runs in a more horizontal direction; the superior is banded in an arched form rather tightly above it; the shape of the entire ring is rendered more oval and its direction more horizontal; but still its relative position with respect to the bone is so far preserved that no hernia can pass, without its internal edge resting on this bone.

In dissecting a hernia of this description from without, after removing the skin and cellular tissue more or less loaded with fat, the fascia superficialis is exposed. This is a tegument investing most parts of the body, though far more dense in some situations than in others, and is situated beneath the subcutaneous fat, with which it is sometimes so much identified as to render its demonstration difficult. At the groin it is usually well developed, and is described as consisting of two distinct laminæ, but may (by such as are curious in these dissections) by care be separated into many more.† The superficial layer is very lax, passes over and has no connexion with Poupart's ligament, and is very generally removed along with the skin and fat by the inexperienced dissector. Its removal exposes some of the glands of the groin. The deep layer is more membranous, and possesses more of the determined character of a fascia. It adheres intimately to the muscular fibres of the external oblique, passes thence inwards over the tendon, to which it cannot be said to be attached, as the connecting cellular tissue is extremely loose, and meets its fellow of the opposite side at the linea alba, to which both are attached. It has an insertion into the pubis, and its adhesion to Poupart's ligament is in many respects extremely intimate. Passing down in front of the thigh, it covers* several of the lymphatic glands, or in many instances leaves small apertures or deficiencies in which glands are lodged: it then reaches the opening in the fascia lata for the transmission of the saphena vein, to the edge of which it adheres more or less closely, and afterwards descends upon the thigh, having this vein interposed between it and the fascia lata. At the external abdominal ring the fascia superficialis sends down a sheath-like process, investing the cord and descending down over the tunica vaginalis and the testicle: it must, therefore, under any circumstances give a covering to the hernial sac. On the removal of this, the fascia that comes from the edges of the pillars of the ring is observed, and this is generally much thicker and firmer than in the normal condition of the parts. When so thickened, it also admits of subdivision into several laminæ. Immediately underneath is the cremaster muscle, its fibres spread out and separated so as to resemble a fascia, though in some instances the contrary may be observed, and they are seen gathered into bundles and greatly thickened. Still deeper are three other layers of fascia, perhaps derived from that which comes from the edges of the internal ring, and finally the hernial sac is exposed.

In herniæ of moderate size, the spermatic artery, veins, and the vas deferens are usually found in one cord and enclosed in one common sheath lying behind the sac: some exceptions, however, to this rule are observed, one of which, wherein the bloodvessels are situated on its anterior and external surface, and the vas deferens posteriorly and internally, has been already noticed and explained. But there is another deviation that seems to be occasioned by the growth of the hernia, and the compression exercised by it on the cellular substance connecting the constituent parts of the cord together. It can therefore only be met with in large and old ruptures. Thus, as the tumour increases, it causes this cellular tissue to be stretched just as if the vas deferens and the artery were pulled asunder in different directions, whilst the sac insinuates itself between them, until finally the vessels come to lie on one side of the hernia, or it may be to occupy its anterior surface. The greatest divarication of these vessels exists, as might *à priori* be expected, towards the lower part of the tumour; it is less towards the middle, and scarcely if at all above, and in the vicinity of the neck of the sac. A knowledge of this fact may teach us to beware how we prolong an incision very far down in operating on large and old herniæ.

Perhaps the next point of practical importance to consider is, whether, with all this anatomical and pathological information, it might nevertheless be possible to mistake this disease and confound it with any other affection. The

* This also has been called an intercolumnar fascia, and a spout-like fascia, &c. It is to be regretted that such a confusion of nomenclature obtains in the description of these parts,—a confusion always embarrassing to the student, and rendering the subject uselessly perplexing and difficult.

† Velpeau describes three distinct layers. Anatomie des Regions, tom. ii. p. 70.

* The inguinal glands are generally described as lying between the layers of the superficial fascia. On dissection, this has not appeared to me to be the case.

hernia just described may exist in two different conditions; one, in which it is still lodged within the inguinal canal, and appears in the form of a tumour in the upper part of the groin, termed bubonocele; the other, in which it has escaped through the external ring, and having dropped down constitutes scrotal hernia.

When the rupture has descended no farther than the groin, there are but two affections that can bear any resemblance to it: these are, the testis itself whilst in the act of descending, if this process has been delayed beyond the usual period of life, and an enlarged inguinal gland. However possible in cases of crural hernia (as shall be noticed hereafter), a mistake of the latter description is not likely to occur in the disease under consideration, but there is an observation of Mr. Colles on this subject deserving of attention. "I do not suppose," says this distinguished professor, "that any surgeon of competent anatomical knowledge could mistake it for inflammation of those lymphatic glands which lie in the fold of the groin, but an enlargement, whether from a venereal or any other cause, of two lymphatic glands which lie on the side of the abdomen, as high up but rather more internally than the internal abdominal ring; an enlargement of these glands will produce appearances resembling those of inguinal hernia."*

It seems almost surprising how the descent of the testicle could possibly be mistaken for a hernia when the mere examination of the scrotum would throw such an explanatory light upon the subject, but a consideration of the following circumstances will be useful in solving the difficulty. 1st, The detention of the testicle within the abdomen until an unusually late period is by no means so infrequent an occurrence as is generally supposed even by surgeons in considerable practice: I have heard a military medical officer observe on the great number of young men that had passed before him for inspection after enlistment, in whom one and sometimes both the testes had not descended. 2d, The symptoms of both affections bear a general though not necessarily a close resemblance; for the situation of the tumour is exactly the same, and if the testicle is compressed and inflamed, the pain and tenderness and the inflammatory fever are to a certain extent like the symptoms of strangulation. But I have not met the same costiveness, at least the same obstinate resistance of the bowels to the operation of aperient medicines, nor the same vomiting, nor the same exquisite tenderness spreading over the abdomen, and the pulse is not that small, thready, hard, and rapid vibration that is produced by peritoneal inflammation. In one case I perceived that pressure on the tumour occasioned that sickening pain and sensation of faintness which a slight injury of the testicle so often produces; and I imagine that in this case a light and very gentle percussion might prove a useful auxiliary diagnostic. But, 3rd, it does not always happen that the surgeon takes sufficient pains to investigate the disease before him. "He is apt," says Mr. Colles,* "at once to set down the case as incarcerated hernia, a complaint with which he is familiar, and does not suspect the existence of a disease which is to him perhaps extremely rare. Boys sometimes indulge in the trick of forcing up the testicles into the abdomen, which may be followed by unhappy consequences, for the gland may not descend again, or if it does, perhaps a portion of intestine slips down along with and behind it, which may then become strangulated, while its presence is unsuspected and the symptoms attributed to compression of the testis." A boy, about seven years of age, had forced the left testicle into the abdomen: ten years afterwards, the inguinal ring having probably become unusually contracted, the testicle passed under the femoral arch with all the symptoms of strangulated hernia, on account of which he was obliged to undergo the operation.†

When the hernia has become scrotal, it then comes more to resemble diseases of the testis and of the cord, but in general these are very easily distinguished, and there are only three that could lead a practitioner into error, and then only through unpardonable carelessness; the hydrocele of the tunica vaginalis testis, the hydrocele of the spermatic cord, and the varicocele or a varicose condition of the veins of the cord.

There is not much likelihood that hydrocele of the tunica vaginalis could, in its earlier stages, be mistaken for hernia: it commences below and increases in an upward direction, while a hernia proceeds from above downwards; and at first in cases of hydrocele, the ring, the cord, and all these parts can be accurately felt. As the disease proceeds and the water reaches the ring, a diagnosis is not so easy; still in almost every case of rupture the testis and the cord, particularly the former, can be easily felt lying behind and at the bottom of the tumour, which is not the case in hydrocele. Besides, hydrocele is lighter as to weight; it gives a sensation of fluctuation to the touch; it never exhibits that soft doughy character that belongs to omental hernia: moreover it is diaphanous, and the light of a candle can be seen through it, if the tumour is examined in a darkened room.

A collection of water within the sheath of the cord must, I should think, be rather an infrequent occurrence; at least it has not fallen to my lot to meet with many examples of it. Still the practitioner must be aware of the possibility of the disease, and that both from the nature of the accident that occasions it, and many of the accompanying symptoms, it may very readily be mistaken for hernia. A young man fell with his groin against the edge of a tub, and in an incredibly short space of time afterwards a colourless elastic tumour appeared in the usual situation of hernia.

* Colles's Surgical Anatomy, p. 46.

* Colles, op. citat.

† Scarpa, op. citat. p. 235.

He was admitted into the Meath Hospital under the care of the late Mr. Hewson, and though some years have now elapsed I can well recollect the variety of opinions pronounced upon it. It could be partially pushed up, but re-appeared instantly on the pressure being removed: it was slightly influenced by coughing, and it was extremely tender to the touch. As the patient was not confined in the bowels, and in fact there was no urgency of symptom, no active treatment was adopted, and the tumour gradually disappeared. It had probably been an effusion of fluid into the sheath of the cord. The manner in which these diseases are said to be capable of discrimination is as follows. Let the tumour be pushed up if possible, and the finger of the operator still be pressed against the ring: if it is a hernia, such pressure will be sufficient to prevent a re-descent; but if it is only a fluid, it will insinuate itself by the side of the finger and the tumour shortly re-appear. Scarpa* denies the sufficiency of this test in cases of omental hernia of small size, when situated so high up as to occupy and dilate the inguinal ring, and asserts that he had repeatedly observed omental inguinal hernia of a cylindrical form, which, when scarcely returned, re-appeared again as before without the patient having changed his posture or made the slightest exertion; and in like manner hydroceles of the spermatic cord, which, when pushed beyond the ring, remained there as long as the patient kept himself in the supine posture without making an exertion. He seems to rely more on the difference of consistence and regularity of surface in the two tumours, and on the circumstance of the hydrocele being always broader inferiorly, contrary to what is observed in omental hernia.

A varicose enlargement of the spermatic vein is not easily confounded with hernia, unless it has increased to such a size as nearly to occupy that side of the scrotum: it is longer in proportion to the diameter of the tumour than hernia usually is, and its surface is hard, knotty, and uneven.† These circumstances, however, are not sufficient to remove all obscurity, and a farther investigation must be made by placing the patient in the horizontal position and endeavouring to empty the vessel; then let him stand up whilst firm and accurate pressure is maintained upon the ring. If it is a hernia, the tumour will not re-appear; but if varicocele, it will return as speedily or perhaps more so than if no pressure had been made. Mr. Colles‡ mentions that a varicose state of the cord may be combined with hernia, throwing great obscurity on the nature of the disease, and for obvious reasons increasing the difficulty of its management.

Inguinal hernia by direct descent.—I now proceed to offer a few remarks on the other form of inguinal hernia,—that by direct descent,* which occurs when, instead of passing through the canal, the protruded viscus is pushed out immediately behind the situation of the external ring, through which it passes directly. The inferior part of the inguinal canal is the weakest of all the parietes of the abdomen. Externally, independent of the external oblique muscle, it is protected as far as the external third or half of Poupart's ligament by the fleshy fibres of the internal oblique and transversalis muscles, and by the fascia transversalis, which is dense and strong in this situation, but becomes gradually weaker internally, and is nearly lost before it reaches the mesial line. More internally it is supported by the conjoined tendon of these muscles, but as it arches over the spermatic cord that portion of the peritoneal cavity which corresponds with the inferior and posterior part of the inguinal canal must depend on the fascia transversalis alone, now becoming weaker and less capable of resistance. More internally still, and immediately behind the external ring, this region is best supported, and there are many natural obstacles to the production of hernia in this situation. Besides the fasciæ already mentioned as tending to prevent the separation of one pillar of the ring from the other, and thereby offer an obstacle to the passage of any viscus through it, there is another† of a triangular shape arising by a pretty broad base from the crest of the pubis, and inserted into the linea alba for about an inch or an inch and a quarter. It lies behind the tendon of the external oblique, and before that of the internal oblique and transversalis, which latter it strengthens materially, and its external edge contributes to close up a part of the external ring. The edge of the rectus muscle extends itself laterally sufficiently far to occupy one-half or one-third of the space behind the external ring, and moreover here the conjoined tendon is particularly strong. Notwithstanding these supports, this part is weak; and yet when a hernia occurs here, it is not in consequence of yielding or stretching, but because the conjoined tendon actually undergoes laceration.

The causes of this hernia are said to be threefold:‡ an unnatural weakness of the conjoined tendon; its absence altogether in consequence of malformation; and its being ruptured by direct violence. Of these, the second is not likely to occur, and an example of it had not been met with by Sir A. Cooper at the time of the publication of his work: the other two in effect amount nearly to the same thing, or at least stand towards each other in the relation of a predisposing to an immediately exciting cause.

* Op. citat. p. 98.

† These symptoms are not certainly characteristic of varicocele. There is a preparation in the Museum of Park Street taken from a man who exhibited them all during life. His disease was an enlarged, knotted, and contorted condition of the vessels of the cord.

‡ Op. citat.

* The internal inguinal hernia of Hasselbach, Jules Cloquet, and Velpeau: hernia on the inner side of the epigastric artery of Sir A. Cooper, and a combination of ventral and inguinal hernia according to Scarpa.

† This is frequently termed Colles's fascia, having been first accurately described by that writer.

‡ Cooper, p. 51.

The hernia by direct descent is distinguished from the oblique, 1st, by the appearance of the groin, the apex of the tumour being at the situation of the external ring, and there being no enlargement whatever in the direction of the inguinal canal: this diagnostic, however, has been found fallacious, for in old oblique hernia the internal ring is dragged down and made to approach the external so as to appear to form one continuous opening. Nor is it easy to point out the difference even in dissection except by the position of the epigastric artery, which in case of oblique descent always lies to the pubic side of the neck of the sac. The neck in some of these cases appears to be arched over and strongly constricted by the superior portion of the ruptured conjoined tendon, which in these cases is more than usually developed, and (as it were) in a state of hypertrophy. It was probably this appearance that led to a belief that strangulation was occasionally produced by the action of these muscles. 2nd, By the relative position of the tumour with respect to the different structures composing the cord. The cremaster muscle in any hernia cannot be felt, but it occupies nearly its usual position in this, being spread out like a fascia in front of it, but rather towards its outside. The spermatic cord properly so called passes on its external rather than on its posterior side; and although all its constituent vessels may be separated in this as in any other species of large and old herniæ, yet generally there is less divarication in this, and the parts lie together more compactly. 3rd, "This tumour differs from the common bubonocele in being situated nearer the penis."* This is certainly true when it is only bubonocele; but when it has descended into the scrotum, the same difficulty that has been noticed as appertaining to old ruptures must also obtain here. In applying this diagnostic the student must recollect that the internal edges of both herniæ are equally near to the pubis: it is by looking to the external border of the neck of the tumour that he can render the test available. Scarpa† states that this hernia is returned without being attended by the gurgling sound: this, however, is an observation perfectly new to me, and which I can by no means verify. Lastly, these herniæ appear more suddenly and attain a larger size more rapidly: frequently they appear as scrotal ruptures almost from the earliest period. This, however, is still an uncertain criterion, and indeed with the assistance of all these circumstances it is always so difficult and frequently so utterly impossible to establish a diagnosis, that no operation should be undertaken under the conviction of the disease being certainly of one form or of the other.

This rupture should present to the anatomist the same number of layers of fascia as that by the oblique descent, the fascia transversalis supplying the place of that given off from the edges of the internal ring; ‡ but the young surgeon should be cautioned not to expect the same facilities of demonstration in the living subject that he possesses in the dead. In the former, the operator often meets with layer after layer of fascia, numerous beyond his expectation, and to which he can give no name; and it is no uncommon circumstance for him to operate on and return a rupture without being able to say of what nature it was—nay, even as to its being inguinal or crural.

Crural or femoral hernia takes place at the superior and internal part of the thigh, below the fold of the groin; the intestine passing out of the abdomen behind Poupart's ligament, between it and the transverse ramus of the pubis, through an aperture that has been termed the crural or femoral ring. A knowledge of the constitution, size, and boundaries of this ring must be of the last importance to the practical surgeon, and accordingly no part of the body has been examined with more minute attention; yet if by these labours anatomy has gained in accuracy of information and very diffuse description, still the student is not much the better for it, inasmuch as almost every anatomist has adopted views peculiar to himself, and thus in the details a degree of confusion has been produced that is extremely embarrassing to the beginner. I shall, therefore, avail myself as little as possible of authorities, and endeavour to describe these parts as they appear upon dissection, commencing from within, which is perhaps the best mode of studying the anatomy of every species of hernia.

The distance between the anterior superior spinous process of the ileum and the angle of the crest of the pubis is in the well-formed female about five and a half inches in length, along which space Poupart's ligament is stretched like a bow-string from point to point. The distance from the ligament thus extended, backwards to the edges of the ileum and pubis forming the border of the pelvis, varies according to the elevations and depressions of these bones; but the entire forms a very considerable space, which is, however, in general so well filled up that unless under peculiar circumstances this region affords sufficient support and protection to the viscera of the abdomen. On examining the corresponding peritoneal surface within, the membrane is found capable of being detruded only at one spot, internal to the view, and about an inch and a half distant from the symphysis pubis. Here, there is a natural aperture varying in size in different subjects, into which the finger may be pushed by a little violence, and a small artificial hernial sac like a thimble be thus produced. On tearing off the peritoneum it is easy to observe the different arrangements that serve to support and strengthen this region of the abdomen.

From Poupart's ligament three distinct layers of fascia pass off in different directions. The fascia transversalis has been already described as passing upwards on the front of the abdomen, where it is gradually lost. From the inferior and posterior part of the arch another fascia passes, at first downwards, then upwards and

* Cooper.
† Scarpa, op. citat. p. 84.
‡ The internal spout-like fascia.

backwards, to expand itself over the iliacus internus and psoas muscles; and it is therefore called the fascia iliaca. These fasciæ are perfectly continuous as far inwards as the external border of the artery, and form a smooth and strong membranous wall for the abdomen in this situation, rather attached to Poupart's ligament than coming off or derived from it.* These fasciæ separate at this spot and unite again between the artery and vein, thus forming a sheath for the former vessel: in like manner a separate sheath is formed for the vein, when they again separate and leave a small opening, which is the crural ring, but unite before they reach Gimbernat's ligament, to the abdominal surface of which they give an investment, but here the fibrous structure is very weak and differs little in appearance from cellular membrane. These fasciæ then form a flat, broad funnel, which has three apertures at top, and the membranous septa are of the greatest use in binding the anterior and posterior faces of this funnel together: hence a hernia cannot escape through in company with the artery nor with the vein, and hence also the vein is not compressed nor its circulation interfered with, even although a hernia close to it is in a state of strangulation. This funnel descends on the vessels, to which it becomes firmly attached, at about an inch and a half below Poupart's ligament, and, according to some anatomists, is there reflected up again on the vessels forming a cul-de-sac or bag. I thus consider the crural ring properly so called to be an aperture formed by a deficiency in the fascia iliaca and transversalis, just as the internal inguinal ring is formed in the latter membrane alone. It is occupied by a loose cellular tissue, and in general by a small absorbent gland.

This ring is of a different size in different individuals; and where it is large, the person may be said to have an hereditary or congenital disposition to the disease; but a liability to it may arise from accidental circumstances also. It is obvious that in proportion as the space beneath the crural arch is well filled, and the muscles tense and plump, the aperture at the ring must be small; also that it will be larger according to the greater breadth between the spinous process and the pubis, or as the space under the crural arch is deep. Hence it may be explained why this kind of rupture is frequent amongst women who have borne many children, with whom the parietes of the abdomen are relaxed; less frequent amongst young and healthy unmarried females, and scarcely known amongst men, the pelvis of the male being narrower, and his muscle better developed by use and exercise.

The crural arch or Poupart's ligament is nothing more than the inferior pillar of the external inguinal ring, and is (as has been before stated) inserted into the crest of the pubis; but it has another attachment to this bone, which, being in intimate relation with femoral hernia, I have delayed the description of until now. As the ligament approaches the pubis, its inferior edge becomes twisted upwards and backwards towards the linea ileo-pectinea, into which it is inserted for a length of from a half to three quarters of an inch. Its shape is triangular, its posterior attachment being somewhat shorter than its anterior; and its base, which has its aspect towards the vein, is somewhat lunated. In the male its situation corresponds nearly with the external inguinal ring; and the spermatic cord rests on it just as it is about to pass from the inguinal canal.

The fibrous funnel-like sheath already described is itself lodged within a cavity which may be called the *crural canal*, and is thus formed. The fascia lata of the thigh in front has two origins, one from the whole length of Poupart's ligament, the other from so much of the linea ileo-pectinea as gives origin to the pectinalis muscle, and from the ligament of the pubis. This latter portion having passed down the thigh unites with the former below the entrance of the saphena into the femoral vein, below which point they form one continuous sheath for the muscles of the limb. The portion, however, which comes from Poupart's ligament requires more attention. At first it lies completely in front of the upper part of the thigh, and of course leaves a triangular space between it and the other portion, in which are lodged the funnel-shaped fascial sheath, with its contents, the artery and vein, lymphatic vessels, and some glands. About half an inch, or in some subjects a little more, below Poupart's ligament the internal portion of this fascia appears to be wanting, leaving the vessels uncovered by it as far down as the point of union of the two fasciæ: I say *appears to be wanting*, because the fascia lata is really continued over this space, joins the pubic portion internally, and sends a process upwards to be inserted into the linea ileo-pectinea, external to the lunated edge of Gimbernat's ligament, and between it and the edge of the femoral ring; but it is here so thin and cellulated that it is generally removed in the dissection. When thus disposed of, the firm portion of the external fascia lata, as it passes to join the internal, assumes a lunated form above and below, and thus the entire apparent deficiency is made to appear of an oval figure, the edges of which are crescentic, and which have been called by the different names of Hey's ligament, Burns' ligament, and the crescentic edge of the fascia lata. A finger pushed from above through the crural ring will easily feel the superior margin of this aperture, and its influence on hernia in this situation will soon be made apparent. The femoral or crural canal then is from one-half to three-fourths of an inch in length, and is formed by the fascia lata: it is bounded above, anteriorly by Poupart's ligament and posteriorly by the linea ileo-pectinea; below, anteriorly by the crescentic

* Their importance in strengthening this part of the abdomen is proved by an experiment of Mr. Colles. "Make in the aponeurosis which covers the iliac muscle an opening capable of admitting the finger. Pass it between the aponeurosis and surface of the muscle, and you will be enabled, without much difficulty, to push the finger under Poupart's ligament down to the fore part of the thigh." Colles, op. citat. p. 68.

edge of the fascia lata or Hey's ligament, and posteriorly by its pubic portion: both externally and internally it is bounded by the junction of these two portions of fascia. Gimbernat's ligament, which is usually described as forming the internal boundary of the crural ring, rarely fills up more than half the space between the crest of the pubis and the femoral vein. This canal, as being composed of fascia, is firm, and unyielding: it cannot be influenced by the actions of any muscle in the neighbourhood, nor even so much as is generally supposed by the position of the limb. It should follow from this constitution of parts that any hernia thus restrained should forcibly compress the vein and artery before it suffered strangulation itself, and so it would if the protrusion had relation to this canal alone, and was not contained within its own proper portion of the funnel-shaped sheath already described.

The neck of the sac of a femoral hernia, then, has behind it the fascia iliaca and the ligamento-cartilaginous material that covers the sharp edge of the linea ileo-pectinea: internally it has the junction of the fascia iliaca and transversalis, the attachment of the fascia lata to the linea ileo-pectinea, and Gimbernat's ligament; internally it must also have the spermatic cord in the male and the round ligament in the female; anteriorly it has the fascia transversalis and Poupart's ligament, and *immediately above the neck* and in close contact with it is the spermatic cord, of course including the spermatic artery: externally is the membranous slip interposed between it and the femoral vein. The epigastric artery is also external to it, but although this vessel is somewhat irregular both in origin and position, yet the full breadth of the vein must be always interposed between it and the neck of the sac. But there is an irregular vascular distribution that must be borne in mind. In a great number of subjects (perhaps one out of every four or five) the obturator artery, instead of coming off from the internal iliac, arises by a common trunk along with the epigastric, which it soon leaves, and passing downwards and inwards crosses the superior aperture of the femoral canal before it dips into the pelvis to reach the obturator foramen. In this course it sometimes passes the border of the canal posteriorly, but much more frequently in front; and in this latter case, if a hernia existed, the vessel would embrace two-thirds of the circle of the displaced peritoneum close to and immediately above the neck. It appears, then, from these anatomical relations that in all subjects a considerable degree of danger may arise from too free and unguarded a use of the knife in operation—a danger that is necessarily enhanced in the male subject: indeed in consequence of the risk of hæmorrhage Scarpa seemed disposed to trust to dilatation and laceration of Poupart's ligament for relieving the stricture, and where these means were insufficient he recommended a new and particular direction to be given to the incision. But from careful dissection and examination of these parts I am disposed to believe there is always sufficient space to free a stricture without endangering either the spermatic or the irregular obturator artery. It must be recollected that if the intestine is sufficiently liberated to permit the passage of gas through the immediate seat of the stricture, its return is perfectly practicable, and a very small incision will be sufficient to accomplish this. Now these vessels lie, not on the neck of the sac, but above it; and there is quite space enough to set the stricture free without interfering with them: when they are wounded, it is in consequence of the introduction of the cutting edge of the bistoury too far within the stricture.

When a portion of intestine has escaped through the femoral ring, (and by reason of the small size of the aperture herniæ here are seldom large,) it lies at first within the crural canal, where it is restricted by the fascia lata, and its existence recognized with difficulty. It has happened that patients have perished from the incarceration of a small fold or knuckle of intestine without the circumstance ever having been discovered during life. But after it has passed the crescentic edge of Hey's ligament, and is relieved from the pressure of the fascia, it comes forward, and if it increases farther, its direction is rather inwards and upwards, so that it may assume the position of an inguinal hernia to the extent of being mistaken for it. Having proceeded so far, the hernial sac has assumed somewhat of the form of an arch: it has passed, first downwards through the femoral canal, then forwards under the sharp edge of the fascia lata, either passing through the weak cellular portion of it or pushing it before, and then upwards and inwards in front. The hollow of this arch looks upwards, and is occupied by the crescentic edge of Hey's ligament. Perhaps this particular position of the hernia, as well as the extreme straitness and unyielding nature of the crural canal, has contributed to the frequency of strangulation to which this form of hernia is liable.

When a person stands erect and without exertion, Poupart's ligament forms nearly a direct line between the anterior superior spinous process of the ileum and the crest of the pubis, and all the fasciæ connected to it are in their natural state and sufficiently relaxed; but if the thigh is strongly extended or the body bent backward, the ligament then becomes tense and is arched backward toward the thigh. The effect of the general tension of the limb in this position would be to convert the arch formed by the hernia into an angle, against the hollow of which the edge of Hey's ligament would be firmly compressed, and a sufficient degree of resistance thus created to the return of the venous blood to produce a congested condition of the viscus. The operation of such a cause as this can hardly be considered as permanent, but the mischief once commenced is not easily controlled, and an intestine might soon be placed in such a condition as to render incarceration at the ring inevitable.

The situations at which crural hernia may be strangulated have not been satisfactorily described, although there is no subject on which more anatomical labour has been bestowed. If

I was to speak from my own experience alone, I should say that though the hernia itself is superficial, the seat of the strangulation is always deep—somewhere at or in the immediate neighbourhood of the neck of the sac. I found the opinion partly on the dissection of subjects that had died of the disease, but more particularly on the phenomena I have observed during the progress of an operation on the living: still the experience of one individual can scarcely ever be sufficient to establish a great pathological principle, and there is authority that cannot be questioned for believing that crural hernia is frequently strictured at a far less depth from the surface. Besides the neck of the sac, by which this hernia is confessedly strictured in very many cases, Sir A. Cooper places the seat of strangulation, first in the crural sheath and semilunar or lunated edge of the fascia lata, and secondly in the posterior edge of the fascia lata.* Mr. Colles says that the neck or constricted part of crural hernia does not always appear at the same depth from the surface, and explains the circumstance thus: "The hernia having descended into the femoral sheath, it escapes through one of those apertures in it for transmitting the lymphatic vessels, and also passes through a corresponding opening in the iliac portion of the fascia lata. As it passes through a small aperture in each of these parts at nearly the same spot, it must there be liable to great constriction; for these two layers of fascia will be compressed together, and thus their strength and resistance be considerably augmented. Hence we should find the seat of stricture in strangulated femoral hernia frequently to be at some distance below and to the pubic side of the crural ring."† The descriptions of Hey and Burns I cannot profess clearly to understand, and I fear they were taken rather from sound subjects than from those in which herniæ were actually present. Scarpa does not distinctly point out the anatomy of the seat of stricture, but from the general bearing of his descriptions, and above all from the anxiety he expresses relative to the danger of wounding the spermatic artery in operation, which vessel, if present, must lie close to the neck of the sac, I would hazard an opinion that he believed the seat of strangulation to be always deeply seated.

In dissecting this rupture from without, or in operating upon it in the living, it will be found to lie at a different depth from the surface, and to possess variety in the number of fascial coverings according to its position with reference to the parts already described. Thus it may be placed within the crural canal, within that triangular space formed by the fascia lata; or having passed beyond its inferior opening or falciform edge, it may present more superficially. In the former case, after the division of the common integuments, the skin and fat, the superficial fascia is exposed and may consist of many layers—at all events of two: next is the dense and resisting fascia lata of the thigh; and deeper still, the funnel-shaped fascia in which the crural ring is situated. Between this latter and the sac another fascia has been described under the name of the fascia propria, which may be supposed to be formed by a condensation of that cellular tissue already described as occupying the crural ring; but I have never been able to satisfy myself as to the existence of this as a distinct membrane, and I must again caution the young operator not to expect to meet with laminæ of fascia as described or demonstrated by the anatomist. A dexterous and careful dissector may make almost as many layers of fascia as he pleases.

After it has passed the inferior border of the crural canal and appeared more externally, the coverings of fascia to be expected must depend on the view taken of the anatomy of this part. If it is believed that the hernia having cleared this point merely swells out on being relieved from the pressure, without passing or pushing through any of the superincumbent structures, then in order to come down upon the sac it would be necessary to divide the skin and cellular tissue, the different laminæ of the fascia superficialis, the cribriform portion of the fascia lata, the anterior portion of the funnel-shaped fascia, and the fascia propria. If, on the other hand, it is supposed that the hernia has escaped through one of the openings in the femoral sheath, and a corresponding one in the iliac portion of the fascia lata, it will lie more superficial by the absence of these investments. In either case the last layer of fascia most adjacent to the sac is almost always remarkable for density and strength.

The general symptoms of this affection are the same with those of inguinal, such as the appearance of the tumour, its diminution or disappearance in the recumbent position, and the impulse imparted to it by coughing, sneezing, &c.: its peculiar symptoms are explicable by its anatomical relations. 1. The crural hernia is generally small and its increase slow: the size of the ring and the compression exercised on it by so many superincumbent layers of fascia will be sufficient to account for this, and also will shew why this rupture is almost always painful, and why position has so much effect on it, relief being constantly obtained by bending the thigh on the pelvis and rotating the limb inwards. 2. The peculiar manner of growth, its first passing downwards, then forwards, and then upwards and inwards, is caused by the attachment of the funnel-like fascia to the vessels at the superior part of the thigh, and by that of the fascia superficialis to the fascia lata near the entrance of the saphena vein; thus its shape is never pyramidal like that of inguinal; it is globular or oval, and its longest diameter is transverse. 3. I have already mentioned its prevalence amongst females advanced in life.

As the testicle is more subject to disease than any structure at the top of the thigh, there are more affections with which scrotal hernia may be confounded; but on the other hand, when a doubt arises on the subject of crural

* Cooper on Hernia, part ii p. 14.

† Colles' Surgical Anatomy, p. 77.

hernia, the diagnosis is vastly more difficult, and often the surgeon has to be guided by the general symptoms of peritoneal inflammation rather than by the results of local examination, however carefully performed. Mr. Colles* states that "this species of hernia is liable to strangulation even before it can be felt externally,"—an observation I was enabled to verify a few months since in a case where a very small knuckle of intestine had not passed the inferior aperture of the femoral canal, but was lodged in an absorbent gland, which seemed to have been hollowed out to receive it.† But the hernia may be much larger and still not discoverable in consequence of some unfortunate complication: I have seen a case of incarcerated hernia‡ in which an abscess was seated at the superior part of the thigh immediately in front of the sac; and after the pus had been evacuated, some time elapsed before decisive symptoms pointed out the existence of the more formidable disease behind. There is, in the Museum in Park-street, a preparation exhibiting a fatty tumour growing on the external surface of a hernial sac. The patient from whom it was taken was the subject of operation, and after the integuments and fascia had been divided and this tumour presented, some doubts were at first entertained as to the presence of a hernia beneath it; but on careful examination the operator discovered the hernial tumour, and cutting cautiously through the other, opened the sac, in which a knuckle of intestine was found incarcerated. The operation was successful, and the patient recovered. "In many instances," says Mr. Colles, "the difficulty of discriminating the disease is considerably increased by an enlarged lymphatic gland lying anterior to a very small hernia."

Perhaps there are no two affections more liable to be mistaken for each other than crural hernia and an enlarged lymphatic gland; and however apparently distinct the two affections may be, and however easy it may seem to form a diagnosis in theory, still the best surgeons speak of the difficulty of discriminating between them, and many acknowledge having fallen into the error themselves. It has happened that a patient has had a hernia on one side and an enlarged gland on the other, and when symptoms of strangulation became urgent, it was the gland that was considered to be the most pressing, and it was selected for the operation. I recollect two cases which occurred nearly at the same time; one in which there was a very minute hernia at the left groin, which had been regarded as a swelled gland, and the patient died of the effects of its strangulation; the other a case of pure peritoneal inflammation, in which the patient happened to have a swollen gland in the groin, which was actually cut down upon and exposed, but the operation did not much injury, for the patient subsequently recovered. It has been said that a diagnosis can be established by attention to the following circumstances. The hernia follows on some sudden exertion, on a blow or a fall, and appears suddenly and at once; whereas the gland in the commencement is very small, perhaps like a moveable kernel, and increases slowly and by degrees. Besides, this diagnostic will be greatly assisted if there is a chancre or other sore to account for the irritation and inflammation of the gland; but on the other hand the hernia does not always assume its given size at once, it is often so small at the beginning that the patient is not aware of its existence, and so far from appearing suddenly after a violent exertion it may have been present for months without being perceived. The hernia receives an impulse from coughing or sneezing, and retires or becomes smaller in the recumbent posture, which are not observed to happen with the gland; but then an enlarged gland may be complicated with a hernia, and the symptoms so mixed and confused that a diagnosis may be very difficult. It is said that a gland may be moved about and withdrawn from its situation in a slight degree, and if it can there is no great danger of mistaking it; but when it has arrived at the size or occupies the place which could make it resemble a hernia, then it does not admit of being moved under the fascia, and the diagnosis is almost impossible. Fortunately, a crural hernia does not often consist of omentum, but when it does there is nothing more likely to exhibit the characters of a gland in a state of chronic disease, and I know not how the two cases can be accurately distinguished. Here the physical evidence derived from a gentle percussion (as already noticed) is utterly and completely valueless.

Lumbar or psoas abscess is another affection that may be confounded with femoral hernia, and Mr. Colles states that he had known the mistake to have been committed. These diseases resemble each other in the following circumstances. Both present very nearly in the same situation at the bend of the groin, are firm and elastic; coughing gives to each the same or a similar impulse; and there are cases on record in which psoas abscess disappeared under pressure or by the patient assuming the recumbent posture. Yet I think the two cases not very difficult of distinction. Psoas abscess is a disease of youth; it does not often occur in the adult except as a critical abscess after fever, or in connexion with caries and curvature of the spine, in either of which cases the collateral circumstances will point it out; whereas femoral hernia is the disease of married women, and of course will not be likely to occur at the same period of life with the abscess. A sense of fluctuation is generally perceptible in psoas abscess; not so with hernia. The abscess is preceded by pain and weight in the loins and by shivering. It is a scrofulous complaint, and there will probably be other indications of the diathesis, such as the transparent skin, the thickened upper lip, or perhaps ill-conditioned scars about the neck. Any of these symptoms

* Op. citat. p. 83.

† This curious case occurred in the Meath Hospital in the summer of 1835.

‡ I use this term in the sense hitherto employed, not implying perfect strangulation.

taken singly may prove but an indifferent diagnostic, but in the aggregate they establish such distinction that it must be the result of sad inattention or of actual ignorance if any serious mistake is committed.

It has been stated that a varix of the saphena vein may present symptoms and appearances strongly resembling crural hernia, inasmuch as the tumour disappears under pressure or in the horizontal posture, and returns again immediately on these influences being removed, and also as it receives a certain degree of impulse from coughing or sneezing. From anatomical considerations it would almost seem impossible that such an error could be committed, and at first sight the observation seems to have been made for the purpose of creating nice distinctions and rendering the subject apparently complete rather than for any practical utility. A case, however, is related by Petit, who distinguished the real nature of the tumour by its dark-coloured appearance and by the general varicose state of the remainder of the vein. If difficulty is experienced in any particular case, it may be easily resolved by making pressure on the trunk of the iliac vein above Poupart's ligament, when the tumour will re-appear, even although the patient maintains the horizontal posture.

"Fatty tumours are not unfrequently found on dissection occupying the exact situation of crural hernia. I have not had an opportunity of seeing any case of this kind in the living body, but have had occasion to remark at least five or six instances of it every season in the dissecting room, from which I presume such tumours are more common than is generally suspected. In all those instances the fatty tumour was connected with or rather seemed to grow from the outer surface of the peritoneum lining the crural ring; and the inner surface of this membrane when viewed from the abdomen had a contracted, wrinkled, and thickened appearance, resembling very closely the appearance of a reduced hernial sac. Whether the peritoneum had been protruded in these instances I cannot pretend to say; nor can I venture to lay down the symptoms which should guide us in our diagnosis in the living body. This much at least is obvious, that these steatomatous tumours will not be accompanied by symptoms of strangulation."*

Umbilical hernia.—The navel is the remnant of an aperture that had been situated nearly in the centre of the front of the belly, but nearer to the pubis than to the ensiform cartilage: it is placed in the linea alba, and of course its edges are tendinous. During fœtal life it serves for the transmission of the umbilical vein and arteries, but its size is greater than would merely suffice for the passage of these vessels, in order that the circulation of the blood through them should suffer no interruption by accidental compression; and in a fœtus of seven months the edge of the aponeurotic opening is still thin, weak, and unresisting. After birth, when the navel string (as it is called) has dropped off, the umbilical aperture begins to close, until finally that puckered cicatrix is formed, the appearance of which is so familiar; but the periods at which this process commences and is completed, and the circumstances that may occur to interfere with it, are of some importance with reference to the phenomena of hernia. Scarpa says that it begins immediately, and that if the finger is passed up the peritoneal wall of the abdomen in a child two months after birth, not only will the navel be found firmly formed and completely cicatrised, but there will be a knot or elevation felt at this spot, shewing that it is then really stronger than most other parts of the abdominal parietes. Lawrence states that the contraction commences about the third or fourth month after birth, and thence inculcates the necessity of an infant being tolerably accurately bandaged anterior to that period in order to prevent the occurrence of umbilical rupture from its struggles or its cries. It is not of much consequence which of these opinions may be correct: probably both are so to a certain extent, for the opening is larger in some infants than in others, and will require a longer time to close, and the process of obliteration does not commence in all exactly at the same period after birth. Whatever variety may exist in this respect, when the process is complete the umbilicus can never afterwards be called an aperture; it never again re-opens; and when ruptures are observed in after-life seeming to occupy this situation, it will be found on examination that some neighbouring parts of the linea alba have given way, and the disease more strictly belongs to the ventral than to umbilical hernia.

It appears then that by the salutary provisions of nature the front of the abdominal parietes is well supported, and the contained viscera protected from protrusion; and even if the operations by which the umbilicus is closed should be accidentally suspended or interfered with, (as by the presence of a hernia for instance,) the disposition is not lost, and the aperture preserves its tendency to close and become obliterated for the first five or six years of childhood. Thus at any time within that period there may be a reasonable probability of obtaining a permanent cure of umbilical hernia; whereas after the age of ten or twelve years this disposition ceases to operate, or at least is greatly impaired, and there is little or no chance of so fortunate an occurrence.

The condition in which the umbilicus exists at and after birth divides the herniæ that occur in this situation into different orders according as they may appear at the period of birth or afterwards. Scarpa considers the disease to consist of only two species, the congenital and the adventitious—the congenital being that which appears in the infant when born, and the other occurring at any subsequent period. Lawrence speaks of three kinds, the congenital, that which appears at birth, and in which the protruded viscera are lodged in the umbilical cord; the umbilical hernia of children occurring after the navel has been formed, but pro-

* This passage is copied from Colles's Surg. Anatomy, p. 84.

truding through the original deficiency in the linea alba; and the hernia of adults, which has some peculiarities that shall be noticed hereafter.

The congenital umbilical hernia seems to depend rather on a deficiency of the anterior walls of the abdomen than on any other cause, and in the cases in which it is observed, the aperture at the navel is much larger than it should naturally be, and its tendinous edges excessively thin and weak. The deficiency of the abdominal parietes ranks amongst natural malformations, and it is astonishing to what an extent it has been observed. The entire of the tendinous front of the belly has been found imperfect, and nearly the whole of the viscera displaced, thus forming an immense rupture covered at its base and for some extent farther by the skin and superficial investments of the body, and in its remaining part by the transparent spongy substance of the umbilical cord. The contents of these ruptures are greatly varied: the liver or a portion of it, the spleen, the stomach, the greater and the lesser intestines have all been occasionally found thus circumstanced, but more particularly the omentum, which, as might be anticipated from its situation, is observed to constitute a part of almost every umbilical hernia both in the old subject and in the young. Whenever there is such a deficiency in the abdominal parietes, the pressure an infant undergoes in coming into the world materially contributes to the production of hernia, and accordingly it is observed most frequently after a protracted and difficult labour; and if it is large, and the contents of the abdomen extensively deranged or displaced, it is in general fatal, the infant seldom surviving beyond two or three days, and perhaps not so long. In this affection there seems to be a want of correspondence between the size of the viscera and that of the abdominal cavity, the former appearing enlarged and swollen; and there is seldom a possibility of returning the rupture, or of maintaining it so if reduced. There is in general also in these cases some other malformation or incomplete development to account for the fatality that so uniformly attends them. But if, on the other hand, the hernia is small, the case is by no means necessarily attended with danger: the rupture may be reduced, but it has a tendency to return whenever the child cries or makes any other exertion, and it is extremely difficult to restrain it by a bandage; but if it can be kept up for a few months, the umbilical aperture closes as it would have done if there had been no protrusion, and the cure is permanent and complete.

If, before the navel has become cicatrized and closed, a portion of any viscus should happen to be protruded through it, and its progress towards obliteration thus interrupted; or if the contraction has been delayed longer than usual, and an aperture thus left ready to favour the escape of a part of intestine from its natural situation, the rupture will be of the second form mentioned, namely, the umbilical hernia of the child. This differs from that of the infant inasmuch as it is covered by the skin and the cicatrized knot of the navel, and does not lie within the cord; and from that of the adult, so far as, if replaced and prevented from again protruding, the aperture will gradually contract, and thus a permanent cure be obtained, which is scarcely to be expected at a more advanced period of life. It has been already mentioned that Scarpa considered the perfect contraction of the umbilicus to be completed in about two months, and at the end of that time that it is even firmer than other parts: he moreover seemed to think this part materially strengthened by the remains of those vessels which before birth made up a part of the cord. The umbilical vein passing from the navel upwards towards the liver, and the hypogastric arteries passing downwards, are at the umbilicus united by a cicatrix to the skin and to each other, and contribute to prevent the yielding of the part as soon as they become ligamentous. The point of union of these vessels must be pushed forwards as well as the integuments in adventitious hernia, and hence it happens that when the umbilical aperture is only of its natural size, the rupture that takes place (if any) is small; and in cases where it is large and the abdominal parietes deficient in this point, the tumour is flatter and more compressed than might have been otherwise expected, and some of these vessels are found lying on it and forming a part of its covering.

In persons more advanced in life in whom the opening in the tendon had been perfectly closed, Scarpa denies that it ever becomes relaxed again, and therefore states that the ruptures which occur from over-distension, from pregnancy, or as the sequelæ of dropsy, are not situated in the original umbilical canal, but in some part of the linea alba that has more recently given way, and of which the umbilicus happens to form a part. He states further that the linea alba is not equally strong and firm in all its parts; that above the navel it becomes gradually thinner, and in women who have borne many children it is uneven in consistence, and in some parts so weak as to be liable to yield and tear on a very slight exertion. Hence it happens that these ventro-umbilical ruptures generally occur rather above the navel; and the almost obliterated remains of this cicatrix (for by the distension it becomes nearly smooth) is scarcely ever observed to occupy the centre of the tumour, but is found to one side and almost placed inferiorly. In the dissection of these tumours a laceration or fissure is constantly met with in the linea alba, sometimes transverse, but more generally longitudinal, and this is one reason why the umbilical ruptures of old persons are not susceptible of a radical cure, for there is a great difference between a natural opening, the tendency of which is to contract and close, and one made by the yielding and laceration of part of the linea alba or other tendinous portion of the abdominal parietes, which certainly cannot be supposed to be endowed with strong reparative properties.

There was a question formerly raised as to whether umbilical hernia possessed a peritoneal sac, and it was generally believed that no such investment had any existence in the disease. Garengeot in his paper on singular species of herniæ expressly states that ruptures of this kind were deficient in this particular, and he was followed by Petit and almost all the elders of our profession, who, to spare themselves the labour of investigation, copied from each other errors as well as truth. It is really curious to observe how a mistake could have so long maintained its ground that could have been set at rest by half-an-hour's dissection; and indeed it is in some respects surprising how such an opinion came to be entertained at all. In every case of umbilical hernia there must of necessity be a sac, because the peritoneum is not deficient at the navel, and the vessels that pass within the cord do not enter the cavity: they lie anterior to it, and are partly invested by the membrane, which is entire and complete behind the navel, and neither intestine nor omentum can be protruded without pushing it out before it, and thus constituting a proper hernial sac. It may be that in large umbilical herniæ the peritoneum shall have become very thin, so that the peristaltic motions of the intestines may be easily perceived through it from without; or it may have been burst accidentally, and in either of these cases there will be an appearance as if there had been in reality no sac. And moreover, the peritoneum immediately behind the navel is not connected to it by the same loose and distensible cellular tissue that unites it to other parts: it is here very closely joined, and consequently in small ruptures only occupying this spot there will be no appearance of a separate and distinct sac, although the peritoneal covering is really there notwithstanding. It must be borne in mind, however, that investments of umbilical ruptures are always very thin, and a proportionate degree of caution is requisite in cutting through them during operation. There are no distinct layers of fascia here as in other ruptures, no laminæ to separate one by one and one after another. In the congenital species the contents of the sac are merely covered by the peritoneum and the sheath of the cord. In the infantile, the coverings are the skin and cicatrix of the navel and the peritoneum; and in the adventitious kind or ventro-umbilical we meet the skin, then the superficial fascia, which is very thin and weak on this part of the abdomen; next the cellular tissue that had united the peritoneum to the adjacent structures, and which may have become condensed so as to form a kind of fascia propria; and lastly, the peritoneum or hernial sac itself.

In almost every case of umbilical hernia occurring in the adult, omentum has formed part of the contents of the sac, at least the observation has been so universally made that the rule may be considered as established. In general it lies before the intestine in such a position as to conceal it altogether and make it appear as if no other viscus was engaged; but sometimes the intestine makes a passage through it and presents first when the sac is opened; or both these structures may be coiled and twisted together in such wise as to render it difficult to unravel and separate them one from another, and highly perilous to return them in that condition into the cavity lest strangulation should take place within. From the circumstance also of containing omentum, umbilical ruptures frequently become irreducible, this structure, when protruded, becoming thickened and enlarged and occasionally loaded with fat, so as to preclude the possibility of its being again returned through the tendinous opening. Or adhesions may have formed between the omentum and the intestine, or between either or both of these and the sac: in short, the rupture may become irreducible from any of the causes already mentioned as capable of producing such a condition of parts, but the one first alluded to, namely, the thickening and alteration of the omentum, is the one most generally observed.

This altered condition of the omentum has also a paramount influence on the case even at a more remote period. Let it be supposed that symptoms of strangulation have supervened, and an operation been deemed necessary to preserve existence, the presence of this mass will be likely to prove extremely troublesome. Every surgeon is conversant with the different opinions that have been entertained as to the manner in which irreducible omentum should be dealt with. Some* speak boldly enough of cutting it off and returning any part that might remain, or allowing it to slip back into the abdomen without feeling any apprehension from the possibility of hæmorrhage. Some have tied a ligature around it to cause it to slough, and Mr. Hey† employed a ligature in another way and with a different view, namely, by applying it so tight as gradually to cut through the omentum by the process of absorption, but without entirely destroying the circulation through the included part. Scarpa‡ left the omentum, merely covering it with the sides of the hernial sac and dressing it lightly until suppuration appeared, when, he said, the pedicle by which it hung might be safely tied and the mass cut away. I notice this diversity of opinion not for the purpose of inculcating any one line of practice, but to shew that the omentum cannot be left there with safety. It is at all times and under every circumstance not very highly organized or able to sustain disease; still less so is it when altered from its natural arrangement, converted into an unwieldy mass of fat, and exposed to the influence of the atmosphere in an open wound. Sometimes it runs into tedious and unhealthy suppurations with profuse and wasting discharges; more generally, if the patient is old and debilitated, into mortification, which may (if the subject lives sufficiently long) pass on to the unaltered omentum within the abdomen, nor cease until it has reached the stomach.

* Pott, op. citat. p. 16. Petit and Ponteau, Mém. de l'Acad. Royale de Chir. tom. vii. p. 338. Colles's Surgical Anatomy, p. 100.

† In this he was anticipated by Moreau, Mém. de l'Acad. Roy. de Chir. t. vii. p. 344.

‡ Op. citat. p. 420.

The symptoms of umbilical hernia are easily understood by referring to those points in which it differs from ruptures situated elsewhere. In the infant the tumour appears long and thin, according to the quantity of viscera protruded through the aperture of the navel, and projects downwards on the belly: its coverings are almost transparent. In the more adult subject, if the patient is thin the tumour is of a pyriform figure, and when permitted to increase without restraint becomes very large and hangs pendulous towards the pubes. If he is fat it may form a less circumscribed swelling, broad and flat, apparently extending in every direction round the umbilical aperture. The sensation imparted to the finger is of a soft and doughy tumour slightly moveable under the skin, but sometimes in consequence of the presence of intestine in the rupture it may possess some elasticity. Occasionally, after an omental hernia has remained for years without producing much inconvenience, it suddenly enlarges towards the centre and assumes a conical chape, the apex being soft and elastic, the base hard and more solid: in this case there has probably been a fresh protrusion of intestine which has burst through the omentum and requires instant attention, as so circumstanced it is extremely liable to fall into a state of strangulation. The collateral symptoms, such as nausea, flatulence, colicky pains, &c., are more severe and more frequent in umbilical than in any other form of hernia, a circumstance that has often given rise to the idea that the stomach formed some part of the protrusion, but perhaps it is unnecessary to resort to such a supposition, for probably the herniæ of the linea alba that have been described as containing part of the displaced stomach were in no wise different from ordinary umbilical ruptures as to their contents, for the omentum being protruded will be sufficient to account for every aggravation of symptom.

When the hernia is strangulated, it is said that the symptoms are less severe and less urgent than in other species of ruptures, a circumstance that has also been accounted for from its so often containing omentum alone. Sir A. Cooper states that more cases of strangulation occur in the seasons when green vegetables are plenty than in others, which would seem to favour the idea of its being often caused by the use of flatulent or indigestible substances. But (except with reference to prevention) it is of little consequence how it may be caused, or whether its progress is rapid or not. When once formed, it must be reduced; and it runs its course with sufficient rapidity to render it extremely alarming. It has destroyed a patient in less than eighteen hours, and although such severity is not generally to be expected, yet in this or in any other kind of hernia the smallest unnecessary delay can never be justified.

"Sometimes a small mass of indurated fat, situated between the peritoneum and its union with the aponeurosis of the abdominal muscles, makes its way insensibly through the separated fibres of the linea alba, and is at last elevated externally in form of a tumour which seems to have all the characters of an omental hernia. The existence of this species of tumour through the linea alba is not only a certain fact and demonstrated by several observations made on the dead body by Morgagni, by Klinkosch and several others, but it is also proved that it makes its appearance in other parts of the linea alba besides that to which the umbilical vein corresponds internally. It may occur that a person in whom a similar small tumour has existed for a long time in the course of the linea alba may be attacked from a quite different cause by violent colic, with nausea, inclination to vomit, and interruption to the alvine excretions. The surgeon, in similar circumstances, is easily led into error," (and Scarpa committed the mistake himself,) "presuming that the tumour is a true incarcerated hernia of the linea alba, subjecting the patient to an operation which has no connexion with the cause of the disease." Never having seen any similar tumour, I have copied the above passage from Scarpa: they are probably of the same nature with those described by Mr. Colles as occasionally presenting at the crural ring. The resemblance must be strikingly obvious to every reader.

(William Henry Porter.)

HIBERNATION; etym. *hiberno*, to winter, to pass the winter; syn. *lethargy*; erroneously, *torpor*; Fr. *sommeil hivernal*; Germ. *Winterschlaf* and *Sommerschlaf*; a term chiefly applied to express that condition in which certain animals pass the winter season.

How often have I been struck with admiration in observing how variously the Creator has provided for certain of the *insectivorous* tribes, the swallow and the bat, for example, against the period when the sources of their daily food are cut off, when spring and summer yield to autumn and winter, and *insects* disappear! The first emigrates to a more genial climate where its nutriment still abounds; the second sinks into a deep sleep, in which food is unnecessary, and which continues through the dreary season of cold and famine.

It has not hitherto been distinctly ascertained to what extent the state of hibernation prevails in the animal kingdom; the bat, the hedgehog, and the dormouse, are the genera which present us with the most marked examples of this singular physiological condition in this country; to these the elegant authoress of "Sketches of Natural History" has added the water-rat and the wood-mouse, observing of the former—

"And when cold winter comes and the water-plants die,
And his little brooks yield him no longer supply,
Down into his burrow he cozily creeps,
And quietly through the long winter-time sleeps."

But before we proceed to discuss this question of natural history, we must consider that of the physiology of hibernation.

There is, in my opinion, an ultimate *law* of animal existence, which seems to regulate the different forms in which the different classes of animals present themselves. The quantity of respiration is inversely as the degree of irritability of the muscular fibre, the former being marked by the quantity of oxygen consumed in a given time, ascertained by the pneumatometer,* the latter by the force of galvanism necessary to demonstrate its existence. The bird tribes have a high respiration and a low irritability; the reptiles have a high degree of irritability and little respiration. This law obtains not only in the different tribes of animals, but also in the different stages or states of the same individual, the *structural* changes from one stage to another being always a change from a lower to a higher respiration, and from a higher to a lower degree of irritability, and the change of state, a change in the opposite direction: thus the changes from the egg to the bird, from the tadpole to the batrachian form, from the larva to the chrysalis and the insect condition, are changes in which, whilst a due ratio is constantly maintained, the quantity of respiration is augmented and the degree of irritability diminished; on the other hand, the *physiological* changes in the degree of activity in animals, during sleep, for example, but especially in that remarkable change which is the subject of this article, the respiration is diminished whilst the degree of irritability is, *pari passu*, augmented.

On what this susceptibility of change depends, and especially on what the power of taking on an augmented irritability depends, is at present unknown. But I think I may affirm that it is upon this power that the capability of passing into the state of hibernation reposes. I suppose that all animals have the faculty of sleeping; during sleep the respiration is slightly diminished, the irritability probably proportionately augmented—probably one ultimate object of this state of repose; but the phenomenon has its appointed limit which it cannot pass. In certain animals, that limit is not so confined,—the quantity of respiration is still further diminished, the degree of irritability still further augmented, and the deeper sleep, or lethargy, of hibernation takes place.

During this lethargy, the law of the inverse ratio of the respiration and of the irritability still prevails, and the animal merely puts on a reptile state in these respects. Were the respiration to be diminished without the appointed augmentation of the irritability, the heart would cease to be stimulated, and the animal would die, as in the cases of torpor and slow asphyxia; were the respiration augmented without the proportionate diminution of the irritability, the heart would be over-stimulated, and death would alike ensue, as in the case of a hibernating animal too suddenly roused from its lethargy, and as (probably) in the case of an animal placed in pure oxygen gas.

The difference between the hibernating and all other animals then is, an ultimate faculty of assuming an augmented degree of irritability of the muscular fibre—a power possessed by all animals within certain limits, but by the hibernating animal beyond the usual limit.

* See Phil. Trans. for 1832, p. 323.

Sleep, however inscrutable in itself, is the connecting link between the two physiological states; a disquisition on hibernation is, therefore, a disquisition on sleep—on profound sleep. It will shortly appear that one eminent philosopher has fallen into the error of assimilating different physiological phenomena by neglecting to take this fact into his consideration. Sleep and hibernation are similar *periodical* phenomena, induced by similar causes, leading to similar effects, and differing only in *degree*. Hibernation appears more extraordinary only because less familiar than sleep. Most animals are, in fact, naturally awake and asleep every revolving day, some being diurnal, others nocturnal. But in summer the bat actually hibernates, loses its respiration, and with its respiration its temperature, acquires vastly augmented irritability, and presents the other phenomena of *complete* hibernation, regularly and periodically every twenty-four hours; and the hedgehog and the dormouse present similar phenomena, only after other intervals.

Sleep then is the first stage of hibernation. The faculty of passing into the second is identical with that of assuming a greatly augmented irritability of the muscular fibre. Such are the results of my long attention to this interesting physiological question. Much error has arisen from viewing hibernation as a simple effect of cold. The influence of cold in inducing hibernation is merely its well-known influence in inducing sleep, concurring with the other causes of this condition. The direct effect of cold on the animal frame is, as I shall shortly have occasion to state particularly, totally different from hibernation. Hibernation is a physiological condition; the direct effect of cold, or *torpor*, is, on the contrary, a pathological and generally a fatal one.

The term hibernation has usually been applied to designate what its etymology implies, the condition in which certain animals pass the *winter* season. An error is, as I have already stated, involved in this view of the subject; for the condition termed hibernation is not confined to the winter season. Cuvier observes, in speaking of the Tenrecs, "ce sont des animaux nocturnes qui passent trois mois de l'année en lethargie, quoique habitants de la zône torride. Burguière assure même que c'est pendant les grandes chaleurs qu'ils dorment."* Hence the term *Sommerschlaf* employed in Germany. It is plain too, from this circumstance, that the state of hibernation is not necessarily connected with a low degree of external temperature, and we are surprised to find this celebrated naturalist, whom I have just quoted, observing, "la seule condition de la lethargie est le froid et l'absence des causes irritantes."†

I must repeat that hibernation is, in every respect, but the parallel of ordinary sleep, varying only in force and duration. It is equally marked by an inexplicable periodicity; it is equally modified by cooperating or opposing

* Règne Animal, ed. 1829, t. i. p. 125.

† Histoire des Sciences Naturelles, 1829, t. i. p. 280.

causes; and it is equally manifested in its peculiar effects, only varying in degree and intensity.

In giving a distinct idea of hibernation we must extend our views to the altered condition of each function in the animal economy, for this peculiar state is not limited to any special function or organ. It is, in fact, a treatise on physiology which should be written, comparing the state of each function and of each organ, in the hibernant or lethargic and in the active condition, a disquisition on *sleep*, indeed, in its various degrees, and in its effects in modifying the various functions.

The first question then is,—*what is sleep?* a question difficult, perhaps impossible, to answer, if we mean by it what is its *nature* or *essence*, but highly interesting to prosecute, if we mean what are its special phenomena and their mutual relations.

In order to treat of sleep properly, I must first observe that, of the nervous system, of which it is primarily a modification, formerly divided into *the cerebro-spinal* and *the ganglionic*, the first division must now be subdivided into *the cerebral* and *the true spinal*, the former being the exclusive seat of sensation, volition, &c.; the latter, the special source of certain actions now designated *excito-motory*, and observed in the orifices, the ingestors, the expulsors, the sphincters, &c. Now it is the *cerebral* system which sleeps, the *true spinal* retaining all its energies.

From this enunciation of the primary fact in sleep, we may trace the whole of the phenomena of this singular condition. In the state of activity, the cerebral system exerts a peculiar and continual influence over the true spinal, which ceases during sleep. In this manner the functions of the latter appear impaired; the respiration especially, and with the respiration the circulation, with which it always maintains a certain relation, becomes slower, irregular, and suspended at intervals. These phenomena observable in ordinary sleep are still more remarkable in the deep sleep or lethargy of hibernation or diurnation.

In order that the effects of hibernation may be traced in relation to all the functions of the animal economy, I must enter into a few brief details relative to the *arrangement* of these functions and the *order* in which I propose to notice them. The most simple and natural arrangement of the functions appears to me to be the following:—

I. Sanguification.

1. The ingestion and } of food.
2. The digestion .... }
3. The formation.... { *a.* of chyme. / *b.* of chyle.
4. Absorption ...... { *a.* by the lacteals. / *b.* by imbibition.
5. The organization of the blood.

II. Respiration.

1. The absorption .. { *a.* of oxygen. / *b.* of nitrogen, &c.
2. The exhalation .. { *a.* of carbonic acid. / *b.* of nitrogen, &c.
3. The results { *a.* augmented temperature. / *b.* a direct ratio between the pulsations and respirations. / *c.* an inverse ratio between the respiration and irritability.

III. The Circulation.

1. The pulmonic.
2. The systemic.
3. The cardiac or coronary.
4. The hepatic.
5. The splenic.
6. The circulation as the carrier .... { *a.* of nutrition. / *b.* of temperature.

IV. Defœcation.

1. Re-absorption by the lymphatics.
2. Excretion........ { *a.* by the lungs. / *b.* by the skin. / *c.* by the liver. / *d.* by the kidneys. / *e.* by the intestines.

V. The Nervous System.

1. The cerebral, or the system of
   a. The sensations, the senses.
   b. Volition, *spontaneous* motion.
2. The true spinal or *excito-motory*, or the system of
   a. The orifices.
   b. Ingestion.
   c. Expulsion.
   d. The sphincters.
3. The ganglionic.

VI. The Muscular System.

1. The irritability.
2. The motility.

I proceed to trace the influence of sleep, and of the deeper sleep of hibernation upon these various functions, beginning with the former.

I. *Of sleep.*—It was first ascertained experimentally by Messrs. Allen and Pepys, that the quantity of respiration is diminished in ordinary sleep.* The acts of respiration are obviously less frequent and less regular, being frequently suspended for a moment and renewed by a deep inspiration. The animal frame becomes more susceptible of the influence of cold. It is most probable that, during this condition, the irritability of the muscular system is augmented, and that this is one of the *final* objects of sleep; experiments, however, are still wanting to establish a fact in reference to ordinary sleep, which is clearly proved in regard to the sleep of hibernating animals, and the deeper sleep or lethargy of hibernation. I shall now proceed to treat of the sleep of hibernating animals.

II. *Of the sleep of hibernating animals.*—In the sleep of the hibernating animal, the respiration is more or less impaired: if the animal be placed in circumstances which best admit of observation, the acts of respiration will be found to have greatly diminished; if it be placed in the pneumatometer, little alteration is

* Phil. Trans. for 1809.

induced in the bulk of the air; if its temperature be taken by the thermometer, it will be found to be many degrees lower than that of the animal in its active state; if it be deprived of atmospheric air, it is not immediately incommoded or injured.

These facts I have observed in the hedgehog,* the dormouse,† and the bat.‡ If other authors have not made the same observations, it is because they have not been aware how easily this sleep is disturbed. To walk over the floor, to touch the table, is sufficient, in many instances, to rouse the animal, to re-produce respiration, and to frustrate the experiment.

The bat, which is a crepuscular or nocturnal feeder, regularly passes from its state of activity to one which may be designated *diurnation*. The respiration and the temperature fail; the necessity for respiration is greatly lessened.

During the summer of 1831, I carefully observed a bat in this condition. If it were quite quiet, its respiration became very imperfect; its temperature was but a few degrees above that of the atmosphere; being placed under water, it remained during eleven minutes uninjured, and on being removed became lively and continued well.

I have more recently watched the habits of two hedgehogs, in a temperature varying from 45° to 50°. These animals alternately awake, take food, and fall asleep. One of them is frequently awake, whilst the other is dormant, and goes to sleep at a time that the other awakes, but without regularity. When awake, the temperature of each, taken by pressing the bulb of a thermometer upon the stomach, is about 95°; when dormant, it is 45°; that of the atmosphere being 42° or 43°. The duration of this sleep is from two to three days, according to the temperature of the atmosphere. On the 4th of February, 1832, the temperature of the atmosphere being 50°, both the hedgehogs were dormant,—the temperature of one was 51°, and that of the other 52°; on the succeeding day, the temperature of the atmosphere had fallen one degree, the temperature of one of the hedgehogs was 49°, whilst that of the other, which had become lively, had risen to 87°; on the succeeding day, the first had become somewhat lively, and its temperature had risen to 60°, that of the other being 85°, and that of the atmosphere 47°.

I have observed precisely the same alternations in the dormouse; except that this animal awakes daily in moderate temperatures, takes its food, and re-passes into a state of sleep, in which the respiration is greatly impeded, and the temperature little higher than that of the atmosphere.

On the day on which the observations were made on the hedgehogs, the atmosphere being 49°, that of two dormice was 52°; on the succeeding day, the external temperature being 47°, that is, lower by two degrees, the temperature of one of these dormice was 92°, and that of the other 94°; and only three hours afterwards, the temperatures were 60° and 70° respectively, with a slight appearance of lethargy.

The hedgehog and the dormouse appear, in fact, to awake from the call of hunger, then to eat, and then again to become dormant, in temperatures which may be termed moderate. The bat, which could not find food if it did awake, does not undergo these periodical changes, except in the summer season. It appears to me, from the most careful observation, that there is every degree between the ordinary sleep of these animals and the most profound hibernation.

It is quite obvious, from these observations, that the ordinary sleep of hibernating animals differs from that of others, by inducing a more impaired state of the respiration and of the evolution of heat, with an augmented power of bearing the abstraction of the atmospheric air. This sleep probably passes into true hibernation, as the blood which circulates through the brain becomes more and more venous, from the diminution of the respiration, and as the muscular fibre of the heart acquires increased irritability.

It is absolutely necessary, in comparing the powers of hibernating and other animals, of evolving heat, accurately to observe whether there be any tendency to sleep. Mr. Hunter's and M. Edwards's experiments are deficient for want of this attention. Mr. Hunter, comparing the common mouse and the dormouse, exposed to a very low temperature, observes, that the temperature of the former was "diminished 16° at the diaphragm, and 18° in the pelvis; while in the dormouse it gained five degrees, but lost on a repetition."* The explanation of these facts is afforded by the observation, that when the dormouse increased in temperature it was "very lively," but that on the "repetition" it had become "less lively;" the mouse was probably in a state of languor from apprehension or for want of food.

M. Edwards omits to mention whether the hibernating animals, in his experiments, were disposed to be lively or dormant, or whether they had recently recovered from the dormant state. He does not even mention whether the experiments on the bat were performed in the evening, its period of activity, or in the morning or day, its period of lethargy or diurnation. Without a particular attention to these points, no correct result could be obtained. The hibernating animal, in a state of vigour and activity, is a totally different being from the same animal disposed to become dormant.

In order to perform this experiment in a satisfactory manner, the bat, for example, should be employed in the evening, when it has naturally awoke from its deep day-slumber, the hedgehog when it has awoke spontaneously to take food; otherwise the disposition to sleep may explain the loss of temperature. We must hesitate, therefore, in subscribing to the following conclusion of M. Edwards: "Nous voyons

* Erinaceus Europæus.
† Myoxus avellanarius.
‡ Vespertilio noctula.

* Animal Œconomy, p. 114.

que les chauves-souris produisent habituellement moins de chaleur que les animaux à sang chaud, et que c'est principalement à cette cause qu'il faut attribuer l'abaissement de leur température pendant la saison froide. En comparant cette expérience sur la chauve-souris adulte avec celles que nous avons faites sur les jeunes animaux à sang chaud, on y aperçoit un rapport remarquable; ils ne produisent pas assez de chaleur pour soutenir une température élevée, lorsque l'air est à un degré voisin de zéro. Mais il y a cette différence, que c'est un état passager chez les jeunes animaux à sang chaud, et qu'il est permanent chez les chauves-souris.

"Il est évident que les autres mammifères hibernans doivent participer plus ou moins de cette manière d'être. Les faits que j'ai exposés suffisent pour nous faire considérer ce groupe d'animaux sous le point de vue suivant; qu'au printemps et en été, dans leur état d'activité et de veille, lorsque leur température est assez élevée pour ne pas différer essentiellement de celle qui caractérise les animaux à sang chaud, ils n'ont pas la faculté de produire autant de chaleur; et tout en admettant que d'autres causes peuvent influer sur leur refroidissement pendant leur hibernation, il faut cependant l'attribuer en grande partie à cette particularité de leur constitution." *

There are, in fact, these differences between the *young* and the *hibernating* animal: 1. the former cannot, when exposed alone to severe cold, maintain its own temperature; if the latter appears to be in the same case, it is only because it has become affected with its peculiar lethargy; in its state of wakefulness and activity it maintains its usual elevated temperature in the same manner as other adult animals; 2. the young animal, in losing its temperature, becomes affected, not, like the hibernating animal, with *lethargy*, but with *torpor*, a totally different and a pathological condition which generally proves fatal. I must conclude these remarks by observing that I think the eminent physiologist whom I have quoted has assimilated the condition of the very young animal and the adult hibernating animal erroneously. The mere phenomenon of loss of temperature is the same; but the rationale of this phenomenon, its causes and its effects, are totally different.

III. *Of perfect hibernation.*—I now proceed to treat of perfect hibernation, of its causes, and of its effects on the various functions which I have enumerated. My observations will consist principally of a detail of a series of observations and experiments made in the course of the year 1831–1832, compared with the results obtained by other inquirers.

I consider that there is *one* special cause of hibernation,—that law imposed by the Creator, according to which *all* animals become affected with sleep at some period of each revolving day, and the hibernating animal at some period of the revolving year. We have thus presented to us the phenomena of diurnal and nocturnal animals, and the winter-sleep and the summer-sleep of hibernating animals.

Exposure to cold, not too severe, disposes to hibernation, as it disposes to ordinary sleep. Severe cold, on the contrary, first rouses the hibernating animal from its lethargy, and then plunges this and all animals into a state of fatal torpor.

The absence of every kind of stimulus or excitant, and a somewhat confined atmosphere,* also conduce to hibernation.

Every excitement, on the contrary, that of hunger, that of the sexes probably, tend to disturb this peculiar lethargy. It is in this manner that we explain the periodicity of sleep and hibernation, though there is probably also some hidden influence of the seasons, of the day or of the year, influences which have been traced by Dr. Prout and by M. Edwards in regard to the quantity of respiration.

I now proceed to treat of the condition of the several functions in hibernation.

The process of *sanguification* is, in some hibernating animals, nearly arrested; in others, it is entirely so.

There is much difference in the powers of digestion, and in the fact of omitting to take food, in the hibernation of different animals. The bat, being insectivorous, would awake in vain; no food could be found: the hedgehog might obtain snails or worms, if the ground were not very hard from frost: the dormouse would find less difficulty in meeting with grain and fruits. We accordingly observe a remarkable difference in the habits of awaking from their lethargy or hibernation, in these different animals.

I have observed no disposition to awake at all in the bat, except from external warmth or excitement. If the temperature be about 40° or 45°, the hedgehog, on the other hand, awakes, after various intervals of two, three, or four days passed in lethargy, to take food; and again returns to its state of hibernation. The dormouse, under similar circumstances, awakes daily.

Proportionate to the disposition to awake and take food, is the state of the functions of the stomach, bowels and kidneys. The dormouse and the hedgehog pass the fæces and urine in abundance during their intervals of activity. The bat is scarcely observed to have any excretions during its continued lethargy.

In the dormouse and the hedgehog, the sense of hunger appears to rouse the animal from its hibernation, whilst the food taken conduces to a return of the state of lethargy. It has already been observed, that there are alternations between activity and lethargy in this animal, with the taking of food, in temperatures about 40° or 45°. Nevertheless, abstinence doubtless conduces to hibernation, by rendering the system

* Des Agens Physiques, p. 155.

* M. de Saissy observes, "la marmotte, que j'ai engourdie par deux fois différentes, ne l'a été, je crois, que parceque je me suis avisé, quand la respiration a été bien affaiblie, de boucher le trou du couvercle. Ce n'a été que de cette manière que je suis parvenu à l'engourdir; car toutes les tentatives que j'avais faites avant ont été vaines."

more susceptible of the influence of cold, in inducing sleep and the loss of temperature. The hedgehog, which awakes from its hibernation, and does not eat, returns to its lethargy sooner than the one which is allowed food.

The *respiration* is very nearly suspended in hibernation. That this function almost ceases, is proved, 1st, by the absence of all detectible respiratory acts; 2dly, by the almost entire absence of any change in the air of the pneumatometer; 3dly, by the subsidence of the temperature to that of the atmosphere; and 4thly, by the capability of supporting, for a great length of time, the entire privation of air.

1. I have adopted various methods to ascertain the entire absence of the acts of respiration. I placed bats in small boxes, divided by a partition of silk riband, the cover of which consisted of glass, and in the side of which a small hole was made to admit of placing a long light rod or feather under the animal's stomach. The least respiratory movement caused the extremity of this rod to pass through a considerable space, so that it became perfectly apparent.

Over the hibernating hedgehog I placed a similar rod, fixing one extremity near the animal, and leaving the other to move freely over an index. During hibernation not the slightest movements of these rods could be observed, although they were diligently watched. But the least touch, the slightest shake immediately caused the bat to commence the alternate acts of respiration, whilst it invariably produced the singular effect of a deep and sonorous inspiration in the hedgehog. It is only necessary to touch the latter animal to ascertain whether it be in a state of hibernation or not: in the former case there is this deep sonorous inspiration; in the latter, the animal merely moves and coils itself up a little more closely than before. After the deep inspiration, there are a few feeble respirations, and then total quiescence. The bat makes similar respirations without the deep inspiration, and then relapses into suspended respiration.

2. As the acts of respiration are nearly suspended during hibernation, so are the changes induced in the atmospheric air.

On January the 28th, the temperature of the atmosphere being 42°, I placed a bat in the most perfect state of hibernation and undisturbed quiet, in the pneumatometer, during the whole night, a space of ten hours, from 1h. 30m. to 11h. 30m. There was no perceptible absorption of gas.

Having roused the animal a little, I replaced it in the pneumatometer, and continued to disturb it from time to time, by moving the apparatus. It continued inactive, and between the hours of 1h. 20m. and 4h., there was the absorption of one cubic inch only of gas.

Being much roused at four o'clock, and replaced in the pneumatometer, the bat now continued moving about incessantly; in one hour, five cubic inches of gas had disappeared. It was then removed. A further absorption took place of ·8 of a cubic inch of gas.

Thus the same little animal, which, in a state of hibernation, passed ten hours without respiration, absorbed or converted into carbonic acid, 5·8 cubic inches of oxygen gas in one hour when in a state of activity. In an intermediate condition, it removed one cubic inch of oxygen in two hours and forty minutes.

I repeated this experiment on February the 18th. A bat, in a state of perfect hibernation, was placed in the pneumatometer, and remained in it during the space of twenty-four hours. There was now the indication of a very slight absorption of gas, not, however, amounting to a cubic inch.

On February the 22d, I repeated this experiment once more, continuing it during the space of sixty hours; the thermometer descended gradually, but irregularly, from 41° to 38°; the result is given in the subjoined table.

Date		External Temperature.	Absorption.	Duration.
Feb. 22	11 P.M.	41°		
23	11 A.M.	38½	·8	12h
	11 P.M.	39½	·75	12
24	11 A.M.	38	·5	12
	11 P.M.	39	·75	12
25	11 A.M.	38	·6	12
			3·4	60

From this experiment it appears that 3·4 cubic inches of oxygen gas disappeared in sixty hours, from the respiration of a bat in the state of lethargy. It has been seen that in a state of activity, an equal quantity of this gas disappeared in less than half that number of minutes. The respiration of the hibernating bat descends to a sub-reptile state; it will be seen shortly that the irritability of the heart and of the muscular fibre generally, is proportionably augmented.

In this experiment it is probable that the lethargy of the animal was not quite complete. Should the temperature of the atmosphere fall, and continue at 32°, I shall again repeat it under these circumstances. The respiration will probably be still more nearly suspended.

It is important to remark, that the registration of the quantity of absorption in these experiments was not begun until several hours after the animal had been inclosed within the jar of the pneumatometer, so that the absorption of the carbonic acid always present in atmospheric air was excluded from the result.

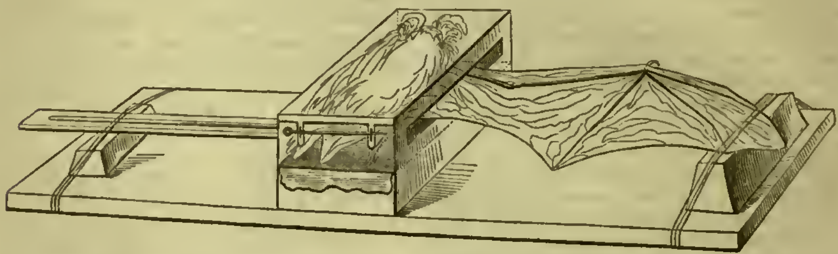
It may be a question whether the slight quantity of respiration I have mentioned be cutaneous. The absence of the acts of respiration would lead us to this opinion. But it may be observed, that these acts have not been watched, and can scarcely be watched continuously enough, to determine the question of their entire absence. Some contrivance to ascertain whether the rod has moved along the index during the absence of the observer would resolve every doubt upon this interesting point. And I think it right to remark, that after the apparent total cessation of respiration, as observed by the means which have just been described, there is probably still a slight diaphragmatic breathing. I am led to this conclusion, by having observed a slight movement of the flank in a favourable light, unattended by any motion of the thorax or epigastrium.

3. Much precaution is required in ascertain-

ing the comparative temperature of the animal with that of the atmosphere. The slightest excitement induces a degree of respiration, with the consequent evolution of heat.

The plan which is best adapted to determine this question in regard to the bat, and which I have adopted, together with every attention to preserve the animal quiet and undisturbed, is the following: a box was made of mahogany, with a glass lid, divided horizontally at its middle part, by a fold of strong riband, and of such dimensions as just to contain the animal. The bat was placed upon the riband, and inclosed by fixing the lid in its place. Being lethargic, it remained in undisturbed quiet. A thermometer, with a cylindrical bulb, was now passed through an orifice made in the box on a level with the riband, under the epigastrium of the animal, and left in this situation. This arrangement is made obvious by the subjoined wood-cut, (*fig.* 306,) which also displays the mode of examining the circulation.

Fig. 306.



It was only now necessary to make daily observations and comparisons between this thermometer and another placed in the adjacent atmospheric air. The layer of silk, and the portion of air underneath, protected the animal from the immediate influence of the temperature of the table, on which the box was placed.

The following table gives the result of observations made during many days, in very varying temperatures.

Date.		Temperature of the Atmosphere.	Temperature of the Animal.

From this table it is obvious that the temperature of the hibernating animal accurately follows that of the atmosphere. When the changes of temperature in the latter are slight, the two thermometers denote the same temperature. If these changes are greater and more rapid, the temperature of the animal is a little lower or higher, according as the external temperature rises or falls; a little time being obviously required for the animal to attain that temperature.

Similar observations were made during the first three days of February. On the 4th, however, the temperature of the atmosphere rose to 50½°; that of the animal was now 82°, and there was considerable restlessness. On the 6th, the temperature of the atmosphere had fallen to 47½°, and that of the animal to 48°, whilst there was a return of the lethargy.

After this period there were the same equal alterations of temperature in the animal and in the atmosphere, observed in the month of January.

It is only necessary to add to these observations, that the internal temperature is about three degrees higher than that of the epigastrium. In two bats, the external temperature of each of which was 36°, a fine thermometer, with an extremely minute cylindrical bulb, passed gently into the stomach, rose to 39°.

The following experiments, made by the celebrated Jenner, illustrate this point:

" In the winter, the atmosphere at 44°, the heat of a torpid hedgehog at the pelvis was 45°, and at the diaphragm 48½°.

" The atmosphere 26°, the heat of a torpid hedgehog, in the cavity of the abdomen, was reduced so low as 30°.

" The same hedgehog was exposed to the cold atmosphere of 26° for two days, and the heat of the rectum was found to be 93°; the wound in the abdomen being so small that it would not admit the thermometer.*

* The animal had become lively. See Hunter on the Animal Œconomy, p. 113.

"A comparative experiment was made with a puppy, the atmosphere at 50°; the heat in the pelvis, as also at the diaphragm, was 102°.

"In summer, the atmosphere at 78°, the heat of the hedgehog, in an active state in the cavity of the abdomen, towards the pelvis, was 95°; at the diaphragm, 97°." *

There is an error in the admirable work of M. Edwards, as I have already stated, in relation to the present subject, which it is important to point out. M. Edwards first ascertained the interesting fact, that the very young of those species of animals which are born blind, lose their temperature if removed from the contact of their parent; and justly concludes that they have not sufficient power of evolving heat, to maintain their natural temperature when so exposed. M. Edwards then subjected hibernating animals to the action of cold, and observing that their temperature also fell, he concludes that they, like the very young animal, have not the faculty of maintaining their temperature under ordinary circumstances.†

It is remarkable that this acute physiologist did not perceive the error in this reasoning. In no instance does the young animal maintain its warmth, when exposed alone to the influence of an atmosphere of moderate temperature. Can this be said of the hibernating animal? Certainly not. In ordinary temperatures, the hibernating animal maintains its activity, and with its activity, its temperature. The loss of temperature in this kind of animal is an induced condition, occasioned by sleep.

There is a point unnoticed in M. Edwards's experiment. It is the condition of the bat in regard to activity or lethargy under the exposure to cold; and upon this the whole phenomena depend.

The differences between the young animal benumbed, and the hibernating animal lethargic, from cold, are both great and numerous. I purpose to point them out particularly on a future occasion.

4. It is in strict accordance with these facts, that the lethargic animal is enabled to bear the total abstraction of atmospheric air or oxygen gas, for a considerable period of time.

Spallanzani placed a marmot in carbonic acid gas, and makes the following report of the experiment in a letter to Senebier: "Vous vous ressouviendrez de ma marmotte qui fut si fortement léthargique dans l'hiver sévère de 1795; je la tins alors pendant quatre heures dans le gaz acide carbonique, le thermomètre marquant —12°, elle continua de vivre dans ce gaz qui est le plus mortel de tous, comme je vous le disais: au moins un rat et un oiseau que j'y plaçai avec elle y périrent à l'instant même. Il paraît donc que sa respiration fut suspendue pendant tout ce tems-là. Je soumis à la même expérience des chauve-souris semblablement léthargiques, et le résultat fut le même." ‡

* Ibid. p. 112.

† Des Agens Physiques, p. 155.

‡ Mémoires sur la Respiration, par Lazare Spallanzani, traduites en Français, d'après son manuscrit inédit, par Jean Senebier, p. 75.

A bat which was lethargic in an atmosphere of 36° was immersed in water of 41°. It moved about a little, and expelled bubbles of air from its lungs. It was kept in the water during sixteen minutes, and then removed. It appeared to be uninjured by the experiment.

A hedgehog which had been so lethargic in an atmosphere of 40° as not to awake for food during several days, was immersed in water of 42°. It moved about and expelled air from its lungs. It was retained under the water during 22½ minutes. It was then removed. It appeared uninjured.

It seems probable that the motions observed in these animals were excited through the medium of the cutaneous nerves.

The power of supporting the abstraction of oxygen gas, or atmospheric air, belongs solely to the hibernating state, and is no property of the hibernating animal in its state of activity. After having found that the dormant bat, in summer, supported immersion in water during eleven minutes, uninjured, I was anxious to know whether the active hedgehog possessed the same power. I immersed one of these animals in water. It expired in three minutes, the period in which immersion proves fatal to the other mammalia. Sir Anthony Carlisle has, therefore, committed an error, somewhat similar to that of M. Edwards, when he asserts that "animals of the class Mammalia, which hibernate and become torpid in winter, have at all times a power of subsisting under a confined respiration, which would destroy other animals not having this peculiar habit." * The power of bearing a suspended respiration is an induced state. It depends upon sleep or lethargy themselves, and their effect in impairing or suspending respiration; and upon the peculiar power of the left side of the heart, of becoming veno-contractile under these circumstances.

The *circulation* is reduced to an extreme degree of slowness, according to a law well-known, but hitherto, I believe, unexplained, according to which the respiration and the circulation are always proportionate to each other.

The wing of the bat affords an admirable opportunity of observing the condition of the circulation during hibernation. But it requires peculiar management. If the animal be taken from its cage, and the wing extended under the microscope, it is roused by the operation, and its respiratory and other movements are so excited, that all accurate observation of the condition of the circulation in the minute vessels is completely frustrated. Still greater caution is required in this case than even in the observation of the respiration and temperature.

After some fruitless trials, I at length succeeded perfectly in obtaining a view of the minute circulation undisturbed. Having placed the animal in its state of hibernation, in a little box of mahogany, I gently drew out its wing through a crevice made in the side of the box; I fixed the tip of the extended wing between portions of cork; I then attached the box and the cork to a piece of plate-glass; and lastly, I

* Phil. Trans. 1805, p. 17.

left the animal in this situation, in a cold atmosphere, to resume its lethargy. (See *fig.* 306.)

I could now quietly convey the animal ready prepared, and place it in the field of the microscope without disturbing its slumbers, and observe the condition of the circulation.

In this manner I have ascertained that, although the respiration be suspended, the circulation continues uninterruptedly. It is slow in the minute arteries and veins; the beat of the heart is regular, and generally about twenty-eight times in the minute.

We might be disposed to view the condition of the circulation in the state of hibernation as being reptile, or analogous to that of the batrachian tribes. But when we reflect that the respiration is nearly, if not totally, suspended, and that the blood is venous,* we must view the condition of the circulation as in a lower condition still, and, as it were, sub-reptile. It may, indeed, be rather compared to that state of the circulation which is observed in the frog from which the brain and spinal marrow have been removed by minute portions at distant intervals.†

In fact, in the midst of a suspended respiration, and an impaired condition of some other functions, one vital property is augmented. This is the irritability, and especially the irritability of the left side of the heart. The left side of the heart, which is, in the hibernating animal, in its state of activity, as in all the other mammalia, only arterio-contractile, becomes veno-contractile.

This phenomenon is one of the most remarkable presented to me in the whole animal kingdom. It forms the single exception to the most general rule amongst animals which possess a double heart. It accounts for the possibility of immersion in water or a noxious gas, without drowning or asphyxia; and it accounts for the possibility of a suspended respiration, without the feeling of oppression or pain, although sensation be unimpaired. It is, in a word, this peculiar phenomenon, which, conjoined with the peculiar effect of sleep in inducing diminished respiration in hibernating animals, constitutes the susceptibility and capability of taking on the hibernating state. On the other hand, as the rapid circulation of a highly arterialized blood in the brain and spinal marrow of birds probably conduces to their activity, the slow circulation of a venous blood doubtless contributes to the lethargy of the hibernating animal.

I need scarcely advert to the function of *defæcation*. It has already been briefly noticed under the head of sanguification, with which it proceeds *pari passu*.

In regard to the *nervous system*, I can only repeat that *sensation* and *volition* are quiescent. In my memoir upon the subject of hibernation,* I committed an error relative to this subject. But I am now satisfied that what I considered to be evidences of an unimpaired sensibility, were phenomena of the *excito-motory* kind. Thus I have observed that the slighest touch applied to one of the spines of the hedgehog immediately rouses it to draw that deep inspiration of which I have spoken. The merest shake induces a few respirations in the bat. The least disturbance, in fact, is felt, as is obvious from its effect in inducing motion in the animal.

It is from the misconception on this point that the error has arisen, that the respiration is not absolutely suspended in hibernation. This function has been so readily *re-excited*, that it has been considered as appertaining to the state of hibernation.

As I have already stated, the cerebral functions sleep, the true spinal functions retain their wonted energy; and if the respiration be nearly suspended, it is because little carbonic acid, the *excitor* of respiration, is evolved.

In the midst of a suspended or partially suspended respiration, the *irritability* of the muscular fibre becomes proportionately augmented.

The single fact of a power of sustaining the privation of air, without loss of life, leads alone to the inference that the irritability is greatly augmented in the state of hibernation. This inference flows from the law already stated, and the fact is one of its most remarkable illustrations and confirmations.

It might have been inferred from these premises, that the beat of the heart would continue longer after decapitation in the state of hibernation than in the state of activity in the same animal; an inference at once most singular and correct.

This view receives the fullest confirmation from the following remarkable experiment: on March the 9th, soon after midnight, I took a hedgehog which had been in a state of uninterrupted lethargy during 150 hours, and divided the spinal marrow just below the occiput; I then removed the brain and destroyed the whole spinal marrow as gently as possible. The action of the heart continued vigorous during four hours, when, seeing no prospect of a termination to the experiment, I resolved to envelope the animal in a wet cloth, and leave it until early in the morning. At 7 o'clock A.M. the beat of both sides of the heart still continued. They still continued to move at 10 A.M., each auricle and each ventricle contracting quite distinctly. At half-after 11 A.M. all were equally motionless; yet all equally contracted on being stimulated by the point of a penknife. At noon the two ventricles were alike unmoved on being irritated as before; but both auricles contracted. Both auricles and ventricles were shortly afterwards unirritable.

This experiment is the most extraordinary of those which have been performed upon the mammalia. It proves several interesting and important points: 1. That the irritability of the heart is augmented in continued lethargy in an

* M. Prunelle observes, "En comparant le sang de deux chauve-souris auxquelles j'avois ouvert les carotides, à l'une pendant son engourdissement et à l'autre dans l'état de veille, j'ai trouvé celui de la dernière beaucoup plus vermeil." Annales du Museum, tome xviii. p. 28.

† Essay on the Circulation, pp. 136-141.

* Phil. Trans. for 1832.

extraordinary degree. 2. That the irritability of the left side of the heart is then little, if at all, less irritable than the right,—that it is, in fact, veno-contractile. 3. That, in this condition of the animal system, the action of the heart continues for a considerable period independently of the brain and spinal marrow.

On April the 20th, at six o'clock in the evening, the temperature of the atmosphere being 53°, a comparative experiment was made upon a hedgehog in its state of activity: the spinal marrow was simply divided at the occiput; the beat of the right ventricle continued upwards of two hours, that of the left ventricle ceased almost immediately; the left auricle ceased to beat in less than a quarter of an hour; the right auricle also ceased to beat long before the right ventricle.

In further proof of the same fact, I may here adduce a remarkable paragraph from the paper of Mangili in the Annales du Muséum:* "J'observai à peu près les mêmes choses dans une autre marmotte en léthargie, que je décapitai le 22 de Mars 1807. Mais en ouvrant celle-ci, j'avois deux objets: le premier, d'examiner l'état des viscères les plus importans, comme le cœur, les poumons et le cerveau. Le second étoit de voir comment procédent les phénomènes de l'irritabilité musculaire; parce qu'ayant entendu dire à un célèbre naturaliste, que l'engourdissement avoit pour cause l'altération ou la suspension de cette irritabilité, il m'importoit de savoir si cette assertion étoit vraie. Dans la chambre où se trouvoit la marmotte, le thermomètre étoit à 6 degrés et demi: l'ayant introduit dans le bas ventre, il monta d'un degré, c'est-à-dire à 7 degrés et demi.

"Je trouvai les poumons dans leur état naturel. Le cœur continua à battre pendant plus de trois heures. Les pulsations, d'abord vives et frequentes, s'affoiblirent et se ralentirent peu-à-peu. J'en avois compté de seize à dix-huit par minute au commencement de la première heure; à la fin de la troisième je n'en comptois plus que trois dans le même temps. Les veines du cerveau me parurent gonflées de sang.

"La tête unie au cou ayant été séparée du tronc, je la mis dans un vase avec de l'esprit-de-vin, et j'y remarquai, même après une demi-heure, des mouvemens assez sensibles. Ce fait prouve, ainsi que plusieurs autres dont je parlerai bientôt, que si dans l'état de léthargie conservatrice la vie est beaucoup moins énergique, le principe vital répandu dans les diverses parties, a beaucoup plus de tenacité, et tarde bien plus à s'éteindre.

"Je séparai du corps de l'animal plusieurs morceaux des muscles qui obéissent à la volonté, et je vis avec étonnement que, trois heures après la mort, ils se contractoient fortement chaque fois que je les soumettois à l'action galvanique. Ces mouvemens convulsifs ne se ralentirent qu'au bout de quatre heures.

"Il suit de là que les marmottes tuées pendant qu'elles sont en léthargie, présentent, relativement à l'irritabilité, à peu près les mêmes phénomènes qu'on remarque dans plusieurs animaux à sang froid.

"Pour savoir ensuite si les phénomènes d'irritabilité étoient les mêmes dans l'état de veille et dans celui de léthargie, le 25 de Juin, j'ai fait périr, précisément de la même manière, une seconde marmotte qui étoit éveillée depuis deux mois, et qui faisoit de frequentes courses dans le jardin. Mon thermomètre marquoit ce jour-là 18 degrés: l'ayant introduit dans le ventre de la marmotte au moment où je venois de la décapiter, il s'éleva à 29 degrés.

"Ayant mis le cœur à découvert, comme je l'avois fait dans mon expérience du mois de Mars, je comptai d'abord vingt-sept ou vingt-huit pulsations par minute. Ce nombre n'étoit plus que de douze au bout d'un quart d'heure, et de huit, au bout de demi-heure: dans le dix minutes suivantes, il n'y eut plus que quatre pulsations très-foibles par minute, et elles cessèrent totalement dans les dix dernières minutes, c'est-à-dire cinquante minutes après la mort de l'animal; tandis que le cœur de la marmotte tuée dans l'état de léthargie, donnoit encore quatre légères pulsations par minute, trois heures après que la tête avoit été séparée du corps. Cette grande différence prouve que le principe de l'irritabilité s'accumule pendant la léthargie conservatrice.

"Les chairs musculaires me semblirent plus pâles que celles de la marmotte en léthargie: elles étoient d'abord très sensibles à l'action galvanique; mais ses signes d'irritabilité s'affoiblirent et disparurent bien plus rapidement. En effet, les chairs musculaires de cette marmotte étoient peu sensibles au bout de deux heures, tandis que dans la marmotte tuée en hiver elles se contractoient fortement au bout de trois heures, et que l'irritabilité ne s'affoiblit notablement que quatre heures après la mort.

"Les chairs des muscles intercostaux et abdominaux conservèrent leur sensibilité au stimulus électrique quelques minutes de plus que celles des membres; d'où l'on peut conclure que le principe de l'irritabilité se conserve d'avantage dans certaines parties du même animal. Mais ce qui est prouvé jusqu'à l'évidence, c'est que ce principe a bien plus de ténacité dans les chairs de l'animal tué pendant l'état de léthargie, que dans celles de l'animal tué pendant l'état de veille."

This author does not appear to have had any apprehension of the extreme importance of this extraordinary change in the irritability, but merely states it as a fact. Its due value can only be known by observing the dependence of the functions of life on that law of the inverse condition of the respiration and of the irritability, of which so much has already been said. In the hibernating animal the respiration is nearly suspended; had not the irritability become proportionately augmented, the actions of life must have ceased!

I must add one remark upon the *motility* of the muscular fibre in hibernation; it is unimpaired. Those physiologists who have asserted the contrary, have, as will be shown shortly, mistaken the phenomena of torpor from cold, for those of true hibernation.

* Tome x. p. 453-456.

If the hedgehog in a state of the most perfect lethargy, uncomplicated with torpor, be touched, its respiration is resumed, and it coils itself up more forcibly than before. The dormouse, in similar circumstances, unfolds itself; and the bat moves variously. Not the slightest stiffness is observed. The hedgehog, when roused, walks about, and does not stagger, as has been asserted. The bat speedily takes to the wing, and flies about with great activity, although exhaustion and death may subsequently result from the experiment. The phenomena are similar to those of awaking from natural sleep. Impaired motility, stiffness, lameness, &c. belong to torpor, and not to true hibernation.

III. *Of reviviscence.* — Not the least interesting of the phenomena connected with hibernation are those of reviviscence. Hibernation induces a state of irritability of the left side of the heart, which, with high respiration and an arterialized blood, would be incompatible with life. Respiration suddenly restored, and permanently excited, is, therefore, as destructive as its privation in other circumstances.

All those bats which were sent to me from distant parts of the country died. The continued excitement from the motion of the coach keeping them in a state of respiration, the animal perished. One bat had, on its arrival, been roused so as to fly about. Being left quiet, it relapsed into a state of hibernation. The excitement being again repeated the next day, it again flew about the room; on the succeeding day it was found dead.

It is in accordance with this law, that we observe hibernating animals adopting various measures to secure themselves from frequent sources of disturbance and excitement. They choose sheltered situations, as caverns, burrows, &c. secure from the rapid changes and the inclemencies of the weather and season. Many form themselves nests; others congregate together. The hedgehog and the dormouse roll themselves up into a ball. The common bat suspends itself by the claws of its hinder feet, with its head dependent, generally in clusters; the horseshoe bat *(ferrum equinum)* spreads its wings so as to embrace and protect its fellows.

All these circumstances are obviously designed to prevent disturbed hibernation.

In the depth of caverns, and other situations sheltered from changes of temperature in the atmosphere, the calls of hunger are probably the principal cause of reviviscence in the spring. The other causes of reviviscence are the return of warmth and external excitements: it is interesting to observe and trace the gradual return of respiration in the former case, and of the temperature of the animal in the latter.

If the hibernating hedgehog be touched even very gently, it draws a deep breath, and then continues to breathe for a short time. If this excitement be repeated, the animal is permanently roused, and its temperature raised. If the temperature of the atmosphere be augmented, the respiration is gradually excited, and the animal is gradually restored to its state of activity.

If a hibernating animal be excited in a very cold atmosphere, its temperature rises variously, and then falls. A bat was perfectly lethargic in a temperature of 36°. A fine thermometer, with a cylindrical bulb, was introduced into its stomach; it rose to 39°. One hour afterwards, the animal not being further disturbed, the respiration was rapid, and the temperature in the stomach 95°. Shortly afterwards the temperature was 90°. The minute circulation was pretty good, and pulsatory in the arteries, the heart beating from twenty-eight to thirty-six times in the minute.

In another bat, in an atmosphere of the temperature of 36°, the thermometer in the stomach rose to 39°. The animal being continually excited, the temperature rose to 65°, but speedily fell to 60°.

The animal excited and revived in this manner is in a state of exhaustion and inanition. It is incapable of maintaining its temperature if exposed to cold, and will die unless it repass into the state of hibernation. It may be compared to the case of the mouse deprived of food in the following experiment of Mr. Hunter. "A mouse was put into a cold atmosphere of 13° for an hour, and then the thermometer was introduced as before; but the animal had lost heat, for the quicksilver at the diaphragm was carried only to 83°, in the pelvis to 78°.

"In order to determine whether an animal that is awakened has the same powers, with respect to preserving heat and cold, as one that is vigorous and strong, I weakened a mouse by fasting, and then introduced the bulb of the thermometer into its belly; the bulb being at the diaphragm, the quicksilver rose to 97°; in the pelvis to 95°, being two degrees colder than the strong mouse: the mouse being put into an atmosphere as cold as the other, and the thermometer again introduced, the quicksilver stood at 79° at the diaphragm, and at 74° in the pelvis.

"In this experiment the heat at the diaphragm was diminished 18°, in the pelvis 21°.

"This greater diminution of heat in the second than in the first, we may suppose proportional to the decreased power of the animal, arising from want of food."*

But extreme cold alone, by a painful effect induced on the sentient nerves, rouses the hibernating animal from its lethargy, as has been remarked already, and is illustrated by the following experiments of Hunter. "Having brought a healthy dormouse, which had been asleep from the coldness of the atmosphere, into a room in which there was a fire, (the atmosphere at 64°,) I introduced the thermometer into its belly, nearly at the middle, between the thorax and pubis, and the quicksilver rose to 74° or 75°; turning the bulb towards the diaphragm, it rose to 80°; and when I applied it to the liver, it rose to 81½°.

"The mouse being placed in an atmosphere at 20°, and left there half an hour, when taken out was very lively, even much more so than when put in. Introducing the thermometer into the lower part of the belly, the quicksilver

* Animal Œconomy, pp. 114, 115.

rose to 91°; and turning it up to the liver, to 93°.

"The animal being replaced in the cold atmosphere at 30°, for an hour, the thermometer was again introduced into the belly; at the liver it rose to 93°; in the pelvis to 92°; the mouse continuing very lively.

"It was again put back into an atmosphere cooled to 19°, and left there an hour; the thermometer at the diaphragm was 87°; in the pelvis 83°; but the animal was now less lively.

"Having been put into its cage, the thermometer being placed at the diaphragm, in two hours afterwards was at 93°." *

In these experiments the animals appear to have been roused partly by the state of the wound in the abdomen, but chiefly by the extreme cold. They can scarcely, however, be considered as experiments upon hibernation, however interesting they may be in reference to reviviscence from that state.

The fact of the fatal influence of excited respiration during the augmented irritability of hibernation, contrasted with the similar fatal effect of suspended respiration, during the diminished irritability of the state of activity, will illustrate many of the causes, kinds, and phenomena of death. Do not these resolve themselves, in fact, into irritability insufficiently or excessively excited?

IV. *Of torpor from cold.*—It is highly important, and essential to the present investigation to distinguish that kind of torpor which may be produced by cold in any animal, from true hibernation, which is a property peculiar to a few species. The former is attended by a benumbed state of the sentient nerves, and a stiffened condition of the muscles; it is the direct and immediate effect of cold, and even in the hibernating animal is of an injurious and fatal tendency; in the latter, the sensibility and motility are unimpaired, the phenomena are produced through the medium of sleep; and the effect and object are the preservation of life.

Striking as these differences are, it is certain that the distinction has not always been made by former observers. In all the experiments which have been made, with artificial temperatures especially, it is obvious that this distinction has been neglected.

True hibernation is induced by temperatures only moderately low. All hibernating animals avoid exposure to extreme cold. They seek some secure retreat, make themselves nests or burrows, or congregate in clusters, and, if the season prove unusually severe, or if their retreat be not well chosen and they be exposed in consequence to excessive cold, many become benumbed, stiffen, and die.

In our experiments upon hibernation we should imitate nature's operations. Would any one imagine that the following detail contained the account of an experiment upon this subject? "Le 31 Janvier," says M. Saissy, "à trois heures du soir, la température atmosphérique étant à 1°·25 au-dessous de zéro, celle d'un hérisson engourdi profondément à 3°·50 au dessus, j'enfermai ce quadrupède dans un bocal de verre entouré de toute part d'une mixtion de glace et de muriate de soude. L'excès du froid le réveilla d'abord, mais trois heures ont suffi pour le replonger dans une profonde torpeur.

"J'avais placé l'animal de manière que je pouvais répéter, autant que je le jugeais nécessaire, les expériences thermométriques. Dès que sa température eut baissé jusqu'à zero, (ce ne fut qu'à 2 heures du matin) je le retirai du bocal et le placai dans une température de 12° et plus au dessus de la glace; mais l'animal était mort." *

To induce true hibernation, it is quite necessary to avoid extreme cold; otherwise we produce the benumbed and stiffened condition to which the term torpor or torpidity may be applied. I have even observed that methods which secure moderation in temperature, lead to hibernation: hedgehogs, supplied with hay or straw, and dormice, supplied with cotton-wool, make themselves nests and become lethargic; when others, to which these materials are denied, and which are consequently more exposed to the cold, remain in a state of activity. In these cases, warmth or moderated cold actually concur to produce hibernation.

When we read of insensibility, of a stiffened state of the muscles, and of a cessation of the circulation, as obtaining in hibernation, we may be certain that a state of torpor has been mistaken for that condition. The actually hibernating animal exposed to continued severe cold is, as M. Saissy correctly observes, first roused from this state of ease and preservation into a painful activity, and then plunged into a fatal torpor.

This subject will come to be considered in a subsequent part of this inquiry, in which I purpose to trace the effects of cold in changing the relative quantity of respiration and degree of the irritability in animals of different ages which do not hibernate; in the meantime, the accurate distinction between mere torpor, which may occur in any animal, and which is a destructivestate, from true hibernation, which is preservative, and the peculiarity of certain animals, will enable us to correct many inaccuracies into which Legallois,† M. Edwards,‡ and other physiologists have fallen. (See IRRITABILITY.)

In conclusion, one of the most general effects of sleep is to impair the respiration, and with that function the evolution of animal temperature. The impaired state of the respiration induces a less arterial condition of the blood, which then becomes unfit for stimulating the heart; accumulation of the blood takes place in the pulmonary veins and left auricle; a sense of oppression is induced, and the animal is either roused to draw a deep sigh or awakes altogether.

* Recherches sur les Animaux hibernans, par M. J. A. Saissy, pp. 13, 14.

† Œuvres de Legallois, Paris, 1824, p. 282.

‡ Agens Physiques, pp. 148, 292.

Such are the phenomena in animals in which the heart has not the faculty of taking on an augmented state of irritability, with this lessened degree of stimulus. But in those animals which do possess this faculty, a property which constitutes the power of hibernation, the heart continues the circulation of the blood, more slowly indeed, but not less perfectly, although its arterial character be diminished and its stimulant property impaired. No repletion of the pulmonary veins and of the left auricle, no sense of oppression is induced, and the animal is not roused; the respiration continues low, the temperature falls, and the animal can bear, for a short period, the abstraction of atmospheric air.

All the phenomena of hibernation originate, then, in the susceptibility of augmented irritability. The state of sleep, which may be viewed as the first stage of hibernation, induces an impaired degree of respiration. This would soon be attended with pain, if the irritability of the heart were not at the same time augmented, so as to carry on the circulation of a less arterial blood, and the animal would draw a deep sigh —would augment its respiration or awake. Occasional sighs are, indeed, observed in the sleep of all animals, except the hibernating. In these, the circulation goes on uninterruptedly, with a diminished respiration, by the means of an augmented irritability. There is no stagnation of the blood at the heart; consequently, no uneasiness; and the animal becomes more and more lethargic, as the circulation of a venous blood is more complete. This lethargy is eventually interrupted by circumstances which break ordinary sleep, as external stimuli or the calls of appetite.

It still remains for me briefly to discuss the question,—what are the hibernating animals? I must first advert to the fact, on which I have already insisted, that hibernation does not present itself in an equal degree in all the hibernating tribes. All animals *sleep* periodically, in the night or in the day. Some sleep for several days together, especially after taking food, and in the cool seasons of the year, as the hedgehog. Perhaps the bat may be the only animal which sleeps profoundly the winter through, without awaking to take food.

These remarks prepare us for a more just view of hibernation and of hibernating animals than is, as I believe, usually taken.

Of the hibernating animals the most unequivocal are the bat, the hedgehog, the marmot, the hamster, the dormouse. It has been said that the bear and beaver belong to the number, but this is extremely doubtful. It has been said also that the swallow belongs to the hibernating class, but this is incorrect. The cold-blooded animals, the Chelonian, the Saurian, the Ophidian, and the Batrachian tribes, all, however, indubitably pass the winter in a state of apathy and lethargy. Some of the fishes also become lethargic during the cold season. The same remark applies to some of the molluscous and insect tribes.

HIP-JOINT, NORMAL ANATOMY OF (in human anatomy).—Fr. *articulation ilio-femorale*; Germ. *Huft gelenk*.—This joint belongs to the class of enarthrodial or ball and socket joints, being formed by the adaptation of the head of the femur to the acetabulum of the os innominatum. These bones are connected by a very powerful capsular ligament, which again is completely covered by strong and thick muscles, under the influence of which the various motions of the joint are performed. We propose to examine *seriatim* the several textures entering into the formation of this joint, and lastly to consider the motions of which it is susceptible.

The bones.—Of the two bones which in the adult enter into the formation of this joint, the os innominatum contributes by the acetabulum, and the femur by its head.

The acetabulum (cotyloid cavity: Germ. *die Pfanne)* is the cup or socket which receives the head of the femur, and is admitted to be the deepest articular cavity in the body. Prior to the adult period of life this cavity serves as the centre of union for the three bones of which the os innominatum is formed, viz., the ilium, ischium, and pubis. These, however, do not enter equally into the acetabulum, inasmuch as the ischium contributes in the proportion of rather more than two-fifths, the ilium of about two-fifths, whilst the pubis yields rather less than one-fifth.

Although the acetabulum is situated nearly in the centre of the separated os innominatum, it has a different position in relation to the entire pelvis. The union of the ossa innominata at the symphysis pubis, and the completion of the pelvis by the addition of the sacrum posteriorly, place the acetabular cavities on either side upon the antero-external aspect of the pelvis, so that a line drawn horizontally from the one to the other would pass through the union of the anterior with the two posterior thirds of the antero-posterior diameter of the pelvis. The aspect of each acetabulum is outwards and very slightly forwards as well as downwards.

Each cavity is surrounded for about four-fifths of its circumference by a sharp but strong lip or margin *(supercilium acetabuli)*, leaving opposite the obturator foramen a notch of considerable extent *(incisura acetabuli)* directed from without downwards, forwards, and inwards, the deepest part of which is smooth and gives passage to nerves and vessels. This notch corresponds to the junction of the pubis and ischium; and we may here observe that the margin of the acetabulum exhibits a slight concavity superiorly, corresponding to the junction of the pubis and ilium, and a similar one inferiorly and externally, corresponding to the junction of the ilium and ischium. These concavities are separated by intervening convexities, and hence the margin of the acetabulum has the appearance of a waving line. Immediately within the margin of the acetabulum we perceive a broad band of smooth bone *(facies lunata)* covered in the recent state by articular cartilage, about seven-eighths of an inch wide at its lower portion, or opposite the ischium, an inch and a quarter to an inch and a half superiorly and externally, where it corresponds to the ilium, and from a quarter to half an inch internally and superiorly at the pubis. This band terminates at each extremity of the notch already described in a process *(cornu)*, the superior of which looks downwards, outwards, and backwards, whilst the inferior, more prominent than the superior, projects towards the notch, forming a kind of gutter between its superior margin, and the deepest part of the notch. Internal to this band, there is a depression, as it were a cavity within the acetabulum, rough and uneven, uninvested by cartilage in the recent state, being continuous with the notch leading towards the obturator foramen. This is the *fovea* or *sinus*, and lodges a quantity of fatty cellular tissue formerly termed *glands of Havers*, from their having been first described by that anatomist. On the upper and lower portions of this inner cavity, various inequalities and foramina are seen, the latter being for the passage of the nutritious vessels of the bone, which is very thin at this point, so much so indeed, that if held up to the light, it will be found transparent. The depth of the acetabulum is not uniform in its different regions. This variety corresponds in a great measure to the breadth of the smooth band of bone *(facies lunata)* already described. Where this is broadest, the cavity possesses the greatest depth, and where it is entirely absent, the cavity is very superficial, as opposite the notch.

The non-articular circumference of the lip of the acetabulum is rough and marked by foramina for the passage of nutritious vessels, and also for the attachment of the capsular ligament.

The head of the femur, representing about three-fourths of a sphere, is supported and connected to the shaft of that bone at an angle varying with age, by a constricted and flattened process termed the neck. A waving prominent line surrounds the head at its junction with the neck, and may be regarded as the boundary line between these two parts, leaving on its inner side the articular surface of the head of the femur, which is smooth, having in the adult its greater convexity directed upwards and inwards. At one point, however, the articular character of this surface is interrupted by a depression, which is not covered with cartilage in the recent state. This depression, situated immediately behind and below the point through which the axis of the head of the bone would pass, gives insertion to the ligamentum teres.

2. *The cartilage.*—That portion of the surface of the acetabulum which corresponds to the facies lunata is alone invested by articular cartilage. This cartilaginous layer is thickest at its external circumference, becoming gradually thinner as it proceeds internally. The head of the femur, on the other hand, is nearly entirely incrusted with cartilage, which, as is usual on convex surfaces, is thickest towards its centre, where it is interrupted by the depression for the ligamentum teres, and becomes progressively thinner towards the circumference.

3. *Fibro-cartilage.*—Immediately surrounding the margin of the acetabulum is a fibro-cartilaginous ring about three lines broad, triangular in shape, having its base attached to the brim of the cavity, whilst its apex is free. This is the so-called *cotyloid ligament (ligamentum cotyloideum, fibro-cartilagineum, labium cartilagineum acetabuli.)* It clearly belongs to the fibro-cartilages of circumference, and is the counterpart of the glenoid ligament in the shoulder-joint (see FIBRO-CARTILAGE), and as it completely removes the irregular character of the margin of the acetabulum, it will be found to be deepest where it corresponds to the concavities of the acetabular border. Its free border is sharp, and directed inwards, *i. e.*, towards the centre of the joint, narrowing the orifice of the acetabulum, at the same time that it increases the depth of that cavity. Its fixed margin constitutes its base, and is connected to the brim of the acetabulum; its external surface covered by synovial membrane corresponds to the capsular ligament, whilst its internal, also covered by synovial membrane, embraces the head of the femur. Having arrived at the notch, it is continued over each cornu of the facies lunata, retaining somewhat of its form, but much diminished in dimensions, and having assumed much more the appearance of pure cartilage than of fibro-cartilage. It ceases at the point at which the concave margin of the facies lunata becomes blended with the convexity of each cornu. It is not stretched across the notch as some anatomists erroneously describe it. The whole extent of this fibro-cartilage, then, corresponds exactly to the convex margin of the facies lunata.

4. *Ligaments.*—The notch of the acetabulum is converted into a foramen, strengthened and in a great degree closed by ligamentous fibres arranged in two layers, and extended from the superior to the inferior cornu. The whole forms the *ligamentum transversale acetabuli* of Winslow. Of these the external and deepest arises from the superior, and is inserted into the inferior cornu of the acetabulum. The external surface of this layer, directed obliquely backwards towards the cavity of the acetabulum, corresponds and gives attachment to the ligamentum teres. Its internal surface is applied to the external layer; its external margin is attached to the capsular ligament, and its internal superiorly to the pubis, but inferiorly it is

free, and bounds a foramen for the passage of vessels. The internal layer of the transverse ligament is attached below to the inferior cornu, and above to the superior, where it appears to blend with the cotyloid ligament. By its external surface it is in apposition with the external layer of the transverse ligament, and its internal surface is directed towards the obturator ligament and external obturator muscle. Some fibres pass from its upper margin to the obturator ligament; but in greatest part this margin contributes to form the foramen already described for the passage of vessels. Its inferior margin affords attachment to the capsular ligament.

Round ligament. (*Ligamentum teres capitis femoris seu ligamentum inter-articulare.*)— This ligament, which was first described by Vesalius, has very improperly received the epithet *round*, inasmuch as in point of fact it is a triangular fasciculus, about an inch and a half in length, having its base attached to the acetabulum and its apex to the depression on the head of the femur. It is most advantageously placed for escaping injury in the various motions of the joint, as, independently of its corresponding to the soft cushion contained in the excavation of the acetabulum, its direction and attachments completely remove it from all danger on this score. It is attached by the superior portion of its base to the upper cornu of the notch, and to the external layer of the tranverse ligament; and by the inferior and larger portion of its base to the lower cornu, as well as to the external layer of the tranverse ligament; from these points of attachment its direction in the quiescent state of the limb, i. e. the femur being placed vertically under the pelvis, is upwards, outwards, and backwards, to its insertion into the head of the femur.*

When the joint is cut into in the recent state, there are processes seen extending from this ligament towards the circumference of the excavation; these should not be mistaken for portions or attachments of the ligamentum teres; they are folds of the synovial membrane proceeding from that ligament over the surface of the acetabulum. Situated in the rough excavation of the acetabulum, and forming a cushion for the ligamentum teres in the several motions and positions of the head of the femur, is the soft pulpy mass of fatty cellular tissue, covered by synovial membrane, already alluded to as the glands of Havers, first described and figured by that anatomist in his Osteologia Nova.

Capsular ligament.—The hip-joint is completed by a strong fibrous investment, termed capsular ligament (*capsula fibrosa ossis femoris*). This is by far the strongest and largest capsular ligament in the body. However it is by no means uniform in its strength and thickness, these being greatly increased by super-imposed fibres in those situations upon which a considerable force is exercised in certain motions of the joint. It not only embraces the articulation, but also includes the neck of the femur, to the base of which it extends from the os innominatum. Its fibres are variously directed from the os innominatum, to which they are firmly attached from the margin of the acetabulum to a considerable distance on the dorsum of that bone. Superiorly and externally they may be traced as far as the inferior anterior spinous process of the ilium in front, whilst posteriorly the great sciatic notch marks their boundary, and an arched line drawn from the inferior anterior spine of the ilium to the spine of the ischium denotes with tolerable exactness their attachment in this direction. Inferiorly and externally they are attached to that portion of the ischium situated between the cotyloid cavity and the external lip of the tuber ischii, and to this latter itself by very strong dense fibres. Superiorly and internally they arise from that portion of the ilium situated between its anterior inferior spine and the ilio-pectineal eminence, and from the pubis as far as the superior cornu of the acetabulum. Inferiorly and internally the capsule is attached to the transverse ligament of the cotyloid cavity.

By this description we perceive that the capsular ligament is firmly attached to the os innominatum; that with the exception of the portion arising from the transverse ligament its origins at all points are from an inch to nearly two inches in extent. Passing in various directions, according to their several situations, the fibres run to be inserted into the base of the neck of the femur, anteriorly into the anterior inter-trochanteric line, superiorly and externally into the surface of the bone close to the digital fossa at the root of the great trochanter, inferiorly and internally to the line leading from the lesser trochanter to the anterior inter-trochanteric line, and posteriorly it is partly reflected upwards, so as to become continuous with the periosteum of the posterior part of the neck of the bone; this reflection taking place along the posterior inter-trochanteric line, and partly inserted into that line, especially at its internal and external extremities. The reflected portion is derived from the deep fibres of the capsule, which in passing upwards to be inserted into the bone at the circumference of the head, contribute to form those bands of fibrous membrane, which are manifest on the posterior aspect of the neck of the femur on opening the capsule, being covered only by synovial membrane. These bands are sometimes of considerable strength, and they are well described and figured by Weitbrecht,* by whom they were designated *retinacula*.

We have already observed that the capsular ligament is not uniform in thickness at all points. At the outer part of its anterior surface its thickness is very considerable, being strengthened and increased by a band of fibres

* [Weber states that, in the erect posture, the direction of the ligamentum teres is vertical. See Mechanik der Menschlichen Gehwerkzeuge, p. 143, and pl. ii. fig. 1.—Ed.]

* Syndesmologia, Petrop. 1742.

of some magnitude (*accessory ligament*), arising from the inferior anterior spine of the ilium and the space beneath, from which they descend, diverging to be inserted into the anterior intertrochanteric line; these fibres are so much developed in some instances as almost to resemble a distinct ligament. At this point the capsule is nearly half an inch thick. Externally its thickness is considerable, though somewhat less than at the point last described. From the pubis a smaller and thinner band of accessory fibres may be traced towards the lesser trochanter, strengthening the capsule in this situation; between the two accessory bands in the centre of the anterior surface, the capsule is extremely thin, and sometimes wholly destitute of fibrous tissue, being altogether composed of synovial membrane, and a little cellular tissue, by which it is separated from the bursa that lies under the tendon of the psoas muscle: this bursa, moreover, sometimes communicates with the cavity of the joint through an opening in this situation.

The internal surface of the capsule invested by its synovial membrane corresponds to the cotyloid ligament, to the neck and a portion of the head of the femur. The external is covered anteriorly by the rectus femoris, psoas, and iliacus muscles, internally by the obturator externus and pectineus; posteriorly it lies upon the quadratus femoris, gemelli, pyriformis, and obturator internus, and superiorly the glutæus minimus adheres very closely to it.

The capsule of the hip-joint, although stronger, is not so long or so loose as that of the scapulo-humeral articulation, neither is it pierced by any tendon.

Synovial membrane.—To facilitate description, let us commence at the greatest circumference of the head of the femur. From this point the synovial membrane passes outwards over the neck of the bone as far as the attachment of the capsular ligament; from the bone it is reflected on to the deep surface of this ligament, along which it passes to the line of its attachment to the os innominatum and transverse ligament: along that line it is reflected again on to the margin of the acetabulum over the cotyloid ligament into the cavity, which it completely lines, and from which it is carried by the round ligament, which it invests, to the head of the femur.

Arteries.—The hip-joint is supplied with blood by branches from the obturator artery, derived from the internal iliac or from the internal circumflex branch of the femoral. These are distributed, some in the fat and cellular tissue, filling the excavation at the bottom of the acetabulum, whilst others ramify on the ligamentum teres, and are conducted by it to the head of the femur. It not unfrequently occurs that the joint receives blood from both these sources.

Nerves.—These are derived from the obturator, which uniting with the deep division of the anterior crural cause the pain to be referred to the knee in some diseases of the hip-joint.

Motions.—The motions of this joint are mostly performed by the femur upon the os innominatum, and consist of flexion, extension, abduction, adduction, circumduction, and rotation.

In slight flexion the head of the femur revolves upon its axis in the cotyloid cavity; the anterior portion of the capsular ligament being relaxed, whilst the posterior is rendered proportionally tense. If this motion be augmented to any considerable extent, the capsular ligament is relaxed to a greater degree anteriorly, whilst posteriorly, in consequence of the distance between its two points of attachment being increased, it is very tense, and rendered convex by being stretched over the head of the femur, which is now very prominent in this situation, resulting from the altered relations between it and the acetabulum. The anterior part of the head of the femur is placed against the deepest portion of the acetabulum, whilst its broad articulating surface situate above the depression for the round ligament is directed backwards, where the acetabulum is too shallow to receive it completely; it therefore forms a projection in this situation, a projection which, in my opinion, ought rather to be attributed in this instance to the natural formation of the parts than to any displacement of the head of the bone.

When excessive flexion is combined with adduction, the head of the femur glides from before backwards, and from within outwards in the acetabulum; its anterior portion is concealed in this cavity, whilst its posterior emerging lies against the capsular ligament, considerably increasing its tension. To produce these motions muscles of great power are employed; in some these agents are not confined merely to one joint, but have two opposite functions to perform, being flexors of one joint at the same time that they extend another.

In abduction, when the lower extremity of the femur is separated from the median line, its head is naturally directed downwards, its inferior portion being forced against the capsular ligament; therefore when the motion is carried to any great extent the ligament is liable to rupture, and allow the head of the femur to escape over the internal lip of the acetabulum into the obturator foramen.

In adduction the same occurs as in abduction, but in an inverse direction, with this exception, that as the motion cannot be carried so far, and as in this case the head of the femur is opposed to the deepest portion of the acetabulum, dislocation cannot occur. Simple adduction, unaccompanied by any flexion of the joint, is very limited. Let any one, while standing in the erect posture, approximate his knees, it will be found that the utmost he can do is to bring them very near to each other, but that he cannot press them against each other; if, however, the hip-joints have been previously very slightly flexed, then the knees may be easily pressed against each other, and the adduction may be carried to a much greater extent, so as to cross the legs. It is limited by the ligamentum teres and the external and anterior part of the capsular ligament.

Circumduction combining the four preceding is a compound movement, in which the inferior extremity describes a cone, the apex of which is at the joint; the head of the femur in the course of this motion successively assumes the several situations already described.

In rotation outwards the head of the femur is directed forwards and inwards, the anterior surface of the neck looks outwards, the posterior inwards resting on the brim of the acetabulum; the capsular ligament is put upon the stretch on its inner side. Any sudden jerk or violence when in this position is liable to produce dislocation upwards upon the pubis.

In rotation inwards the bone assumes the contrary direction, and the capsular ligament and ligamentum teres are equally put upon the stretch. In this case dislocation may occur either upon the dorsum of the ilium or into the sciatic notch. For this motion we have but few muscles, this position being produced merely by the tensor vaginæ femoris and anterior fibres of the gluteus medius muscles. The disparity between the number of muscles influencing the motions of rotation outwards and inwards is very striking, but this may be attributed to the direction of the acetabulum from within outwards and forwards naturally tending to produce rotation inwards. Consequently before the opposite motion can be effected there is this inequality to be overcome, and hence the disparity between the muscles.

(H. Hancock.)

HIP-JOINT, ABNORMAL CONDITIONS OF THE.—In this article we shall adopt an arrangement similar to that which we have followed in our former observations on the abnormal conditions of particular joints, and consider these states under the heads of, 1. congenital malformations; 2. the effects of disease, and, 3. the results of accident.

SECTION I. *Congenital malformation of the hip-joint.*—The peculiar affection termed by the continental surgeons congenital or "original luxation" of the hip-joint, has not in our islands attracted the notice that it seems to us to merit. When we reflect upon the very valuable additions which have been made to our knowledge of the pathology of the articulations by British writers, and observe their silence upon this abnormal state of the hip-joint, we might be led to infer that this malformation had no existence in these islands; this, however, unfortunately is not true.

In the very valuable museums in London we can easily recognise many unquestionable specimens of this congenital malformation of the bones of the hip-joint. In Dublin we know some living examples of it, and our museums contain preparations shewing some of its varieties and most of its usual anatomical characters.

At the meeting of the British Association in Dublin in the year 1835, Dr. Hutton made some interesting observations on this affection to the section of medical science, and gave an account of a well-marked example of it affecting one hip-joint. On that occasion Dr. Handyside observed that he had met with a case of congenital luxation of *both* hip-joints, in a subject which had been brought into his anatomical rooms at Edinburgh; and he added that the appearances of the joints corresponded very closely with those noticed by Dr. Hutton. The Professor of Anatomy and Surgery to the University of Dublin, Dr. Harrison, laid before the Surgical Society last winter the results of two accurate post-mortem examinations which he had made of this malformation of the hip-joint. The history of these cases, as far as Dr. Harrison could make it out, shewed that the subjects of them had during life presented the ordinary signs of the infirmity in question. In one of them, one hip-joint only was affected; in the second, not only was the arrest of development such as to leave the acetabulum a plane surface by depriving it of border of any kind, but the ligamentum teres, the head and greater part of the cervix femoris were also deficient on both sides, so that the femora at their upper extremity presented a rude resemblance to the ossa humeri. In this case (*fig.* 307) the capsular ligament was of an extraordinary length, and permitted the rudiment of a head and neck, with the trochanter major, to ascend and descend on each side on the dorsum ilii, and to pass backwards on the ischium to the very edge of the ischiatic notch, in the different movements of the patient.

The case of congenital malformation of the hip-joint has not escaped the notice of continental surgeons,* although perhaps the nature of the affection had not fully attracted the attention of the profession until Dupuytren† gave the results of his observations of twenty-six cases of this malformation which were presented to him in the course of his public and private practice. He seems to have met with the affection more frequently in the female than in the male, in the vast proportion of twenty-two females to four males, and from his description it would appear that he has usually found, in the same individual, both hip-joints affected. In the cases we have witnessed, we have not observed this very great preponderance of female over male cases; and although we have noticed the defect to be double in the same individual, we have more frequently observed but one joint engaged. This is of importance to be recollected, as mistakes in our diagnosis are more likely to occur when only one joint is affected, than in those cases in which the defect is double in the same individual.

The characters, says Dupuytren, of this "original luxation" are nearly similar to all those we notice belonging to the ordinary luxation upwards and backwards on the dorsum of the ilium: the limbs are shortened and inverted; the superior extremities of the femora are carried upwards, backwards, and outwards, into the external iliac fossa, where a considerable prominence can be seen, caused by the unusual elevation of the great trochanter; the thighs, unusually slender, are obliquely directed down-

* Palletta, Lafond, Callard, Bellomeir.

† Repertoire d'Anatomie, Leçons Orales.

wards, forwards, and inwards, and this obliquity is greater in proportion as the pelvis is broader; hence the deformity in the female increases about the age of puberty: there is, in consequence of this breadth of the pelvis, a tendency of the limbs to cross each other inferiorly, and the movements they are found to enjoy are very limited, particularly those of abduction and rotation; hence the individual finds great difficulty in performing the different functions belonging naturally to the inferior limbs. When we examine a person with this double defect standing, we are struck at once with the apparent want of proportion between the superior and inferior parts of the body, with the imperfection of the lower limbs, and with the peculiar attitude of the patient. The trunk is fully developed, says Dupuytren, whilst the inferior limbs, short and slender, seem as if they were suited only to an individual of smaller stature. When we view the patient laterally, we observe that the chest and superior part of the body are carried very much backwards, while the anterior part of the abdomen is thrown very prominently forwards, and at the same time we notice there is a corresponding hollowing posteriorly in the region of the loins, and that the nates jut out backwards most conspicuously. A very characteristic circumstance relative to the standing position of these malformed individuals is, that they rest on the ground only by the anterior part of their feet; most of the peculiar circumstances relating to the attitude of these persons follow as the necessary consequence of their hip-joints (or in other words the centre of motion of the lower extremities) being placed behind their ordinary situation with respect to the pelvis.

If a patient so unhappily constituted wish to walk, we see him incline the superior part of his body towards the limb which is now intended to support the weight of the body; he as it were balances himself on the anterior part of the foot of this side; he next raises from the ground the opposite foot, and transfers laboriously his weight from one side to the other—indeed each time this motion takes place, the head of the femur which receives the weight of the body, ascends upon the external iliac fossa, and is sustained by its ligaments and muscles; the pelvis is at the same time depressed, and all the signs of displacement become more obvious on this side, while they diminish sensibly on the other; in a word, progression thus becomes an awkward and waddling movement.

It may appear singular that running and leaping should be executed by these patients with more facility than walking, yet such is the fact; for in those exertions the energy of muscular contraction, and the rapidity with which the weight of the body is transferred from one limb to the other, are such, that the want of a true acetabulum is not so much felt as in walking. Any of these exercises, however, very soon induce fatigue, which we can readily account for when we recollect the friction which the head of the femur must undergo against the side of the pelvis, and the great efforts which the muscles have to sustain in supporting the weight of the body, during the balancing or waddling motion described. When persons afflicted with this malformation lie down horizontally on their back, the signs of their infirmity become so slight as to be scarcely perceptible, because in this situation of complete repose the muscles do not draw upwards the lower limbs, nor does the weight of the body depress the pelvis. Dupuytren found that in this situation of the body he could elongate or shorten the affected limbs of the patient; to elongate them, he says, it was merely necessary to pull slightly downwards at the knee or ankle, and to shorten them, to push them upwards; the head of the femur will undergo in such experiments a displacement of one, two, or even three inches (Dupuytren), and all these displacements will be affected without causing any pain and with the greatest ease, convincing us that no proper cavity exists fit to receive and retain the head of the femur.

It is of importance that this congenital malformation of the hip-joint should be well understood, not only that dangerous errors in diagnosis may be avoided, but that this defect, when it really exists, may be recognized early, so that timely and proper treatment may be resorted to. It presents to the superficial observer many of the signs which belong to a disease of the hip-joint; and of the cases seen by Dupuytren, few, he says, had been recognized by the surgeons previously consulted: almost all these unfortunate patients had been subjected to painful and worse than useless treatment. Many individuals afflicted with original luxation of the hip-joint have been, in consequence of the errors or ignorance of their medical attendants, condemned to keep their beds during many years. "I have seen others," says be, "whom they had forced to submit to numberless applications of leeches, blisters, issues, and moxas; among others I remember the case of a young girl, who suffered the application of twenty-one moxas around the hip, without this barbarous treatment having effected any favourable change in the situation of this unfortunate patient."

We can easily distinguish this original luxation from disease of the hip-joint, as there is no pain felt by the patient either in the hip or knee; there is neither heat, swelling, nor abscess, no evidence of inflammation chronic or acute, nor is there any cicatrix; consequently nothing exists which can induce us to believe that heretofore there ever existed any abscess or fistula, consequences so very usual in cases of disease of the hip-joint, when this disease has arrived at the stage of luxation.

Dupuytren's description of this condition of the hip-joint seems to apply altogether to the case in which both joints are engaged; when one articulation only is affected, so far as it is concerned, the features of the congenital defect are just as well marked as those above alluded to. The usual signs of the dislocation upwards and backwards on the dorsum ilii, and the same range of ascent and descent of the head of the femur on the ilium and towards the ischiatic notch, is noticed as in the former case; as, however, the weight of the body is almost entirely thrown on the unaffected limb, the latter becomes much larger and stronger than usual, while the malformed limb falls into a state of more or less of atrophy from want of use; its circulation in general seems more languid, and its nervous energies and temperature are less than those of the well-formed extremity; add to this, as we have already noticed (what might be expected,) that in consequence of the centre of gravity being so uniformly thrown on the sound limb, a lateral curvature of the spine takes place, and a great mobility of the sacro-lumbar articulation exists.

Anatomical characters of this affection.— Opportunities for ascertaining the anatomy of this congenital defect, whether both hip-joints be implicated or one only affected, are very rare. Although Dupuytren has seen so many patients afflicted with this malformation, he has had very few opportunities, he says, of studying its anatomy, because the affection is not a disease, but an infirmity which has no tendency to shorten life. With respect to the *muscles* he has remarked, that some of them around the joint are found to be well developed, while others are in a state of atrophy: the first are those which have still preserved their functions, the second are those whose action has been restrained by changes induced in the position and form of the parts: some of these latter, he says, are reduced to a sort of yellow fibrous tissue, in which we can scarcely discover muscular fibre.

The cotyloid cavity of the os ilii in some cases scarcely can be said to exist, so irregular are the traces of it; sometimes an irregular bony eminence occupies its place, having no cartilaginous covering, no rudiment of cotyloid ligament; it is merely surrounded by resistant cellular tissue, and covered by muscles which pass by it to be inserted into the little trochanter. Sometimes, says Dupuytren, I have found the ligamentum teres of the articulation much elongated, flattened superiorly, and worn as it were in certain points by the pressure and friction of the head of the femur; the latter is lodged in a cavity analogous enough to that which we find formed in cases of luxation upwards and outwards, which have been left for a long time unreduced. This cavity (if such it can be called) is situated in the external iliac fossa, above and behind the usual situation of the cotyloid cavity, at a height proportioned to the shortening of the limb, or degree of ascent of the head of the femur. The superior portion of the femur preserves in all its parts, its form, its dimensions, and its *natural relations*, only the internal side, and the anterior part of the head of this bone has sometimes lost its rounded form, a circumstance which would appear to result from the friction which it has been subjected to by its frequent contact with parts which have not been organized to receive it.

The writer's observation does not entirely correspond with this account of the superior portion of the femur preserving its form and natural relations with the rest of the bone. He has usually noticed that the head of the femur has lost its spheroidal shape, and presents somewhat of a conical appearance, as Dupuytren well describes; but two other circumstances he has observed in almost all the cases he has examined, whether in the recent dissections he has himself witnessed, or in the macerated bones he has seen in Dublin or elsewhere:— 1st, that the neck of the femur, instead of having its axis directed, as it naturally is, from behind forwards, upwards, and inwards, has in this malformation lost its usual relation with the shaft of the thigh-bone, and the axis is directed upwards, and almost directly forwards. This alteration in the direction of the axis of the neck of the thigh-bone did not escape the observation of Dr. Hutton, in his remarks on his case already alluded to; he expressed his idea of the altered direction of the axis by saying that the axis of the neck in this case fell *directly* on the *anterior* part of the upper extremity of the shaft: "the relative position of the neck and shaft appeared as it might be supposed to do if, the lower portion of the femur being fixed, the upper portion were twisted *forwards*, the head moving through one fourth of a circle." 2dly. The other circumstance which the writer has noticed must be viewed in connection with this altered direction of the usual axis of the neck of the femur just alluded to; it is that in all the cases he has as yet seen of this original luxation of the femur, the head of the thigh-bone, instead of being directed *backwards*, as it is in the ordinary luxation on the dorsum ilii, on the contrary has been directed *forwards*, and has been placed beside the anterior inferior spinous process of the ilium, while the trochanter major has been directed backwards on the dorsum ilii.

It is rather strange that a relative position of the bones of the hip-joint, so different from what has been observed in the ordinary dislocation upwards on the dorsum ilii, and one so usually met with in the case of original luxation of the hip-joint, should have heretofore escaped observation.

In one of the specimens of malformation of the hip-joint preserved by Mr. Harrison in the Museum of the University of Dublin, this relative position of the femur and the anterior inferior spine of the ilium can be noticed, while the trochanter major is placed posterior to both. And in two preparations preserved in the Richmond Hospital Museum, the same observation can be made,—the atrophied heads of the thigh-bones are directed forwards; the great trochanters lie behind these heads on the sides of the pelvis.

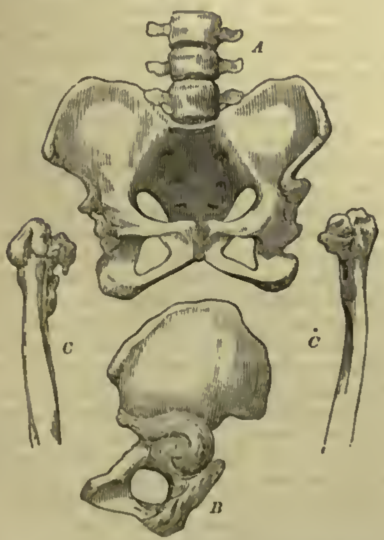
These are circumstances important for us to keep in mind, when we are considering the diagnosis of the various affections of the hip-joint.

We say that such a remarkable circumstance demands notice from us, because in the cases of this affection we have as yet observed in the living subject, the thigh, leg, and foot of the malformed limb has not been so much inverted as it always is in the ordinary luxation upwards and backwards on the dorsum ilii; indeed in the case of a lad, named Hannon, whom the writer has frequently examined, (*fig.* 308,) the thigh, leg, and foot were by no means inverted, the ordinary aspect of the front of the femur, patella, &c. was directed as much forwards as it naturally is; the shortening and other signs of luxation upwards on the dorsum ilii existed, and, in consequence of the emaciated state of the limb, the relative position of the head and neck of the femur, above adverted to, was easily recognized, when the hand was laid upon the head of the bone, and a strong movement of rotation outward was communicated to the malformed extremity.

We do not mean to assert that in all cases this relative position of the head and neck of the femur will be found to exist; in this, as in other congenital defects, much variety may be expected to be found. When in these cases the soft parts are removed, the bones of the pelvis present appearances which are remarkable enough, although we believe that these appearances have heretofore escaped the observation of anatomists, who seem to have confined their attention to the abnormal condition of the head of the os femoris and the acetabulum.

The anterior spines of the ilium, particularly the inferior, we have usually found to be directed very much inwards, towards each other (*fig.* 307); the external iliac fossa to be more convex, and the internal iliac fossa more concave than usual: beneath the anterior inferior spine we notice a deep groove directed outwards, through which the united tendon and fibres of the psoas and iliacus pass to the lesser trochanter of the femur, which process is always in these cases placed so much behind as well as above its normal situation. The sub-pubic angle is remarkably obtuse, the rami of the pubes and ischia are very oblique, and the tuberosities of the ischia greatly everted.

Fig. 307.



Many of these which we would call characteristic features of the double congenital defect now under consideration have heretofore escaped the notice of all those who have written on "the original luxation" of the hip-joint. Sandifort in his Museum Anatomicum has, however, given a delineation of a pelvis belonging to a subject in which he says both hip-joints were found dislocated: what this author has there drawn was probably not understood in his day, but any one who has seen many specimens of the deformity we are now endeavouring to describe, will agree with us, we are sure, in considering Plate LXIV a true representation of congenital luxation in both hip-joints.

When only one of the hip-joints is affected we find a lateral curvature of the spine to exist, and the bones of the pelvis to be in a state of atrophy on the malformed side. The portions of the os pubis and ischium which circumscribe the thyroid foramen are generally long and slender, and the tuberosity of the ischium is at a greater distance from the symphysis of the pubis on the malformed than on the opposite side.

Many of the anatomical characters we have here stated may be supposed to be the gradual result of causes acting from early infancy on bones as yet soft and cartilaginous. The weight of the body so constantly acting unfavourably on badly-formed bones and over-distended ligaments, the efforts of muscles by their repeated exertions endeavouring to supply the deficiencies in the ligaments and in the articular surfaces of the bones, are so many causes which must act on and alter the direction of the head and neck of the femur, distort the tuberosities of the ischia, and draw towards the middle line the spines of the ilium; but we may inquire does the first fault in these cases consist in the arrest of development in the bones? in the muscles? or should we look to the nervous system for the primitive source of these intra-uterine defects? These are inquiries which cannot, we believe, in the present state of our knowledge, be satisfactorily replied to. Andral remarks that in almost all cases in which one of the cerebral hemispheres is atrophied we find the limbs of the *opposite* side less developed than natural; but he does not venture to express an opinion as to whether the imperfect development of the brain is the cause of the malformed extremity, or the repose and want of use of the latter the reflected cause of the atrophy of the brain. No doubt we have, in one solitary instance already quoted,* shewn that a congenital malformation of the left hip-joint coincided with a deficiency of the cerebral convolutions of the right hemisphere of the brain, but this coincidence we have reason to believe must be exceedingly rare.

Some surgeons of eminence, whose opinions must have considerable weight with the profession, have stated it to be their belief† that "a simple paralytic condition of the muscles of the lower extremity, as a consequence of the irritation from teething arising during infancy," is the starting point of disease in these cases,

* Dr. Hutton's case, Dublin Journal, volume viii
† See Lancet for 1825-6.

and would of course consider all the phenomena of the malformation we have dwelt on, as the mere consequences of the paralytic condition of the muscles. With such a doctrine we are not at all disposed to agree; in no other instances do we find paralysis produce similar results; besides, the muscles of the hip-joints in many of these cases seem in the exercise of running and leaping endowed with very energetic powers of action. It is perfectly clear that to refer all in these cases to a paralysis of the muscles is quite unsatisfactory, because the abnormal conditions of the several structures around the affected joints are in these cases so varied and numerous that we feel that they never can be rationally referred to this single source. In some instances we find a very well marked oval eminence on the side of the pelvis for articulation with the malformed head of the femur, while no trace of cotyloid cavity exists; in some the defect is slight, in others the deformity is great; thus the ligamentum teres may be a long and slender thread without vascularity or strength in some cases, in others we have seen it four inches long, and at the same time of considerable breadth; while in others again no trace of ligamentum teres or head of the femur existed, the imperfect representation of a head being retained by a lengthened capsular ligament, supported by the smaller muscles around the malformed articulation.

These observations satisfy us that we cannot refer to "paralysis of the muscles of the lower extremity as a consequence of irritation from teething arising during infancy," the phenomena that this affection termed congenital malformation of the hip-joint presents.

We have no doubt seen some instances in which a certain paralytic tendency and other congenital defects seemed combined with the malformation of the hip-joint; but again we have seen many others in which there was no paralytic tendency, and in which no other defect than a double congenital luxation of the hip-joint existed; and in Dupuytren's twenty-six cases no mention is made of paralysis, nor of atrophy of the cerebral convolutions.

We confess we are glad to feel ourselves able successfully to oppose the hopeless idea of paralysis of the muscles being in fault, because we have reason to believe that mechanical treatment of the malformed hip-joint has succeeded, when early applied, in lessening the infirmity. The idea of paralysis of the muscles being the root of the evil, precludes all hope of mechanical treatment being at all serviceable to these unfortunate individuals.

History of a case of congenital malformation of the left hip-joint, with the anatomical examination of the articulation.—A man named John North, æt. 31, of weak intellect, was admitted under the care of Dr. Hutton, July 1835, into the Richmond Hospital; he was afflicted with a most severe form of inflammation of the larynx, trachea, and lungs. I was asked to visit him, and report my opinion as to whether the operation of tracheotomy should be performed, or whether such a measure would be calculated to relieve the urgent symptoms of dyspnœa which seemed in this case to threaten suffocation. While I was examining the patient he wished to get out of his bed, and then I noticed that besides having an atrophied and contracted state of the left forearm and wrist, his left lower extremity was deformed, and seemed much shorter than the opposite limb. Upon even a very superficial view of this left hip-joint and the position of the limb, all the more obvious features of a dislocation upwards and backwards on the dorsum ilii, were recognized. Upon inquiry it was ascertained, as far as could be from such a patient and from his ordinary attendants, that the hip-joint had never suffered any accident, and that, although he had issues inserted, he never had had any acute disease or suffering in the deformed hip, which deformity, with the contraction of the upper extremity, was coeval with their earliest recollections of him.

I agreed with those in consultation on the case that the state of the lungs would speedily bring about the death of the patient, and that no operation, such as tracheotomy or laryngotomy, should be resorted to. I also expressed my conviction that the left hip-joint presented a very fine illustration of the abnormal state of this articulation, which Dupuytren and others had described as a congenital or original luxation of the hip. The next day the patient died of the inflammatory affection of the chest, and a post-mortem examination was made by Dr. Hutton, at which Mr. Smith and the writer were present. There were observed the same appearances of luxation on the dorsum ilii as before noticed; the body being held up and maintained in the erect posture, the pelvis was seen to be very oblique and elevated towards the malformed side, the left lower extremity seemed three inches shorter than the right or perfectly formed limb, but on measurement it was plain that the deformed limb was not really shortened, but had merely ascended on the dorsum ilii. The trochanter major (naturally on a level with the horizontal ramus of the pubis) was elevated two inches above this bone. In the prominence and elevation of the great trochanter, in the semiflexion and adduction of the limb, in the circumstance of the motions of rotation and abduction being limited,—in all these the case nearly resembled the ordinary luxation on the dorsum ilii, whether produced by accident or the result of an old caries; but the history of the case was opposed to either of these conjectures, and the marks of issues placed there through ignorance were not to mislead us, or induce us to alter our opinion already expressed, as we were well aware that in almost all the cases seen by Dupuytren similar evidences of surgical ignorance of the true nature of the affection had existed. Besides the unusual prominence and elevation of the trochanter major already mentioned, the head of the femur could itself be plainly enough felt, when a movement of rotation outwards was given to the shaft of the bone; but when the limb was forcibly elevated or extended, even now in the dead subject, its range of movement of ascent and descent was not more than half an inch; in this particular this case differed from those given by Dupuytren, because in his cases the range of motion of ascent and descent of the head of the femur on the os innominatum, which could be communicated, amounted to two inches.* The body having been placed on its face, and the integuments removed from the glutæus maximus, this muscle looked somewhat paler in its colour than natural, its lower margin (which in the natural state has a descent of obliquity amounting to three inches) was placed nearly transversely. When this muscle was removed, the trochanter major presented itself; it lay on the dorsum of the ilium, near to the ischiatic notch, above the pyriformis and below the range of the glutæi (medius et minimus), which were in a state of atrophy. The head of the femur, smaller than usual, was in advance of the great trochanter, and was placed immediately external to the anterior inferior spinous process of the ilium, and was here covered immediately by the capsular ligament and some scattered fibres of the lesser glutæi: the tensor vaginæ femoris lay in front of the head of the bone.

The pyriformis and quadratus were very oblique in their course, passing upwards and outwards: all the muscles in the front of the thigh, such as the pectinalis and other adductors, passed from the os pubis outwards with a degree of obliquity three or four inches less than natural. The psoas magnus was drawn a little outwards, and its edges were twisted so that the internal edge was directed backwards and its external edge forwards. All the muscles of this extremity were smaller and less developed than those of the other; but with the exception of part of the obturator externus which looked fatty, their fibres had a natural appearance. There were no marks of previous violent injury or chronic disease.

The capsular ligament was attached as usual to the circumference of the acetabulum on one part, and to the base of the neck of the femur on the other; it was strong and at the same time elongated, so as to allow the head of the femur to rest on the dorsum of the ilium, but ligamentary bands passed from this part of the ilium to the external surface of the capsule, where it invested the head of the femur; these must have served to strengthen and fix the capsule and thus prevent any great range of motion over the ilium. When this capsule was cut into, the head of the femur was found somewhat conical in its form and much smaller than usual; the cartilaginous covering, thin and of an azure hue, did not form a very uniform or perfect covering for the head of the bone; there seemed no deficiency of synovial fluid within the joint. The inter-articular ligament or ligamentum teres, as it is called, presented a very remarkable appearance; it was of unusual dimensions, being more than four inches long; of a yellowish colour like tendon, and as thick as the tendo Achillis near the os calcis; instead of being firm, round, and thick, it was soft and could be easily spread out to the breadth of an inch: its fibres were connected by means of a thin transparent membrane like a synovial structure. This substitute for the normal ligamentum teres was continuous with the cotyloid ligament, or arose from that part of it which completes the notch of the acetabulum within. From this origin or attachment, the ligament passed, as it were, from within outwards and upwards to be attached to the head of the femur, presenting in its course an inverted arch, the cavity upwards and inwards, the convexity downwards and outwards. On its inferior surface it corresponded to the head of the femur, where it was hollowed out from before backwards, so as to accommodate itself to the head of the bone, for which it formed a kind of cup which followed the movements of the femur, affording it always a receptacle as the inter-articular cartilage does for the condyle of the lower jaw. This broad ligament had no connexion by synovial folds or fibrous productions with the bottom of the acetabulum. The cotyloid ligament was flattened out round the brim of the acetabulum, and was otherwise imperfect: the fatty and vascular cellular structure named Haversian gland existed in rather large quantity.

When a comparative view of the bones of the pelvis and lower extremity of each side was taken, it was manifest that the left lower extremity was in a state of atrophy, that the thigh-bone was straight and slender, and that the atrophy extended downwards to the bones of the leg, and included also the whole of the left os innominatum; the anterior spines and crest of the ilium were inverted, the internal iliac fossa was much deepened, and the external surface of the ilium rendered more convex than usual. The rami of the os pubis and ischium seemed more attenuated and slender than those of the opposite side, and the foramen ovale wider. The circumference of the acetabulum of this side included nearly as large a space as usual, but the upper and outer portion of its brim or its supercilium was deficient. This cavity was shallow, its surface scabrous or uneven, and was no where invested with cartilage; a flattened surface above it marked the point of habitual contact of the head of the femur and ilium: the bone was not excavated in this situation to receive the head of the femur, which was retained here, as already mentioned, by ligamentous bands, which extended from this part of the ilium to the external surface of the capsular ligament. The femur, it has been said, was atrophied at this side and slender, but it was of the same length as the opposite bone, diminished only in the circumference of the shaft. The axis of the head and neck was directed from the shaft of the bone upwards and inwards, but it was straighter, and its direction was by several degrees more forward than natural.

As we have detailed this case merely as an illustration of the congenital malformation of the hip, and do not wish here to enter into minute particulars as to the morbid appear-

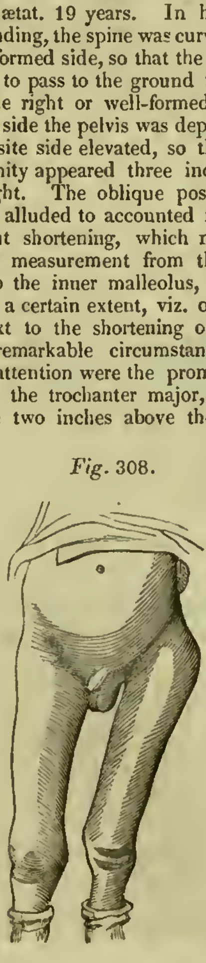
* See Dr. Hutton's account in the Dublin Journal, vol. viii.

ances which the post-mortem examination further disclosed, we merely state that evidences of diffuse inflammation of the mucous and submucous tissues of the pharynx and larynx, with purulent infiltration in the submucous tissue, existed with extensive bronchitis, as well as splenization of the lungs. It was moreover discovered that the right hemisphere of the brain was deficient, and that a cyst five inches in length and between two and three in its transverse diameter occupied the interval (which was an inch in depth) between the surface of the atrophied brain and interior of the calvarium; this cyst was filled with limpid serum.

The whole of the left upper extremity was in a state of atrophy, flexed at the elbow and wrist-joints, and the forearm and hand were rigidly pronated.

A case of congenital luxation of the left hip-joint very similar to the foregoing was under the writer's observation for some time as an out-patient of the Richmond Hospital. This lad was on different occasions seen and prescribed for by Dr. Hutton, who first recognized the nature of the case, and the other surgeons of the institution. His name was Martin Hannon; he was a labourer, ætat. 19 years. In his ordinary attitude, standing, the spine was curved laterally to the well-formed side, so that the line of gravity seemed to pass to the ground through the centre of the right or well-formed thigh and leg: on this side the pelvis was depressed, and on the opposite side elevated, so that the left lower extremity appeared three inches shorter than the right. The oblique position of the pelvis above alluded to accounted for much of this apparent shortening, which nevertheless, by accurate measurement from the spine of the ilium to the inner malleolus, was proved to be real to a certain extent, viz. one inch and a half. Next to the shortening of the limb, the most remarkable circumstances which caught our attention were the prominency and elevation of the trochanter major, which was found to be two inches above the horizontal

Fig. 308.



ramus of the pubis. The trochanter major was also behind its usual situation (*fig.* 308). The hip-joint possessed a certain degree of the motions of flexion and abduction, and when the patient was directed to extend the thigh backwards, the motion about the sacro-lumbar articulations seemed preternaturally free. When the hand was placed on the left hip-joint, the head of the femur could be felt plainly to be situated in a very unusual position, namely, forwards and upwards, close to the anterior inferior spine of the ilium, and in advance of its neck and the great trochanter, which lay towards the ischiatic notch: if now a motion of rotation outwards were communicated to the femur, the trochanter major moved backwards, while the head of the femur rolled forwards and outwards; and so very thin was the patient that the head of the bone could be seen and easily felt moving in this novel situation. The deformed thigh was at its upper part thrown much outwards (*fig.* 308), and to recover, as it were, this deviation outwards above, it passed much inwards towards its lower extremity; the thigh and leg were cold and atrophied, and the poor lad had also that malformation of the ankle called valgus.

He walked with the assistance of a stick, and in consequence of the double defect of the left hip-joint and ankle very imperfectly.

The sound limb, which seemed, in standing, to bear the whole weight of the body, was very muscular, and was larger in proportion than to be expected, when compared with the left or deformed leg, thigh, chest, and upper extremities, which last presented no peculiarities.

Such were the notes the writer had taken of this case in December 1837, when the lad applied to him at the hospital to be relieved of an indolent ulcer he had on the weak limb. In the beginning of the spring of this year he became affected with phthisis, and died of that disease in the Whitworth Hospital on the 12th June, 1838. Mr. Smith had a cast taken of the lower part of the body, pelvis, and lower extremities, which is preserved in our Museum. The interior of the thorax presented the usual effects of phthisis.

Left hip-joint.— The muscles around the joint were remarkably pale and greatly attenuated; they held the same position relatively to the head of the bone, as in the preceding case of North, but they were more atrophied; in many places all appearance of muscular fibre was lost, and its place supplied by a yellow fatty fibrous tissue. The muscles of the rest of the extremity, particularly the gastrocnemius and solœus, were in a similar condition. The sciatic nerve had not a very healthy aspect; it was yellowish; and its fibres, though firm, were more loosely connected than usual.

The capsular ligament was remarkably thick, and was lined on its interior or synovial surface with a very red vascular membrane, like scarlet cloth. The internal ligament of the joint or ligamentum teres was fully three inches long, and much stronger than usual (*fig.* 309); it

Fig. 309.

grew to the cotyloid ligament at the notch, as is usual, and had no other connexion with the acetabulum, which contained no Haversian gland, and was not lined by cartilage. The cotyloid ligament was very flat and imperfect.

Bones.—In the general aspect of the bones of the pelvis and of the femur, there existed a very striking resemblance between this case and the former detailed. The os innominatum of the left or deformed side, together with the femur and other bones of the left lower extremity, were much smaller than the os innominatum and bones of the right lower extremity; the former, besides being deformed, were also in a state of atrophy in circumference and length, while the latter were evidently larger and better nourished than one would expect to find them in so delicate an individual. In a word, there was a compensatory growth of the skeleton on the right side, as it were to make up for the deficient growth of the left or malformed side. The head of the right femur and the corresponding acetabulum were both very large, the right half of the pelvis too, in all its bony prominences, was well marked, and the anterior spines of the ilium were inverted; the inter-vertebral substance intervening between the last lumbar vertebra and base of the sacrum was much thicker than usual.

Section II. *Disease.*—The abnormal appearances we notice in the articulation of the hip, produced by disease, are usually the result of inflammation, which may have been either acute or chronic; arising either in the synovial membrane, the cartilage, or the bone. Indeed, in modern works on the diseases of the joints, we have laid down for us rather positively the symptoms and anatomical characters of synovitis, chondritis, and osteitis; but much as we would wish to adopt an arrangement that the pathology of Pinel and Bichat would suggest, and which comes commended to us by the experience of Brodie, we do not think that this arrangement can be strictly adhered to. In acute rheumatic arthritis, we have the synovial or fibro-synovial structures of the articulation engaged, with little, if any, implication of the cartilage or bone, but in any of the cases commonly denominated "disease of the hip," the inflammation, as far as our experience has gone, never long confines itself to any one structure entering into the composition of the joint. In a work, however, like this, the opinions of the highest authorities on such a question must be quoted. According to Sir Benjamin Brodie,* synovitis coxæ, or inflammation of the synovial membrane of the hip-joint, may take place in different degrees of intensity; but for the most part it has the form of a chronic or slow affection, which, while it impairs, does not destroy the functions of the articulation. In the hip, less frequently than in other joints, is the fluctuation of the effused fluid perceived, but the existence of swelling is sufficiently evident beneath the muscles: there is fulness of the groin and pain, which is not "referred to the knee, as in cases of ulceration of cartilage, but to the upper and inner part of the thigh, immediately below the origin of the adductor longus; the weight can be borne on the affected limb, and pressure against the heel gives no pain; this (the pain) is often severe, yet it does not amount to that excruciating sensation which exhausts the powers and spirits of the patient, in whom the cartilages of the hip are ulcerated."

The following case Sir B. Brodie adduces as an example of inflammation of the synovial membrane of the hip, terminating in dislocation.

Master L.,† being at that time about eight years of age, was attacked towards the end of September, 1824, with what was believed at the time to be inflammation of one of the parotid glands, attended with a good deal of fever; after six or seven days, and apparently in consequence of the application of cold lotions to the cheek, the inflammation left the parotid gland, and attacked one shoulder and arm; and at the end of two or three days more it left the shoulder and attacked one of the hips. For six or eight weeks he suffered most severely from pain referred to the inside of the thigh, extending from the pubes as low down as within two or three inches of the inner condyle of the femur, and attended with a great deal of fever. There was no pain in the knee. The surgeon who was then in attendance applied leeches to the hip, lotions, &c. &c., and afterwards made an issue with caustic behind the great trochanter. The fluctuation of fluid was perceived at the posterior part of the hip; and it was supposed that an abscess had formed; however, no puncture was made, and the fluid gradually became absorbed. In March, 1825, Master L. was sufficiently well to be able to walk about, but it was discovered that the limb was shortened. In November, 1825, Sir B. Brodie was consulted respecting him; at this time there were all the marks of a dislocation of the hip upwards and outwards, the limb was shortened, the toes turned inwards, and the head of the femur was distinctly to be felt on the posterior part of the ilium, above the margin of the acetabulum.

Now, if we may be permitted to give an

* On Diseases of the Joints, 3d edit.

† Case XI. Brodie, page 51, 3d edition.

opinion as to this case, we would certainly question much the correctness of the conjecture, that the inflammation of the hip-joint was altogether limited to the synovial membrane: no doubt, so far as the hip was concerned, the inflammation began in the synovial structures; but who can doubt that in this case the cartilages became secondarily engaged, that the acetabulum itself was after a time implicated, and that an abscess had formed? For our parts, we have little doubt that all the structures entering into the composition of the articulation were implicated in the inflammation of the joint.

It has been above stated, as the opinion of the author now cited, that synovitis has for the most part the form of a chronic affection, but as a proof that a disease, apparently slight, and of a part no way concerned in the vital functions, may produce such a degree of disturbance of the constitution as rapidly to occasion death, he adduces the following case.* Sir B. Brodie considers it a case of inflammation of the synovial membrane, (synovitis coxæ,) which ran its course to a fatal termination in the short space of a week.

A young lady, nine years of age, being at play on the 1st of January, 1808, fell and wrenched her hip; she experienced so little uneasiness, that she walked out on that day as usual; in the evening she went to a dance, but there was seized with a rigor, was carried home, and put to bed. Next morning she was much indisposed, and complained of pain in the thigh and knee; on the following day she had pain in the hip, and was feverish. These symptoms continued; she became delirious, and died just a week from the time of the accident. On inspecting the body on the following day, the viscera of the thorax and abdomen were found in a perfectly healthy state. The hip-joint on the side of the injury contained about half an ounce of dark-coloured pus, and the synovial membrane, where it was reflected over the neck of the femur, was destroyed by ulceration for about the extent of a shilling. This was an awful case, and such, fortunately, are rare; however it has been our lot to witness some very similar in their course and unhappy termination, and we have always looked upon them as specimens of that terrible disease "diffuse inflammation."

The next case, No. XVI. in Sir B. Brodie's work,† we look upon exactly in the same light. The following the writer saw under the care of his lamented friend, the late Dr. M'Dowel.

Synovitis coxæ with periostitis succeeding to a fall on the hip—death in eight days.—Peter Neale, æt. 12, admitted into the Richmond Surgical Hospital, January 11, 1833. Four days previous to admission he fell from a wall of moderate height, on the left hip, which was so much contused, that he was unable to stand upon the limb, and was carried home. The pain and constitutional disturbance increased daily; on admission it was found that the left hip-joint was very tense and swollen; the pain was so excruciating that he was unable to move in bed without assistance; his countenance anxious, sunken, and expressive of intense suffering, tongue furred, black sordes on his teeth; he was delirious, and screamed without intermission; his hip became more tender, tense, and swollen; he also now complained of pain in the right shoulder and elbow. To these symptoms succeeded drowsiness, tendency to coma, occasional muttering delirium; he now had a peculiarly wild and frightened look. He died on the morning of the 15th; the fourth from his admission into the hospital, and the eighth from the time of the fall on the hip. The post-mortem examination took place four hours after death. On cutting through the left glutæal muscles, matter issued from numerous small points; the muscular fibres were of a deep red colour; the periosteum was detached from the entire of the ilium by a quantity of dark brown pus, which passed through the great sciatic notch, and separated the membrane from the whole concavity of the bone, which was of a pink colour; the fluid had passed through a small ulcerated opening in the capsule of the joint from the cotyloid cavity; small portions of lymph were found on the head of the bone, and the synovial membrane, covering the fatty mass at the bottom of the acetabulum, bore evidences of acute inflammation having existed here; and the surface of the synovial membrane was also covered with lymph. There was no ulceration of the cartilages. The right shoulder-joint healthy. In the right elbow-joint a fluid in small quantity, resembling that which was contained in the hip-joint.*

Cartilage.—The inflammation and ulceration of the cartilages of the hip-joint are said by Sir B. Brodie to be most frequently met with in those who have passed the age of puberty, and who are under thirty or thirty-five; but that they are sometimes seen in young children, and occasionally in those advanced in life: when the cartilage covering the bones which enter into the articulation of the hip-joint are affected, the progress of the case is slow; the pain is at first trivial, the degree of lameness slight; but as there is no effusion of pus or increased secretion of synovial fluid, there is no appreciable external swelling; but the pain, the wasting of the limb, and lameness gradually increase, with the spasmodic startings, and abscess and dislocation follow, as in cases in which the inflammation originated in other tissues. To exhibit the disease of the cartilage where this structure alone is engaged, we must have some opportunity of witnessing it in an individual who has died of some other complaint. The following case well illustrates the opinion of the first authority on such a subject.

John Catmah, 44 years of age, was admitted into St. George's Hospital on the 29th of September, 1813, with pains of the lower limb of

* Case XV. p. 64, 3d edit.
† Page 65, 3d edition.

* See Dr. M'Dowel's observations in the 3d and 4th volume of the Dublin Journal, on Synovitis, &c.

the right side, extending from the hip to the knee, and resembling the pains of rheumatism. He attributed these pains to his having caught cold about a month before his admission. He laboured also under a complaint of his bowels, of which he died on the 4th of December. On dissection, no preternatural appearances were discovered, except in the right hip. The capsular ligament and synovial membrane were in a natural state, the cartilages covering the head of the femur and lining the bottom of the acetabulum were destroyed by ulceration in about one-half of their extent, and wherever the cartilage was destroyed an ulcerated surface of bone was exposed; the round ligament was readily torn in consequence of ulceration having extended to it at the part where it was inserted into the acetabulum. The bones possessed their natural texture and hardness; there was no pus in the joint. It was observed that the ulcerated surface of the acetabulum corresponded to that of the femur, these surfaces being exactly in contact in the position in which the patient had remained since his admission into the hospital.

Mr. Aston Key, from the cases he had an opportunity of examining of ulceration of the cartilage of the hip-joint in the early stage of the disease, is of opinion that the ulceration of the cartilage is preceded by inflammation of the ligamentum teres. He adduces the following interesting case.

A young female, who, for six months prior to her death, had laboured under the usual symptoms of chronic inflammation of the hip-joint, and when the symptoms had nearly yielded to the treatment employed, was attacked with another disease, of which she died.

The ligamentum teres was found much thicker and more pulpy than usual from interstitial effusion; the vessels on its investing synovial membrane were distended and large, without being filled with injection. At the root of the ligament where it is attached to the head of the femur, a spot of ulceration in the cartilage was seen commencing, as it does in other joints, by an extension of the vessels in the form of a membrane from the root of the vascular ligament. The same process had also begun on the acetabulum, where the ligamentum teres was attached.*

Bone.—The scrofulous affection of the hip-joint or morbus coxæ of Ford is, according to modern writers, a specimen of strumous osteitis. The disease, as far as the hip-joint itself is concerned, commences deep in the cancellous structure of the bones, and in general is remarkably slow in its progress.

While the disease goes on in the cancellous structure of the bones, before it has extended further, and while there is no swelling, the patient experiences some degree of pain, which, however, is never so severe as to occasion serious distress; it is often so slight, and increases so gradually as scarcely to be noticed; after a time the external parts sympathize with those within, and serum and coagulated lymph being effused into the cellular membrane, the joint appears swollen: should the patient be a child, it not unfrequently happens that this swelling first attracts the attention of the nurse or parents. The swelling is puffy and elastic, with blue veins meandring over its surface, but though usually more in degree than in those cases in which ulceration of the cartilage occurs as a primary disease, it is not greater in appearance, because the muscles of the limb are not equally wasted from want of exercise; the pain increases, but is not severe until matter has formed, and the parts over the abscess have become distended and inflamed, but then it is immediately relieved upon the abscess bursting. The skin, under these circumstances, assumes a dark red or purple colour, the abscess is slow in its progress, and when it bursts or is opened it discharges a thin pus, with portions of a curdy substance floating in it; afterwards the discharge lessens in quantity, becomes thicker in consistence, and at last nearly resembles the cheesy matter which is found in scrofulous absorbent glands. In most instances several abscesses take place in succession, but at various intervals, some of which heal, while others remain open, assuming the form of fistulous sinuses, at the bottom of which carious bone may be distinguished by means of a probe. The principal difference which is to be observed between the symptoms of this affection and that in which the cartilage is primarily the seat of inflammation, is in the degree or amount of pain which the patient endures, and which is much greater in the latter than in those cases where the disease exists in the cancellous structure of the bones. A girl laboured under an affection of the hip-joint, in which the nates were flattened, and an abscess had broken on the outside of the thigh, but it was observed she had suffered comparatively little pain. Under these circumstances she died, and when, says Sir B. Brodie, I was about to examine the body, I observed to those who were present, that there was little doubt but that the origin of the disease would be found to have been, not in the cartilages, nor in the bony surfaces to which they are connected, but in the cancellous structure of the bone. The appearances verified this remark: the cartilages were ulcerated and the bones destroyed to some extent; the latter were soft, so that they might be cut with a scalpel, and on dividing the articulating extremity of the femur longitudinally, a considerable collection of thick pus was found in the neck of that bone below the head, which either had not escaped at all, or had escaped in very small quantity by oozing through the cancelli which were interposed between it and the cavity of the joint. The hip-joint wears externally the peculiar aspect of a white swelling, and internally the anatomical structure will be found similar. In this disease of the joints the cancellous structure of the bones is the part primarily affected, in consequence of which ulceration takes place in the cartilages covering their articulating surfaces. The cartilages being ulcerated, the subsequent progress of the disease is in many respects the

* See Medico-Chirurgical Transactions, vol. xviii.

same as where the ulceration takes place in them in the first instance. Rust is of opinion that, under the influence of the disease in question, the head of the bone becomes more voluminous than in the normal state, and that from its gradual increase the cavity destined to receive it can no longer contain it; that the centre of the eminence becomes very vascular and softened, and presents evident traces of inflammation, which Rust thinks always begins in the membranous medullary tissue which occupies the interior of the cancelli of the head of the bone. Roche and Sanson, from whom we have taken this account of Rust's opinion, add that sometimes the articular head of the bone is not changed in volume, but that the cavity for receiving the head is filled by a swelling of the cartilage which clothes it, and by that of the cellular flocculi or Haversian glands.

Having stated the opinions of those who would wish to arrange and distinguish from each other the different morbid affections of the hip-joint according to the different structures they originate in, we regret to feel obliged here to express our dissent from this arrangement, as we find the greatest difficulty in adhering to it practically.

We have no doubt but that the disease of the hip, whether acute or chronic in its attack, may begin by an inflammation of the synovial membrane of the joint, and that occasionally, particularly in scrofulous subjects, the cancellary structures of the bones may be the first seat of the local disease; we might even yield an assent to the opinion of some, that the cartilages may in rare cases be the structures first engaged; but if we seek for facts to convince the mind of the truth of all such speculations, we shall find but little that is satisfactory to guide us. Post-mortem examinations seldom reveal to us the state of the joint, until the disease has made great ravages, and until several structures have been implicated; the external signs of synovitis, chondritis, and osteitis, cannot, in our judgment, be distinctly recognized in all cases in an articulation so covered by muscles and so remote from the surface as the hip-joint is. We feel convinced, therefore, that in the present state of our knowledge the effects of disease on the articulation of the hip may be best considered under the following heads: 1. acute arthritis coxæ; 2. chronic strumous arthritis coxæ; 3. chronic rheumatic arthritis coxæ.

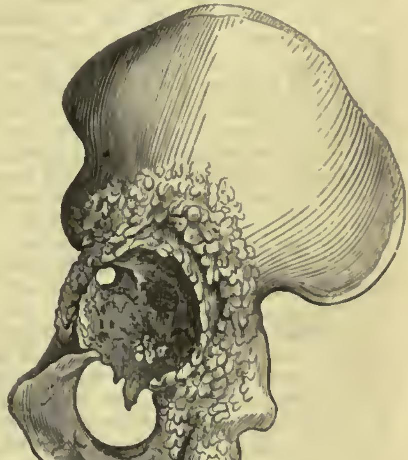
1. *Acute Arthritis coxæ.*—The following case presents an example of an ordinary case of acute arthritis coxæ. Daniel Reddy, æt. 18, a labourer, was admitted into the Richmond Hospital on the 11th of October, 1838. He now had all the symptoms of a very severe attack of acute inflammation of the hip-joint. He stated that he had always been remarkably healthy until about four weeks ago, when in consequence of having lain for some hours on damp grass, he had a shivering, which was succeeded by fever; on the following morning he had severe pain deep behind the great trochanter; he became so very lame and unable to walk from the pain in his left hip-joint, that he was compelled to keep his bed; he also complained of pain in the groin and startings in the limb. When the patient was supported as far as it was possible in the erect position, we observed posteriorly that there was a remarkable flatness and breadth of the nates of the affected hip, and that its lower fold had disappeared; there was a gradual pyriform tapering down of the hip into the thigh, which was already much wasted; the pelvis itself was rotated on the spine, the left side being directed backwards, and the spinal column much curved forwards, rendering the abdomen very prominent in this direction. There was at first an apparent elongation of the limb, which soon became flexed on the pelvis, and so strongly adducted as to cross the median line, if the term adduction can be so applied. There was great heat all around the hip-joint; when pressure was made either on the great trochanter or in the groin, it caused great pain to the patient, and if the least movement was communicated it seemed almost insupportable. In bed he lay on the right or sound side, with the left side of the pelvis directed backwards, the left thigh and leg both much flexed and directed inwards, as already remarked, across the middle line; he kept the limb by holding it grasped with both hands near the knee. There was some fulness, fluctuation, and tenderness on pressure over the left iliac fossa, and shooting pain passed down to the knee. There was constitutional fever and much general heat of surface. To rest and active treatment by leeching, blistering, and calomel with opium, his symptoms yielded for a time, then he relapsed, and such alternations occurred thrice, and then all the urgent symptoms subsided. In March his fever and constitutional disturbance had disappeared, and from the recovery of his flesh and expression of countenance, we judged that this attack had passed over, but had left him liable to fresh and dangerous returns of inflammation from the most trivial causes, either local, such as injuries, or constitutional. In April there was a shortening of one inch and a half, the foot of the affected limb rested on the instep of the other in standing, and in lying the knee was supported by a cushion placed above the other knee; adduction extreme; and although the thigh, leg, and foot were habitually somewhat inverted, eversion was admissible; behind there was a great widening of the buttock and retraction of the trochanter major; no fluctuation of matter could be felt about the joint, nor had he any pain in the knee or hip.

Such, we imagine, is the more ordinary course of acute arthritis coxæ. In this case acute synovitis followed the lying on the damp grass; there was noticed an apparent elongation of the limb, which was of very short duration, and was succeeded by a shortening at first very trifling, scarcely appreciable, but after a month half an inch, and at last fully an inch and a half. In consequence of the very decided elevation on the dorsum ilii of the great trochanter, with the habitual inversion, flexion, and adduction of the whole limb, we might be led to infer that in this case the articular ligament and fibrous capsule had yielded from ulceration, and the muscles had dislocated the head of the femur from the acetabulum on the dorsum ilii; but the shortening was not sudden, as we have known it to have been in such cases, but gradual, nor by a careful examination of the dorsum of the ilium, and searching deeply behind the situation of the great trochanter, could we feel the head of the femur where it should be, were it really dislocated from the cavity of the acetabulum, nor by a forced rotation inwards of the whole limb could the head of the bone be rendered manifest. Our strongest reason, however, for concluding that the head of the bone is not really luxated on the dorsum ilii is, that although the foot may habitually be directed a little inwards, still the foot is susceptible of rotation outwards to a greater extent than is compatible with any idea of the head and neck of the femur being thrown, as in the ordinary luxation, on the dorsum ilii.

The following case of acute arthritis coxæ presents a remarkable example of this affection, in which the course of the disease was rapid, its symptoms obscure, and death occurred suddenly and unexpectedly.

On the 11th of January, 1829, I was requested by my friend Mr. Speedy, then one of my pupils at the Richmond School of Medicine, to assist him at the post-mortem examination of a grenadier, who died with a psoas abscess rather suddenly and unexpectedly. The man, aged 32, had been only one month complaining of pains about his loins and hip-joint, and was only a few days confined to bed. The body was thin, though not emaciated; in the inguinal region a large fluctuating swelling was perceived, which evidently extended into the abdominal cavity, and had assumed the situation and form of a psoas abscess. While cutting into the cavity of the abdomen, pus was noticed to issue from some of the veins which were divided, and particularly from the epigastric. When the abdomen was opened, we observed that the sheath of the psoas muscle was distended as high up as the diaphragm, and on puncturing it a quantity of purulent matter escaped. A second abscess was discovered in the true pelvis, which extended from the back part of the thyroid foramen to the sacrum, lying outside the bladder and rectum. We next laid fully open the sheath of the psoas muscle, which we observed had not been organized into the usual form of a cyst, and search was made for some point of diseased bone along the spinal column, but none was found here; we then directed our attention to the hip-joint; we found the capsular ligament perfect, except where it arises from the transverse ligament of the notch near the thyroid foramen. Here a large perforation existed in the capsular ligament, through which the finger could be passed on through the thyroid foramen into the interior of the abscess in the true pelvis; the sac of this last abscess we traced as high as the bifurcation of the aorta and junction of the common iliac veins with the vena cava; here this latter vessel was found firmly adherent to the sac, and on carefully removing both in connection, and slitting up the vena cava posteriorly, we had a view of a perforation in its anterior wall, close to its junction with the iliacs; this perforation was large enough to admit a goose-quill, and established a free communication between the vein and the cavity of the abscess, by which blood and purulent matter had an easy passage from one to the other. How long this communication had existed we could not ascertain; but thus was satisfactorily explained the extraordinary phenomenon which had attracted our attention in an earlier stage of the dissection, viz. the issue of pus from some of the veins of the abdominal parietes which were cut across. On prosecuting the examination still further, we found that close to the anterior inferior spine of the ilium and iliopubal eminence, where the united tendons of the psoas and iliacus muscles pass over this part of the horizontal ramus of the os innominatum, a vertical perforation of the brim of the acetabulum existed, half an inch deep, of a funnel shape, with its largest part towards the acetabulum, and capable of allowing at its smallest part a large sized bougie

Fig. 310.



to pass; through this the matter had passed up and elevated the psoas muscle or distended its sheath, which thus presented the ordinary characters of a psoas abscess, but which we learned had appeared suddenly and without having been preceded by the usual premonitory signs. There was no trace of cartilage, Haversian gland, or synovial membrane on the acetabulum; the round ligament was gone, and the cartilaginous covering of the head of the femur had been removed, as well as the synovial membrane of the neck of this bone. The exposed surfaces of the bones were carious, but the acetabulum had suffered more particularly; it was deeper, but not wider than usual; its fundus, where formed by the ischium, was thin as paper, but yet no perforation had taken place in this part of the cavity, as thickened periosteum supported the bone, while the ulcerative absorption was so active in the interior of this cavity, removing the bone, osseous spiculæ or stalactiform growths, such as we are familiar with as being produced around scrofulous joints, had been deposited around the entire circumference of the acetabulum; some of these had much narrowed the usual extent of the obturator foramen, at that point where matter had passed from the joint into the interior of the pelvis. The bones have been macerated and preserved in the Richmond School Museum, and verify many of the statements made relative to this very singular case.

What influence the communication between the cavity of the abscess and the interior of the vena cava had in producing the fatal result in this case, we do not feel ourselves called upon to determine, nor is this the place to dwell on this obscure subject. The usual phenomena of apparent elongation at first and real shortening of the limb afterwards, either did not exist or were so trifling as not to be appreciated in this case, and the disease ran its course rapidly to a fatal termination, the head of the bone remaining in its normal position in the acetabulum. It was probably from having witnessed such cases as the foregoing that that experienced surgeon, Boyer, was induced to make the following remark:—"On a observé un variété de la carie qui n'attaque que le fond de la cavité cotyloïde; de sorte que ce fond seulement est detruit, tandis que ces bords restent intacts; alors la matière purulente de mauvaise qualité, qui la remplit, se porte jusque dans le bassin, ou elle forme un foyer plus ou moins considérable; dans ce cas, la maladie fait perir le sujet, sans deplacement du femur."

We will adduce but one example more of the acute arthritis coxæ, with the post-mortem examination.

Alexander Clarke, æt. 17, on admission into the Richmond Hospital, it was observed that there was much swelling about the hip-joint; the integuments over it were tense and shining, the glands in the groin were swollen and very tender; he suffered from pain, shooting to the knee and spasmodic startings, which awoke him at night; he could not permit the slightest motion of the limb, which was shortened one inch and a quarter; it was habitually inverted and flexed on the trunk; the constitutional disturbance was considerable. From the treatment adopted he derived benefit, and a partial recovery resulted. He left the hospital, but soon returned, in consequence of an aggravation of all the former symptoms, caused by a fall on the diseased hip. A deep abscess formed in the groin and extended under Poupart's ligament; hectic symptoms showed themselves. There were alternate diarrhœa and attacks of vomiting. The abscess in the iliac fossa increased, the tumefaction around the joint diminished, the shortening and inversion of the limb became greater, and œdema of the foot and leg occurred; he now became suddenly insensible; his left arm was totally paralyzed, while the right was convulsed and constantly in motion; his face too was distorted by twitchings, and he passed his discharges involuntarily; he lay thus for several days and died, being in all eighty days ill.

Post-mortem examination.—Upon cutting down to the hip-joint the capsular ligament was found to have been extensively removed anteriorly; posteriorly and laterally it was not ulcerated, but seemed to have been greatly lengthened and widened; the synovial membrane was lined with a yellowish-green membrane, just like what we see investing the interior of the sac of an old chronic abscess; the ligamentum teres and cartilage, which invested the head of the bone, had been removed, the bones were rough, unusually red and vascular, and were coated with yellowish-green lymph; the acetabulum was much enlarged, and the head of the bone was drawn to the upper and outer part. The left iliac fossa was entirely filled by an immense abscess, lying between the muscle and bone, passing down under Poupart's ligament as far as the lesser trochanter. The iliac vessels and the anterior crural nerve were pushed forwards; half an inch below Poupart's ligament a process of the abscess had passed outwards and backwards, which communicated with the hip-joint, and having the muscles posterior to the joint, which were thinned and matted together, to form its wall in that direction. In the brain purulent matter was found on the arachnoid surface as well as between the several convolutions of the right hemisphere. The neighbouring portion of the brain was softened and vascular; there was no effusion into the arachnoid sac or into the ventricles.*

Sometimes the acute arthritis coxæ is an essential disease, and the only one present at the time in the constitution, being simple and confined to the one articulation, as in the case of Reddy before quoted. Sometimes, however, the acute inflammation of the hip-joint is a symptom of another disease. In acute rheumatic fever the hip-joint is, in its turn, sometimes severely visited. Finally, the cases yet published of acute periostitis and synovitis combined, and of acute puerperal rheumatism, in which the hip-joint became implicated, need not be discussed here. We are of opinion that such cases should be looked upon as true specimens of that almost intractable disease called diffuse inflammation.

Anatomical characters.—From the post-mortem examinations of cases of acute arthritis coxæ which have been hitherto made, we can collect that all the structures around the joint are in a state of active vascular congestion. The synovial membrane and subsynovial structure present the ordinary characters of active congestion and the results of acute inflammation. Sometimes there is an increased secretion of synovial fluid, and sometimes, in its stead, purulent matter distends the articulation. The synovial membrane, where it is reflected over the neck of the femur, has been found de-

* See Dublin Journal, vol. iii. and iv., also preparation in the Richmond Hospital Museum, which the writer has recently inspected.

stroyed by ulceration. Sometimes the purulent matter has been known to have escaped from the articulation by ulcerated openings in the capsule of the joint, and to have passed into the pelvis, and penetrated between the muscles. The fatty mass at the bottom of the acetabulum has been found swollen, inflamed, and covered with a membranous layer of lymph, at the same time in some of these cases the neighbouring periosteum has been found detached from the bone, which was redder than usual. These are appearances which have been noticed in those who have died of acute arthritic inflammation, whether it may have arisen from diffuse inflammation or simple acute disease confined to the one articulation. In acute cases, actual dislocation of the bones, we believe, has not been noticed, as the disease seldom arrives at its second or third stage under such circumstances, but the cartilage and synovial membranes have been altogether destroyed, and the porous structure of the bones has been exposed, digital depressions have been seen produced by acute caries in the acetabulum and head of the femur. The bones have then presented a rough vascular surface, and in many cases lymph has been found to cover the convexity of the head of the thigh-bone and to line the acetabulum. The head of the femur sometimes is but little altered, either as to form or position, but when the acetabulum is largely excavated by disease, the head of the thigh-bone will be found to be drawn by the muscles to its upper and back part. Even in acute arthritis coxæ in the young subject, the epiphysis of the head of the femur has been found detached.* The ligamentum teres is generally absorbed early, and the capsular ligament is usually ulcerated in some one part, so that, on the post-mortem examination, the bones are found to be very moveable on each other. They are usually observed to be highly vascular, and some imagine the head of the femur is enlarged. Hyperosteotic depositions or stalactiform productions, which are very friable, exist around the diseased joint.

2. *Chronic strumous arthritis coxæ.*—The scrofulous disease of the hip-joint is very generally slow in its progress, and is seldom seen, except in persons who bear other evidences of the strumous diathesis; there are examples of it occurring in individuals who have passed the age of thirty years, though generally seen in those of more tender years. This affection of the joint, although slow and insidious in its attack, yet is attended with the usual phenomena of an inflammatory or sub-inflammatory action. Many of the writers who have described the "disease of the hip-joint," have assigned to it three periods or stages, as Ford has done, while succeeding authors have added to the description of the three stages of Ford, a period which they call the period of the invasion of the disease. In this their first stage, there is pain in the thigh, extending to the knee, which appears and disappears alternately; a marked weakness in the thigh, and a sense of feebleness in the whole limb; the gait is limping, and some tension is felt in the groin. This period lasts sometimes but a few days, at other times many months. In the second period the limb is wasted, and apparently, though not really, elongated; the trochanter is placed lower down, and is more outward than that of the opposite side; the buttock is flattened, and its fold is lower than natural; the patient's lameness is characteristic; he moves the affected limb round with a shuffling motion, the foot scraping the ground, and he sometimes assists the elevation of the thigh with his hand. At this time the knee is painful, and not unfrequently a puffy swelling appears in it, both which circumstances often too much attract the attention of patient and surgeon, and divert it from the true seat of the disease. The third period is characterized by a real shortening of the limb; this is sometimes sudden, and the immediate consequence of caries of the brim of the acetabulum and luxation of the head of the femur upward and backward on the dorsum of the ilium. The shortening of the limb, however, is more commonly gradual, and the consequence of the slow ulceration and widening of the acetabulum.

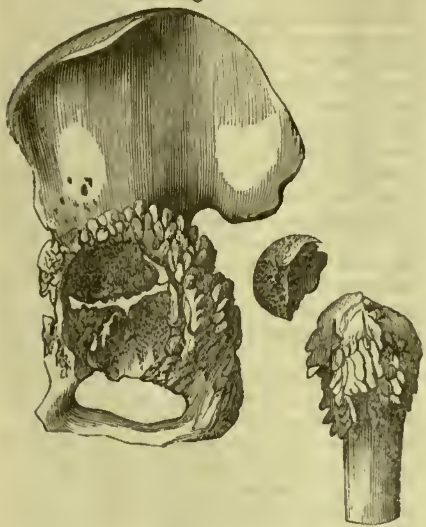
It has of late been truly observed, that the luxation is not so common as generally imagined, but when it does occur, it usually takes place in the direction upwards and outwards; when the fibrous capsule and other ligaments are destroyed by ulceration, the head of the femur escapes by the superior and posterior part of the acetabulum, and obeying the action of the glutæi muscles, it glides from before backwards and without inwards upon the convex surface of the ilium; the thigh is flexed, adducted, and turned with a strong rotation inwards; the great trochanter approaches the crest of the ilium, the muscles are raised up by the head of the femur, and the buttock is rounded, and becomes very protuberant posteriorly. Although this is the direction in which the luxation usually takes place, still it has been noticed to have occurred in a direction horizontally backwards towards the ischiatic notch (Earle). It has also been seen in the direction downwards and inwards towards the foramen ovale, in which case the limb is elongated and directed outwards. Still more rarely has it been thrown upwards and inwards on the horizontal ramus of the pubis. In one instance, says Brodie, I have seen the dislocation in the direction forwards, the head of the femur resting on the pubis, the knee and toes being turned outwards.

It would be wrong, however, to suppose that a true dislocation of the head of the femur from the ulcerated acetabulum is a very common occurrence; although all these cases, above alluded to, have been witnessed, we believe very frequently the shortening of the limb in the third and fourth stage of the disease arises from ulceration and widening of the acetabulum and destruction of the head of the femur. The head of the femur sometimes sepa-

* See a preparation in the museum of the College of Surgeons, Dublin, presented by the late Professor Todd.

rates at its epiphysis from the neck of the bone, and the latter is drawn up, (*fig.* 311,) and the

Fig. 311.



whole limb shortened greatly, and the toes are as much everted as when fracture of the neck of the femur occurs from accident. The shortening is usually, but not invariably, the precursor of abscess; when this occurs, the disease is in its fourth stage. This period, or that of of the formation of matter, is generally marked by an aggravation of the pain, by frequent spasms and startings of the muscles, by greater wasting of the limb, occasional œdema of the foot, (which is a very unpromising feature,) &c. These chronic symptomatic abscesses may present themselves in various directions; the matter may remain for months without undergoing any change, and even after this be rather suddenly absorbed, or the pus may escape through openings made by nature or by art; the external orifices of these abscesses frequently degenerate into fistulæ, from which exfoliations occasionally take place, and these exfoliations are sometimes so small as to be almost sabulous, sometimes larger pieces come away with pain; such are to be considered not unfavourable indications. The writer has known two examples of the head of the femur thus separated at their epiphysis from the neck of the bones; in these cases the patients recovered, with the usual deformity.* Of the numerous situations around the hip-joint, in which matter has been found deposited, there is one variety which demands the special attention of surgeons, in consequence of the difficulty which has been experienced in recognizing the disease, namely, the case in which the caries affects the bottom of the acetabulum, so that the fundus alone is destroyed. Sir B. Brodie met with one case, where in the bottom of the acetabulum there was an ulcerated opening, just large enough to admit a common probe, communicating with an abscess within the pelvis. Mr. Tagart* alludes also to a case in which this perforation exists. (*Figs.* 312 and 313.) Of such per-

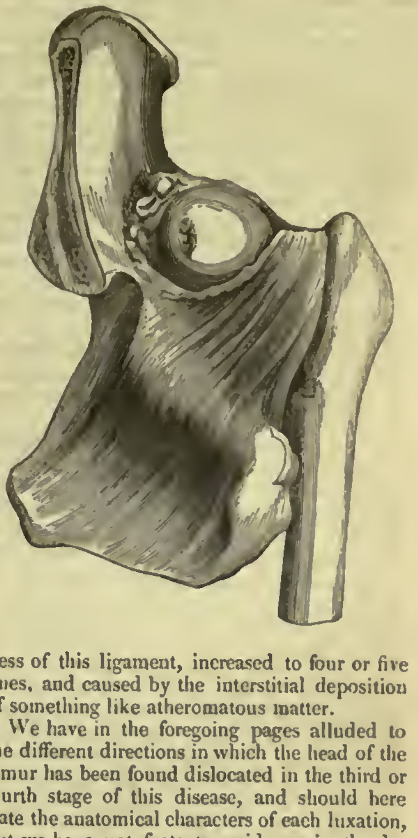
forations the writer has seen in different museums a great variety: in many instances the opening is small, in others of sufficient size to admit easily the head of the femur. These cases are in the beginning obscure, and when abscesses form, they are concealed within the cavity of the pelvis.

Anatomical characters.—When opportunities have occurred of examining the interior of the hip-joint in those who have died of other complaints, this articulation being, at the time of death, in the early stages of the chronic disease we are now considering, the adipose cellular mass which occupies the fundus of the acetabulum, the cellular structure which connects the fibres of the inter-articular ligament, the subsynovial cellular tissue which surrounds the corona of the head of the femur, as well as the interior of the bones themselves, have been found to wear an unusually red appearance from increased vascularity. The cartilage has been found softened, to have lost its usual lustre, to be slightly elevated, and too easily torn from the subjacent bone; in some cases thinned, in others detached in flaps; in some it has presented a corroded appearance, and coinciding with these changes purulent matter has been found in the interior of the joint, the capsular ligament thickened, and the lymphatic glands in the groin enlarged. In the anatomical examination of those who have died in the advanced stages of the scrofulous disease of the hip, if the patient have not arrived at the age of puberty, we find that very frequently the original portions of the os innominatum are separated from each other for several lines, that the epiphysis of the head of the femur is completely detached from the shaft of this bone; the greater and lesser trochanters are sometimes in very young subjects removed by absorption, and evidence of devastating caries is found in the bottom of the acetabulum. (*Fig.* 311.)

In some cases the head of the bone has been found dislocated on the dorsum ilii, previous to which occurrence all the ligaments have been destroyed, the acetabulum has the superior and posterior part of its brim removed by caries, and the bone thus abandoned to the action of the muscles takes the position it ordinarily does in the common luxation upwards and backwards on the dorsum ilii. This complete dislocation is not so common an occurrence as generally imagined; there are, however, some specimens of it preserved in the museum of the College of Surgeons in Dublin. In one preparation, the cartilage of the head of the femur is perfect, the round ligament is gone; the further ascent of the head of the bone on the dorsum ilii seems principally restrained by the obturator muscles (*fig.* 314). The interesting circumstance in the preparation to be noticed is, that the acetabulum is occupied to the level of its brim with a very dense atheromatous matter or yellowish green lymph, apparently an unorganized substance resembling what we see contained in crude scrofulous tubercles: what remained of the capsular ligament around the neck of the femur has been cut crucially, and the everted edges of the flaps shew the thickness of this ligament, increased to four or five lines, and caused by the interstitial deposition of something like atheromatous matter.

Fig. 314.



We have in the foregoing pages alluded to the different directions in which the head of the femur has been found dislocated in the third or fourth stage of this disease, and should here state the anatomical characters of each luxation, but we have not facts to guide us in the description.

When a section is made of the bones entering into the composition of the hip-joint, when the patient has died of this disease in an advanced stage, they will be found to be softened in the interior, and to contain a fatty or a yellowish cheese-like matter in their cells; when opportunities have occurred for examination in an earlier stage of this scrofulous caries, these organs have been generally found preternaturally red and vascular, (as before stated,) with a deficient proportion of earthy matter, admitting not only of being cut with a knife without turning its edge, but yielding and being crushed under very slight pressure. A modern author,* after quoting the authority of Lloyd on scrofula as proof of the truth of some of the foregoing observations, adds his own opinion, " that in simple inflammation, uninfluenced by the scrofulous diathesis, particularly when it becomes of a chronic character, bone is secreted in abundance, but that the striking feature in this kind of inflammation is, the absence of all secretion or deposit of bone." With the latter doctrine we cannot at all agree, and must conclude we do not rightly apprehend the

* Coulson on the Diseases of the Hip-joint, Lond. 1837, 4to. p. 39.

author, as we have very generally found osseous growths exterior to the hip-joint in the os innominatum and femur, (*fig.* 310), as the result of scrofulous inflammation of the articulation. These growths are generally friable stalactiform productions which beset the bones, and are to be seen in the numerous specimens illustrating the morbid anatomy of morbus coxæ, which are contained in our museums in Dublin.* Notwithstanding these osseous productions or vegetations, the bones are found to have diminished much in their specific gravity. I have always found them float when thrown into water. These growths are, however, only met with in the post-mortem examination of such chronic cases as have manifested in their course various alternations of improvement and reverses; they are almost invariably found when the caries of the bones had been arrested, and an imperfect attempt at anchylosis had been made.

We have also opportunities of examining anatomically the hip-joints of persons who have had this disease in their youth, in whom it had been arrested in the second or third stage, and who had attained advanced life, and died of some other complaint. In some, besides the bony growths already alluded to, we find examples of anchylosis or of a false joint; indeed, although an absolute union and consolidation of the bones, viz. the os innominatum and the head of the femur may not have taken place, still in most cases there is very little real motion of the two bones upon each other; the flexor and adductor muscles of the thigh and hip-joint are usually in a state of spastic contraction; they admit of but little increase of flexion: whenever we attempt extension, we find the thigh is readily brought down from the abdomen, the lumbar vertebræ are arched forwards, and this portion of the spine and the sacrolumbar articulation are the seat of motion, which often is erroneously referred to the hip-joint. The os innominatum follows the head of the femur just as freely almost as the scapula accompanies the various changes of position impressed upon the humerus, when anchylosis of the shoulder-joint has taken place. I was called upon about eight years ago to examine the body of a woman, aged 26 years, who died in the Whitworth Hospital of an acute disease. This young woman had walked very lamely for many years, in consequence of her having had a most tedious and dangerous attack of hip-disease twenty years before her death, but after her recovery from the first attack she never had any pain or inflammation in the joint; there were no evidences of suppuration ever having occurred; marks of issues were on the nates. When making an examination of the structures around the articulation and of the joint itself, the muscles were found remarkably firm, but somewhat paler than usual; the ligamentous structures around the junction of the femur with the os innominatum were very strong, and so close was the union of the bones that on a superficial view we might easily imagine that true bony anchylosis had occurred. I removed the bones, and they are preserved in the Richmond School Museum. The whole head of the femur has been absorbed, and only one-fourth part of the neck of the bone remains; the place of the cotyloid cavity is supplied by a rough scabrous surface, of an oval form transversely, and about one inch and one line in this its longest diameter; the two rough bony surfaces with eminences and depressions confronted to each, and reciprocally adapted, were joined by a species of strong fibrous capsule; no motion whatever existed between these bones, yet when the ligamentous connexion between them was cut, it was evident that no bony union had taken place. In this case the false anchylosis had occurred in a very unfavourable direction; the thigh was flexed to so great a degree that the knee was really elevated above the level of the hip-joint, and so much adducted at the same time, that the knee crossed much the middle line. When she stood up straight on the right and perfect limb, the left heel did not approach within twelve inches of the ground: the texture of the bones was as hard as iron.

We find in a modern author the observation, which must be admitted to be correct, that true bony anchylosis of the hip-joint is rare; but, he adds, that many pathologists doubt that such an occurrence ever takes place: that the many specimens of true bony anchylosis of the hip we have witnessed, were all examples of union of bony surfaces in scrofulous cases, we would not wish to maintain, but we imagine many of them must have been the result of the ordinary hip disease cured, as it is called, by anchylosis. Sir Philip Crampton has shewn me a very fine specimen of anchylosis of the hip-joint, which very much resembles the preparation represented (*fig.* 312); the acetabulum had been the principal seat of the disease; it was much widened, and the head of the bone was drawn towards its upper and outer part, where firm anchylosis had taken place. In this case Sir P. Crampton assured me the patient had a constitution eminently scrofulous. He got well of the hip-disease by anchylosis, the thigh-bone having been judiciously preserved in a vertical direction during the progress of the cure. He walked afterwards tolerably well, but at the age of 26 became attacked with phthisis, and died. This case proves that true bony anchylosis can occur in the scrofulous subject, and that attention may occasionally overcome the disposition to excessive flexion and adduction of the limb.

The museum of the Richmond Hospital contains three specimens, in which the junction of the os innominatum with the femur is as solid as if they formed but one bone, and a vertical section through the united bones shews as free a communication of the cells of the cervix femoris and those of the os innominatum as if these bones had never been separately formed. These seem to have been examples

† These osseous vegetations we have already alluded to in this work, when speaking of the chronic strumous arthritis of the elbow: see p. 79, Elbow-joint, Abnormal Anatomy of.

of early affections of the hip-disease, in which little or no displacement of the head of the femur occurred.

The acetabulum, we know, is generally widened in this disease, and the head of the femur is drawn upwards and outwards; if at this period the inflammation be arrested, true bony anchylosis may occur; and if a happy direction can be given to the shaft of the femur, a very useful limb may remain, even though the hip-joint itself has lost all motion; the sacro-lumbar joint and the neighbouring intervertebral structures admit of much freedom of motion.

In examining anatomically the hip-joints of those who, having had the chronic scrofulous disease of this articulation in their youth, and have recovered and lived for years, though lame, in these, instead of anchylosis, we find a false joint is formed. Of this imperfect cure of hip disease we have seen some examples, and we possess one remarkable specimen of it. In this the acetabulum was altogether removed, and a triangular space, encircled by a rounded brim covered with a compact stratum of bone, existed. The removal of the neck of the femur was so complete that a plane or rather concave surface corresponded to the inner side of the trochanter major, from which the neck of the bone naturally arises.

It has been stated that luxation on the dorsum of the ilium sometimes happens as a consequence of chronic disease of the joint; sometimes the disease which carried away, in this instance, the borders of the acetabulum, seems, as it were, to have been transferred to the new surface of the os innominatum with which the head of the femur came in contact, and we find the process of ulceration has even continued its course; again it sometimes happens that anchylosis or a false joint has been formed.

Albers and Rust have described the change which the bones of the pelvis undergo in their form and situation. The pelvis, in those who have for a long time gone lame, is pushed upwards, and the sacrum is flat and straight. In a few cases, however, it is more curved than in the natural state; the coccyx is bent strongly forwards, and the connexion of the last lumbar vertebra with the sacrum forms a right angle; the ilium of the affected side stands higher, and has in general a perpendicular direction, and more of a triangular form; the external surface is smooth, whilst the iliac fossa appears more hollowed than usual; this hollowing probably depends on the action of the iliacus internus, which is greater than that of the glutæi. The horizontal ramus of the pubes often seems lengthened and lower than in the natural state, and the ischium is usually drawn outwards and forwards; the perpendicular direction of the foramen ovale is changed more to a horizontal one, and the opening assumes more of a triangular form, its base being turned towards the acetabulum. In consequence of the changed situation of the bones of the pelvis, its different diameters undergo an essential deviation from the natural state, the superior apertures of the pelvis are commonly somewhat oblique, and the pelvis is broader on the affected side from before backwards.*

The *muscles* in advanced cases are in a state of atrophy, of a greenish hue, and often matted together; sometimes they form the walls of scrofulous symptomatic abscesses, containing a thin serous pus mixed with flakes; sometimes the pus is inodorous, of ordinary character. Usually the contents of the abscess make their way to the skin, more rarely to the mucous surfaces. In more advanced cases these abscesses are found to contain fetid air and purulent matter of a very bad quality; in these latter circumstances we discover either an external or internal fistulous opening; the walls of the abscesses have collapsed, and have been converted into fistulous canals lined by false membranes; these have become, as it were, the excretory canals, through which the matter has been discharged from the interior of the diseased joint, and through which sabulous matter, small hard pieces of bone, or pieces as large as the epiphysis of the head of the femur, as elsewhere noticed, have made their way. The abscesses are found, on dissection of those who have died of morbus coxæ strumosæ, pointing or to have opened in various directions.

We have already stated that the capsular ligament has been found perforated by fistulous openings, and that in the advanced stage of the disease little or no vestige of the capsule is left. The abscesses, therefore, we meet with on dissection may be considered as reservoirs for the matter which proceeds from the carious bones; occasionally, no doubt, we shall find around the joint abscesses which have no communication whatever with the diseased articulation: not only in the soft parts around the joint have we met with such isolated collections of matter, but also in the body of the os ilii, and in the centre of the trochanter major of the femur.

We have given an account of an acute case of morbus coxæ, in which a psoas abscess was found to have originated in a carious hip-joint. The communication of the carious bones with the interior of the sheath of the psoas took place through a small perforation in the horizontal ramus of the os innominatum. In this case also an abscess existed in the true pelvis, and death was the consequence of it, having burst into the vena cava. In Mr. Liston's collection there is a specimen shewing extensive destruction of the acetabulum, head and neck of the femur, with several sinuses leading from the joint, and one in particular of large size, leading towards the rectum through the foramen ovale; there is also the rectum corresponding to this preparation, with a rounded opening sufficient to admit the point of the little finger, about an inch and a half above the anus. In this case the abscess lay across the pelvis; by one of its extremities it communicated with the diseased hip-joint through the foramen ovale and ulcerated capsular ligament, and by its posterior extremity with the rectum. The case of pelvic abscess I have so often adverted to was very similarly

* Coulson, p. 42.

situated, but instead of opening by its posterior extremity into the rectum, its fundus was elevated somewhat higher in the pelvis, and burst into the vena cava. The late Dr. M'Dowel, in the fourth volume of the Dublin Journal, says that in two cases of hip-joint disease he had seen several years since, the matter had passed into the pelvis through the bottom of the acetabulum, and there accumulated in such quantity as to compress the bladder and cause retention of urine, requiring the daily use of the catheter. He also adds, that this route for the matter is not uncommon, and in its progress that it may form a tumour of considerable size by the side of the rectum, and occasionally burst into the cavity of this intestine. Sir A. Cooper mentions the latter occurrence in one instance. Dr. M'Dowel adds, I had an opportunity of witnessing it. Abscesses take their course from the diseased joint into the pelvis, and open into the vagina. Sir B. Brodie mentions a case of this kind in a child aged 11 years; and in Dr. Kirby's collection, which he presented to the College of Surgeons, is a similar example. Dr. M'Dowel, in the paper already alluded to, observes that he is not aware of its being recorded that an iliac abscess may result from a caries of the hip-joint, yet in four cases, he adds, I have found it to occur. The fluid escaping through an opening on the inside of the capsular ligament, passes upwards behind the psoas and ascends into the iliac fossa, detaching the muscles from the bone. In such cases we have considerable fulness in the groin, which can be traced upwards behind Poupart's ligament; from the stretching of the filaments of the anterior crural nerve more neuralgic pain attends this case than we usually find in disease of the hip-joint. The iliac vessels are displaced, become flattened and adherent to the sac; from the compression of the vein much more œdema of the limb is present than in ordinary cases. The cœcum or the sigmoid flexure of the colon may be considerably displaced or united to the sac.* Sometimes it passes behind the vessels, and accumulating, it may compress the bladder and rectum, which then form the inner wall of the abscess.

In a very interesting case of iliac abscess which was treated in the year 1833 in the Richmond Hospital, ulceration of a portion of the ilium adhering to the wall of the abscess occurred, and its contents, after being poured into the abscess, escaped externally through a fistulous opening near the spine of the ilium; ulceration also of the external iliac artery took place about an inch and a half above Poupart's ligament, and sudden death resulted from the blood escaping in large quantity into the cavity of the abscess. The preparation is preserved in the museum of the Richmond Hospital. The anterior and crural nerves are often found on the stretch. We have already mentioned a case of this kind, (Clarke,) and Sir B. Brodie mentions one in which he found two enlarged lymphatic glands, each the size of a walnut, immediately below the crural arch in the fore part of the joint, and these lay in contact with and immediately behind two branches of the nerves, so as to keep the latter on the stretch, like the strings passing over the bridge of a violin.

We must not forget that the diseased action in these cases of chronic strumous arthritis is not confined to the joint. We have seen examples in the living and specimens in museums, proving that at the same time both hip-joints may be engaged in the same individual. In acute cases we have given an example of the membranes of the brain having been affected, so also in chronic cases; tubercles have also been found in the lungs, the mesenteric glands extensively enlarged, and ulcers in the intestines, and tubercular accretions in the peritoneum.

3. *Chronic rheumatism.* — (*Morbus coxæ senilis, or chronic rheumatic orthritis of the hip.*) By these terms we would wish to designate a very peculiar disease of the hip-joint, the morbid results of which are now pretty well known to pathological anatomists; but it must be confessed that very little has been done to make the profession acquainted with its symptoms or appropriate treatment.

History of the disease.—We will venture to assert that there cannot be a more graphic illustration given of this disease and its consequences than those to be found in the Museum Anatomicum of Sandifort, who has not confined his delineations to the head and neck of the thigh-bone, but has also shewn the various alterations of form which the acetabulum undergoes.* For many years this disease has been accurately described in the clinical lectures delivered in the different hospitals in Dublin, and the importance of distinguishing it from the other affections of this articulation has been pointed out. Mr. Benjamin Bell, in his work on the bones, has, under the head of "interstitial absorption of the neck of the thigh-bone," alluded to this disease, and detailed many of its external signs, as well as the morbid changes which the neck of the bone suffers; and in the sixth volume of the Dublin Journal, Mr. Smith, in a paper on the diagnosis of injuries of the hip, has given a very good and concise account of this remarkable affection of the hip-joint.

The writer of this article long ago, in his lectures, gave the name of *morbus coxæ senilis* to the disease in question, but as he has since met with many instances of it occurring so early as at the age of thirty or forty, he is now disposed to substitute for this name that of *chronic rheumatic arthritis* of the hip-joint, and he considers it as the same disease precisely as he has elsewhere in this work described as affecting other articulations. (See Elbow, Hand, Knee, Shoulder.)

As to the cause of this chronic disease of the hip-joint, we believe little is known. We have heard it frequently attributed to the effects of cold and wet; and an acute attack of rheu-

* The matter, which is generally prevented from passing down into the true pelvis by the connexion of the fascia iliaca, sometimes makes its way into this cavity by ulceration of this fascia.

* Mus. Anatom. Lugduni Batavorum, 1793, vol. ii. tab. lxix. ad lxxiii.

matic arthritis of the hip-joint produced by cold, we can easily conceive may occasionally merge into the chronic affection we wish to describe. We have also reason to think that falls upon the great trochanter have given rise to the first symptoms of this disease; but in many cases no satisfactory cause can be assigned by the patient for the origin of the affection.

Symptoms, &c.—The patient complains of stiffness in the hip-joint and about the great trochanter; also of a dull boring pain which extends down the front of the thigh to the knee. The stiffness is most felt in the morning when the patient commences to walk; but after exercise the movements of the joint become somewhat more free. In the evening of a day the patient has had much walking exercise, the pain is always more severe. The uneasiness, however, gradually subsides after he has retired to bed. The pain is always increased when the patient throws the weight of his body fully on the affected joint. But let the surgeon press on the great trochanter, or adopt any other expedient so as to push the head of the bone even rudely against the acetabulum, and these manœuvres are the sources of no uneasiness whatever to the patient. Although we can easily satisfy ourselves that no actual anchylosis exists, still it is evident enough that the motion of rotation is lost, and that the other movements, particularly flexion, are confined within very narrow limits. When we place the patient in a horizontal position, and endeavour to communicate any of these movements to the hip-joint, the patient complains of pain, and an evident crepitation can be heard and felt deep in the articulation. The limb is apparently shortened by from two to three inches; the apparent shortening arises from the obliquity of position of the pelvis relatively to the spine, and the elevation of the affected side is such that the crest of the ilium and the last short rib approach nearer to each other at this side in the ordinary attitude of standing by two inches than those of the opposite side. All these circumstances account for the apparent shortening of the limb, which however, on accurate measurement, will be found not to be really shortened more than an inch. The patient walks very lame, and with the foot and whole limb greatly everted. The nates of the sound side is unusually prominent, while that of the affected side is quite flat, and no trace of the lower fold of the glutæus is seen. The muscles of the thigh also seem somewhat atrophied, still they do not want for firmness; and we may uniformly observe that the calf of the leg of the affected limb is not inferior in size and firmness to the other. When we minutely examine the great trochanter, we find it larger and more prominent than usual; and about the situation of the acetabulum, horizontal branch of the os pubis, and lesser trochanter, bony protuberances can, upon careful examination, be recognized. This disease, when once fully established in the hip-joint, rarely or never extends itself to the other articulations. We have known, however, a few examples in which it affected both hip-joints in the same individual. The chronic inflammation of the various structures of the joint in which the disease consists, is never accompanied by any appreciable degree of heat or external swelling of the soft parts, and we have never heard of the inflammation going on to suppuration.

The following case will shew the necessity of making the profession fully acquainted with this disease, as it proves how very obscure are the early signs of the affection, and that even the morbid appearances may be confounded with those which are the result of accident. At the meeting of the British Association in Dublin, in the year 1836, one of its most distinguished members, Mr. Snow Harris of Plymouth, made the following communication to the medical section :—"Sir A. Cooper and many other eminent surgeons had doubted the possibility of union taking place in fracture of the neck of the thigh-bone, within the capsular ligament. A case had lately fallen under his (Mr. H.'s) notice, which he thought would tend to set the question at rest. It was that of a gentleman who had received an injury by being thrown from his gig ten years ago. He had got up and walked immediately after the accident, but continued lame from that period up to the time of his death. He had been attended by some of the most celebrated surgeons in London, but they had not been able to determine whether there was a fracture of the bone or not, but kept him lying on a sofa for nearly twelve months. The injured limb was shortened, the foot everted, the thigh wasted, and owing to the constant inclination of the body forward on one side, a lateral curvature of the spine took place. Some time ago the gentleman died of disease of the heart; and Mr. Harris, being anxious to examine the parts, removed the acetabulum and a portion of the thigh-bone, which he then presented for the inspection of the meeting. He had found the trochanter higher up than natural, and the neck of the bone shortened; a section of the bone had been made, and the line of union, in Mr. Harris's opinion, was clearly manifest." *

When Mr. Harris exhibited this specimen to the medical section of the British Association which met in Dublin, it excited much interest, first as the individual, the subject of the case, was the celebrated comedian Mr. Matthews, and secondly, as at the announcement of the case it was asserted that it settled in the affirmative the much agitated question, whether the intra-capsular fracture of the cervix femoris was or was not susceptible of osseous union. The writer was present at the communication of this case to the section, and upon the presentation of the specimen expressed his doubts that this case, either from its history or post-mortem appearances, was an example of the intra-capsular fracture, and rather held the opinion that it was one of this chronic rheumatic affection which he has been endeavouring to describe; in which opinion he was most decidedly confirmed upon inspecting the acetabulum, the widening of this cavity, the complete filling up

* See Dublin Journal, vol. viii.

of the fossa which is normally destined to contain the substance called Haversian gland, the shortening of the neck of the femur and depression of the head towards the lesser trochanter, and the ivory deposition on it. In this view Mr. Smith, who had so well described the disease in question, and the hospital surgeons around him, concurred, and Mr. Snow Harris himself quickly became a convert to our views, and we are satisfied from what we observed of his liberality, that we have his full permission to communicate this case in its present form to the profession. The sketch (*fig.* 315) is taken from the cast of the

Fig. 315.

Mr. Snow Harris's case.

head and neck of the femur presented by Mr. Harris to the College of Surgeons, Dublin. The upper part of the head of the femur was exceedingly rough on its surface, and of an oval form from above downwards; the axis of the neck was at right angles with the shaft, and seemed to run horizontally inwards and backwards, so that the length of the fossa which exists posteriorly between the corona of the head and the posterior inter-trochanteric line, was in this case less than a quarter of an inch, a fossa which we know naturally measures two inches. In viewing the oval form of the head, we conclude the movement of rotation must have been impossible; from the shortening of the neck posteriorly, we can infer that the toe and foot must have been greatly everted, and from the depression of the head, to the level of the trochanter, the femur must have been nearly one inch shorter than the other. The lamented individual had not suffered from the disease more than ten years, so that the morbid appearances were not to the same amount as we are accustomed to see as the result of this very slow disease.

The following case is that of an individual who has been, to the writer's knowledge, suffering for many years under this disease.

Patrick Macken, now aged seventy-seven years, was brought up as a postilion and groom, but for the last seventeen years has been quite unfit for service in consequence of his having been afflicted with a very severe pain in his right hip; from the first attack of which he became lame, and ever since the lameness has been slowly but gradually increasing. In every

Fig. 316.

Chronic rheumatic arthritis of the Hip.

other respect his health is excellent, except that he has some wandering rheumatic pains in other joints, particularly in the right shoulder.

He walks with great labour and pain, and now requires the assistance of a stick in each hand (*fig.* 316); in the morning his movements are stiff and confined, but they become freer on exercise; in the evening of a day he has walked much, the pain and stiffness are worse and increased in proportion to the excess of exercise and labour he had undergone in the day. While he remains in bed he rests on the affected hip, and suffers no pain whatever except he suddenly turns himself incautiously. As soon as he gets up and throws his entire weight on the diseased hip-joint, the pain commences; if asked in what particular part of the joint he feels most suffering, he points to the back part of the great trochanter and to a point which corresponds to the situation of the lesser trochanter; he says the pain shoots from these points down the front of the thigh to the knee. These pains are sometimes more severe, and sometimes less, without his being able to assign any cause for these alterations, and he cannot observe that the state of the weather has any influence on them whatever.

As he stands at rest, he throws the weight of his body on the left or unaffected limb, while the right leg hangs in front and slightly across the left, and seems to be at least three inches shorter; he leans slightly back and supports himself on two sticks: as he walks the right foot is considerably everted, and when he moves without sticks (which he accomplishes with the greatest difficulty) he places the whole sole of the foot flat upon the ground. He never, however, ventures of his own accord to move without the help of two sticks, by the assistance of which he is enabled to walk quicker; while moving along thus, the heel of the affected limb does not quite reach the ground, and the lumbar vertebræ undergo great motion. He cannot under any circumstances flex the thigh on the abdomen, so that when he assumes the sitting posture, he is obliged to place himself forwards on the very edge of the seat, the right thigh remaining in the same line as the axis of the trunk, the leg usually flexed and placed under the chair, or across behind the other, and he finds the utmost difficulty in putting on his stockings and shoes. He has scarcely any motion in the hip-joint. When we view the hip in front, and examine it, we see and can feel a considerable bony fulness, corresponding to the horizontal branch of the pubis: the trochanter major seems placed very high up, and is extraordinarily large as if surrounded with ossific deposits. The thigh is somewhat atrophied, being an inch and a half less in circumference than the other, but the calf of the leg is not reduced, and the muscles seem firm; the apparent shortening of the limb, when he rests on the sound one, arises from the lumbar vertebræ being much curved to the opposite side, and the pelvis being elevated on the affected side, while the real shortening ascertained by accurate measurement amounts only to half an inch.

If we place the patient horizontally and attempt to communicate to the hip-joint any movement, as of rotation, flexion, abduction, a well-marked crepitus is elicited, and the range of motion is found to be very limited indeed; a little abduction is admitted; rotation and flexion seem just to a sufficient degree to shew that no anchylosis exists. The movements give some pain to the patient, but we can press the trochanter firmly so as to direct the head of the bone deep against the fundus of the acetabulum, and we can even strike the heel and sole of the foot with violence without giving the patient the slightest sensation of pain.

The anatomical characters of this disease are very well marked. The muscles are usually of a paler colour than natural, and are found not to be so well developed as those of the opposite or sound hip. The fibrous capsule of the joint is greatly thickened, the cotyloid ligament is either ossified or absorbed, and the ligament which completes the notch, and in the natural state gives origin to the ligamentum teres, is usually converted into bone, leaving generally beneath its arch whether bony or not a space for the transmission of bloodvessels to the interior of the joint;* when the disease is fully established the ligamentum teres is altogether removed, the synovial fluid is deficient in quantity, and the cartilage is removed from the bottom of the acetabulum, and upper surface of the head of the femur. If here and there some vestige of the synovial membrane or sub-synovial tissue remain, it is in a highly vascular condition, presenting an intensely red colour. In a case of dissection which Messrs. Smith, Brabazon, and the writer witnessed lately of this disease, we observed that the shortened neck of the femur was entirely surrounded with a number of red villous-looking productions of the synovial membrane. These were of a rounded and conical form, half an inch long and two or three lines broad at their bases. They resembled much in form the long conical papillæ to be seen on the tongue and about the fauces of herbivorous quadrupeds; however, instead of being white and firm they were soft and villous, and of an intensely red colour. The line of the corona of the head was absorbed and excavated in points, and the different foveæ or depressions were completely occupied by these vascular fimbriæ. Still more recently the writer met with a similar specimen which he presented for inspection to the Pathological Society, in which these vascular fimbriæ were equally conspicuous.*

The acetabulum is generally much larger and deeper than natural, and forms a circular cup often two inches deep with a complete level brim, which is sometimes so much narrowed as to render the extraction of the head of the femur difficult. This is the most frequent abnormal appearance the acetabulum presents; but occasionally it is increased in size, and is at the same time very shallow and of an oval form.

When we examine the bottom of the acetabulum we find it widened and not any trace of Haversian gland is left; the interior presents a worn and porous appearance, the cartilage and compact stratum of bone which the cartilage normally covers, having been removed, and in some places where the friction and pressure from the head of the femur have been greatest, instead of a rough and worn porous appearance, resulting from the exposure of the cells of the bone, a dense enamel has been as it were ground into these pores, and here the surface presents the polish, smoothness, and hardness of ivory. This mechanical removal of the cartilage and exposure of the interior of the cells of the bone, and substitution for the cartilage of a dense inanimate enamel, we imagine, are processes which are not confined to the acetabulum; but their results are seen also on those parts of the head of the femur which are subjected to pressure and friction; hence we find the effects of friction, above alluded to, most

* Cruveilhier, livraison iv. p. 1. La presence d'un nerf et d'un vaisseau, ces parties fondamentales de l'organisation, semblent en quelque sorte respectées par les lesions organiques, qu'elles soient ces lesions circulent tout autour, mais ne les envahissent presque jamais, ou du moins les envahissent après tous les autres tissues lorsquelles sont parvenus à leur dernière periode.

* Dublin Journal for March 1839, No. xliii.

upon the upper surface of its head which supports the acetabulum in standing and progression. The form of the head of the bone becomes changed and flattened from above downwards; something like a bending or yielding of the neck of the bone may now be observed, and sometimes the inferior part of the circumference of the head of the femur is so much depressed that the under surface of the head has approached to the lesser trochanter.

Fig. 317.

Upon a cursory examination, it looks as if the " head of the bone were forced downwards by the action of some great pressure from above, and cases have occurred in which at last the head of the femur seemed to have sunk even below the level of the great trochanter, and to be supported by the lesser." *(B. Bell.)*

But besides these which we attribute to the effects of physical causes, there is, in the contemplation of the morbid results of this chronic disease of the hip-joint, sufficient to satisfy us that a very active *vital* process is going on in the interior of the bones, as well as in all the structures around the diseased joint. The thickening of the fibrous capsule, and hyperæmic state of the synovial structures, the exuberant growth of bone which we see around deepening the acetabulum, or surrounding its brim with bony nodules; the enlargement of the head of the femur, so as to make this head assume an oval convex surface, measuring in circumference ten inches and a half, as in the specimen from which the drawing *(fig.* 317) was taken, all these are sufficient proofs that besides the interstitial absorption going on in the interior of the cervix femoris in these cases, a very active condition of the minute arteries exists externally, giving birth to those exostotic deposits which encircle the head and intertrochanteric lines of the femur. It has been remarked, and we think with much truth, that those specimens which have been frequently produced and mistaken for united fracture of the neck of the femur, have been examples of interstitial absorption of the neck of this bone combined with external exostotic deposits; but these mistakes, however, we trust are not hereafter likely to occur.

Section III. *Accident.*—The hip-joint is, of course, like the other articulations, liable to sprains and to contusions. These do not require any special notice here; but fractures and luxations of the bones of this important articulation demand from us full consideration.

I. *Fractures.*—Fractures of the os innominatum may traverse the bottom or fundus of the acetabulum, or some portion of the brim of this articular cavity may have been broken off.

1. *Fracture of the acetabulum.* A. *Fracture of its fundus.*—When fracture of the bones of the pelvis happens to traverse the bottom of the acetabulum, the prognosis is unfavourable, as it is in all cases of fracture of the bones of the pelvis. When this fracture through the fundus of the acetabulum is the consequence of a fall on the feet, knees, or trochanter major of the femur, it sometimes happens that the head and neck of the femur unbroken are driven into the cavity of the pelvis. " Nous avons observé," says Dupuytren, " plusieurs fois, l'enfoncement de la cavité cotyloide par la pression exercée par la tête du femur, à la suite d'une chute sur le pied ou les genoux." In this case, the head of the femur is driven with force against the fundus of the acetabulum, and the latter breaks, and is crushed in, " enfoncé." The most remarkable case observed by Dupuytren was the following:—"The bottom of the cotyloid cavity had been driven in, and the head of the femur had passed entirely into the pelvis. The neck, which had not suffered any solution of continuity, was so strongly engaged in the opening, that, even when making the anatomical examination, I found it very difficult to disengage it, and to reduce this new species of luxation."* As these important remarks of Dupuytren are not accompanied by all the detail that is to be desired, where novel observations are reported, we shall here adduce the following case of fracture of the fundus of the acetabulum, with displacement of the head of the femur into the pelvis. Death occurred on the fortieth day after the injury, from diffuse inflammation. An opportunity was afforded to us of investigating anatomically the precise nature of the lesions in this case.

On the 3rd of December, 1834, a man, named William Sherlock, æt. 26, a painter by trade, was admitted into Jervis-street Hospital, under the care of the late Mr. Wallace. A few minutes before his admission, this poor man had fallen from a ladder, from a height reported to be fifty feet, on the flags of the street. On the next day, the 4th of December, when he had recovered from the insensibility and collapse which had succeeded to the fall, we found him complaining of intense pain of the right hip. He was quite unable to move the right thigh, and would not permit any examination of the hip, as the slightest movement communicated to the limb produced intense agony. The integuments covering the trochanter were discoloured, and there was much swelling around the hip-joint. The right or injured extremity was two inches shorter than the left, which circumstance he attributed to a

* Leçons Orales.

fracture of the femur, which had occurred some years previously. Besides this severe injury of the hip, it was also manifest, from some dyspnœa, cough, and bloody expectoration, that his chest was also injured, but venesection and other suitable treatment having been resorted to, the affection of the chest seemed to subside. His cough and dyspnœa for a time had disappeared, and his pulse fell to 80. On the twenty-third day from the accident, he said he felt that he had caught a most severe and violent cold, from a window having been kept open over his head. On this (23rd) morning, I found him suffering from great difficulty of breathing and violent fits of coughing, accompanied by scanty frothy expectoration. His pulse was 110, and hard, his tongue was brown and dry, his skin was hot, and I learned that these symptoms had succeeded to a rigor. They were attributed by me to pneumonia with acute pleuritis and considerable effusion, of which there were found, on examination of the chest by auscultation and percussion, very evident signs. These were actively combated by the ordinary treatment, but without success. His pulse was generally 120. He had cough, with muco-purulent expectoration, and dyspnœa. He still obstinately refused to permit any accurate examination of the limb to be made. He said his right thigh was now as powerless as at first, but the injury did not prevent him sitting up in bed, when, from the urgency of the dyspnœa, he felt the desire for this position; on one occasion he had himself taken up, and placed for a time sitting up in a chair. On the thirty-third day after his admission, I found that his right leg and thigh had swollen, that he had raved much during the night; and that he had alternate flushings and paleness of countenance, which betrayed much distress. He now complained of pain in the right shoulder. His pulse was 130, small and compressible. He had retention of urine. His temper was irritable; his tongue was red, and morbidly clean and dry. He had much thirst. His lips were pale and bloodless. He died on the 12th January, the fortieth day from the accident.

Post-mortem examination.—There was effusion of pus into the cavity of the right pleura, and the usual results of acute pleuritis; pus also in the cavity of the pericardium, and a thin reticulated layer of lymph on the surface of the heart. An incision made through the soft parts to expose the bones of the hip-joint gave exit to a large quantity of dark brown serum, mixed with pus. This collection of matter extended from the superior part of the thigh, under the peritoneum up to the kidney. The soft parts having been removed, and the bones exposed, it was found that the shaft, head, and neck of the femur were uninjured, but the head of the bone was driven through the fundus of the acetabulum, which was fractured in a stellated manner, having been divided into three portions. The spiculated edges of the cavity protruded into the pelvis to the extent of one inch. They were sharp and hard. Nature had not made the slightest attempt at reparation. The finger could be passed along the neck of the thigh-bone into the cavity of the pelvis, through the perforation in the bottom of the acetabulum. The pelvis had been broken in several places. There was a comminuted fracture of the horizontal ramus of the pubis near its crest. There was another fracture of this ramus at its junction with the ilium, and a fracture through the body of the os innominatum extended from the anterior inferior spinous process to the great sciatic notch.

B. *Fracture of the brim of the acetabulum.*—The superior and back part of the cotyloid cavity, which overhangs the head of the femur, which is called by Soëmmering the *supercilium*, is sometimes broken off, and it follows almost as a necessary consequence, that a dislocation upwards and backwards of the head of the femur shall occur. It is an accident most liable to be mistaken, and most difficult to manage. We believe, indeed, in all the cases which have occurred, that permanent lameness has been the result. In such cases, the luxation of the hip is reduced without much difficulty, but displacement again shortly recurs. In symptoms and effects the case has a strong resemblance to the congenital luxation of the femur. I was once invited by my friend, Mr. Hilles, (now of London,) to see a case of supposed dislocation upwards and backwards on the dorsum of the ilium. I met the late Dr. M'Dowel in consultation on the case. It was as follows:—

Thomas Venables, æt. 25, on the 4th of October, 1834, received a severe injury of the right hip-joint in leaping across a ditch, having alighted with force upon the right leg. He fell immediately, and was unable to rise from the ground, or to walk or stand when raised. When the patient was supported in the erect posture, he had the ordinary symptoms of dislocation of the thigh-bone upwards and backwards on the dorsum of the ilium. No crepitus was discovered. On the following morning an extending force having been applied by the pulleys, the head of the bone resumed its natural situation, and the deformity of the limb disappeared. When the patient was visited on the following morning, (the 6th,) it was found that during the night the head of the bone had started from the acetabulum, and that all the former signs of the injury had reappeared. On the 7th, the displacement was again reduced. While the bone was yielding to the force of the pulleys, the writer had the palm of his hand pressing on the great trochanter, as this last advanced slowly towards the acetabulum. He was sensible of a rough grating sensation, which was communicated to his hand, and gave him the idea as if the head of the bone were dragged along a scabrous rough surface. The case proceeded favourably until the night of the 10th, when, owing to the disturbance occasioned by the action of a purgative medicine, the dislocation recurred a third time. It was observed that, although when the patient was supported out of bed the foot was inverted, still the toes could be somewhat everted. An accurate examination being now instituted to ascertain whether a fracture existed, a distinct crepitus was discovered at the upper and back part of the acetabulum. The crepitus and frequent recurrence of the displacement rendered it sufficiently obvious that the brim of the acetabulum had been broken in the above-mentioned situation. The bone was a third time restored to its place, and a strong band placed around the pelvis. In 1836, I admitted the man into the Richmond Hospital. He was at this time unable to walk without the assistance of a crutch. The injured limb was one inch and a half shorter than the other. When standing, he rested it upon the points of the toes, the heel being drawn upwards; but a slight degree of extension was sufficient to restore it to its natural length; and when the man was lying in bed there was hardly any difference perceptible in the length of the two limbs. The breadth of the injured hip was occasionally greater than that of the sound one, and the head of the femur could be pushed upwards easily, and, of course, it always ascended, when the patient endeavoured to support his weight upon it; and in many motions of the joint, the rubbing together of the broken surfaces was distinctly audible.

After having remained in the Richmond Hospital under our observation for two months, he was discharged. Nothing could be devised to make his limb more useful to him. The fracture, therefore, of the supercilium of the acetabulum is a very serious injury, which it behoves surgeons to be well acquainted with. A successful mode of managing such cases has not yet been exemplified.*

2. *Fracture of the superior extremity of the femur.*—The head of the femur is so protected by the acetabulum, that it is seldom or never fractured, except by gunshot injuries. The neck and rest of its superior extremity are, however, we find, subjected to various accidents. The general symptoms of fractures of the neck and upper extremity of the femur are, that the affected limb is shorter than the other, the heel rises to the level of the opposite malleolus, the patella, leg, and foot seem much everted; there is a flattening of the natis, and a fulness of the groin. The patient does not attempt to stand, much less to walk. There is in the part itself, as it were, a conscious inability to support the weight of the body, and even when the patient is lying on a horizontal plane, as in bed, we find that he cannot, by the unassisted effort of the muscles of the injured limb, elevate it from the horizontal level, upon which it lies powerless. When the surgeon, standing at the foot of the bed, seizes the affected limb, and pulls it towards him, so as gradually to overcome the contractile power of the muscles, the limb is restored to its natural length, and if now we resort to the painful expedient of rotating the thigh, crepitus is rendered manifest. Whenever the surgeon relaxes the force by which the limb was restored to its natural length, the shortening, eversion, and deformity of the limb recur. Such are the general signs of fracture of the upper extremity of the thigh-bone. The portion of the bone, called the neck, may be fractured transversely with respect to the direction of its long axis, either within or without the capsular ligament. The first is denominated the *intra-capsular* fracture, the second the *extra-capsular* fracture. Oblique fractures of the neck of the bone are not impossible.

A. *Intra-capsular fracture of the neck of the femur.*—This fracture has been seldom seen in the young subject, but is one of the most common accidents to which elderly people are liable. In such persons many circumstances in their organization appear to account for their great liability to this accident. Their muscles have lost their firmness, and are more or less in a state of atrophy; the trochanter major becomes peculiarly prominent; the neck of the femur yielding somewhat, perhaps, to the weight of the body, descends and loses some of its obliquity. This atrophy of the muscles and bones is not so frequently noticed in the male as in the elderly female, in whom the breadth of the pelvis is greater and the trochanter major more projecting. These observations account sufficiently for the great liability to the intra-capsular fracture, which we notice in the elderly subject, and for the more frequent occurrence of the accident in the aged female than in the male. In the young subject the trochanter major does not project so much, the muscles surrounding the hip-joint are remarkably firm, and when falls on the side occur, the surrounding muscles and the os innominatum share, with the great trochanter, the weight of the fall. The bone in the young subject is better calculated from its form and its organization to resist the effects of falls on the trochanter, and in these fractures of the neck of the femur have been rarely witnessed. In the young subject, too, the neck of the femur is comparatively shorter than in the aged, the angle of union of the neck with the shaft of the bone is more open, and the axes of both neck and shaft are more in a line. The great proportion of animal matter existing in the bones of the young, and consequent elasticity of the bone, render it capable of resisting fracture, while, on the contrary, the comparative deficiency of animal matter, and the consequent redundancy of earthy material in the aged subject, render the neck of the femur friable. In a word, the tissue of the bones in general does not escape, in the aged, that atrophy which affects the rest of the system, and when we recollect the functions which the neck of the thigh-bone has to perform, we shall not be surprised to learn that the effects of this atrophy are more readily felt and seen in this part of the osseous system than perhaps any other. The superincumbent weight of the body and the action of muscles must have a tendency to diminish the obliquity of the neck of the thigh-bone, to render it more horizontal, and consequently less capable of bearing up against the effects of concussion.

Besides the loss of obliquity of the neck of the thigh-bone, we find two other circumstan-

* In the twelfth volume of the Dublin Medical Journal, Mr. R. Smith has made some valuable observations on this case, in relation to the diagnosis of obscure cases of injury of the hip and shoulder-joints.

ces relative to the neck of the bone itself, rendering it very liable to fracture in the aged. I mean the expansion of the cells, by which the strength of the interior of the bone is diminished; and, secondly, by the partial removal by absorption of that long bony arch of compact tissue, upon which in the adult depends, we believe, the principal strength of the neck of the bone (*fig.* 318); and even in many aged subjects, we find the partitions of the bony cells removed, and a large cavity filled with fatty medulla occupies the centre of the cervix femoris. All these alterations obviously weaken this portion of the thigh-bone, and we feel very little doubt but that when the condition of the bone above alluded to exists, even without a fall a fracture may occur. We have noticed specimens of senile degeneration of the neck of the femur in museums, in which the neck of the femur had been removed gradually by absorption, so that the head of the bone had approximated to the trochanters. Such specimens, where the history of the case was unknown, have, we doubt not, been from time to time adduced as evidences in favour of the possibility of bony consolidation of the intra-capsular fracture. These observations on the effects of senile degeneration of the neck of the thigh-bone sufficiently account for the remarkable frequency of the intra-capsular fracture of the cervix femoris in the aged subject from the most trivial causes. The fracture, under such circumstances, should, in our minds, be looked upon more as a stage of morbid alteration, from which no amendment is to be expected, than as an accidental lesion, which the efforts of nature and the aid of surgery can be deemed adequate to repair.

B. *Extra-capsular fracture of the neck, and fracture of the superior portion of the shaft the femur.*—Fracture of the neck of the femur may occur in a part of the bone immediately external to the synovial sac and capsular ligament; it may pass obliquely through the cervix femoris and trochanters, or it may occur in the cellular and spongy portion of the bone which is immediately external to these processes. In all these cases the accident is usually met with in young and vigorous individuals, and is often very severe. There is in these cases much deformity, great eversion of the limb, with considerable shortening and swelling. The fracture having traversed the bone external to the capsular ligament, there is but little to resist the full force of muscular action upon the lower fragment of the bone, while the upper is forced downwards by the weight of the body, so that, from both these causes, much shortening is produced. The muscles are in a state of spasm, and at first resist the surgeon's efforts to bring down the limb to its normal length. The muscles gradually yield to gentle and continued extension, and if now a movement of rotation be communicated to the broken femur, a crepitus can be felt by the hand pressing on the great troch nter, which on rotation of the femur is perceived to move in a small circle. Eversion of the whole limb, in cases of fracture of the upper extremity of the femur, has been noticed as one of its most prominent symptoms, and the cause of it may be fairly attributed to the preponderating influence of the rotators outwards, to which the lower fragment is abandoned when fracture has occurred: the rotators outwards are the glutæus maximus, the three adductors, the pectinalis, the psoas magnus, and iliacus internus, together with the obturators, pyriformis, and other muscles, inserted into the posterior inter-trochanteric line. These muscles are solely opposed by the rotators inwards, which are few and comparatively weak. Notwithstanding the violence of the injury in general, and the deformity, the prognosis in these cases is much more favourable than in the case of the intra-capsular fracture, because in the former a solid bony union of the fragments may be reasonably hoped for.

In considering the symptoms of fracture of the superior extremity of the shaft and of the neck of the femur, whether the seat of fracture be within or without the synovial capsule, it should be recollected that extraordinary cases may occur; thus there may be fracture combined with inversion of the limb. The cause of this inversion, in particular cases, has been sought for, and Mr. Guthrie gives ingenious anatomical reasons for this rare symptom, depending upon the line of direction the fracture may have taken; if, for example, the fracture may have taken such a course as to detach from the shaft of the femur the neck, and at the same time also the lesser trochanter, to which is attached the great rotator outwards, the psoas and iliacus, and if at the same time the attachments of the gemini, obturators, and pyriformis be destroyed, in this case Mr. Guthrie supposes that there is an anatomical reason for the rotation inwards, as the tensor vaginæ femoris and the anterior fibres of the glutæus medius remain unopposed. This explanation is ingenious, but the cause of occasional inversion of the limb in fracture, noticed by Petit, Desault, and all subsequent writers, has not yet, in our mind, been sufficiently elucidated. The phenomenon of inversion of the foot, in cases of fracture of the upper extremity of the femur, is extremely rare, but it has been noticed in the intra-capsular fracture, (Stanley, Smith,) in the extra-capsular fracture, (Guthrie,) and we have ourselves seen it in all these cases. The deviation inwards, says Dupuytren, is so rare, that we can scarcely reckon upon meeting it once in a hundred cases. The surgeon of the Hôtel Dieu attributes much of the rotation outwards in fractures of the neck of the thigh-bone to the action of the adductor muscles, but adds, "il faut dire aussi, qu'on notice presque aucune partie d'une autre cause, qui cependant peut seule rendre compte de la deviation en dedans, et apprendre à y remedier. Je veux parler de l'obliquité des fragmens dans la fracture du col du femur, si le fragment interne se porte en arrière, et l'externe en avant, il y a alors deviation en dehors. Si, au contraire, la fracture est oblique, en sens inverse, la deviation aura lieu en dedans. C'est donc par l'obliquité des fragmens, que ces variétés de deviation peuvent être appreciées."

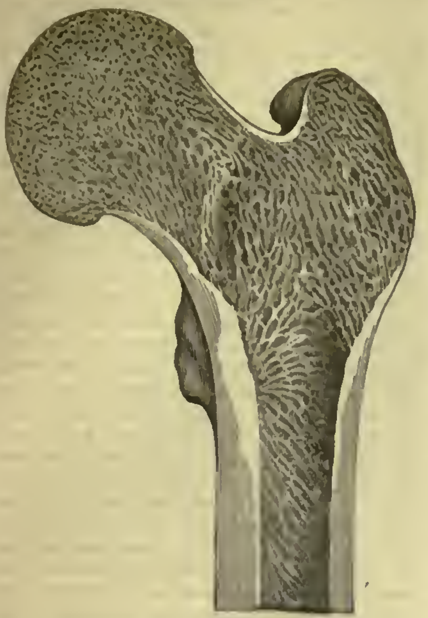
C. *Fracture of the neck of the femur, compli-*

cated with fracture through the trochanter major.—In the thirteenth volume of the Medico-Chirurgical Transactions, Mr. Stanley has remarked that among the more complicated injuries to which the hip-joint is liable, that of fracture of the trochanter major, combined with fracture of the neck of the femur, has, under certain circumstances, a strong resemblance to dislocation of this bone. Whenever the fractured portions of the trochanter can be brought into contact, a crepitus will be perceived, which will enable the surgeon to ascertain the precise nature of the injury; but when from the direction of the fracture, one portion of the trochanter major has been drawn by the muscles towards the sciatic notch, no crepitus can then be discovered. A direct source of mistake will then arise from the positive resemblance of the fractured portion of the trochanter to the head of the femur, the former occupying the place which the latter would do in dislocation, and if, with these circumstances, there should happen to be inversion of the injured limb, the difficulty of diagnosis must be considerably increased. The writer has seen such cases as those alluded to by Mr. Stanley, and when he confined his observations to the consideration of the joint only, he felt all the difficulty alluded to in forming an opinion; but in these cases the limb can in general be brought down to its natural length by forcible extension, and it is possible, too, to flex the thigh on the abdomen, which we know to be impracticable in the case of luxation. In most of the cases which the writer has witnessed of the fracture traversing obliquely the superior extremity of the shaft of the femur, detaching the trochanters, the foot and whole of the injured extremity were everted, a position it were impossible for the limb to assume, were the globular-shaped head of the bone on the dorsum of the ilium, or placed towards the ischiatic notch, and indeed, in the cases which he has seen, with inversion of the limb, the inverted position was not permanent, as when the patient was raised out of bed, and assisted to stand for a few minutes on the sound extremity, the injured limb gradually assumed an inclination forwards and outwards; the inclination, though slight, was always to a degree which it were impossible to give to the limb if the head of the bone were placed on the sciatic notch. Finally, as to the remarkable symptom of inversion of the limb, combined with fracture, we have never seen this inversion so rigid as it is in the luxation; the inversion can be overcome, and we have mostly found that in the cases in which this symptom was noticed, there existed a comminuted fracture of the superior extremity of the shaft of the femur, and the limb, if left to itself, would be found sometimes to be everted, sometimes to be inverted, and generally to possess a remarkable degree of flexibility, yielding to any movements the surgeon wishes to communicate to it. Such has been the result of the writer's individual observations on these cases.

D. *Fractures of the neck of the thigh-bone, with impaction of the superior or cotyloid fragment into the cancellated tissue of the upper extremity of the shaft of the femur.*—We have spoken of a fracture of the neck of the thigh-bone, in which the fracture runs transversely with respect to the direction of the axis of the neck of the bone, and also of oblique fractures of the cervix femoris (Dupuytren). In the former, i. e. the transverse fracture of the neck, the two opposite surfaces of the fragments are generally fairly confronted to each other, and each presents a granular broken surface; but instances have been met with in which there existed an interlocking of these surfaces. A bony spicula or dentiform process, as it were, has been seen to proceed from the broken surface of the superior or cotyloid fragment, and to sink into an alveolar-like depression on the upper surface of the lower fragment; to use the words of Cruveilhier: "L'engrènement des fragmens s'observe moins souvent, peut-être dans la fracture intra-capsulaire que dans la fracture extra-capsulaire. Cependant je l'ai observée plusieurs fois; dans un cas de fracture intra-capsulaire du col, observé sur un adulte très vigoureux, j'ai trouvé un engrènement reciproque formé ainsi qu'il suite le fragment superieur et le fragment inferieur presentaient chacun une cavité, et une avance osseuse; la cavité de l'un recevait l'avance de l'autre et reciproquement, l'engrènement était, qu'il y avait immobilité complete."

In the species of fracture which we are now about to consider, the superior or cotyloid fragment is firmly impacted into the cancellated structure of the superior part of the shaft of the femur. In this case the limb is shortened somewhat, though not much, and consequently the case may be mistaken for the intra-capsular fracture. When, however, the surgeon endeavours to bring the limb to its normal length, and to elicit crepitus, or by rotation of the femur he endeavours to ascertain whether the trochanter moves in a larger or smaller circle, he finds that he cannot elongate the shortened limb, nor elicit crepitus by rotation, nor can he learn anything satisfactory by the movement of the trochanter. In general the fracture is complete of the compact and reticular tissue of the neck of the bone, and the upper fragment is wedged into the lower, as is the fang of a tooth into its alveolus; but cases, we believe, have occurred, in which the fracture of the cervix femoris was incomplete, and had engaged merely the under stratum of the compact tissue of the neck of the bone. To comprehend well what occurs in the partial as well as in the impacted fracture, we should attend a little to the normal anatomy of the interior of the cervix femoris, and the disposition of the compact and reticular tissue, a subject the writer has elsewhere stated has been much overlooked, see Dublin Journal, vol. vi. p. 222, from which we quote the following words: "Let us make a vertical section through the neck of a healthy femur, in the direction of its long axis, and continue it down through the shaft of the dry bone, the section leaving one-half of the femur in front, and the other behind with the lesser trochanter, as has been done in the specimen of the healthy femur of a well-formed adult man, from which *fig.* 318 has been taken. This simple view shews us, that the principal strength of the neck resides in an arch of compact tissue, which begins small

Fig. 318.



where the globular head joins the under part of the neck, but which gradually enlarges downwards towards the lesser trochanter, and even so low as the middle of the femur, where it will be found nearly twice the breadth of the opposite wall of the shaft of the bone; the compact stratum which, scarcely thicker than a wafer, invests the entire of the head, upper part of the neck, and trochanter, seems to have little reference to any design of imparting strength or resistance to this portion of the bone, and the same may be said of the whole of the reticular tissue of these processes, while, on the contrary, the compact tissue of the under surface of the neck seems artfully arranged, if we can so say, so as to give support to the weight of the body in the erect position; hence do we find this compact stratum thrown into an arch, upon which the weight of the body falls, as that of a carriage does on the C spring which sustains it.

When we fall or leap from a height on the feet or knees, the thin upper stratum of the neck, and the whole of the reticular tissue of the bone will first receive, and probably yield somewhat to, the weight, by which some of the force of the shock may be decomposed, but to the bony arch of compact tissue, to which we have alluded, must ultimately be referred any violence which the neck of the femur can receive from any impulse transmitted from above.

We seldom hear of a fracture of the neck of the femur occurring to a healthy adult when he falls with violence on his feet or knees, for the weight of the superincumbent body is thrown in the most favourable manner on the bony arch of compact tissue before alluded to, which from its density and form, and strength derivable from both, it is almost always able to resist; and even a fracture of the acetabulum or rupture of the capsular ligament and dislocation are accidents more likely to happen under these circumstances.

But, on the other hand, let us suppose a person to fall on the trochanter major, which is resisted by the ground, while the weight of the pelvis, &c. acting obliquely on the under surface of the neck, will have a tendency to bring the neck of the femur into a straight line with the shaft of the bone, or in other words, to efface its obliquity; here the compact tissue, so often alluded to, receives the force from below in a most unfavourable manner, and this tissue cracks across, and if no more happens for the present, we shall have the simplest form of partial fracture of the neck of the femur.

While circumstances are in this state, we can conceive the possibility of a patient being able to stand after such an accident, and even walk for some distance; and when examined by the surgeon, we can understand how the latter, as it has often happened, might be deceived into the opinion that there was really no fracture. Again, we can easily imagine how under such circumstances an awkward movement or a fall may render the fracture complete, or how, from a severe secondary injury, or even the continued action of the first impulse, somewhat varied in its direction, the upper fragment of the broken neck of the femur could be wedged into the cancelli of the shaft.

Anatomical characters of fracture of the neck of the thigh-bone.—In those cases in which opportunities have occurred of making recent anatomical examinations of those who have died shortly after having suffered fracture of the neck of the thigh-bone, blood has been found extensively extravasated beneath the skin, among the interstices of the muscles, and we find the line of the fractures through the trochanters and upper portion of the shaft of the femur itself marked out by blood in a coagulated state, which had insinuated itself into and among the interstices of the broken bones. When we examine a case of intra-capsular fracture which had taken place a long time previously to the death of the patient, very remarkable changes in the structures around the joint are noticed. The muscles, when compared with those of the opposite side, are more or less atrophied. This observation, however, only applies to the greater number of the muscles around the hip-joint, as some of the smaller ones (in cases of ununited fractures of the neck of the thigh-bone of long standing) are usually found to have undergone a considerable change in their appearance and structure; of all these, the obturator externus seems to be the most changed and thickened. This is easily accounted for, when we recollect that when the neck of the femur is fractured, there is a strong tendency in the muscles around the joint to drag up the femur, and cause its shortening; indeed, the capsular ligament and the obturator externus alone resist the ascent of the head of the bone on the pelvis. The tonic force of the muscles has constantly this tendency to elevate the femur on the dorsum of the ilium, and when the patient begins to walk, and to throw his weight on the fractured limb, then it is more particularly that the power of the obturator externus is called into action to restrain the ascent of the trochanter major, which is kept downwards by the obturator and by the strength of the capsular ligament, which undergoes a corresponding change of structure. The capsular ligament has been found semi-cartilaginous, and occasionally even spiculæ of bone have been found in it; we have also known it to be much elongated, so as to allow the lower fragment to ascend much on the dorsum of the ilium. We have found the capsular ligament usually entire in old cases, but occasionally the bursa, which exists in front of or under the psoas muscle, seems to have freely communicated with the interior of the joint. In some cases the natural thickness of the capsule is not much increased; in others it is very considerably so. In one of the cases alluded to by Mr. Colles, the capsular ligament was a quarter of an inch thick, in some places half an inch, and it had, at the same time, a firmness of texture which might be termed semicartilaginous. Two or three particles of bone were found in it. The synovial membrane, where it meets the neck of the femur, has been frequently found lacerated in recent cases; in older, inflamed, and in older still, adhesions of the synovial structures to each other have been observed. Thus the head of the fractured femur has been found adherent to the acetabulum, and we have frequently found filamentous adhesions between the synovial membrane of the neck of the bone and the interior of the synovial lining of the fibrous capsule. The synovial membrane, in the normal state, where it invests the narrowest part of the neck of the bone, is thrown into longitudinal plicæ or folds; some of the lowest and most distinct of these are denominated by Weitbrecht "retinacula." We do not believe that this accurate anatomist gave this name to these fibro-synovial folds with any practical knowledge of the functions which they occasionally perform in cases of fracture; but we know very well by experience that, in recent cases of the simple intra-capsular fracture of the neck of the femur, it very frequently, if not generally, happens that, although the neck of the femur is broken transversely with respect to its longitudinal axis, the cylinder of fibro-synovial membrane, which is reflected over the neck of the bone, is sometimes left unbroken, or is only partially lacerated. The fibrous periosteum, which is here added to the synovial investment of the neck of the femur, strengthens much this part of the membrane, and both together, in cases of intra-capsular fractures, serve the purpose of keeping nearly in apposition the broken fragments; and in cases in which the greater part of this cylindrical investment of the neck of the bone remains entire, or nearly so, the unbroken membrane and the vessels which pass along it must be the medium of vascular communication between the fragments.

The phenomena which extra-capsular fractures present are not unlike those which are the result of fractures elsewhere of the femur. We may remark, however, that one of the results of this lesion of the neck of the femur (as it is, indeed, of almost all other injuries or alterations of structure of this part of the bone) is, that the posterior part of the neck of the femur is diminished one-half in its normal length; the posterior inter-trochanteric ridge of bone approaches to within half an inch of the circular line which marks the junction of the head and neck of the bone. A large quantity of callus is usually thrown out in the line of the extra-capsular fracture, and the trochanter major becomes much deformed by it, and the neck so much shortened, that there is danger of the motions of the hip-joint being interfered with.

In recent cases in which intra-capsular fracture had occurred, little or no change has been observed worth noticing; but in old cases several phenomena of importance present themselves. 1st, In some cases we find a false articulation to have been formed; 2dly, there is union of the broken surfaces of the upper and lower fragment by means of ligamentous bands; 3dly, it is reported that complete bony union is effected, but the controversy upon this subject can scarcely be said to be yet terminated.

Very soon after intra-capsular fracture has occurred, the surfaces of the broken fragments undergo changes; they are smoothed off by the power of the absorbents, or are mechanically rubbed down by the friction of the broken surfaces, or by both these processes combined. In general the neck of the femur disappears altogether, and the basis of the head of the bone corresponds to the level of the circular brim of the acetabulum. The surfaces are generally brought into contact by the muscles, and frequently adhesions are formed between the neck of the bone and the internal surface of the capsular ligament, which, as has already been remarked, is greatly thickened; an oily fluid, resembling natural synovia, is shed over the broken surfaces, and here are all the elements of a false articulation present. The trochanters are, in consequence of the removal of the neck of the bone, brought near to the edge of the acetabulum, and bony growths generally shoot out from these processes and from the inter-trochanteric line posteriorly. These bony projections or vegetations sometimes rise as high as the edge of the acetabulum, and when the patient stands or walks, these bony growths rising up from the trochanter are supposed to afford a prop to the pelvis, and thus to assist somewhat the structures which perform the functions of the false articulation. It has been noticed that, in general, the removal of bone from the upper fragment extends as far as the basis of the head and the level of the circular brim of the acetabulum; but in some cases this fragment has been hollowed out. Again, in obedience to influences which we cannot explain, it has happened that the lower surface of the upper fragment formed an uniform convex surface, looking downwards, and corresponded to a large excavation formed in the substance of the great trochanter. This, we find, occurred in one of Mr. Colles's cases: the lower surface of the upper fragment was convex, and covered with spots resembling ivory, while the upper surface of the lower fragment was widely expanded into a cup. We have, in our museum, a very remarkable specimen of this abnormal condition of the hip-joint. The upper or cotyloid fragment seems united to the acetabulum by an imperfect anchylosis, while the lower surface of this fragment represents perfectly the half of a sphere looking downwards; the neck of the femur has been entirely removed, and a cup is hollowed out in the great trochanter to receive the convex surface of the upper fragment above alluded to. This surface, as well as the cavity formed in the trochanter, have the polish and hardness of ivory. The history of the case, as to how the functions of the joint had been performed, is unknown. The patient died in the Richmond Hospital, under the care of Dr. Hutton, of a disease unconnected with the chronic affection of the hip-joint. In the examination of old cases of intra-capsular fracture, we have found the capsular ligament short and strong, as already mentioned, and that it retained the trochanters close to the brim of the acetabulum, the cervix femoris having been altogether removed. In a case which Mr. Brabazon and the writer examined lately, of an old woman who had fractured the neck of her femur several years before her death, and in whom there was shortening of the extremity for two inches and a half, the neck of the femur had altogether disappeared to its base The surface on the internal part of the shaft of the femur, from which the neck of the bone nominally springs, was plane and smooth, and no vestige even of the lesser trochanter existed. The under surface of the globular-shaped head of the femur was removed to the exact level of the brim of the acetabulum, in which the remainder of the head was still retained by an inter-articular ligament, which seemed to have been reduced to the structure of loose cellular membrane. The acetabulum of this side, too, was evidently smaller than that of the opposite side, and the cartilage covering it, and that also investing the remnant of the head of the bone, were partially removed. From want of use, it would appear that all these parts were in a state of atrophy. In this respect there was a correspondence between the internal and external structures of the broken limb, for the whole extremity was deformed, shortened, and, as is usual, much reduced in size when compared with the opposite limb. Union by means of a ligamento-cartilaginous substance is by no means uncommon. In this case, as in almost all others, the neck of the thigh-bone altogether disappears, and the trochanters are brought up to the level of the acetabulum, which still retains the remnant of the head of the bone. The broken surfaces are united closely enough to each other by a fibrous substance, and this union is sufficiently analogous to that which we frequently see in cases of fractured olecranon or patella.

We have spoken of a species of fracture which is called the *impacted* fracture. In this case the femur is broken generally at the basis of the neck, not far from the inter-trochanteric lines: sometimes it is only the under part of the neck which is broken, and then the fracture is only partial; but generally the compact tissue all round this portion of the neck is, by an accident, cracked across, and the superior fragment, that is, the whole of the cervix femoris, is impacted into the cellular structure of the superior extremity of the shaft of the femur (*figs.* 319, 320). The limb is shortened half an inch, and in general everted. In the Dublin Hospital Reports, vol. ii. Mr. Colles has given a good delineation of this species of fracture. In Sir A. Cooper's work, also, similar specimens may be seen of this impaction of the upper fragment. " La realité de ce fait interessant" seemed new to the editors of Dupuytren's " Leçons Orales," in 1832, in which we find it stated that the superior fragment of the broken neck of the thigh-bone is sometimes driven into the thickness of the spongy texture of the superior extremity of the inferior fragment, and the consolidation is effected readily enough. To conclude in the words of the Leçons Orales: " plusieurs pièces d'anatomie pathologique, tirées du Museum de l'Hôtel Dieu, et représentant les fragmens ainsi consolidés, ont été montrées à l'amphithéâtre, et ont convaincu chacun de la realité de ce fait interessant. Il est utile de noter cette cause de deviation; elle peut rendre compte, suivant les cas, de quelques faits exceptionnels de deviation du pied en dedans dans la fracture du col du femur, faits exceptionnels, qui ont été observés par plusieurs auteurs."* In the museum of the Richmond Hospital we have some specimens of this fracture. *Fig.* 319 represents a section of the supe-

Fig. 319.

rior extremity of the femur of a woman who met with this species of fracture. The history of her case, as recorded in the catalogue, is as follows:—" Mary M'Manus, æt. 52. Fracture of the neck of the femur external to the capsule. The upper fragment has been driven down, and has become firmly impacted in the cancelli of the shaft of the bone. The trochan-

* Leçons Orales, tom. ii. p. 100.

ter minor is split, the fissure passing at right angles with the body of the femur. The descending ramus of the pubis was broken obliquely, the fracture passing downwards and inwards from the thyroid foramen. There was a large effusion of blood into the crushed cancelli of the bone. The patient, from whom the preparation was taken, was thrown down by a cart loaded with hay. The horse and cart passed over her. The injured limb was shortened three quarters of an inch, the foot was everted, and the slightest motion was painful. She died on the fourth day after the occurrence of the accident, having never recovered from the shock." Another specimen (*fig.* 320) shews

Fig. 320.

this species of fracture in the case of a woman who survived the accident. "Alicia Sherlock, æt. 64. Section of the head and neck of the femur, shewing fracture of the cervix external to the capsule. The neck of the bone has sunk nearly to a right angle with the shaft. The compact structure which lines the concavity of the cervix has been broken, while the very thin stratum which invests the upper surface has yielded to the force without breaking, but the cervix has sunk into the cancellated texture of the shaft at a right angle, and is now supported upon the lesser trochanter. There is no motion whatever between the broken surfaces, nor the slightest trace of fracture at the central part of the neck of the bone. The injury was produced by a fall on the trochanter. There was but little alteration in the position of the foot, but the tendency was to eversion. The shortening amounted to half an inch, and crepitus was not distinguishable. The patient lived three months and a half after the receipt of the injury." In both these cases we have a confirmation of our opinion, that the reduction of the compact arch of bone which occupies the under surface of the neck of the femur to a thin lamina, predisposes to fracture of this portion of the neck of the thigh-bone. In the case in which the examination was made four days after the accident (*fig.* 319) we find, of course, that there was no osseous deposition around the inter-trochanteric lines, but that, on the contrary, in the case, A. Sherlock, (*fig.* 320), which survived the accident for more than three months, exuberant growths of bone surrounded the seat of fracture, and contributed to form a kind of socket, which received the superior fragment, by means of which the patient was enabled to throw her weight on the injured limb, and even to walk. The lesser trochanter, in most of the cases which we have examined, was greatly increased by bony depositions, and became a prop to support the head, and it is probable that, in these cases, the acetabulum is propped up by the growths of bone from the shaft of the femur. "This is a mode of union," says Mr. Colles, (alluding to the impaction,) "very little inferior to callus in point of firmness, but very different in its nature," and which, he conceives, is peculiar to fracture of the neck of the thigh-bone. In these cases Mr. Colles has found a thin cartilaginous plate every where interposed between the neck and shaft. The new osseous production could have very little assisted in keeping the fractured pieces in apposition, for it was principally thrown out about the trochanters, a small portion only being formed below the neck, yet the motion allowed between the fragments was so very inconsiderable, that it required a close inspection to discern it, so that, in this instance, the new osseous matter contributed very little to the consolidation of the broken bone, the firmness of which (inferior only to bony anchylosis) must therefore be ascribed entirely to the interposed thin plate of cartilage. In one of Mr. Colles's cases, No. XI. a vertical section shewed that the neck had been fractured near to the trochanters, and lay across the top of the shaft; its broken extremity being in contact with the outer plate of the shaft. The external solid walls of the neck were very thin.* In a specimen of fracture of the cervix femoris, which we possess in our museum, the neck of the bone has been broken at its basis, near the inter-trochanteric lines, and was impacted nearly transversely into the cancellated structure of the shaft of the femur, and the force of the fall was so considerable that the upper fragment has absolutely penetrated the outer wall of the trochanter, and would have been in naked contact with the tendon of the glutæus maximus, had it not been for the existence of the bursa there situated.

From the specimens that we have examined, and have in our possession, we entertain no doubt but that solid bony union may take place between the impacted cervix femoris and the superior extremity of the shaft of the femur. In all cases of the impacted fracture, when the patient had survived the accident for a month or more, whether the union was complete or incomplete, exuberant growth of bone had sprung from the inter-trochanteric lines.

Does bony consolidation of the intra-capsular fracture of the cervix femoris ever occur?— This question has for the last twenty years been

* Dublin Hospital Reports, vol. ii. p. 351.

much agitated; Desault, Platna, and John Bell long ago expressed their opinion that a fracture within the capsular ligament would not admit of union by callus. Sir A. Cooper in his Treatise on Dislocations and Fractures (p. 127) says, "In all the examinations which I have made of transverse fractures of the cervix femoris entirely within the capsular ligament, I have never met one in which a bony union had taken place, or which did not admit of motion of one bone upon the other. To deny its possibility and to maintain that no exception to the general rule can take place would be presumptuous, especially when we consider the varieties of direction in which a fracture may occur, and the degree of violence by which it may have been produced; as, for example, when the fracture is through the head of the bone and there is no separation of the fractured ends, or when the bone is broken without its periosteum, and the reflected ligament which covers its neck torn, or when it is broken obliquely, partly within and partly externally to the capsular ligament; but all I wish to be understood to say is, that if it ever does happen, it is an extremely rare occurrence, and that I have not met a single example of it."

Sir A. Cooper's opinions, when they were published, particularly in Paris, excited astonishment, and many observations were made in the clinical lectures and works of the day upon the supposed error of the doctrine, that the intra-capsular fracture of the neck of the thigh-bone was not susceptible of bony consolidation. Messrs. Roux, Dupuytren, and others contended that they had treated many cases of the intra-capsular fracture of the neck of the thigh-bone successfully, and that bony consolidation had been effected, and besides shewed to their classes what they considered as decided examples of such union of this fracture. They did not content themselves by referring to living cases, because these were likely to be questioned, but they produced various specimens obtained by post-mortem examinations of persons who had recovered from the effects of the fracture, but had died of other disease. Some of these specimens were examined by Mr. Crosse, and some were sent to London to Sir A. Cooper, but they failed to convince either Mr. Crosse or Sir Astley that they were true instances of the intra-capsular fracture consolidated by bone. We may say the same of some preparations in the museum of the Royal College of Surgeons, London, which were supposed to be proofs of a bony union of the neck of the thigh-bone subsequent to a fracture within the capsular ligament, but says Mr. Wilson, "I have attentively examined these two preparations, and cannot perceive one decisive proof in either of the bone having been actually fractured." One of these cases was published in the Edinburgh Medical and Surgical Journal as an example of united fracture. The writer has known many specimens adduced as proofs of bony consolidation of the intra-capsular fracture of the neck of the thigh-bone, which, upon examination, were found to have been the result of disease. The neck of the thigh-bone, we know, is greatly shortened when the hip-joint is the seat of that abnormal change which we have stated to be the result of chronic rheumatic arthritis, but in this case the previous symptoms, the history of the case, and when these cannot be collected, the state of the acetabulum and other appearances, sufficiently point out the difference. Again, the effect of senile degeneration of the cervix femoris is very liable to be mistaken for an united intra-capsular fracture. In this, however, the history of the case, the co-existence of the same condition on both sides, the penetration of the interior of the attenuated cellular structure by an oily medulla, and other characters of the senile degeneration, will serve to prevent false conclusions. Lastly, we have also frequently known specimens of the impacted fracture, where the whole cervix has been firmly driven into the substance of the great trochanter, mistaken for examples of bony union of the intra-capsular fracture. The quantity of callus that is in these cases added to the great and lesser trochanters, which encloses the impacted neck of the bone, is calculated on a superficial examination to induce erroneous conclusions, but a section of the bone, as represented in *fig.* 320, will explain the true nature of the case.

Various cases have been laid before the public and read before different learned societies, which have been considered as very decided evidences of bony consolidation of the intra-capsular fracture of the neck of the femur.

Case 1.—In the year 1827 Mr. Langstaff presented to the Medico-Chirurgical Society of London a specimen of what he considered to have been an intra-capsular fracture united by bone. The case was that of a woman who was 50 years of age when the fracture occurred. She was confined for nearly twelve months to bed after the injury, and during the remainder of her life, that is, for ten years, she walked on crutches. On dissection it was found that the principal part of the neck of the femur was absorbed, and the head and remaining portion of the neck were united principally by bone, and partly by a cartilaginous substance. The capsular ligament was immensely thickened and embraced the joint very closely, the cartilaginous covering of the head of the bone and acetabulum had suffered partial absorption, the internal surface of the capsular ligament was coated with lymph. On making a section of the bone, it was evident that there had been a fracture of the neck within the capsular ligament, and that union had taken place by osseous and cartilaginous media. With a view of ascertaining whether there was real osseous union the bone was boiled many hours, which discoloured it, but by destroying all the animal matter it satisfactorily proved the extent and firmness of the osseous connexion, and the vacant spaces occupied with cartilaginous matter. These appearances are represented by a drawing made shortly after boiling.*

Case 2.—Dr Brulalour, surgeon to the hospital at Bourdeaux, sent to London the parti-

* Vol. xiii. of the Society's Transactions.

culars of a case of fracture of the neck of the femur, which were read before the Medico-Chirurgical Society on the 5th of June, 1827. The following is an abstract of it. Dr. James, an English physician, æt. 47, in good health, was thrown from his horse on the 20th of March, 1826. He fell directly on the great trochanter, but got up and walked a step or two, which occasioned such acute pain in the hip-joint that he instantly fell again. On examination immediately after the accident, Dr. Brulalour observed the principal signs of fracture of the neck of the femur. Extension of the limb was kept up for two months so as to preserve it of its natural length. He recovered the full use of the limb so as to be able to walk without any assistance, even that of a cane. Dr. James, on the 20th of December, about nine months after the accident, was attacked with hæmatemesis, which in two days terminated fatally. The post-mortem examination of the right coxo-femoral articulation shewed—1st, the capsule a little thickened; 2d, the cotyloid cavity sound; 3d, the inter-articular ligament in a natural state; 4th, the neck of the femur shortened, from the bottom of the head to the top of the great trochanter was only four lines, and from the same point to the top of the small trochanter six lines; 5th, an unequal line surrounded the neck, denoting the direction of the fracture; 6th, at the bottom of the head of the femur and at the external and posterior part considerable bony deposit had taken place. A section of the bone was made in a line drawn from the centre of the head of the femur to the bottom of the great trochanter so as perfectly to expose the callus. The line of union indicated by the callus was smooth and polished as ivory. The line of callus denoted also that the bottom of the head of the femur had been broken at its superior and posterior part.

Case 3.—Mr. Stanley, surgeon to St. Bartholomew's Hospital, in May 1833 read before the Medico-Chirurgical Society of London a case of bony union of a fracture of the neck of the thigh-bone within the capsule, occurring in a young subject æt. 18. In the examination of the body of this young man, who died of what was considered to be small-pox about three months after the accident of the hip-joint, no other morbid appearances were discovered besides those of the injured hip-joint. The capsule of the joint was entire but a little thickened, the ligamentum teres was uninjured, a line of fracture extended obliquely through the neck of the femur, and entirely within the capsule, the neck of the bone was shortened, and its head, in consequence, approximated to the trochanter major. The fractured surfaces were in the closest apposition and firmly united, nearly in their whole extent, by bone. There was an irregular deposition of bone upon the neck of the femur, beneath its synovial and periosteal covering along the line of the fracture. Mr. Stanley adds, "the foregoing case is remarkable from the occurrence of a fracture of the neck of the femur within the capsule at an early age, and it is, I believe, the only example of it on record."

Sir A. Cooper has published a letter in the Medical Gazette, April 1834, vol. xiv., which is intended to explain his sentiments upon this subject, and to set the profession in general and the French surgeons in particular right as to the conceptions formed of the doctrine he held as to the susceptibility of the bony consolidation of the intra-capsular fracture. In it we find the following case.

Case 4.—Mrs. Powell, aged above 80 years, fell down in the afternoon of the 14th of November, 1824. Sir Astley Cooper saw her soon after, and found her complaining very much of pain in the left hip. The limb could be moved in every direction, but this motion produced excessive pain. She lay on her back with the limb extended, and nothing whatever was done, except to apply fomentations, in the first few days. He believed there was a fracture of the neck of the thigh-bone although the limb remained quite as long as the other, and he could perceive neither a crepitus nor any altered appearance in its position, except a slight inclination of the toes outwards. She had more constitutional irritation than Sir Astley ever observed from a similar accident. She suffered much pain in the hip, and was in consequence obliged to take an opiate, but she got very little rest. She generally had much thirst. There was the utmost difficulty in keeping her bowels open, and she had great pain and difficulty in making water. She had no appetite for common food, and for three weeks appeared so weak that she was under the necessity of taking wine and brandy. For some time all her urine and stools were passed in bed, but not involuntarily, and only because she could not be persuaded to use proper means; in consequence her back became very sore. Latterly she complained of pain in the abdomen, which was very tender on pressure, and even the weight of the bed-clothes was inconvenient. Her tongue became very dry and brown, and the last twenty-four hours she was insensible. She died on the morning of the 19th December about five.

Examination.—This took place at seven in the evening. There was some ecchymosis amongst the muscles about the injured part and in the cellular membrane about the sciatic and anterior crural nerves. The greatest part of the fracture of the neck of the thigh-bone, which was entirely within the capsular ligament, was firmly united. A section was made through the fractured part, and a faint white line was perceived in one portion of the union, but the rest appeared to be entirely bone. This case, says Mr. Swan, beautifully shews the principle which Sir A. Cooper has advocated, viz. that when the reflected ligament remains whole, and the bones are not drawn asunder, the nourishment to the head of the bone continues, and union will be produced even in the short space of five weeks, by only placing the knee over a pillow, and in other respects leaving the case to nature.

We find Mr. Samuel Cooper is of opinion that a bony consolidation of the intra-capsular fracture is proved. He says,* "Sir A. Cooper

* Surgical Dict. p. 575, last ed.

has satisfied himself that osseous union sometimes takes place, and he has in his own collection a most unequivocal specimen of it, which he was kind enough to show me two years ago. The possibility of bony union is now universally acknowledged, but the cure in this way is far less frequent than that by means of a ligamentary connexion."*

It does not appear to us that this question is yet so entirely settled as the last writer's observations would lead us to imagine; although in this city (Dublin) the subject has been carefully investigated for many years, we do not find our museums yet contain a single specimen of the intra-capsular fracture united by bone. In Paris we find Cruveilhier, one of the most eminent pathologists in France, expressing himself in the most unreserved manner, that a bony consolidation of the intra-capsular fracture was impossible. Not unaware, as must be supposed, of the eight cases referred to by his pupil, M. Chassaignac,† (amongst which are those of Langstaff, Stanley, and Sir A. Cooper,) Cruveilhier, to whom Chassaignac's memoir is dedicated, thus expresses himself:—"Je suis porté à considerer comme des cas de deformation de la tête et du col, la plupart, si non la totalité des faits, que l'on invoque généralement pour établir la reunion de fractures intra-capsulaires du col du femur, à l'aide d'un cal osseux, le cal est impossible, parceque les fragmens libres, au milieu de la synovie, ne sont point entourés des tissues chargés de la reparation de la solution de continuité." Thus not content with asserting that bony union is impossible, he further adds that he is convinced from numerous pathological observations, and from experiments on animals, that the ideas of bony union by means of a first, a provisional callus, and then by means of a final callus, are erroneous; he is certain that there is but one and the same callus, which passes through different stages of development, until the ossification is complete; he is of opinion that the ends of the broken bone, no matter how confronted or held together, never are directly united. This union, he thinks, can only take place through the intervention of callus, which is always thrown round the bones where fractured, like a clasp or bony ferule; therefore, he reasons, the cause of the difference between the intra-capsular and extra-capsular fracture, with reference to their susceptibility of bony consolidation, is, that in the first the fragments are as it were abandoned to themselves to effect an union; here there is no bony ferule or clasp possible, while in the second the fragments are in the same condition as in all other fractures; that is to say, they are surrounded by soft parts, by the ossification of which the bony clasp is formed. Thus does he not only deny the possibility of bony consolidation in the case of the intra-capsular fracture, but endeavours to explain why the union is impracticable.

We cannot agree with this eminent pathologist in the observations that the ends of the bones themselves take no part in effecting a bony union, for in cases of impacted fracture alluded to by us in a preceding article, particularly in the case of Sherlock, from which *fig.* 320 has been taken, bony consolidation had taken place in almost the whole line of the fracture, and could only have been effected by the union of the two bony surfaces which were confronted to each other. No doubt the union here was further fortified by the external effusion of new callus, which surrounded the bone at the seat of the fracture. When we reflect on the cases adduced in proof of the bony consolidation of the intra-capsular fracture, we must either disbelieve the facts, or admit that the union is not impossible.

It would have been satisfactory if the test by boiling the specimens of the united fractures had been resorted to in all these cases, as it had been in Mr. Langstaff's; this observation particularly applies to the case reported by Dr. Brulalour, of Bourdeaux. We find in Chassaignac's report of this same case, taken from the memoir sent to the Academy of Medicine of Paris, (Seance du 16 Avril, 1827) in alluding to the specimen in question he says:—"Scié, dans toute sa longueur le cal se présentait sous la forme d'une ligne oblique, raboteuse, d'une couleur moins blanche et d'un consistence un peu moins ferme que le reste de l'os."

We had thus far entered into this much agitated question, when an interesting opportunity occurred to us of making the post-mortem examination of a case of united intra-capsular fracture. The history of the case was this:—

Owen Curran, æt. 70, was for the last five years an inmate of the pauper department of the House of Industry; he was very infirm on his limbs, and his mind was in a state of dotage; on the 1st of August, 1837, while walking across his ward, he fell on his right side; he was unable to rise, and complained of pain in his right hip; he was carried to bed, and was immediately visited by the late Mr. William Johnstone, who was then acting for me as clinical pupil, who found the limb everted, and only half an inch shorter than the other. Mr. Johnstone considered the case a fracture of the cervix femoris, which required no other surgical treatment than that of placing and preserving the limb in a semiflexed position over pillows. The old man suffered but little pain in the injured part, at all events he did not complain of it. In about five weeks after the accident he was raised out of his bed, and when placed standing, he was able to put the heel of the injured limb to the ground. On the 30th of September, that is, about eight weeks after the accident, my friend Mr. Smith entered in his note-book the following memorandum of this case:—"As the patient lies in bed he can elevate the injured limb by the unassisted efforts of its own muscles. The eversion is slight, and the degree of shortening amounts to one inch; no force can bring the limb down to the length of the other. From the history and symptoms, this seems to have been a case of impacted fracture." This man survived the accident one year and nearly

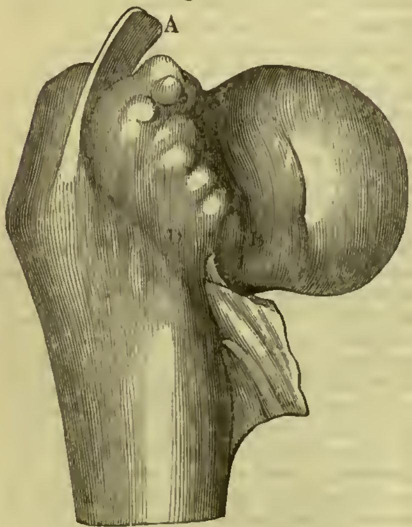
* Loc. cit.

† De la Fracture du col du femur. Par E. Chassaignac, M.D., Paris, 1835.

ten months, during which time he was contented to remain most of the time in his bed, but when placed on his feet, could stand very well, and was able but unwilling to walk. On Tuesday the 20th of May he got an attack of bronchitis, which, the following Friday, terminated fatally. At twelve o'clock, on Saturday, the 25th May, assisted by Mr. Brabazon and some of the pupils of the hospital, I made an examination of the body. The right leg and thigh were much everted. The trochanter major was elevated, and projected much outwards; the degree of shortening just amounted to one inch; the muscles presented a healthy appearance, the capsular ligament was of a yellowish colour, and somewhat thickened. The femur was removed from the acetabulum; this latter cavity presented a healthy appearance, except towards the margin of it; here the cartilage was softened. The round ligament was sound.

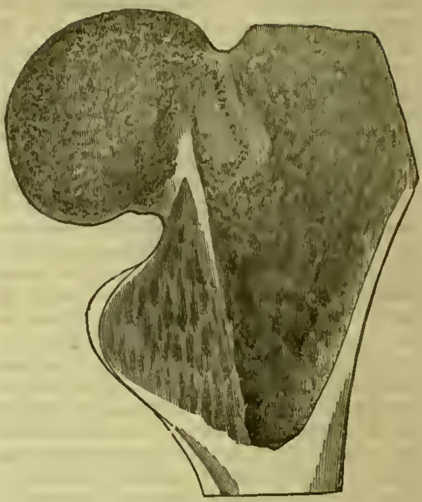
The head and neck of the bone had lost their normal obliquity, and were directed nearly horizontally inwards (*fig.* 321); the cervix presented, both anteriorly and posteriorly, evidence of a transverse intra-capsular fracture having occurred; the globular-shaped head was closely approximated behind and below to the posterior intertrochanteric line, and to the lesser trochanter, so that the neck seemed altogether lost except anteriorly, where a very well-marked ridge of bone shewed the seat of the displacement and of the union of the fragments.

Fig. 321.



This ridge is evidently the upper extremity of the lower fragment of the cervix. The fracture of the neck posteriorly was found to have been closer to the corona of the head than anteriorly, and the fibro-synovial fold in the former situation remained unbroken. A section has been made of the bone through the head, neck, and trochanter; one portion has been subjected to maceration and to boiling; and the bony union has been unaffected by these tests. Scarcely any portion of the neck can be said to have been left.

Fig. 322.



The section, *fig.* 322, shews the compact line which denotes the union of the fragments; the head and shaft seem to be mutually impacted into each other, and almost the whole of the cervix has been absorbed; the line of union is serrated, solid, and immoveable; and the cells of the head and substance of the shaft seem to communicate freely in all places, except where the thin line of compact tissue here and there points out the seat of the welding together of the remaining portions of the head and neck of the femur.

The bone was in its recent state, on the 25th of May, laid before a meeting of the Pathological Society. It seemed to be the universal opinion of the members present that it was a decided specimen of the intra-capsular fracture of the cervix femoris, which had been solidly united by bony callus. This case may be adduced in formal contradiction to the observation and theories of that very eminent pathologist, Cruveilhier. It cannot be said to invalidate the more guarded opinions of Sir A. Cooper, who, in his observations upon this subject, distinctly stated that "he would not be understood to deny the possibility of union, when the bone was broken, without its periosteum and reflected ligament being torn, or when there was no separation of its fractured ends."

Cases such as the foregoing are certainly rare, but they appear to the writer to belong to the class of impacted fractures; they differ from those alluded to in the foregoing article merely in this, that in the former the fracture of the cervix takes place at its basis near the trochanters, and that, in the latter, the fracture occurs near to the head of the bone, and is thus entirely intra-capsular, or rather may be considered as fractures of the intra-capsular portion of the cervix femoris. The question then, viz. does bony consolidation of the intra-capsular fracture of the cervix femoris ever occur? seems to us replied to in the affirmative.

When an impaction of one, or a mutual

impaction of both of the fragments has taken place, then under such peculiar circumstances a firm bony consolidation of the fragments may be expected.

Finally, although this is not the place to speak of the surgical treatment of such cases, we may remark that the most valuable practical information, in our mind, derivable from the discovery of facts like the foregoing, is that the lenient method of treatment, viz. by position alone, and without splints, may be eminently successful, so far as the accomplishment of a firm reunion of the fragments is concerned.

II. *Luxations.*—Luxations of the head of the femur from the acetabulum are by no means so frequent as fractures of the bones which enter into the composition of the hip-joint.

This comparative immunity from this form of accident arises from these circumstances,—that the acetabulum which lodges the head of the femur has great depth, and that the fibrous membranes which secure this bone in the cotyloid cavity have great strength, and restrain within certain limits its movements. Independently, however, of congenital luxations, and of those which are the result of disease, there are six distinct forms of dislocation of the hip-joint to be described as the result of accident alone.

The dislocations of the head of the femur from accident may be classed as follows:—*a.* dislocation upwards and backwards on the dorsum ilii; *b.* directly backwards towards the ischiatic notch; *c.* downwards and inwards into the foramen ovale; *d.* upwards, forwards, and inwards on the horizontal ramus of the pubes. Besides these, of late years two more unusual luxations have been described and verified by post-mortem examinations, viz. dislocation downwards towards the tuberosity of the ischium, and dislocation upwards between the anterior inferior spine of the ilium and the ilio-pubal eminence.

a. Dislocation of the head of the femur upwards and backwards on the dorsum of the ilium.—When the head of the thigh-bone is thrown on the dorsum ilii, the limb on the luxated side is from one to two inches shorter than the other; the thigh is slightly flexed, or a little advanced upon the other, and carried into a state of abduction, and of marked rotation inwards. The patella and inner side of the dislocated limb look directly inwards, and the great toe corresponds to the tarsus of the opposite foot. The great trochanter, carried forwards and upwards, approaches the crest of the ilium and its anterior and superior spine, and forms there a very well marked tumour; the nates raised up by the head of the femur is very salient towards its superior and posterior part. If we make attempts to bring the limb backwards into a state of extension or abduction or of rotation outwards, we find we give much pain to the patient, and that we cannot move the bone in any of these directions. We can, without causing suffering to the patient, augment a *little* the flexion towards the abdomen, and adduct the dislocated thigh, and we can also increase the rotation inwards already existing, or, to use the words of Sir A. Cooper, "when the leg is attempted to be separated from the other it cannot be accomplished, as the limb is firmly fixed in its new situation, so far as regards its motion outwards. The thigh can be slightly bent across the other and towards the abdomen, but extension of the thigh and rotation outwards are impossible." Rotation inwards, on the contrary, is to a great extent permitted, so much so indeed that we have seen the back part of the heel turned forwards, while the toes pointed backwards. During these extreme motions of rotation inwards, if the hand be pressed on the dorsum of the ilium deeply, the head of the femur will be perceived to roll on the ilium, and its trochanter major also can at this time be felt to be nearer than natural to the anterior superior spinous process of the ilium; the trochanter is less prominent than that on the opposite side, for the neck of the bone and the trochanter are resting in the line of the surface of the dorsum ilii. Upon a comparison of the two hips, the roundness of the dislocated side will be found to have disappeared. A surgeon, then, called to a severe and recent injury of the hip-joint, looks for a difference in length, change of position inwards, diminution of motion, and decreased projection of the trochanter.

The explanation of the manner in which the dislocation of the head of the femur upwards and backwards on the dorsum ilii takes place has been the subject of some difference of sentiment. The late Mr. Todd has, in our opinion, given some judicious observations on this subject;* he says, "the elementary work on luxations most generally read and referred to in this country, is Dr. Farrell's translation of Boyer's Lectures, arranged by Richerand. The following is the description therein given of the manner in which the luxation of the femur, at present under consideration, is produced.

"When by a fall from a place, more or less elevated, on the soles of the feet, or on the knees, the thigh is pushed forwards and inwards, the head of the femur, forced towards the superior and external part of the acetabulum, breaks the internal and orbicular ligaments, escapes through the laceration in the latter, and ascends on the external face of the os ilium; but as the part of the os ilium immediately above and at the external side of the cavity is very convex, the head of the femur soon abandons its first position, and slides backwards and upwards into the external fossa of the os ilium, following the inclination of the plane towards the fossa, and obeying the action of the glutæi muscles, which draw it in this direction. The head of the femur, in ascending thus on the external face of the os ilium, pushes upwards the glutæus minimus, which forms a sort of cap for it, and the glutæus maximus and medius are relaxed by the approximation of the points into which they are inserted. The pyriformis is nearly in its natural state; the gemini, obturatores, and quadratus femoris are a little

* Dublin Hospital Reports, vol. iii. p. 397.

elongated. The psoas magnus and iliacus internus are relaxed, as are also the other muscles inserted into the trochanter minor."*

From the foregoing opinions Mr. Todd dissents in the following words:—"To admit of the head of the femur being 'forced towards the superior and external part of the acetabulum,' and of its ascending 'on the external face of the os ilium,' it will be obvious to those who carefully examine the mechanism of the articulation, that the thigh must be extended on the trunk, and the dislocating force applied externally and inferiorly, so as to produce what may be termed an excess of adduction. To the limb assuming such positions, which appear to me to be quite essential towards the production of this dislocation in the manner described by Bayer, some considerable obstacles exist. In the first place, I believe it seldom happens that a person who falls from a height will reach the ground with the thigh extended on the trunk; in the descent the superior power of the flexor muscles will predominate, and at the moment of the application of force to the limb it will be more or less in a bent position. It is scarcely necessary to observe that this circumstance must materially influence the direction in which the head of the bone will be protruded from the articulating cavity.

"Secondly, should the thigh and leg be completely extended at the time that the force is applied, it is probable that the other limb will be extended also, and will thus prevent a movement of the stricken limb inwards beyond a certain point; or, in other words, the opposite limb will prevent that extent of adduction inferiorly which is necessary to remove the head of the femur from the acetabulum, and to admit of its being forced upon the anterior convex surface of the dorsum ilii. But whether the opposite limb be extended or not, it must oppose a certain limit to adduction, if that term can be applied with propriety to a lateral movement of the lower extremity, by which it is carried beyond the middle line of the body.

"Sir Astley Cooper attributes this direction of the limb to the circumstance of the injury being inflicted when the knee and foot are actually turned inwards; however, it appears to me that muscular action is also in favour of the limb assuming this position.

"If it be admitted that the thigh is generally in a state of demiflexion when the force causing this dislocation is applied, it must also be admitted that in this state the pyriformis, obturatores, and gemini have but little effect as rotators, the power of these muscles as such being greater or less, according as the junction of their fibres with the femur approaches or deviates from a right angle; and that the power of the anterior portion of the glutæus medius and of the tensor fasciæ latæ, as rotators inwards, is increased in this position, the angle which their fibres form with the thigh-bone being augmented; thus the last-mentioned muscles will appear to possess much influence in determining the inverted position of the limb, as they must draw forwards the trochanter major and external side of the thigh, at the moment in which the head of the bone escapes from the acetabulum.

"The inclination of the thigh forwards and inwards which constitutes so remarkable a feature of this dislocation, may be attributed partly to the tension of the psoas magnus, the iliacus internus, and the pectinalis, and also to the peculiar form of the surface of the pelvis, to which the upper part of the femur is applied; but certainly not as Mr. Samuel Cooper has asserted, to the tense state of the triceps and gracilis, for these muscles are relaxed."

Anatomical characters of the luxation of the head of the thigh-bone on the dorsum ilii.—The appearances which have been noticed in the anatomical examination of the hip-joints of individuals who, having had a luxation of this articulation, have died very soon afterwards of other severe injuries received at the same time, may be collected from the study of some facts of this nature already published. Of these none gives us a better idea of the recent effects of a dislocation upwards and backwards on the dorsum ilii than the case related by the late Mr. Todd, in the third volume of the Dublin Hospital Reports, which is as follows:—

Case.—In the summer of 1818, a robust man, in attempting to escape from his bedroom window in the second floor of a lofty house, fell into a flagged area, by which accident his cranium was fractured, and his left thigh dislocated upwards and backwards.

The dislocation was reduced without difficulty; however, an extensive extravasation of blood having taken place on the brain, the patient lingered in a comatose state for about twenty-four hours, and then died. On the day after dissection was performed, and the following appearances were observed in the injured joint and the parts contiguous to it.

On raising the glutæus maximus, a large cavity filled with coagulated blood was found between that muscle and the posterior part of the glutæus medius. This was the situation which had been occupied by the dislocated extremity of the femur. The glutæus medius and minimus were uninjured. The pyriformis, gemini, obturatores, and quadratus were completely torn across. Some fibres of the pectinalis were also torn. The iliacus, psoas, and adductors were uninjured. The orbicular ligament was entire at the superior and anterior part only, and it was irregularly lacerated throughout the remainder of its extent. The inter-articular ligament was torn out of the depression on the head of the femur, its attachment to the acetabulum remaining perfect. The bones had not sustained any injury.

Cruveilhier, in the 28th and 29th livraisons of his valuable work on Pathological Anatomy, has given two cases of what he considers to be old luxations of the head of the femur upwards and outwards on the dorsum ilii, which had been left unreduced; the history of these

* Lectures of Boyer, p. 156.

cases was unknown. When we carefully examine the author's account of them, and refer to the eight accompanying drawings he has given of them, doubts may well arise in the mind as to whether these are to be considered congenital luxations, or the result of accidents which had occurred after birth. The author does not himself seem free from suspicion on this matter, for, in commencing his observations on the pathological anatomy of cases of luxation of the femur on the dorsum ilii, upwards and outwards, he says, "elles sont tantôt congeniales, tantôt posterieurs à la naissance. Existe-t-il des différences notables entre les unes et les autres sous le point de l'anatomie pathologique? Il m'est permis d'en douter jusqu'à ce que des faits positifs aient établi le contraire." We have in some of the preceding pages adduced what we have considered positive proofs that the anatomical characters of the congenital luxation of the hip-joint are altogether peculiar, and the appearances either in the living or the dead are in our opinion by no means to be confounded with those which are the result of luxations which have occurred after birth, and have been left unreduced.

When opportunities have occurred of examining the hip-joints of those who have for many years survived a dislocation of the head of the femur upwards and backwards on the dorsum ilii, and which had been left unreduced, remarkable changes have been noticed to have taken place in the bones and surrounding structures.

Muscles.—The muscles of the dislocated hip have been found for the most part in a state of comparative atrophy, and the direction of their fibres has of course been altered by the ascent of the superior extremity of the femur. Among the muscles of the hip-joint the condition of the glutæus minimus has been most dwelt on by authors.

It is stated on the respectable authority of Boyer, that when the head of the femur is dislocated upwards and backwards on the dorsum ilii, it passes between the external iliac fossa, and the little glutæus; that it carries this muscle up, and is as it were capped by it ("pour ainsi dire coiffée"). This muscle, he elsewhere adds, envelopes immediately the head of the femur; it undergoes very remarkable changes; it becomes pale; its fibres disappear almost entirely, and are changed into a fibrous substance which is firm and solid, and which has been sometimes seen converted into bone. Cruveilhier seems to have adopted Boyer's idea as to the change this muscle undergoes in these cases. But if it be true, as we believe it is, that at the moment the luxation we are now considering occurs, the limb is in a state of semiflexion, we shall find it difficult to conceive how the head of the bone in passing can encounter any of the fibres of the glutæus medius or minimus, except it be the most posterior and inferior of them.

Mr. Wallace has, in the Transactions of the College of Physicians in Ireland,* given a very minute and valuable account of a case of dislocation of the head of the femur on the dorsum ilii. The history of the case was unknown; but the state of the parts engaged left no doubt on his mind that it must have been many years since the bone had been dislocated, and from the appearance of the body he concluded that the subject was not less than fifty. The glutæi muscles were in a state approaching to that of atrophy: the posterior edge of the glutæus medius ran exactly over the head of the femur; the texture of the glutæus minimus resembled adeps more than healthy muscular fibre.

The pyriformis did not extend to the trochanter major, but terminated at the distance of some inches from this process, in the new capsule which covered the head of the femur. There was not a trace of the obturator internus, its place having been occupied by a quantity of fat of a peculiarly gristly texture; the quadratus and gemelli were pale and small, and were bisected by an irregular tendinous line. The direction of these muscles between their points of attachment was more oblique than natural; the psoas and iliacus were diminished in size, and their line of direction from the brim of the pelvis to their connexion with the lesser trochanter was altered, as was also the direction of the triceps, pectinales, and obturator externus, all which were carried upwards above the level of their usual course by the elevation of the upper extremity of the femur on the dorsum ilii.

The femoral vessels and nerves having passed under Poupart's ligament, were sunk into a deep fossa, and extended backwards and outwards until they approached the lesser trochanter; they ran more in a serpentine or tortuous course than the corresponding vessels of the opposite limb; the sciatic nerve was flattened, its direction curved, and its vessels were varicose. Its entire structure appeared as if it had been the seat of chronic inflammation.

Ligaments.—In this case a very strong ligamentous fasciculus extended below the anterior and lower part of the ilio-pubic eminence and the lesser trochanter; this must have performed the function of a check ligament to the motion of eversion, for any attempt at turning the limb outwards rendered this ligament very tense. A thick capsule surrounded the new articulating surface of the ilium, and also the head and neck of the femur; although the inner surface of this was smeared with synovia, it had not the smooth aspect of an original synovial membrane. There was imbedded in the capsule a piece of bone of a rounded figure, half an inch in diameter.† There were no remains of round ligament.

Bones.—The great trochanter was thrown forwards with respect to the head of the bone: the anterior internal and inferior portion of the head of the femur was applied to the dorsum ilii, and there was an articulating surface worn

* Vol. V. p. 252.

† Mr. W. imagined this to be a portion of the acetabulum.

on the head of the femur, which marked its point of contact with the os innominatum: the articulating surface thus formed on the head of the femur was very slightly convex, about one inch and a half in diameter, smooth, whitish, hard, and polished, though not uniformly so; for in some parts the bone appeared red and porous; the remaining portion of the head of the femur was not opposed to bone, but applied to the capsule which surrounded the joint; the head had lost its natural rounded form, was very irregular, and deprived of its cartilage, but some parts of it were covered by a substance of the nature of ligament. There were several small pits on the head of the femur, but none of them appeared to have been the depression for the attachment of the round ligament. There was an irregular ossific deposit round the lesser trochanter.

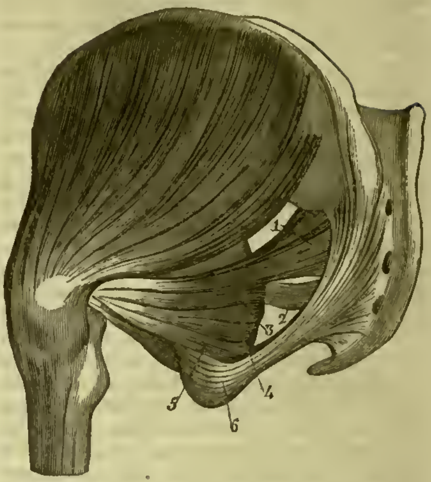
The surface of the ilium, to which the head of the bone was applied, was elevated half an inch above the level of the surrounding bone, so that this cavity appeared to have been formed upon a plate of bone which had been planted, as it were, on the ilium. The superior and posterior portion of the new acetabulum, or about two-thirds of its whole extent, was smooth and polished, and presented a suitable corresponding surface to receive the head of the femur; the aspect of the articulating surface on the ilium was backwards, outwards, and upwards. There was scarcely a vestige of the old acetabulum in its site; there was a superficial fossa, of a triangular form, filled with a fibrous substance, continuous with a surrounding cellular tissue. There was no articular cartilage on any portion of the bones which formed the new joint. There was a deep groove, one inch in depth, formed on the outer side of the ilio-pubic symphysis, for the lodgement of the conjoined tendons of the psoas and iliacus muscles in their passage over the brim of the pelvis to the lesser trochanter.

The pelvis, in this case, was much elevated on the side corresponding to the luxation.

b. Luxation backwards or towards the ischiatic notch.—The space which is called the ischiatic notch is bounded above and anteriorly by the ilium, posteriorly by the sacrum, and inferiorly by the sacro-sciatic ligament (*fig.* 323). It is formed for giving passage to the pyriformis muscle and to the sciatic nerve, as well as to the great arteries, the glutæal, ischiatic, and internal pudendal. Its situation, with respect to the acetabulum in the natural position of the pelvis, is a little above its level, and it is also placed behind it; when the head of the bone is thrown into this space, it is placed backwards and upwards with respect to the acetabulum. Therefore though called the dislocation backwards, it is to be remembered that it is a dislocation backwards and a little upwards.

In this dislocation the head of the thigh-bone is placed on the pyriformis muscle, between the edge of the bone which forms the upper part of the ischiatic notch and the sacro-sciatic ligaments, behind the acetabulum, and a little above the level of the middle of that cavity.

Fig. 323.



1, *Pyriformis*; 2, *lesser sacro-sciatic ligament*; 3, *gemellus superior*; 4, *obturator internus*; 5, *gemellus inferior*; 6, *tuber ischii*.

It is the dislocation most difficult both to detect and to reduce; to detect, because the length of the limb differs but little, and its position is not much changed as regards the knee and foot, as in the dislocation upwards; to reduce, because the head of the bone is placed deep behind the acetabulum, and it therefore requires to be lifted over its edge, as well as to be drawn towards its socket.

The signs of this dislocation are, that the limb is about half an inch shorter than the other, but generally not more than half an inch; that the trochanter major is behind its usual place, but still remains nearly at right angles with the ilium, with a slight inclination towards the acetabulum; the head of the bone is so buried in the ischiatic notch that it cannot be distinctly felt, except in thin persons, and then only by rolling the thigh-bone forwards, as far as the comparatively fixed state of the limb will allow. The knee and the foot are turned inwards, but not so much as in the dislocation upwards, and the toe rests against the ball of the great toe of the other foot. When the patient is standing, the toe touches the ground, but the heel does not quite reach it; the knee is not so much advanced as in the dislocation on the dorsum ilii, but is still brought a little more forwards than the other, and is slightly bent. The limb is fixed, so that flexion and rotation are in a great degree prevented.

The following case of dislocation backwards towards the ischiatic notch affords us a good example of this accident. John Magee, æt. 54, a strong muscular labourer, was admitted into Jervis-street Infirmary, 10th of November, 1831, under my care, in consequence of his having been severely injured in his left hip. He stated that while carrying on his back a sack of potatoes, (about 3 cwt.) he unfortunately placed his foot upon a round stone, which rolled from under him, and he came down with considerable violence on his left knee and side; when raised, he was incapable of walking, and was immediately carried to hospital. The following morning, on examination, we made the following observations: while standing, the body was bent forwards, inclining towards the left or affected side; the left knee and foot were turned inwards; the knee somewhat more advanced and higher than the other, half flexed, and the toes were resting on the ball of the great toe of the opposite foot; posteriorly, the natis was prominent, and its lower fold was obliterated; the distance between the anterior superior spinous process of the ilium and trochanter major was less by one inch than between the same points on the unaffected side; the head of the bone could not be distinctly felt; the limb could be drawn inwards across the opposite thigh, but any attempt to move it in the contrary direction was productive of considerable pain; he complained of much uneasiness in the groin (which was attributed to the tense state of the muscles inserted into the trochanter minor); the patient complained greatly of numbness extending along the posterior and outer part of the thigh and leg to the foot. The bone was, in this case, easily reduced, not, however, without the assistance of the pulleys.

This dislocation is improperly denominated by some, luxation downwards and backwards. Some surgeons, on the other hand, describe cases of this accident, and yet name them dislocation upwards and backwards on the dorsum ilii. Of this class, is an interesting example published by the late Dr. Scott, of the Armagh Infirmary, in the third volume of the Dublin Hospital Reports. The man, the subject of the accident, died thirty-six hours after the injury.

Dr. Scott says:—"When the patient was lifted out of bed and placed erect, the limb retained the posture before described; it was nearly two inches shorter than the other; the knee rested above its fellow; the toes were turned inwards, and lay above the opposite instep. On viewing the hip, the trochanter was manifestly higher on the maimed side than the other. The hollow naturally formed behind that process had disappeared—the buttock was shorter and rounder, but flaccid; the head of the bone could not be felt through the glutæi muscles. No effort of the patient could extend the limb, but he had the power of bending it a little towards the abdomen, by making the opposite leg a fulcrum for the inverted toes to creep upwards upon. The dislocation was reduced, and he died in thirty-six hours afterwards, in consequence of the injury some of the organs in the abdomen received, at the same time that the hip-joint was dislocated." It is stated, that "on dissecting down to the hip-joint, an extensive extravasation of blood presented itself in the cutaneous cellular membrane, covering the trochanter major, and also beneath the fascia lata of the thigh, extending several inches above and below the trochanter. The glutæus magnus being raised from its origin, a considerable extravasation was found in the loose cellular tissue under the glutæus medius. A cavity capable of containing a pullet's egg was also brought into view. This cavity was situated directly where the great sciatic nerve passes under the pyriform muscle; it contained fluid blood; its boundaries were the pyriformis above, the sciatic nerve before (supposing the body upright), the trochanter major, and insertion of the glutæus medius external and posterior; the glutæus maximus directly posterior. Here the displaced head of the femur had been lodged. The fleshy substance of the gemelli and quadratus muscles was found torn across. The pyriformis and obturator internus were perfect; the extravasated blood followed the course of the sciatic nerve deep into the thigh; there was also extravasation between the glutæus medius and minimus muscles. The internal and upper part of the capsular ligament of the joint was ruptured; the external portion remained unbroken. On turning the head of the bone out of its socket, the ligamentum teres was found to have been torn from its insertion into the dimple of the head of the thigh-bone; the brim of the acetabulum, at its upper part, was fractured to the extent of about one inch; the fractured portion lay loose and nearly unconnected; a fracture traversed the acetabulum." In this case it is manifest, from the dissection, that the head of the bone lay beneath even the level of the lower edge of the pyriform muscle, as Dr. Scott states that the boundaries of the cavity (capable of containing a pullet's egg, and filled with coagulated blood,) which no doubt was the new situation that the head of the dislocated femur for a time rested in,—that the boundaries of this cavity were "the pyriformis above," &c. The dissection we consider a valuable one, adding something to our knowledge of the anatomical characters of the luxation into the ischiatic notch; differing, however, in some few particulars, from that of Sir A. Cooper, Dr. Scott's, it is to be recollected, was the dissection of a case in which the bone had been only a few hours misplaced. When we analyse the previous symptoms of Dr. Scott's case, we do not, it must be confessed, read the characteristic features detailed of the dislocation backwards; still the pain the patient suffered along the course of the sciatic nerve rather pointed the attention to a dislocation on the sciatic notch, than to the ordinary one of dislocation upwards on the dorsum ilii, in which the nerve is not, at least directly, interfered with; and the observation added, that "the head of the bone could not be felt through the glutæi muscles," also would lead us to infer that among many of the symptoms this patient laboured under, some were such as would lead us to suspect that the luxation was that backwards towards the sciatic notch, a suspicion that, in the writer's mind, the dissection given by Dr. Scott would fully justify.

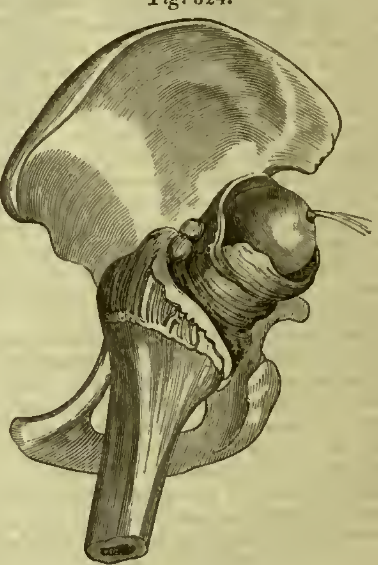
We suspect, also, that one of the cases

published by Mr. Bransby Cooper* as one of dislocation on the dorsum ilii, was rather the dislocation we are now considering, namely, the luxation towards the ischiatic notch. Among some of this patient's symptoms, it is mentioned that the trochanter major was plainly felt behind and a little above the natural situation with respect to the ilium; the head of the bone could be felt neither in the sitting, standing, nor lying posture. Indeed, Mr. B. Cooper himself remarks that, "upon taking into consideration all these diagnostic marks, I was induced to consider the accident a luxation on the dorsum of the ilium; although the head of the bone was not drawn up so high as usual, as indicated by the slight shortening of the limb; and the trochanter major was also drawn further backwards than is usual, in the dislocation on the dorsum, so that, perhaps, this might by some surgeons have been described as a dislocation to the ischiatic notch." Mr. Cooper further adds:—"I doubt, however, if this appellation as applied to a certain variety of dislocation of the hip, does not rather mystify than facilitate our diagnosis, for it leads to the supposition that the head of the bone sinks into the osseous hiatus,—a circumstance which could not occur even in the skeleton itself, from the size of the head of the bone, and much less could it happen in the living subject, when this notch is filled up with ligaments, muscles, vessels, and nerves." This respectable surgeon proposes, therefore, to expunge from the classification of dislocations the luxation into the notch, but to consider it only as a variety of the dislocation on the dorsum ilii, distinguishing the one as a luxation upwards, the other backwards, on the dorsum. To this proposition we cannot by any means assent, for we consider that a dislocation backwards behind the ischium, and to the ischiatic notch which is below the level of the ilium, never can be properly designated a variety of the dislocation on the dorsum ilii, although we might assent to the proposition to consider it a variety of the dislocation backwards. The case as described by Sir A. Cooper, of dislocation on the sciatic notch, we are satisfied is to be seen occasionally, though rarely, in the living; and the dissection made by Sir Astley himself, in which he found the head of the bone resting behind the acetabulum on the pyriform muscle, the preparation of which is to be found in the museum of St. Thomas's Hospital, should, we imagine, place the matter beyond dispute.

Anatomical characters.—We have, says Sir Astley Cooper, a good specimen in the collection of St. Thomas's Hospital, which I met accidentally in a subject brought for dissection. The original acetabulum is entirely filled with a ligamentous substance, so that the head of the bone could not have been returned into it. The capsular ligament is torn from its connection with the acetabulum at its anterior and posterior junction, but not at its superior and inferior. The ligamentum teres is broken, and an inch of it still adheres to the head of the bone. The head of the bone rests behind the acetabulum, on the pyriformis muscle, at the edge of the notch above the sacro-sciatic ligaments. The muscle on which it rests is diminished, but there has been no attempt made to form a new bony socket for the head of the os femoris. *Fig.* 324.

Around the head of the thigh-bone a new capsular ligament is formed; it does not adhere to the articular cartilage of the ball of the bone which it surrounds, but could, when opened, be turned back to the neck of the thigh-bone, so as to leave its head completely exposed.

Fig. 324.



*Luxation in the sciatic notch.**

Within the new capsular ligament, which is formed of the surrounding cellular membrane, the broken ligamentum teres is found. The trochanter major is rather behind the acetabulum, but inclined towards it relatively to the head of the bone. This dislocation, he adds, must have existed, from the appearances of the parts, many years. The adhesions were too strong to have admitted of any reduction, and if reduced, the bone could not have remained in its original socket.

c. Luxation upwards and inwards on the pubes.—This luxation is more easy of detection than any other of the thigh. It happens from a person while walking putting his foot into some unexpected hollow in the ground, and his body at the moment being bent backwards, the head of the bone is thrown forward upon the os pubis.

The limb in this species of dislocation is an inch shorter than the unaffected one; the knee and the foot are turned outward, and

* Guy's Hosp. Reports, Jan. 1836.

* From Sir A. Cooper, pl. iv. on Fractures and Dislocations.

cannot be rotated inwards, nor flexed without causing acute suffering. The inguinal region is the seat of the principal pains, which however from this point extend along the thigh, and are the consequence of the stretching which the anterior crural nerve necessarily suffers as it is raised up at the neck of the bone.

The striking criterion of this dislocation is, that the head of the thigh-bone may be distinctly felt upon the pubes, above the level of Poupart's ligament, and it feels as a hard ball, which is readily perceived to move by bending the thigh-bone. The femoral artery has been usually felt pulsating along the inner side of the head of the bone, but Mr. Smith presented lately to the Pathological Society the cast of a case of this luxation, in which he had noticed that the femoral artery ran in a tortuous manner directly across the head of the dislocated bone.

The great trochanter is drawn upwards and forwards, so as to be situated in the trajet of a line which would pass from the anterior inferior spine of the ilium, downwards and forwards. In a case of a dislocation of this species which was left a long time unreduced, the motion of the knee backwards and forwards was fully twelve inches. The following case was admitted into Jervis Street Hospital, under the care of Mr. O'Reilly, during the time I was one of the surgeons to that institution, and as it seemed to me the best marked case of the kind I had ever witnessed, I beg here to lay it before the reader from my case-book.

Case.—P. Bryan, a powerful man, aged 37, was admitted into Jervis Street Infirmary, Dec. 4, 1828. He was intoxicated when the accident which produced the luxation occurred, and consequently was unable to give any idea as to how the injury was produced.

As the patient lay on his back in bed the affected limb appeared to lie parallel to its fellow, but then there was an eversion of the whole limb, and the foot of course turned outwards. One circumstance particularly caught our observation, viz. the preternaturally arched appearance which the upper third of the shaft of the femur presented; the adductor muscles were full and prominent; there was an unusual prominence underneath Poupart's ligament; the anterior superior spinous process appeared retired.

On making more minute examination it was found that the eversion of the foot was permanent, and we were surprised to find that there was but little difference between the length of both limbs; certainly the injured one was little more than half-an-inch shorter than the sound one. A considerable depression existed where formerly the trochanter major lay; this process of bone was very evident, and could be readily felt about two inches below and somewhat anterior to the anterior superior spinous process of the ilium, and about the same distance internal to it a well-marked prominence in the inguinal region shewed the new situation which the head of the femur occupied; along its inner side were seen and felt the pulsations of the femoral artery. On communicating a motion of rotation outwards, the head of the bone could be easily felt under the soft parts; the nates was flattened; the femur was but little moveable with respect to the pelvis, and any attempt to draw the thigh backwards caused great pain to the patient: to flex it was impossible. A motion of rotation outwards could be communicated to the dislocated femur, but no rotation inwards was permitted. Adduction of the limb was admissible, even to permit the knees to touch. When the patient stood up, he naturally threw his weight on the sound limb, and the affected one was flexed slightly at the knee, and the heel touched the inside of the opposite foot, as in the "first position" of dancers. The reduction of the dislocation was effected in the ordinary method; indeed the rules laid down by Sir. A. Cooper were fully adopted, and in due time succeeded.

Anatomical characters of this luxation.—Sir. A. Cooper gives us an account of the dissection he made of one of these luxations of the femur on the pubes, which had been a long time unreduced; he found the original acetabulum partially filled by bone, and in part occupied by the trochanter major, and both are much altered in form; the capsular ligament is extensively lacerated, and the ligamentum teres broken. The head of the thigh-bone had torn up Poupart's ligament, so as to be admitted between it and the pubes (*fig.* 325). The head

Fig. 325.

*Luxation on the pubes.**

and neck of the bone were thrown into a position under the iliacus internus and psoas muscles, the tendons of which, in passing to their insertion over the neck of the bone, were elevated by it and put on the stretch. The crural nerve passed on the fore-part of the neck of the bone,

* From Sir A. Cooper, loc. cit. plate v.

upon the iliacus internus and psoas muscles. The head and neck of the thigh-bone are flattened, and much changed in their form. Upon the pubes a new acetabulum is formed for the neck of the thigh-bone, for the head of the bone is above the level of the pubes. The new acetabulum extended upon each side of the neck of the bone, so as to lock it in a certain direction upon the pubes. Poupart's ligament confines it on the fore-part; on the inner side of the neck of the bone passed the artery and vein, so that the head of the bone was seated between the crural sheath, and the anterior and inferior spinous process of the ilium.

d. Luxation downwards and inwards into the foramen ovale.—When the femur is in a forced state of abduction, if violence be in any manner applied so as still further to exaggerate this movement, the head of the femur having previously glided from above downwards in the acetabulum to its utmost, applies itself to the interior of the capsular ligament, which it stretches; if the force be continued the capsule soon gives way, and the head of the femur, bursting through the rent, is dislocated and lodged in front of the obturator foramen.

Fig. 326.

Luxation into the foramen ovale.

The symptoms by which we recognize this accident are very well marked, as the limb in this dislocation is two inches longer than the other. The body is bent forwards owing to the psoas and iliacus internus muscles being put upon the stretch (*fig.* 326). The knee is considerably advanced; if the body be erect it is widely separated from the other, and cannot be brought without great difficulty towards the middle line or made to touch the other knee, owing to the extension of the glutæi and pyriform muscles. The foot, though widely separated from the other, is generally neither turned outwards nor inwards, although it varies a little in this respect in different instances, but the position of the foot does not in this case mark the accident. The adductor muscles are elongated and form a round prominent line which extends from the pubes to the middle of the thigh. The foot and the knee are turned outwards because the adductor and the other muscles which execute the movement of rotation outwards are on the stretch and elongated. The thigh cannot be adducted, and when we wish to communicate this movement to the limb the patient feels severe pains because of the tension which the glutæi and rotators outwards suffer. The reason of the flexion of the leg is two-fold; first to relax the hamstring muscles which are put upon the stretch by the dislocation, and to establish an approach to an equality in the length of the limb.

When we examine closely the injured hip, we notice a considerable hollow at the upper and outer part of the thigh where the great trochanter is normally seen projecting, and a depression is noticed below the centre of Poupart's ligament. The head of the dislocated bone can be felt occasionally at the inner and outer parts of the thigh towards the perineum. The position of the head of the bone is below the acetabulum and a little anterior to it. The bent position of the body, the separated knees, and the increased length of the limb constitute the striking and characteristic features of this rare accident.

That excellent practical surgeon, Mr. Hey of Leeds, had not during a period of public and private practice for thirty-eight years seen a case of this accident of luxation downwards and inwards into the foramen ovale, until in the year 1797 three patients were brought into the infirmary of Leeds. In one of the best marked examples of this accident the dislocated thigh appeared much thicker at the superior part than the other; the adductor muscles, it appears, were upon the stretch, and the inguinal hollow we can collect was effaced (perhaps by the tension of the skin and effusion). Mr. Hey says, the head of the bone could not be distinctly felt through the muscles; yet, from the appearance and the touch, it was sufficiently evident that the head of the bone lay upon the great foramen of the os innominatum. It seemed probable that it had passed so far from the acetabulum as to be in contact with the descending part of the os pubis.

There was in this case a considerable hollow at the upper and outer part of the thigh where the great trochanter is usually felt projecting.

The following case of dislocation of the femur into the foramen ovale I saw in Steevens's Hospital, and my friend Dr. Osbrey has obliged me with his notes of the case, which were as follows:—

Michael Murphy, æt. 21, a labourer, admitted June 4th, 1834, under Mr. Colles with dislocation of the head of the femur into the foramen ovale.

He stands with his entire weight upon the sound side, the left thigh flexed on the pelvis, his knee bent, and toes turned out and resting on the ground, from which the heel is raised; the thigh is abducted so that he cannot bring his knees nearer than within five inches of each other, when standing up not within nine, and at this time his toes are thirteen inches asunder; the thigh is wasted, and he cannot support any weight on the limb. When asked to walk without support he places his hand firmly on the knee, and bears his weight on the arm and leg without throwing any of it on the thigh. His pelvis is lower on the injured side, and there is a slight curvature of the spine, the convexity to the same side, in consequence of which there is great apparent lengthening of the limb. The real difference when measured from the symphysis pubis to the point of the inner ankle is two inches and a half, but there is little or no difference when measured from the spine of the ilium; and when the measurement is taken from the tuber ischii the dislocated limb is two inches longer than its fellow. There is considerable deformity about the joint; a deep hollow exists immediately below the anterior spine of the ilium, through which the sartorius runs obliquely, joining a prominent ridge when the muscle is in action. The prominence of the trochanter is altogether lost, and that process can be with difficulty felt. The fold of the buttock is completely obliterated, and there is a fullness towards the upper and back part of the thigh, caused by the head of the bone, which can be felt through the adductor muscles, and seems to be situated further inwards than is usually described in this accident. He states that he received the injury five weeks ago; he was thrown down on his right side obliquely against a wall, by a horse running away with a cart, and the wheel of the cart passed over his left hip above the trochanter; he felt great pain at the time which was chiefly referred to the inside of the knee. He was carried home and nothing was done for him for a fortnight, when he went to a hospital, where several attempts were made at reduction; all, however, failed, and after remaining there a fortnight longer he came up to Dublin in the state above described.

On the 12th of June two attempts to reduce the bone failed altogether, and the man returned to the country.

Anatomical characters.—It seems probable that the head of the dislocated femur passes so much forwards and inwards from the acetabulum as to be in contact with the inner margin of the thyroid foramen, where this foramen is completed by the rami of the ischium and pubes. The convexity of the great trochanter has the acetabulum behind it, and the lesser trochanter is placed immediately external and anterior to the tuberosity of the ischium. The ligamentum teres and lower part of the capsular ligament have been torn through, and the head of the bone "become situated in the interior and inner part of the thigh upon the obturator externus muscle."

We have, says Sir Astley Cooper, an excellent specimen of this accident in the collection of St. Thomas's Hospital, which I dissected many years ago. The head of the thigh-bone was found resting on the foramen ovale, but the obturator externus muscle was completely absorbed, as well as the ligament naturally occupying the foramen now entirely filled by bone. Around the foramen ovale bony matter was deposited so as to form a deep cup, in which the head of the thigh-bone was inclosed, but in such a manner as to allow considerable motion; and the cup thus formed surrounded the neck of the thigh-bone without touching it, and so enclosed its head that it could not be removed from its new socket without breaking its edges. The inner side of this new cup was extremely smooth, not having the least ossified projection at any part to impede the motion of the head of the bone, which was only restrained by the muscles from extensive movements.

The original acetabulum was half filled by bone, so that it could not have received the ball of the thigh-bone if it had been put back into its natural situation (*fig.* 327). The head of the thigh-bone was very little altered, its articular

Fig. 327.

*Luxation into the foramen ovale.**

* From Sir A. Cooper, pl. ii.

cartilage still remained, the ligamentum teres was entirely broken, and the capsular ligament partially torn through. The pectinalis muscle and adductor brevis had been lacerated, but were united by tendon. The psoas muscle and iliacus internus, the glutæi and pyriformis, were all upon the stretch.

c. Cases of unusual dislocations.— In Guy's Hospital Reports we find the account of two cases of dislocation of the head of the femur upwards and outwards towards the anterior superior spinous process of the ilium.

In the first of these cases, detailed by Mr. Morgan, the affected leg (the left) was shortened to the extent of at least two inches, the foot was excessively everted, so much so as almost to give the toes a direction backwards. The injured limb had a tendency to cross that of the opposite side, so that the heel was thrown over the instep of the opposite foot; nevertheless when the feet were placed side by side, they remained in that position. The limb was susceptible of all the natural motions to some extent, with the exception of rotation, but the man complained of great pain when under examination. The projection of the trochanter major was entirely lost, whilst the luxated head of the bone might be felt under Poupart's ligament, just below and to the inner side of the anterior superior spinous process of the ilium, and it apparently lay between the anterior and inferior spinous process of the ilium, and the junction of this last bone with the pubes; it thus rested upon the brim of the pelvis, and projected upwards towards the abdomen; the femoral artery was not displaced in this dislocation, but could be traced taking its usual course, and consequently situated to the inner side of the displaced bone.

In this case a speedy reduction of the dislocated bone was effected, but in the second case I have alluded to, the bone was left unreduced for years. We are indebted for the publication of the whole case, accompanied with the dissection, to Mr. Bransby Cooper, who tells us that the preparation which illustrates the accident the patient suffered from, was presented to Sir Astley Cooper, by his friend Mr. Oldknow of Nottingham, and the bones are preserved in the museum of Guy's Hospital. The subject of the accident was a lunatic, aged 28, and as far as we can learn from the detail of the case given, his symptoms were very much those which Mr. Morgan's patient presented before the dislocation was reduced.*

Upon dissection it was found that the old acetabulum was deprived of articular cartilage, and was in part filled up by bony deposit, so as to be rendered wholly unfit for the reception of the head of the femur. The new acetabulum was nearly directly above the original cavity, and was bounded on the outside by the two anterior spinous processes, and on the inside by the line of junction of the ilium and the horizontal branch of the pubes, that is to say, by the ileo-pubal eminence. The form of the new cavity for the reception of the head of the femur was very like the natural acetabulum, but not quite of equal dimensions; it is protected above by a growth of bone which overlapped the head of the femur, and must have formed the principal point of support of that bone. The inferior part of the new acetabulum was the most deficient. The trochanter major sunk partly into the old acetabulum, and polished points on both the old and new acetabulum indicated where the head of the femur and trochanter major played in the various motions this imperfect joint enjoyed.

We are not informed how the muscles were altered from their normal state, but may infer that most of them were more or less atrophied; it is probable, however, that both the obturator externus and internus were put much upon the stretch, and retained the bone more or less downwards. It would have been interesting to have learned the precise situation of the rectus femoris, tensor vaginæ, and sartorius, psoas, and iliacus, but we can easily imagine that the latter were much shortened, and that they were raised up from the pubes by the dislocated bone, the tendon of the rectus must have been thrown outwards over the rest of the femur and trochanter major. The head of the femur was altered from its original figure, so as to be adapted to the new acetabulum, portions of it being diminished where it did not come in contact with the new cavity, so that its spheroidal figure was lost. The periosteum of the femur, as well as of the new acetabulum, assisted in forming the new capsular ligament. The articular cartilage of the head of the femur has been absorbed, and the same porcelain-like concretion, as is seen in the acetabulum, is provided at corresponding points. From the form of the articulating surfaces, and the fixed position of the femur, both at the head and the trochanter major, it will be observed that no other motion than flexion could be permitted, and even that motion, from the closeness of the attachment at the trochanter, but to a limited extent.

Luxation of the head of the femur downwards and backwards. — This luxation may be considered as a very rare accident. When the last edition of Sir A. Cooper's work on Fractures and Luxations was published, the baronet had not seen such an accident, as he remarked, "it is to be remembered that there is no such accident as a dislocation of the hip downwards and backwards."

Dupuytren says, "I have only twice or thrice seen this luxation downwards and backwards. The limb was then twisted inwards, a little elongated, and it was impossible to adjust it to its ordinary place and position, without reducing the luxation, which once accomplished, the displacement did not a second time recur."

My friend Mr. Wormald, assistant-surgeon to St. Bartholomew's Hospital, has published an account of an accident of this kind in the Medical Gazette, June 28, 1837, and the preparation, which shews the relative position of the head of the dislocated bone, &c. and the acetabulum,

* Guy's Hospital Reports, January, 1836, p. 99.

is preserved in the museum of the hospital. *Fig.* 328.

Dislocation downwards and backwards.

B, *obturator internus*; C, *trochanter major*; D, *the acetabulum*; E, *obturator externus*; F, *sciatic nerve*; I, *shaft of the femur.*

" A maniac who eluded the vigilance of his keepers, leaped from a third story window. Besides dislocating his thigh, he received other injuries, of which he died in about an hour.

" On examining the dislocated limb, it was found considerably shortened and inverted, forming about half a right angle with the body, the shaft of the femur crossing the symphysis pubis was fixed immoveably in this situation; as the patient was sinking, no attempt was made at reduction.

" Twelve hours after the death of the patient I commenced the dissection, by reflecting the glutæus maximus, when I found some of the fibres of the glutæus medius and minimus ruptured at their posterior edge. The pyriformis and gemelli were also partially torn, but those portions of the tendon of the obturator internus which pass through the lesser ischiatic notch were drawn out, and separated from their connexion with the muscular fibres; the head of the femur presented itself through a rent of the capsule, opposite to the upper part of the tuber ischii above the quadratus, so that the great sciatic nerve was somewhat displaced and pressed against the tuber ischii.

" In this case there was no difficulty in detecting the nature of the injury, as, besides the symptoms already described, the head of the femur could be felt resting on the tuber ischii, covered by the outer edge of the glutæus maximus.

" If this patient had been in a condition to attempt reduction of the dislocation by fixing the pelvis, and employing extension in the direction of the shaft of the bone, at the same time everting the limb, the head of the femur would have been brought opposite the rent in the capsule, and would have been in all probability replaced in the acetabulum without greater difficulty than is usually experienced."

(*Robert Adams.*)

HYPERÆMIA AND ANÆMIA, (ὑπὲρ, *super*; α, negative; and αἷμα, *sanguis*) (in morbid anatomy). These are terms employed to denote opposite conditions of the various membranous or parenchymatous textures of the body as regards the quantity of blood contained in their bloodvessels; the former, as its derivation denotes, indicating a superabundant supply of blood, the latter a deficiency of that fluid. They are useful terms to the anatomist, inasmuch as they express simply the state of a texture, without any theory being involved respecting the cause or origin of that state. It ought always to be the first business of the anatomist to observe carefully the actual condition of the parts submitted to his examination; this having been done, he should search diligently for some cause, mechanical, chemical, or vital, which will satisfactorily account for the phenomena.

All vascular textures, it is obvious, are liable to these conditions; and it is equally evident that the relative frequency of their occurrence in different textures will coincide with the natural facility of the flow of blood to or from them, as well as the quantity of blood contained in them in the normal state. Thus the lung or the spleen is favourable for the formation of hyperæmia, as well from the large supply of blood in each as from the free communication between their respective arterial and venous systems, and between the ramifications of vessels of the same kind.

A bleached state of the same organs may be taken as a good example of the opposite condition, or anæmia; but the most complete anæmia is, of course, to be found in organs or tissues which, in the natural state, contain but a small quantity of blood.

It is important to notice that hyperæmia may occur independently of disease and altogether as a cadaveric phenomenon, and there is no mistake more frequently committed by the incautious observer than that of attributing to the influence of a morbid process during life appearances which simply result from the ordinary physical laws which death has allowed to exert full sway over the tissues. Indeed, it is only since anatomists have ceased to regard every instance of an unduly injected tissue as a diseased one, that valuable practical conclusions have been drawn from post-mortem observations.

We may pronounce hyperæmia not to be morbid, when it is found to occupy only the most dependent parts of organs, the blood having deserted the vessels of the more elevated parts. At every post-mortem examination we have abundant examples of hyperæmia of this kind; if the body have been laid on the back, as is usually the case, the whole of the skin of that region is largely injected with blood; the subcutaneous cellular tissue is in a similar condition, and the adjacent muscles more or less so likewise. The blood in these cases is chiefly contained in capillaries and veins, the ramifications of which will be found fully injected. The dependent parts of all the vascular tissues and organs of a body thus placed, exhibit similar appearances. The scalp on the occiput, the posterior lobes of the brain, and the cerebellum are much more injected than the anterior parts of the same textures. The posterior parts of the lungs, of the stomach and intestines, of the spleen, liver, and kidneys exhibit the same state of vascular congestion. That this results altogether from position and the blood in the vessels obeying the universal law of gravitation, may be clearly proved by reversing the position of the body, when after a little time the blood will desert the former dependent but now elevated parts, and those portions of the texture which before were almost devoid of blood from their elevated position, now have their vessels filled with it.

When hyperæmia results from a mechanical obstacle to the circulation, it is not accumulated at one part of an organ or viscus, but all parts appear equally gorged with the blood. In certain diseased states of the heart and liver, the intestinal canal presents an example of this general hyperæmia, owing to the mechanical obstacle to the free circulation of the blood in the right heart. The circumference of the intestine is every where reddened by the blood accumulated in its capillaries.

Andral, by whom of late years the term hyperæmia itself was brought into use in morbid anatomy, gives the following varieties of it. 1. Active or sthenic hyperæmia, denoting the state indicated by the ordinary expression *acute inflammation*. 2. Passive or asthenic, resulting from diminished tone in the capillary vessels. 3. Mechanical, from an obstacle to the venous circulation. 4. Cadaveric or post-mortem, being the result of those physical and chemical laws to which all inorganic matter is subject, and to which all organized bodies are also subjected when the vital spark has ceased to animate them.* This last variety, moreover, he subdivides into two genera. *First genus*, hyperæmia produced at the moment of death.—Cause; the contractility of tissue which resides in the small arteries, continuing to act after the heart has ceased to beat. *Second genus*, hyperæmia produced at a certain period after death. This genus comprehends the following species:—1. Hyperæmia by hypostasis or dependent position. 2. Hyperæmia by transudation of the blood or of some of its component parts through the parietes of its vessels. 3. Hyperæmia by chemical affinities.

Anæmia, a term long in use to express a general exsangueous and cachectic condition of the body, is also applied to a local state of exsangueousness. Any cause which would impede or cut off the wonted supply of blood to a part will occasion this condition in it; the diminution in the calibre of the principal artery of an organ, from mechanical pressure or disease in the vessel, or a depressed state of the nervous influence. Hyperæmia of one organ may give rise to anæmia of another, the former as it were attracting the blood away from the latter.

The general condition of anæmia is not unfrequently brought under the physician's notice either as the result of some excessive and long-continued hemorrhage or of some deranged state of general nutrition, giving rise to a deterioration in the quality of the blood, or a general deficiency in the powers of the nervous influence. The surface of the body is pale, the mucous membranes, as far as they can be seen, partake of the same exsangueous state, the secretions are defective and vitiated, the tone of the muscular and vascular systems is considerably diminished, and this state may go on without any specific morbid change in any organ, beyond its participation in the general scanty supply of the blood, or it may co-exist with an organic disease, which, although it may have been at first the result of the primary exciting cause of the anæmia, now serves to increase it, or offers the greatest impediment to its removal.

* Path. Anat. by Townsend, vol. i. p. 15.

HYPERTROPHY AND ATROPHY, (ὑπερ, *super*, α, *priv.*, and τρεφω, *nutrio*), (in morbid anatomy). When any organ or tissue has acquired a certain increase of developement, without any manifest alteration of its natural structure, it is said to be in the state of *hypertrophy*—the increase being due to a greater activity of the nutritive process in the part affected. A familiar example of hypertrophy, although not morbid, is afforded by the augmentation which muscular fibre acquires in consequence of increased action. If the biceps muscle of one arm be actively exercised, while that of the other does not undergo any considerable degree of action, the former acquires a great increase of size, it becomes denser and firmer, and manifests the physical and vital phenomena of the muscular tissue with more than ordinary energy.

There is no texture in the body which does not occasionally exhibit evidence of the hypertrophous condition. The circumstances which favour its production are an abundant and a free afflux of blood to the part, an energetic nervous influence and an increased demand upon the organ, or increased exercise if it be muscular; and indeed these are the almost invariable conditions under which hypertrophy is manifested. The heart becomes hypertrophous under an exalted nervous influence, or from a necessarily increased exercise from the effort to overcome some obstacle to the free circulation of the blood through its cavities; one kidney acquires a great increase of size if the other one be incapable of performing its function. It may be said that the liver is in a state of hypertrophy in the fœtus in utero, for it has a larger supply of blood than in extra-uterine life, and the lungs have not as yet begun to share with it in the office of decarbonizing the venous blood. The bladder also, like the heart, acquires an enormous developement of its muscular coat, when any obstacle obstructs the free flow of the urine from it. The physical condition, then, of a hypertrophous organ differs but in degree from that of the part in its normal state. There are, in general, increase of size, of weight, and of consistence, with more or less alteration of shape consequent upon the former; an increased supply of blood, and a consequent heightening of colour. To judge therefore how far an organ has experienced hypertrophy, the anatomist must carefully compare its present condition, as regards size, weight, colour, consistence, and supply of blood, with the average state of the parts in health.

Atrophy is not only opposite in its nature to hypertrophy, but it results from causes of an entirely opposite kind. A defective state in the nutritive process is its immediate cause:—the affected part shows manifest signs of wasting; it diminishes in size and in consistence; it loses its colour from the deficient supply of blood; its physical and vital properties are manifestly altered, and are fully developed. When the wasting has gone to its greatest extent, the natural texture disappears, or is so altered as to present but few of the characters of its normal condition. As frequent exercise and use favour the production of hypertrophy, so on the other hand disuse and inactivity give rise to atrophy. Neither the vascular nor the nervous systems of such parts afford their wonted supplies; and those physical characters which are present in hypertrophy in an exalted condition, are in atrophy either absent altogether, or but feebly developed. The muscles of paralytic limbs, the hearts of old persons which have been overloaded with fat, the diminution in size and almost total disappearance of the thymus gland in the adult, the diminution of the left lobe of the liver in extra-uterine life, the obliteration and conversion into a fibrous cord of certain disused venous and arterial canals, and the wasting of the optic nerve where the eye is destroyed, are examples of atrophy of every day's occurrence. (See the articles on the morbid anatomy of the different textures and organs.)

(R. B. Todd.)

ILIAC ARTERIES* (so called from their situation in the iliac regions) are three upon each side of the body, viz. the primitive iliac, the internal and the external iliacs; they are the main arteries of the pelvis and the lower extremity.

Primitive iliac arteries *(common iliacs, arteriæ iliacæ primitivæ, s. communes, s. pelvi-crurales;* Fr. *Artères iliaques primitives;* Germ. *Gemeinschaftliche Hüft-pulsadern,)* are two, one on each side: they are vessels of great size, from three-eighths to four-eighths of an inch in diameter, but short, their length varying from one and a half to two and a half or three-quarters of an inch, the arteries being longer or shorter, according to the height at which the aorta divides. They arise from the termination of the aorta, their origin corresponding, as a mean point, to the interval between the bodies of the fourth and fifth lumbar vertebræ, and somewhat to the left of the middle line of the vertebral column; the exact height of their origin, however, varies considerably, ranging in ordinary between the bodies of the third and fifth vertebræ; but they have been found to arise very near to the diaphragm.* From their origin they descend, and at the same time incline outward and backward, forming with each other an acute angle, but more so in the male than in the female subject, because of the greater width of the pelvis in the latter, until they reach a point ranging between the body of the fifth lumbar vertebra and the sacro-iliac articulation,† where they terminate by dividing into the internal and external iliacs. The point of reference usually assigned for this division is the sacro-iliac articulation; but this appears not to be strictly correct, the exact point varying as well on the opposite sides of the same as in different subjects; for the most part the division takes place between the two points, which have been mentioned; at times nearer to one, at times to the other, and according to Velpeau, it usually occurs nearer to the spine upon the right than upon the left side; hence, according to the same authority, the right external iliac artery is longer than the left, and were it possible to ascertain these diversities of origin during life, advantage would result therefrom, inasmuch as the prospect of success in high ligature of the external iliac must be influenced by the height of its origin, and the difficulty of reaching the primitive or the internal iliacs must be increased in the same proportion. These views appear well-founded; the division of the primitive iliac rarely takes place so far outward as the sacro-iliac articulation, and for the most part it is nearer to the body of the vertebra, or higher upon the right than the left side, and therefore the external iliac of that side is usually the longer, but this disposition is not constant; the division of the right primitive artery is not always higher than that of the left, nor consequently the right external longer, and therefore while probability is in favour of the conclusion which the facts stated indicate, it cannot be absolutely relied upon.

The primitive iliac arteries are of the same size, and nearly the same length; the right, however, is considered for the most part somewhat the longer, because of the situation of the

* But little dissection is necessary to display the iliac arteries; the abdominal wall having been divided and thrown back, the peritoneum may be detached from without inward, along with the contained viscus, from the iliac fossa, which having been done to a sufficient extent, care being at the same time taken to leave uninjured the spermatic vessels the vas deferens and the ureter, the iliac arteries will be exposed still covered by their immediate investment.

* Velpeau, who cites Petscho on the authority of J. F. Meckel.

† Bogros.

aorta upon the left side of the spine; Velpeau, however, seems to question the existence of any difference in the length of the two vessels, inasmuch as the right divides generally nearer to the spine than the left, the inclination of their origin to the left being thus compensated, but to whatever extent this view may hold good, it is by no means strictly correct; in fact the length of the arteries, whether comparative or absolute, is far from regular; nor is the preponderance, when present, always upon the same side; the opinion generally entertained is probably correct, the right artery being in the majority of instances somewhat longer than the left; but the writer has found the left the longer of the two, and the same disposition has been observed by J. F. Meckel; this is, however, an unusual disposition.

The relations of the arteries are simple. During their descent they are situate in front of the bodies of the lumbar vertebræ, with the intervening fibro-cartilages, of one, two, or more of these bones, according to the height at which the arteries arise, and also of the lateral part of the base of the sacrum; they are both covered upon three sides by the peritoneum, viz. in front and laterally, the membrane descending upon them from the root of the mesentery; the mesentery itself also and the small intestines are placed before them, and the latter overlap them upon either side. Farther, they are in front of the superior branches of the middle sacral artery and of the sympathetic nerve. That of the right side at its outset is placed before the left primitive iliac vein, which it crosses at its junction with the cava, and partially before the commencement of the cava itself; during its course it is in front of the right primitive vein, at first only partially, but, as it proceeds, covering it to a greater extent, until at its termination it is directly before it.

External to both, but on a plane posterior to them, are the psoæ muscles, the left artery however being nearer to the muscle than the right, between which and the psoas the right primitive vein and the cava intervene, being at the same time posterior to it.

Internal to both at their origin is the middle sacral artery; on the left side the left primitive vein lies along the inside of the artery, but on a plane behind it.

Anteriorly the arteries are crossed at their termination by the corresponding ureter, that duct being interposed between the peritoneum and the vessel, but more adherent to the former. The relation of the ureter to the iliac arteries is not uniform, either on opposite sides or in different subjects; the bifurcation of the primitive iliac may be assumed as the mean point of reference for its transit, the duct descending into the pelvis between the external and internal iliacs, and before the internal; but its precise relation will depend upon the height at which the bifurcation takes place and the side of the body to which it belongs, and hence it very frequently, if not usually, crosses the external iliac upon the right and the termination of the internal on the left.

The artery and vein, the relations of which differ remarkably upon the two sides, the vein being external upon the right and internal upon the left, and upon both posterior, are enclosed within a condensed cellular investment, prolonged upward upon the aorta and downward upon the secondary iliacs; upon the primitive vessels it is so thin that it may at times seem absent; but, as it descends, it increases in thickness, and acquires upon the external iliacs considerable strength.

The primitive iliac arteries ordinarily give only minute branches to the adjoining parts, viz. the ureter, the peritoneum, the vein, lymphatic glands and cellular structure; but occasionally they have been found to give off the ilio-lumbar artery, and more rarely a renal or spermatic artery.*

Although, according to the view usually taken, the primitive iliac terminates by dividing into internal and external, yet in many instances it will be found that the primitive and external iliacs appear as one vessel giving off the internal from its posterior side, and nearly at right angles, while in the fœtus the reverse seems the case, the primitive and internal being continuous and rather giving off the external.

Internal iliac artery.† (*Arteria iliaca interna*, s. *hypogastrica*, s. *umbilicalis*; Fr. *artere iliaque interne, ou hypogastrique*; Germ. *Becken-pulsader* oder *innere Huft-pulsader.*) This artery from the time of birth supplies the viscera and parietes of the pelvis, both externally and internally; prior to that epoch it is the channel through which the blood is transmitted from the body of the fœtus to the placenta, whence it may then be termed with propriety the "placental artery," since such is its chief office, the other distribution being of inconsiderable extent, and the divisions of the artery intended for it small in proportion; hence the vessel presents a remarkable contrast at the two periods of life, in the fœtus being a large and long vessel extending from the termination of the aorta, for, as has been before stated, it seems at that time the continuation of the primitive iliac artery, to the placenta giving off in its course small branches to the viscera and parietes of the pelvis, while in after life the placental artery has disappeared, and in its stead is found a short trunk of considerable size,—the commencement of the placental artery as it had been—from which arise numerous vessels for the pelvis and its viscera.

The internal iliac arises from the posterior side of the primitive iliac artery,‡ between the body of the last lumbar vertebra or the sacro-vertebral angle, and the sacro-iliac articulation, but generally higher upon the right side than the left; it descends into the pelvis in front of

* J. F. Meckel.

† The internal iliac and its branches should be examined first with the pelvis complete, the peritoneum and viscera being detached from its lateral wall, and the latter alternately empty and distended; afterward a section of the pelvis may be made through the symphysis pubis and the middle of the sacrum, preserving the viscera with their attachments to one side; but this should not be done until after the dissection of the perineum.

‡ See primitive iliac for point and mode of division.

the sacro-iliac articulation or of the lateral part of the sacrum, as it may be, inclining backward and outward, and describing a curve concave forward, until it reaches the superior part of the great sciatic notch, where it usually divides; this however is by no means uniform, the point of its division ranging between the brim of the pelvis and the notch. The internal iliac is an artery of great size, but in the adult smaller than the external; its course is somewhat tortuous and short, from one and a half to two and a half inches.

During its descent the artery is placed before the lumbo-sacral nerve, on the left side before the primitive iliac vein, and on both before the sacro-iliac articulation or the lateral part of the sacrum. Before it are in the male the bladder or its lateral connections, in the female the uterus and its broad fold of peritoneum; externally the artery corresponds to the internal iliac and the commencement of the primitive iliac veins, to the inside of the psoas magnus muscle, to the brim of the pelvis, to the obturator nerve, which it crosses nearly at right angles, to the lumbo-sacral and first of the anterior branches of the sacral nerves, and to the superior attachment of the pyriformis muscle: the ilio-lumbar artery is also external to the internal iliac, between it and the wall of the pelvis. Internal to it are the peritoneum, the rectum with its mesentery, and the superior hemorrhoidal vessels, (these parts being nearer to the artery upon the left than the right,) and the small intestine when in the pelvis.

The external iliac vessels are above, before, and external to the internal.* In the fœtus the condition of the internal iliac differs remarkably from that which it presents in after life; in it both in size and direction this artery appears the continuation of the primitive trunk, exceeding the external as much as afterward it is exceeded by it. It is the channel which conveys the blood to the placenta, and it is generally entitled the "hypogastric or umbilical artery;" "placental" would certainly be preferable. It passes from the primitive iliac or rather from the aorta, for there the primitive iliac appears only the commencement of the placental artery, downward and at first outward as far as the sacro-iliac articulation, where it gives off the external iliac artery, then forward to the side of the bladder, descending but little into the pelvis and at the same time giving off pelvic branches; it next changes its direction and ascends inclining inward toward the umbilicus, at first by the side of the bladder and then in the anterior abdominal wall, between the peritoneum and the rectus muscle or its sheath, and on either side of the urachus; thus forming a curve convex downward through the concavity of which pass the vas deferens or round ligament before, the ureter posteriorly and the rectum, the extremity of the ilium and the appendages of the uterus in the mean space. Having reached the umbilicus the artery escapes through it from the body of the fœtus and is conducted by the umbilical cord to the placenta; during their transit to the placenta the arteries at the very early periods of utero-gestation, are straight, but afterwards, in proportion as the developement advances, they become tortuous, and are twined round the umbilical placental vein, whence the length of the arteries exceeds that of the cord which varies from one to two feet. At the placenta the two arteries are connected by a considerable anastomosis, and divide into numerous branches, which subdivide minutely in the lobes of that structure, the ramifications of the several lobes being distinct from each other; ordinarily the two vessels are distinct until they approach the placenta, but they have been found to unite into a single one before escaping from the abdomen of the fœtus.* The placental arteries give off within the body of the fœtus branches similar in number and destination with those of the primitive iliac of the adult, but in a rudimental condition; between the summit of the bladder and the umbilicus however they do not furnish branches, and hence, the circulation through them between these points ceasing at birth, they become obliterated to the same extent and connected into impervious cords, known by the name of umbilical ligaments; these hold the same course and relation with the original vessels, and are less distinct in proportion to the age of the subject; they are covered upon their abdominal aspect by the peritoneum, which is reflected upon them to a greater or less extent according to the subject, and thereby forms triangular falciform folds, the base of which is below in the iliac fossa, and the apex above toward the umbilicus, and in the free edge of which the ligament is contained. At a point intermediate to the brim of the pelvis and the upper part of the sacro-sciatic notch the internal iliac artery divides into branches; these are numerous, amounting altogether in the male to nine, and in the female to eleven; but in their mode of origin they vary very much, arising sometimes separately, sometimes by common trunks, but for the most part from two, into which the iliac divides; these are an anterior one giving off the hemorrhoidal, the umbilical, the vesical, the uterine, the vaginal, the sciatic and internal pudic, and a posterior, from which arise the ilio-lumbar, the lateral sacral, the obturator and the gluteal. Another diversity in the mode of their origin is that of the obturator from the epigastric or external iliac.

The branches of the internal iliac are arranged either into four sets, viz. posterior, anterior, internal, and inferior,† or into two, internal and external,‡ the former distributed within, the latter without the pelvis; the latter seems the more simple division, and is the one which will be adopted in this article.

The *internal* branches are in the male five, in the female seven; they are as follow—

1. The *iliolumbar artery* varies in size and origin; for the most part it arises from the posterior

* This is to be understood to refer to the recumbent posture; in the erect posture the external are not superior to the internal vessels.

* Cloquet.
† Cloquet.
‡ Harrison.

division of the internal iliac, at times from the iliac itself; at times from the gluteal, occasionally from the primitive iliac, and frequently by a trunk common to it and the lateral sacral; from its origin, which is somewhat below the base of the sacrum, it runs upward, outward, and backward toward the iliac fossa, passes in front of the sacro-iliac articulation and the lumbo-sacral nerve and external to the obturator nerve; having surmounted the outlet of the pelvis it passes behind the psoas muscle, the external iliac vessels and the anterior crural nerve, and emerges from behind them at the superior and internal part of the fossa, where it divides. As the artery emerges from the pelvis it gives off a branch which descends along the brim, gives small branches to the inside of the psoas, and finally anastomoses with a branch from the epigastric artery; while concealed by the psoas it gives branches to it and the iliacus internus. Finally it divides into two sets of branches, superior or ascending, and external or transverse; the former ascend beneath the psoas, supply it, the iliacus and the quadratus lumborum, send a branch into the vertebral canal through one of the inferior intervertebral foramina, and finally communicate with the inferior lumbar arteries. The external set pass outward into the iliac fossa, and are distinguished into two, a superficial and deep; the former run across the iliacus muscle, superficial to it and beneath the iliac fascia, supply the muscle and anastomose freely with corresponding branches from the circumflex branch of the external iliac artery: the superior of the superficial branches runs round the crest of the ilium within its inner edge, as it proceeds it gives branches downward to the iliacus and upward to the quadratus lumborum, the transversalis and oblique muscles, some of which turn over the crest and communicate with branches of the gluteal artery; finally it ends in a direct and free anastomosis with the ultimate branch of the circumflex artery, the fossa having thus an artificial circle formed around it internally, between these branches and the original iliacs. The branches of the deep set pass into the substance of the iliacus muscle, and between it and the bone, and are distributed to the muscle, the periosteum, and the bone, one of them entering the ilium through the canal to be observed at the bottom of the fossa; their deep branches also communicate with the circumflex iliac, the gluteal and the external circumflex femoral arteries. Sometimes there are two ilio-lumbar arteries.

2. The *lateral sacral artery* may be either single or double, and arises either from the posterior division of the iliac, from the iliac itself on its inner side, from the gluteal, or the sciatic, and frequently in common with the ilio-lumbar: it runs downward, and inward in front of the lateral part of the sacrum, the sacral nerves at their exit from the anterior sacral foramina, and the pyriform muscle external to the middle sacral artery and the sympathetic nerve; it descends to the extremity of the sacrum and then anastomoses with the middle sacral and the artery of the other side; at times instead of terminating thus it enters the sacral canal through the third or fourth foramen and is distributed internally. Its branches are distinguished into two sets, an anterior or internal and a posterior or external. The former are distributed to the sacral nerves within the pelvis, to the pyriform muscle, to the pelvic cellular tissue and glands, to the levator ani muscle and to the sacrum. The posterior are the larger, they are usually four, but at times more numerous, two branches sometimes taking the same course; they pass backward along the sacral nerves, through the sacral foramina, into the canal, and then divide into two, of which one is distributed within the canal to the nerves and their ganglia, to the membranes and the sacrum; the other escapes backward through the posterior sacral foramen, and is distributed upon the back of the sacrum in the sacro-vertebral channel, anastomosing with the adjoining vessels.

3. The *middle hemorrhoidal artery* is sometimes wanting, its place being supplied by branches from the other divisions of the iliac; it is of about the same size as the previous arteries, and varies very much in its source, arising from the anterior division of the iliac, from that vessel itself or from the pudic, the sciatic or lateral sacral arteries, it runs downward, forward, and inward along the side and front of the rectum, at first between the intestine and the levator ani, and then between it and the fundus of the bladder in man and the vagina in the female, and divides into branches, of which the greater part are distributed to the rectum, anastomosing with the branches of the superior hemorrhoidal from above and with those of the inferior hemorrhoidal from below; others are distributed to the fundus of the bladder, the prostate and vesiculæ in man, and to the vagina in the female.

4. The *vesical arteries* are subject to great variety; they are numerous and smaller than the last described: they are distinguished by Harrison into three sets, inferior, middle, and superior; the inferior set consists of those branches given to the fundus of the bladder by the middle hemorrhoidal, pudic, and sciatic arteries; the superior, furnished by the umbilical, are two or more in number, and are distributed to the superior region of the bladder, but the middle is a single vessel larger than the others, and given off by the iliac artery, though frequently arising from some of its branches, particularly the umbilical: it is entitled by Chaussier " vesico-prostatique:" it passes downward and inward to the fundus of the bladder, and then divides into branches distributed to the bladder, and in the male also to the prostate, the vesiculæ and neck of the bladder.

5. The *umbilical artery*. In the adult subject a small arterial canal usually from an inch and a half to two inches and a half long extends from the termination of the internal iliac, or from one of its branches to the superior lateral part of the bladder; there it is continued with, or seems to have attached to it superiorly the umbilical ligament, the artery appearing

rather to be continuous with the last branch arising from it. A variable number of branches arise from it; these are generally the superior vesical, at times the vaginal or the uterine; and according to their number and size its size varies; it is not destined to any part, but only gives rise to these branches, being in reality not a branch of the iliac but so much of the vessel, originally the umbilical or placental, as intervenes between the origin of the great branches and the point at which it becomes impervious, which remains open because of the origin of the vesical arteries, &c. from it, but is thus reduced in size because of their minuteness.

6. *The uterine artery* arises either from the anterior division of the iliac, or from the pudic, or at times from the umbilical; it runs forward, inward, and somewhat downward, until it reaches the superior lateral part of the vagina, and entering the broad peritoneal fold of the uterus it ascends in it along the lateral region of the uterus in a very tortuous manner, its tortuosity increasing as it proceeds. As it ascends, it gives off a considerable number of transverse branches, which attach themselves to both surfaces of the organ, penetrate its substance, and supply it with blood, anastomosing, at the same time, freely with those from the other side. When it has reached the attachment of the ligament of the ovary, the artery anastomoses with the spermatic artery. Before the artery attaches itself to the uterus, it gives a considerable branch to the vagina, which descends along it to a greater or less extent and is distributed to both its aspects. Branches also go from it to the Fallopian tube, the round ligament, and the ligament of the ovary, and likewise communicate with branches of the spermatic.

The uterine artery in the unimpregnated condition of the uterus is a small vessel, little, if at all, larger than the hemorrhoidal or vesical arteries, but during impregnation, and the more so in proportion as that state advances, it undergoes a remarkable change, becoming greatly enlarged, so much so as to equal or exceed in size any of the other branches of the internal iliac; and at the same time assuming a most tortuous arrangement as well in its branches as in its trunk.

7. *The vaginal artery* arises also, when present, from the anterior division of the iliac, or from the pudic, the uterine, the umbilical, or hemorrhoidal; it is therefore very irregular and often absent, its place being supplied by branches from others. It runs forward and downward along the side of the vagina, distributing branches to it, and also to the bladder and rectum. At the extremity of the vagina it terminates in the external genital organs, and communicates with the branches of the pudic artery.

The *external* branches of the internal iliac artery are four, viz.

1. The *obturator* or *thyroid artery*, (*artere sous-pubio-femorale*, Chauss.) is a vessel of considerable size, inferior only to the gluteal, pudic, and sciatic branches, and about equal to the epigastric artery, but irregular in that as well as in other respects. It arises most frequently from the posterior division of the internal iliac or from the iliac itself immediately before its division; it runs forward and somewhat downward along the lateral wall of the pelvis toward the superior posterior part of the subpubic or thyroid foramen, through which it escapes from the pelvis into the superior internal part of the thigh. The course of the vessel may be divided into three parts:—1st, that within the pelvis; 2d, that in the subpubic canal; 3d, that in the thigh. Within the pelvis the artery is nearly parallel to the brim of the pelvis, or ilio-pectineal line, and from one-half to three-fourths of an inch beneath it, it holds a similar relation to the external iliac vessels, which are above the line and from which it is distant from three-fourths of an inch to one and one-fourth. It is accompanied by the obturator vein and nerve, and is placed between them, the nerve being above and the vein beneath it. It is situate within the pelvic fascia; externally it rests against this fascia above the origin of the levator ani muscle, and separated by it from the internal obturator muscle; internally it corresponds in front to the side of the bladder to an extent proportioned to the degree to which that viscus may be distended, and is connected to it by cellular substance; posteriorly it corresponds to the peritoneum of the pelvis, the ureter, and at times to the anterior division of the iliac artery or some of its other branches. In this part of its course it gives off a branch which ascends to the iliacus and psoas, branches to the obturator internus, to the lymphatic glands of the pelvis and the bladder; lastly, as it approaches the subpubic foramen it gives an important branch, which ascends posterior to the pubis, distributes small branches as it proceeds, and ends in an anastomosis with a branch, which descends from the epigastric artery. Harrison has occasionally found a considerable branch given off in this situation, which passed to the side of the prostate and the perineum, supplying the place of deficient branches of the pudic artery.

In escaping from the pelvis the artery is contained in an oblique canal leading inward and forward. This canal, the subpubic, is bounded superiorly and externally by the pubis, which presents on the under surface of its horizontal ramus an oblique channel, by which the roof of the canal is formed; inferiorly and internally it is bounded by the margins of the obturator muscles and ligament; toward the pelvis it presents a defined aperture circumscribed above by the pubis and below by the pelvic fascia, the attachment of which to the bone is interrupted at the part at which the artery passes out, and which describing a curve beneath the vessels, between its points of attachment at either side contributes thus to form a rounded aperture through which they escape without perforating the fascia; a thin prolongation of the fascia is detached from it beneath the vessels into the canal. Hernia occasionally protrudes through this canal, and the artery has been found by Cooper behind the neck of the sac and rather to its inner side. While within the canal the artery gives outward a considerable branch—its posterior or external, or it might be with propriety called its thyroid branch—which runs downward and backward along the external margin of the *thyroid* foramen, between the two obturator muscles, giving them branches, and at times altogether consumed in them. Having reached the tuberosity of the ischium, it gives branches to the quadratus and adductor magnus muscles, to the upper attachments of the flexors of the leg, and to the ilio-femoral articulation, into which it sometimes sends through the cotyloid notch a branch more frequently supplied by the internal circumflex (femoral) artery; it also sends another round the thyroid foramen, which meets a similar branch from the obturator. It anastomoses with the internal circumflex and the sciatic arteries. At its entrance into the thigh, the obturator artery is situate above and before the obturator externus muscle, and behind the pectinalis, which with some of the fibres of the adductor longus must be divided in order to expose the vessel. It descends between the pectinalis, the long and short adductors, and is distributed to them, the adductor magnus, the gracilis, and the integuments upon the upper and inner part of the thigh. It gives also a branch, which runs round the margin of the thyroid foramen, and meets the branch already described from its thyroid branch. The artery anastomoses freely with the internal circumflex artery.

The obturator artery presents many varieties as to its source, of which some are deserving of particular attention. According to J. F. Meckel its ordinary source is the posterior division of the internal iliac, either immediately or by a trunk common to it and the ilio-lumbar, but at least once in ten times it arises from another source. The next most frequent is the internal iliac itself above and before its division; then the anterior division of the iliac; occasionally the external iliac, and sometimes the femoral, even so low as two inches from Poupart's ligament. The most frequent variety, and which according to the same authority is as common as the origin from the internal iliac itself, is that the artery arises from the epigastric, or from a trunk common to both. Sometimes it has a double origin, being formed by the union of two branches of equal size, one from the epigastric, and the other from the internal iliac, and at times it has a different source upon opposite sides. In every case the destination of the artery is the same; it runs to the inner aperture of the subpubic canal, in order to escape to the thigh, and in so doing it holds a very intimate relation to the internal femoral ring in those instances in which it proceeds either from the epigastric or from the femoral. When it arises from the epigastric, it runs obliquely downward, backward, and inward, above the crural arch, toward the superior aperture of the pelvis, then entering the pelvis posterior to the pubis it turns downward beneath it, and gains the subpubic foramen. During its descent into the pelvis the artery superiorly is covered by the peritoneum, and inferiorly corresponds to Poupart's ligament and the internal femoral ring, but the side of the ring, at which it may be placed, varies in different instances. When the common trunk from which the epigastric and obturator arise is short, the obturator lies close to the inside of the external iliac vein and then is situate on the outer side of the ring, while when the common trunk is long the artery is more remote from the vein, coasts along the base of Gimbernat's ligament, and thus runs obliquely across the front and inner side of the aperture. According to the case, therefore, will be the relation of the artery to the neck of femoral hernia; in the former it will be situate external and posterior to it, in the latter anterior and internal.

When hernia descends not only into the lymphatic compartment of the sheath, but, as has been observed by Burns, also into that belonging to the vein, thus forming a double protrusion, the artery may, if the common trunk be short, be situate external to the neck of the former and internal to that of the latter.

The comparative frequency of this mode of origin of the obturator artery has been differently estimated. According to Monro it occurs in one of twenty cases; Velpeau coincides in this opinion; Lawrence states it to be once in ten; J. F. Meckel considers it to be as frequent as that from the internal iliac; and according to the observations of Cloquet the proportion of instances in 250 subjects in which the artery was found to arise from the epigastric, whether on one or both sides, was one in three, and that of all the origins from the epigastric to all those from other sources was still greater, about 1.2½. A more important question is the proportion borne by those instances in which the obturator arising from the epigastric is situate on the inside of the neck of the hernia, to the total number of such cases, or to that of cases of femoral hernia requiring operation, for it is obviously with it that the operator is concerned. Cooper has not met the artery on the inside of the hernia, though in six of twenty-one cases he found the origin from the epigastric; and Lawrence states that the proportion of the former cases does not exceed one in eight or ten, and therefore that the obturator artery would be endangered only once in eighty or one hundred operations.

When the obturator arises from the femoral artery, which Cloquet found in six of 250 subjects, it ascends into the abdomen beneath the crural arch, along the pectinalis muscle and internal to the femoral vein, and in femoral hernia is found behind the sac.

We are indebted to J. F. Meckel for solving the apparent irregularity of these origins of the obturator, and reducing them to a mere variation of the normal condition; the obturator, as has been stated, is normally connected with the epigastric by an anastomotic branch, and hence may be considered as having two origins, an anterior and a posterior, a disposition the reality of which is more manifest at the earlier periods of life, and according as the one or the other may be deficient or more developed, the obturator will be derived principally or altogether from the internal iliac or from the epigastric; when both are equally so it will present the double origin.

2. *The glutæal artery*, denominated also *posterior iliac*, is the largest branch of the internal iliac, and arises from, or is the continuation of the posterior division of that vessel; it runs downward, backward, and outward, until it reaches the superior part of the great sciatic notch; it then changes the direction of its course, and making a turn passes directly outward between the lumbo-sacral and the anterior branch of the first sacral nerves, and escapes from the pelvis through the upper part of the notch above the pyriformis muscle, and accompanied by the superior gluteal nerve. As soon as the artery has escaped from within the pelvis and gained its external aspect, it divides into branches. The trunk of this artery, as it is the largest, so is it the shortest of the branches of the iliac; within the pelvis it corresponds externally to the lumbo-sacral nerve, internally to the rectum, and inferiorly to the first sacral nerve and the pyriformis; it gives small branches to the rectum, the pyriformis, and the surrounding cellular structure; at times it also gives off the ilio-lumbar, the lateral sacral, or the obturator.

At its exit posteriorly from the pelvis it is situate between the adjoining margins of the pyriformis and the gluteus minimus, and it is covered by the gluteus maximus.

The branches into which it divides after its escape are two, a superficial and deep one. The first passes outward and upward between the glutei maximus and medius, and divides into numerous branches, which are distributed to these muscles, particularly to the maximus; many of them descend in its substance toward its insertion, and there meet branches of the circumflex (femoral) and sciatic arteries; others pass through the muscle, become superficial, and supply the integument and subcutaneous fat; others again pass onward, traverse the attachment of the gluteus maximus to the sacrum, and are distributed to the muscles and integuments of the posterior sacral region.

The second, the deep branch, passes outward, upward, and forward, between the glutei medius and minimus muscles toward the superior anterior spinous process of the ilium in an arched course around the attachment of the gluteus minimus. As it proceeds it gives off numerous branches upward from its convexity and downward from its concavity; the former are distributed to the gluteus medius; the latter are chiefly two, of which one runs forward and downward toward the anterior part of the great trochanter between the two muscles, gives branches to both, and finally throws itself into the gluteus medius near the trochanter, and is consumed in it: it communicates freely with the external circumflex artery. The other runs downward and forward toward the back of the trochanter, lies for some way upon the gluteus minimus, or over the interval between it and the pyriformis, gives branches to both muscles, and then gains the surface of the os innominatum by traversing the gluteus or by passing between it and the pyriformis, pursues its course upon the bone, to which it gives an artery, above the ilio-femoral articulation, to the capsule of which it also gives branches, and approaching the anterior inferior spinous process of the ilium it terminates in supplying the gluteus minimus, and anastomosing with the external circumflex artery.

The deep division of the gluteal artery having run round the line of attachment of the gluteus minimus, and reached the superior anterior spinous process, terminates in an anastomosis with the circumflex iliac, the ilio-lumbar, and the external circumflex arteries; branches also turn over the crest of the ilium, and so communicate with the iliolumbar. The deep division, also, furnishes a nutritious artery to the ilium, the canal for which is to be seen on the dorsum of the bone. The branches of the gluteal artery are numerous and large; in order to expose them the gluteus maximus having been dissected clean may be detached from the femur and raised toward the sacrum, when the branches may be displayed running in every direction as from an axis.

The situation of the gluteal artery external to the pelvis permits the trunk of the vessel to be secured; the gluteus maximus being the only muscle by which it is covered, it may be exposed by the division of that muscle; the situation of the artery may be first determined "by drawing a line from the posterior spinous process of the ilium to the midspace between the tuberosity of the ischium and the great trochanter; if we divide this line into three, we shall find the gluteal artery emerging from the pelvis at the juncture of its upper and middle thirds."* The ligature of this artery in case of aneurism has been very much superseded in favour of that of the internal or even of the primitive iliac, the latter of which has been tied by Guthrie for aneurism of the gluteal artery; the propriety of this proceeding, however, may be questioned; the ligature of either the internal or the primitive iliac must be regarded a more serious operation than that of the gluteal, and the latter has proved so efficacious in the many instances in which it has been had recourse to, that, while it is practicable, the other can be hardly justifiable.

3. *The ischiatic artery* arises from the anterior division of the internal iliac, which, after having given off its internal branches, divides into two, of which the posterior and larger is the ischiatic; it is the second in size of the branches of the iliac, being smaller than the gluteal; but in the adult it appears, for the most part, in direction the continuation of the original vessel; its course within the pelvis is long; it descends, at the same time inclining forward, and forming a curve convex backward, toward the inferior part of the great sciatic notch, and escapes through it from the pelvis, superior to the sacro-sciatic ligaments and inferior to the pyriformis muscle; it then descends

* Harrison.

behind the ischium between its tuberosity and the great trochanter of the femur, and gives off as it descends numerous branches distributed in the superior posterior region of the thigh. Within the pelvis the artery is situate internal to the sacral nerves and the pyriformis muscle, external to the rectum and the peritoneum, in front of the sacrum, the nerves and the attachments of the pyriformis, and posterior and external to the pudic artery; in escaping from the cavity it passes between the pyriformis and ischio-coccygeus muscles, and is accompanied by the pudic artery, to which it holds the same relation as before, but is closer to it, and by the sciatic nerve; within the pelvis it is internal and anterior to the sacral plexus, but as it goes out it passes between its branches, and thus becomes posterior to the nerve.

Without the pelvis the ischiatic artery corresponds in front to the spinous process of the ischium, the gemelli, with the obturator internus muscles, and the quadratus; posteriorly, it is covered by the gluteus maximus and the integuments; it is situate at first behind the sciatic nerve, but as it descends it becomes internal to the nerve, the distance between them increasing at the same time. While behind the spinous process of the ischium the ischiatic artery is external to the pudic artery, and more superficial, i.e. still posterior; but as the pudic passes to the inside of the tuberosity of the bone, while the ischiatic runs on its outside, the two vessels immediately separate and cease to be related.

Within the pelvis the ischiatic artery gives some irregular and small branches to the rectum, the bladder, the uterus, the vagina, the cellular tissue, the pyriformis and levator muscles; at times it is considered as giving off also the pudic, the hemorrhoidal, or obturator arteries. The branches which it furnishes external to the pelvis are numerous; among them are distinguished the following:—1. The *coccygean* branch, of considerable size, runs downward and inward toward the coccyx, across the pudic artery and posterior to it, passes through the great sacro-sciatic ligament, and divides into branches, which are distributed to the ligament, to the gluteus, the coccygeus, and levator ani muscles, to the posterior aspect of the sacrum and coccyx, and to the fat and integument; its branches communicate with those of the pudic. 2. A considerable branch or set of branches, which run outward and downward toward the back of the great trochanter upon the internal obturator, gemelli, and quadratus muscles, supply them with branches, and anastomose with the circumflex (femoral) arteries. 3. A branch or branches to the inferior part of the gluteus maximus, prolonged through it to its insertion, and then meeting the circumflex and perforating arteries. 4. A branch or branches, which attach themselves to the sciatic nerve, naturally of small size, but regular, and remarkable for the extraordinary change they undergo after the interruption of the main artery of the thigh; they arise about the tuberosity of the ischium, and descend along the nerve giving it branches, and communicating with branches from the perforating arteries, which also attach themselves to the nerve, whereby a chain of anastomoses is established along it, which, when the main channel has been interrupted, becomes amazingly enlarged and forms, as it were, one remarkably tortuous vessel along the entire length of the nerve. 5. A very considerable branch, the termination of the artery, distributed to the upper extremity of the flexors of the leg, the biceps, &c. and of the adductor muscles; the ramifications of which communicate with the perforating and internal circumflex arteries.

The ischiatic artery is circumstanced external to the pelvis so similarly to the gluteal, that, if necessary, it might be exposed during life by a similar operation; for a method of determining its situation prior to operation, the reader is referred to the description of the pudic artery.

4. The *internal pudic artery* arises from the anterior division of the internal iliac, which for the most part, after having given off its other branches, divides into the ischiatic and the pudic; the height at which the division takes place is uncertain; at times it does not occur until the trunk has descended to the sciatic notch, or even escaped from the pelvis. The pudic artery is smaller than the sciatic; it passes downward, forward, and inward, until it reaches the inferior part of the great sciatic notch, through which it escapes from within the pelvis in company with the ischiatic artery, the pudic, and sciatic nerves; having escaped from the pelvis it crosses the extremity of the spinous process of the ischium and the attachment of the anterior sacro-sciatic ligament, and returns into the cavity through the anterior notch, accompanied by the pudic nerve; having re-entered the pelvis, it then runs forward, inward, and downward internal to the tuberosity of the ischium, until it reaches its anterior extremity, whence it continues its course upward along the inside of the rami of the ischium and pubis toward the arch of the pubis, and beneath the latter finally divides; the course of the artery, therefore, forms a considerable curve convex downward and backward, during which the vessel is contained within the pelvis at its commencement and its termination, and is without the cavity during the intermediate part. Its course is thence divided into three stages, during two of which it is within, and in the third without the cavity.

The first stage of the artery's course, throughout which it is contained in the pelvis, extends from its origin to the lower part of the posterior sacro-sciatic notch, through which it escapes from the cavity; it is of variable length, in consequence of the variable height at which the vessel arises. The relations of the artery during this stage are posteriorly and externally the sacral nerves, the pyriform muscle, and the sacrum; internally the peritoneum and the rectum; it is posterior and external to the fundus of the bladder and the vesiculæ seminales, and anterior and internal to the ischiatic artery; previous to its exit it sometimes passes between the sacral nerves before forming the plexus. It goes out from the pelvis below the pyriformis and above the spinous process of the ischium and the anterior sacro-sciatic ligament, passing between the pyriformis and the ischio-coccygeus muscles, and having the ischiatic artery and sciatic nerve both external and posterior to it. Its second stage is situate without the pelvis; it is usually its shortest one, lasting only while the artery is crossing the extremity of the spinous process of the ischium, and not exceeding an inch in length; it is here situate behind and above the spinous process and the anterior or lesser sciatic ligament; it is covered posteriorly by the superior edge of the posterior ligament and by the gluteus maximus muscle; it is internal to both the ischiatic artery and sciatic nerve, and it is crossed posteriorly by the coccygean branch of the former.

The third stage of the artery is its longest and most important one; during it the vessel is situate within the skeleton of the pelvis, though not within the pelvis, in the ordinary sense of the phrase, i. e. within its visceral cavity, being excluded therefrom by the structures which form its floor; it lies along the inside of the tuberosity of the ischium and the rami of the ischium and pubis, and its course and relations being different at the posterior and anterior parts of the stage, they may with advantage be considered separately. In the posterior part, or as far forward as the anterior extremity of the tuberosity or the base of the triangular ligament of the perinæum, the artery descends; in the anterior it ascends; in the posterior it is situate in the outer wall of the space which intervenes between the inside of the tuberosity of the ischium and the rectum—the ischio-rectal space. This space is cuneiform, its base below, toward the surface; its apex above, toward the pelvis; its inner wall is formed by the levator ani and the dense thin expansion by which the muscle is covered externally or inferiorly, its outer by the obturator fascia attached inferiorly to the edge of the great sacro-sciatic ligament and of its falciform process, and by the obturator muscle: the space is occupied by a mass of adipose cellular structure, traversed by some branches of the pudic vessels and nerves. In a canal in the obturator fascia the artery is contained through the posterior part of the third stage; by some it is maintained to be between the fascia and the muscle, in a sort of canal formed internally by the fascia, externally by the muscle and tuberosity, and inferiorly by the great sciatic ligament; but this is not correct; the vessel being in the fascia, and not external to it; the line of its course is convex downward, about an inch and a half from the under surface of the tuberosity of the ischium at its most depending part, and from two to two and a half inches from the surface, this distance varying of course according to the condition of the subject; the line approaches the margin of the ramus or the spinous process, thence forward or backward. In the anterior part of the stage the vessel is enclosed in the triangular ligament along its attachment to the bone; consequently, it is separated from the surface by the superficial stratum of this structure first, in the second place by the crus penis, covered by the ischio-cavernous muscle, and behind it by the transversus perinei muscle; and lastly, by the superficial structures of the perineum. As the artery proceeds it becomes more superficial, and finally emerges from the triangular ligament, beneath the subpubic ligament, as the dorsal artery of the penis.

It is in its third stage that the pudic artery is exposed to danger in the lateral operation of lithotomy; it may be wounded in either of the two steps of dividing the urethra and prostate or the subsequent division of the superficial structures: in the former case, the danger of the accident will be greatest when the section is effected with the scalpel or gorget, and in proportion to the width of the blade, and the degree to which the cutting edge may be directed outward, will the danger be enhanced; in the second, the risk will be alike with all cutting instruments, and will be determined by the width of the blade, the attention paid to a proper degree of lateralization, the manner in which the instrument is made to effect a division of the parts, and the extent of the section. The branches of the pudic artery are numerous, and may be conveniently arranged according to the stage of its course, in which they are given off. In its first, before its exit from the pelvis, it gives branches to the bladder, the rectum, the vesiculæ, prostate, vagina, and uterus; it also frequently furnishes the middle hemorrhoidal.

In its second stage, while external to the pelvis, it gives branches to the gluteus, the pyriformis, the obturator and gemelli muscles, the sacro-sciatic ligament, the ischium, and sacrum; they anastomose with the ischiatic, the gluteal, and internal circumflex arteries.

Those which arise in its third stage are the most important. 1. The artery gives, while on the inside of the tuberosity of the ischium, branches which are distinguished into external and internal; the former are small, and go to the adipose structure beneath the tuberosity, to the attachment of the biceps, to the obturator internus, and the integuments: the internal are larger; they come through the obturator fascia, run inward toward the anus, and are distributed to the adipose cellular structure of the ischio-rectal space, to the levator and sphincter ani, to the extremity of the rectum, and the margin of the anus; they anastomose with branches of the middle hemorrhoidal artery and with those of the other side: they are variable in number, being one, two, or three, and are denominated "external hemorrhoidal;" they are liable to be divided in operations in the vicinity of the anus, e. g. in the superficial incision in the lateral operation or in operation for fistula; they are, however, so small that they seldom give trouble, either ceasing to bleed spontaneously, or being commanded by brief compression.

2. *The perineal artery.*—At a short distance from the base of the triangular ligament the pudic gives off a branch of considerable size and length, by many regarded as one of its ultimate branches; the pudic, according to them, terminating by dividing into two branches, an inferior, "the perineal," and a superior.

The perineal artery comes through the obturator fascia, and descends to the perineum, posterior to the transverse muscle, though at times before it; when it has got below the muscle it changes its direction, and runs forward, upward, and inward, superficial to the triangular ligament, toward the root of the scrotum; at this part of its course it is situate along the outer side of the interval which separates the crus penis and the corpus spongiosum urethræ, internal and parallel to the crus, and covered by a superficial lamina of the fascia of the perineum, a deeper layer of which intervenes between it and the muscles of the crus and bulb and the triangular ligament; as it proceeds it gives the following branches: 1. outward, one to the integument and subcutaneous structure beneath the anterior part of the tuberosity of the ischium; 2. inward, one which runs to the interval between the front of the rectum and the bulb of the corpus spongiosum, superficial and parallel to the transverse muscle; it supplies the integument and subcutaneous structure of the perineum, and the common insertion of the superficial sphincter, the transverse muscle, the bulbo-cavernous and the levator ani in front of the rectum. This branch is at times furnished by the pudic itself; it is denominated by some "the proper perineal," by others "the transverse perineal." 3. A branch to the bulbo-cavernous; 4. one to the ischio-cavernous muscles.

The perineal artery having reached the back of the scrotum sends long branches into the subcutaneous structure and integument of that part, and entering the septum scroti, terminates in it as the "artery of the septum." In the female, the ultimate branches of the artery are distributed to the labia majora.

The perineal artery, from its superficial situation, is exposed to be divided on many occasions; in lateral lithotomy it may be cut, but for the most part it escapes, its course being external to the line of incision; some of its branches, however, cannot escape, the transverse perineal particularly must, as a matter of course, be divided. Having given off the perineal artery, the pudic pursues its course, enclosed in the triangular ligament, along the rami of the ischium and pubis, toward the arch of the pubis; arrived under cover of the crus penis, it gives off a considerable branch, destined principally for the urethra and the corpus spongiosum, and denominated hence by Chaussier "urethro-bulbaire," by Harrison "arteria corporis bulbosi vel spongiosi urethræ," but by Boyer and Cloquet "artère transverse;" it is short, runs transversely inward, enclosed in the triangular ligament about a quarter of an inch from its base, but nearer to it externally than internally; at the bulb it divides into two parts, of which one, the smaller, is distributed to the ante-prostatic gland; the other enters the bulb and ramifies through its vascular structure, being prolonged through it as far as the glans, supplying at the same time the membrane of the urethra and its lacunæ; a branch from it passes into the corpus cavernosum, and anastomoses with the artery of that structure. In the female, the branch corresponding to this is distributed to the vascular plexus which surrounds the orifice of the vagina.

The artery of the bulb is one of much practical importance; it is liable to be wounded in lithotomy in the act of opening the urethra; this accident is incurred when the canal is opened too high, i. e. too near to the arch of the pubis, or too much from the side rather than from beneath, and in either case is pretty certain to occur; the proceeding by which to avoid both the artery and the bulb itself, is to cut into the urethra as far back, i. e. from the surface, and as far from the arch as the guidance of the staff will assure the operator to be safe, the point of the knife being directed as much from below as the interference of the bulb and the lateral line of incision will permit; further, it is the design of the operator to open the canal in the membranous portion and behind the bulb; and in order to effect this, the incision should be made as near as may be to the base of the triangular ligament, or, if possible, behind it. If divided, the artery of the bulb may be tied, though not without some difficulty; it is prevented from retracting by being enclosed in the triangular ligament, but it is situate deep; its distance from the anterior surface of the ramus of the pubis being about three-fourths of an inch; its shortness as well as its being concealed by the crus penis and by the bulb with their muscles, and being in the superior angle of the wound, must also increase the difficulty of securing it.

The pudic artery having reached the base of the subpubic ligament divides into its two final branches, the artery of the corpus cavernosum and the dorsal artery of the penis.

3. *The artery of the corpus cavernosum* arises from the pudic between the crus penis and the ramus of the pubis and immediately enters the crus obliquely; it is prolonged through the vascular tissue of the corpus cavernosum to its extremity, distributing branches to either side, and communicating with that of the other. For the peculiar distribution of the arteries of the corpus cavernosum and spongiosum, according to Müller, see the article Erectile Tissue.

4. *The dorsal artery of the penis*, which appears in direction the continuation of the original vessel, comes through the triangular ligament and ascends in front of the subpubic ligament through the angle formed by the crura penis at their junction; having surmounted the crus it attaches itself to the dorsal aspect of the penis and runs forward upon it on either side of the suspensory ligament parallel to the artery of the other side, and contained together with it, the dorsal vein, and nerves, in the groove formed by the apposition of the crura, internal to the nerve and external to the vein; it is prolonged to the anterior extremity of the corpus cavernosum, where it breaks up into branches, which uniting with those of the other form an arterial zone behind the corona glandis, and sinking into the glans are distributed to its tissue.

During their course along the dorsum of the penis the arteries are tortuous, communicate frequently, are covered not only by the skin and subcutaneous cellular structure, but also by a dense filamentary expansion, or fascia, which invests the penis beneath them, and they give branches to those structures as also to the fibrous membrane of the corpus cavernosum, and finally to the prepuce. The dorsal artery is at times furnished by the obturator, or the external pudic artery.

Beside the varieties of origin which have been mentioned, the pudic presents some important varieties in its course. It has been found by Burns in four instances, "instead of passing out of the pelvis between the sacro-sciatic ligaments to attach itself to the lateral and inferior part of the bladder, and to traverse the upper segment of the prostate gland in its course to the ramus of the ischium." Another variety is described by Harrison, in which the proper trunk of the pudic is found unusually small, and the dorsal artery of the penis arises originally and separately from the internal iliac, runs along the side of the bladder and prostate gland, and escapes from the pelvis along with the dorsal vein of the penis beneath the arch of the pubis. The latter disposition, *mutatis mutandis*, has been found by Tiedemann in the female as well as in the male, and is figured in his thirtieth plate. It is described by Winslow as the normal arrangement, only that according to him the vessel, which takes this unusual course, arises sometimes from the common pudic, at others from the iliac. Haller questions the occurrence of this disposition, but describes another, in which the inferior vesical artery arising from the middle hemorrhoidal is continued on the dorsum of the prostate into the dorsal artery of the penis, given, as in ordinary, from the pudic.

Among the varieties of the arterial system few possess greater interest than these, inasmuch as no foresight or skill can guard against the untoward accidents which attend their presence in lithotomy; their possibility forbids a section of the prostate upward; but fortunately they are rare.

The situation of the pudic artery upon the exterior of the pelvis admits the possibility of tying the vessel in the living subject; the plan of operation necessary for the purpose is similar to that to be adopted with the gluteal artery, only it must be performed lower down; it is the same with that for the ischiatic artery; for determining the situation of which or the pudic the following directions are given by Harrison:*—"Place the individual on his face with the lower extremity extended and the toes turned inwards: feel for the summit of the great trochanter, and for the base or articulated end of the coccyx; these two points are on a level; then draw a line from one to the other, and we may be certain that the pudic artery and the spine of the ischium are opposite the junction of the middle and internal thirds of this line." The ischiatic artery may be reached as easily, or even more so, than the gluteal; but the difficulty which must attend the seeking for the pudic must be extreme.

* Vol. ii. p. 103.

THE EXTERNAL ILIAC ARTERY, (*arteria iliaca externa*, Lat.; *artère iliaque externe*, Fr.; *portion iliaque de la crurale*, Chauss.; *Aussere Hüft-pulsader*, Ger.) is the vessel destined for the supply of the lower extremity, of which the portion contained within the abdomen, in the iliac region, is denominated the "external" iliac, in contradistinction to the artery of the pelvis, the "internal."

It commences at the division of the primitive iliac artery, at a point intermediate to the body of the last lumbar vertebra, or the sacro-vertebral prominence, and the sacro-iliac articulation, and it terminates at the crural arch, at a point midway between the superior anterior spinous process of the ilium and the spinous process of the pubis,* or at the outer side of the ilio-pectineal eminence of the os innominatum. The point at which the vessel commences is not uniform either in all subjects or on the two sides of the same; depending upon the point at which the primitive iliac divides, which is variable, it will be higher or lower, nearer to the vertebra or to the articulation, according to the situation of the bifurcation of that vessel: on the right side of the body the artery commences for the most part nearer to the body of the vertebra than on the left, on which it is of course nearer to the articulation; hence the artery arising higher upon the former is longer upon that side than upon the latter, the difference in length varying from a quarter to half an inch. The external iliac terminates in the femoral or crural artery, strictly so called; but the distinction between the two is one only of convenience, inasmuch as they are but different stages of the same vessel; there appears therefore much propriety in the

* The situation of the artery at its termination is differently stated by different writers; Boyer states it to be midway between the spinous process of the ilium and the symphysis pubis; Cloquet, midway between the spine of the ilium and the spinous process of the pubis; Harrison, about half an inch to the pubic side of the centre of the crural arch. The relation of the vessel to the points between which it is placed, is probably not the same in all cases; but that assigned to it by Cloquet seems most generally applicable. According to Cooper, with whom Cloquet concurs, there are, in the male, 3¼ inches from the symphysis pubis to the middle of the artery, and in the female 3¾, while the distance to the superior anterior spinous process of the ilium is in the former 5¾, and in the latter six inches; the artery must therefore be external to the mid-point, being for the most part concave forward and inward above, and convex forward below; but in this particular it is not uniform, being sometimes nearly straight; the degree of its tortuosity also appears to depend upon the age of the subject and the plenitude of the vessel. The direction of the artery is oblique, and as the primitive iliac and it are continuous in the adult, the course of both the vessels may be defined, during life, by a line extending from the umbilicus, or from half an inch below it, at its left side, to a point midway between the superior anterior spinous process of the ilium and the spinous process of the pubis, the upper extremity of the line varying according to the situation at which the aorta divides.

designation adopted by Chaussier, which, while it recognises the identity of the vessel throughout its course, sufficiently marks the grounds of distinction between its two portions. The external is somewhat smaller than the primitive iliac, but in the adult considerably larger than the internal; its direction is downward, outward, and forward, and hence it forms with the primitive iliac a curve convex backward, and seems the continuation of that vessel; its length is from three to four inches, and during its course it forms one or more curvatures.

Such is the disposition of the vessel in the adult; but in the younger subject it is different in some respects; in the fœtus the external iliac is considerably smaller than the internal, and does not seem the continuation of the primitive iliac, which at that epoch is continued into the internal; the external appearing rather as a branch or a smaller division from a trunk common to the other two: after birth the relative disposition of the iliacs gradually changes, until they acquire that of the adult.

The relations of the external iliac artery are as follows: posteriorly, it corresponds through the upper half of its course to the lateral part of the superior aperture of the pelvis; inclining outwards as it descends, it corresponds in its lower half to the os innominatum, and the more perfectly, the nearer it approaches the crural arch, at which part it is placed in front of the bone, crossing it nearly at right angles, and separated from it by an interval occupied by the psoo-iliac aponeurosis and the psoas muscle.

At its outset the external iliac vein is directly behind the artery, and on its right side, also the commencement of the primitive iliac vein, the artery crossing the junction of the two vessels, on that side, obliquely in its descent; during the remainder of its course, the vein, though posterior to it, is also internal; throughout the lower half of its course it lies upon the psoo-iliac aponeurosis, supported by the os innominatum, and at first separated from the bone only by the aponeurosis; but as it proceeds separated from it also by the tendon of the psoas parvus when present, and by the inner margin of the psoas magnus, it is very near to the os innominatum, external to the ilio-pectineal eminence, and being here supported by bone, and made steady by its connections it may with certainty be compressed and its circulation perfectly commanded. Internally, the artery corresponds above to the aperture of the pelvis, to its viscera more or less intimately, according to their state of distension or contraction, and also to the small intestines which descend into it; in the lower half of its course, the external iliac vein, which at its outset is behind or beneath the artery, is internal, though still somewhat posterior to it; at the crural arch the artery and vein are nearly upon the same level, being supported by the os innominatum; the artery however somewhat anterior to the vein, but as the vein recedes from the arch it inclines less inward than the artery, and at the same time retreats more from the surface; and hence it gradually gets more completely behind the artery until at its junction with the primitive vein it is concealed by it anteriorly.

The artery is covered by peritoneum, upon its inner side through a considerable part of its course; above the membrane covers it completely; but as it descends the extent becomes less in consequence of the ascent of the vein; which thus gradually intervenes between the artery and the membrane, and removes the latter from it altogether in the lower part of its course. When the primitive iliac divides at a high point, the ureter descends into the pelvis internal to the external iliac immediately after its origin; this occurs more frequently upon the right side than the left. Beneath the peritoneum the artery is covered by an investment, of which presently again, attaching it superiorly to the peritoneum and inferiorly to the vein.

Externally the artery corresponds through its entire course to the psoas magnus muscle, but it is separated from it by the psoo-iliac fascia, to which it is connected by its immediate investment; the relation of the artery and the muscle are, however, somewhat different at the upper and lower parts of the vessel's course; above, the artery does not lie upon the muscle, but rests against its inner side along its anterior part, while inferiorly it lies upon the inner margin of the muscle at the same time that it rests against it externally.

The genito-crural nerve is situate along the outer side of the artery; this nerve, long and slender, a branch of the lumbar plexus, descends upon the psoas, extenal to the artery, and at first at a little distance from it; as it proceeds, it approaches the vessel, and lies close to it enveloped in the fascia propria; at the lower part of its course its genital branch frequently passes in front of the artery. The anterior crural vein is also external to the artery; but it is considerably posterior to it, separated from it by the outer margin of the psoas, between which and the iliacus it lies, and also by the fascia iliaca, which covers it; the nerve is about half an inch from the artery at the crural arch; as it recedes from the arch the distance increases.

In front, the artery is covered immediately by a cellular investment, formed by the sub-peritoneal cellular structure—the fascia propria—upon the posterior wall of the iliac fossa; this encloses both the artery and the vein and at the same time connects them; it varies in its condition according to the subject, in some it appears a dense, but still cellular expansion, in others from the deposition of fat it forms an adipose stratum, which however still presents a more condensed character in immediate contact with the vessels; it adheres closely to the surface of the fascia iliaca upon either side of the vessels and thus attaches them to it; it is prolonged upward upon the primitive iliac vessels, and below, it ascends between the peritoneum and the fascia transversalis upon the anterior abdominal wall; upon the primitive iliac it is very thin and proportionally weak; but as it descends it increases in thickness and strength until at the lower part of the external iliac. It forms a stratum of some thickness and considerable resistance, deserving of much attention in a practical point of view; there are imbedded in it immediately above the crural arch, and superficial to the artery, one or more lymphatic glands; the genito-crural nerve also descends enclosed in this structure, at the outside of the artery. Beneath the investment, and immediately above the crural arch, an expansion of limited extent, presenting frequently a true fibrous or aponeurotic character, arises from the front of the vessels, and passing forward becomes identified with the fascia transversalis upon its internal surface; thus connecting the vessels to the anterior part of the superior aperture of the femoral sheath, and closing the interval between these parts, which otherwise would be unguarded.

In the second place the artery is covered anteriorly through about four-fifths of its course by the peritoneum of the iliac fossa; in the inferior fifth, i. e., for from half to three-fourths of an inch immediately above the crural arch, the membrane passing from the front of the artery to the anterior wall of the abdomen leaves the iliac artery uncovered; and hence the practical inference that the external iliac artery may be tied without disturbing the peritoneum.

Beneath the peritoneum the artery is crossed at the inferior part of its course by the spermatic vessels, and at the superior, upon the right side very frequently by the ureter.

Thirdly, the viscera of the iliac fossa on the one hand, or of the pelvis on the other, according to circumstances, cross or overlap it; on the right, the cœcum and the termination of the ileum; on the left, the sigmoid flexure and the commencement of the rectum, and on both sides the small intestines are placed in front of it. And when the viscera of the pelvis become distended and rise from the cavity they overlap it from that side.

The third relation of the artery in front is the anterior wall of the iliac region; the details of this it is not proposed to examine at length, but only so far as they may be concerned in the relations of the artery; the structures composing the wall being numerous, they may be conveniently arranged into three sets, viz., the superficial, the intermediate, and the deep or lining structures.

The superficial structures are three, the skin, the subcutaneous cellular tissue, and the fascia. Of these the first does not require to be dwelt upon; the second is subject to much variety in its condition; it forms a stratum of considerable thickness in every case; when, however, the superficial cellular structure of the body is charged with much adeps, it then forms an uniform and thick stratum of fat without any distinction into laminæ; this is best exemplified at the early periods of life, particularly in children cut off by an acute disease; when, on the contrary, the body is emaciated, it forms a condensed cellular expansion much thinner than in the former case, and divisible frequently into laminæ. This structure is continued from the iliac over the other regions of the abdomen, downward upon the thigh, and in the middle line upon the spermatic process of the male and the organs of generation. Numerous superficial vessels are contained in and ramify through it; these are derived from several sources, but that which is proper to the iliac region is the superficial epigastric artery which ascends from the femoral superficial to the aponeurosis of the external oblique muscle and intermediate to the inguinal rings.

Beneath the subcutaneous stratum is the third superficial structure, the fascia; this is a thin dense expansion by which the external oblique muscle and its aponeurosis are covered; it is not confined to the abdomen, but is continued into a similar expansion upon the adjoining regions whether upward or downward; it adheres closely to the muscular portion of the oblique, particularly at the junction of the muscular fibres with the aponeurosis along the linea semilunaris, but its connection to the aponeurosis itself is more free, an extensible and delicate cellular tissue being interposed. Hence it is easily detached from the latter; it is most dense, fibrous, and strong upon the iliac region; as it ascends thence it becomes less dense and fibrous, and assumes more of a simply condensed cellular character; it is not equally distinct in every subject, in all it can be recognized at the crural arch, and for some distance above it, but as it recedes from the arch it frequently seems to be gradually resolved and to cease. Below, it is attached posteriorly to the outer edge of the crest of the ilium, and along this line it meets the insertion of the fascia lata of the back of the thigh; in front between the superior anterior spinous process of the ilium and the spinous process of the pubis it descends over the crural arch, having only a cellular connection to it, and being separable with ease from it, as well as from the aponeurosis of the oblique; immediately below the arch it is united to the superficial surface of the fascia of the thigh, both externally and internally, on the latter side passing back to the pectineal line of the pubis, into which it is inserted along with the pubic portion of the fascia lata; in the interval between the spinous processes of the pubis it is prolonged downward upon the spermatic processes, and is continued upon them in the form of a sheath into the scrotum, where it invests the testicle; it is very thin and transparent upon the spermatic process. The existence of this structure, to which attention appears to have been first directed by Camper, can always be demonstrated however fat or young the subject may be, though, as has been stated, it is not always equally manifest; it seems distinct from the subcutaneous cellular structure, which frequently forms a uniform and thick stratum of fat between it and the skin. Different views have been taken of its nature; by Scarpa it is regarded as a prolongation of the fascia lata of the thigh, while others and the majority consider it as a continuation of the superficial fascia, so called, of the same part, and formed by the deep stratum of the abdominal subcutaneous cellular structure converted by condensation or removal of its adeps into an expansion; to me it appears that the view taken of its nature by Scarpa is correct, not in the sense that it is a prolongation of the fascia lata, but that it is of the same nature, and that it is to the abdomen the same structure which the fascia lata is to the thigh; it is a question entitled to consideration only for accuracy's sake, but I have frequently verified the inferior connections of this expansion such as they have been detailed, and further it appears to me that it is not properly continuous with the superficial fascia of the thigh, for if it be detached from the aponeurosis of the oblique muscle and the crural arch without injury to its connection with the fascia lata, and be then held perpendicular to the latter, the superficial fascia of the thigh may be removed from the angle which it will thus form with the fascia lata, and its connection still remain perfect: a favourable subject and a careful dissection will certainly be required for the purpose, but this circumstance will not invalidate the conclusion; it is also to be recollected in making the dissection, that the fascia detaches processes over the inguinal lymphatic glands.

The structures of the second order of parts concerned with our subject, are the aponeurosis of the external oblique muscle, the internal oblique and the transversalis muscles; of these the first, which is immediately beneath the fascia, extends over the entire anterior wall of the fossa reaching from the linea semilunaris above to the crural arch below; internally it is united with that of the other side in the linea alba, and inferiorly it forms the crural arch by its border, which is attached externally to the superior anterior spinous process of the ilium, internally to the spinous process of the pubis, and in the interior to the iliac fascia and the fascia lata. The direction of this band is to be borne in mind, for it does not run directly from one of these points of bone to the other; but it descends toward the thigh, and recedes from the surface at the same time that it passes inward, hence it is concave both forward toward the surface and upward toward the abdomen; the cause of this direction is its connection inferiorly and posteriorly with the fascia lata and the fascia iliaca. The aponeurosis consists primarily of tendinous fibres which run in the same direction as the fibres of the muscle, i. e., downward and inward, parallel to each other, and also to the crural arch, though rather converging toward it internally, and thereby form a tendinous expansion; the longitudinal fibres of the aponeurosis are crossed by others which run downward and outward; these are very irregular in number and do not interlace with the former, to which they are superficial; hence the aponeurosis does not possess great strength in the transverse direction, and its longitudinal fibres are liable to be separated, and deficiencies to be thereby formed in the aponeurosis, which are not unfrequently to be observed. The superficial inguinal ring is seated in the aponeurosis; this aperture, for the particulars of which see the articles ABDOMEN and HERNIA, is of variable form and size; in some cases it is elliptical, in others triangular; in the male it is larger than in the female; its position is oblique, the longer diameter inclining from the pubis upward and outward toward the superior anterior spinous process of the ilium; its actual length is extremely variable, in some instances not amounting to half an inch, in others exceeding an inch.

The inferior part of the internal oblique and of the transversalis muscles, which alone is concerned in the anatomy of this part of the abdominal wall, may be distinguished into two parts, viz., their muscular portion and their aponeurosis. The muscles are both, but more particularly the latter, very thin, though of great width; they are placed the one within the other, and the internal oblique, which is superficial to the transversalis, also descends a good deal lower, so that its inferior margin approaches very close to the crural arch, leaving only sufficient space between them for the escape of the spermatic process, which it covers beneath the aponeurosis of the external oblique, and which in some instances passes between its fibres,* while the margin of the transversalis is at some distance from the arch, and rarely covers the process, at least to any extent, the process escaping from the deep ring, for the most part below the margin of the muscle; Cloquet has even seen the margin of the muscle so far as two fingers' breadth above the point of escape of the cord, and its fibres are usually pale, fine, and scattered. The muscular fibres of the lower part of the two muscles are attached to the anterior extremity of the crest of the ilium and to its spinous process, also to the superior aspect of the outer part of the crural arch, the oblique to nearly the outer half of the arch, the transverse to the outer third or fourth, but the ultimate attachment of the latter is to the surface of the fascia iliaca above the arch, to which they adhere very intimately as they pass forward from the fascia; they run inward nearly transversely, but convex forward in proportion to the prominence of the abdomen, those of the oblique over the deep ring, and the spermatic process within the inguinal canal, those of the transverse above the ring, until they have both passed that point; they then descend along the inside of the process, and at the same time recede from the surface so that they become posterior to it, and terminate as they descend in a thin irregular aponeurotic expansion common to the fibres of both muscles, and thence denominated "the conjoined tendon;" though designated by an especial name, this is in reality only the inferior part of the general conjoined tendon of the two muscles which terminate between the umbilicus and the pubis in a common expansion; this is placed superficial to the rectus muscle, and is inserted into the linea alba, the anterior margin of the crest of the pubis as far as its spinous process, and thence outward into the pectineal line of the bone, there forming the "conjoined tendon" of the anatomy of hernia. This structure is situate behind the spermatic process,

* Cloquet.

between it and the fascia transversalis; it approaches very near to the inner margin of the deep ring, and at its insertion into the pectineal line it meets and is identified with Gimbernat's ligament; it is closely adherent to the surface of the fascia transversalis, and hence that fascia presents an appearance of thickness and strength upon the inside of the deep ring, which it does not really possess. From the inferior margin of the internal oblique and from the superior side of the crural arch the cremaster muscle descends upon the anterior and external part of the spermatic process, forming one of the coverings of the process within the inguinal canal, of course concealing it after the division of the aponeurosis of the external oblique, and requiring to be detached from the arch along with the lower fibres of the internal oblique in order that the process may be fairly exposed.

The deep structures of the anterior wall of the iliac fossa are also three, viz., the fascia transversalis, the fascia propria, and the peritoneum.

1. The fascia transversalis is most remarkable in the iliac region, but it is not confined to it, being to be traced upward to the surface of the diaphragm, and backward round the interior of the lateral walls of the abdomen. In the iliac region this fascia is inferiorly first identified with the fascia iliaca from a short distance behind the anterior superior spinous process of the ilium to the outer side of the external iliac artery, or about the middle of the crural arch; the line of its connection with the fascia iliaca runs downward, forward, and inward, at a short distance within the crest of the ilium and the crural arch, approaching the latter, however, as it descends, until at the outside of the artery it touches it; it is separated along this line into two laminæ which enclose the circumflex iliac artery between them; there is, therefore, an interval between the arch and the line of connection of the two fasciæ in which the fascia iliaca intervenes, and to the surface of this part of the fascia it is that the internal oblique and transverse muscles are attached. In the second place the fascia transversalis descends into the thigh beneath the crural arch, between it and the iliac vessels, and forming the front of their sheath; and, thirdly, it is attached upon the inside of the vessels, along the pectineal line of the pubis posterior to the conjoined tendon of the internal oblique and transverse muscles, between it and the peritoneum, and separated by it from the spermatic process, which is in front of both.

Internally the fascia transversalis is connected to the edge of the tendon of the rectus.

Midway between the superior anterior spinous process of the ilium and the spinous process of the pubes, and at from half to three-fourths of an inch above the crural arch, the spermatic process escapes from the abdomen, descending within a cylindrical prolongation of the fascia by which the process is enclosed, and which thus forms a sheath for the process. By detaching this prolongation from the fascia around the process, a circular aperture is formed in the fascia, which is the deep inguinal ring, the situation of which has been just defined. On the inside of this opening are situate the epigastric vessels, the artery, and vein or veins, the artery in the former case being next the ring, in the latter at times the outer of the two veins.

2. The fascia propria is a cellular stratum interposed between the peritoneum and the structures of the abdominal walls which it lines; it varies in thickness and condition at different parts and in different subjects; at times it contains adeps, at others it is purely cellular, or forms a condensed expansion; in the iliac region it is thicker upon its posterior than its anterior wall; on the latter it increases in thickness as it descends towards the crural arch, being so thin towards the umbilicus that the peritoneum adheres very closely to the tendinous expansion of the muscles; at the deep inguinal ring it is more dense, and the peritoneum, the fascia transversalis, and it, are more intimately connected than at either side; external to the ring, between it and the spinous process of the ilium, it is so free that the peritoneum may be separated without difficulty from the interior of the fascia transversalis, and along the crural arch it forms, from the external iliac artery outward, a soft mass, sometimes thick, occupying the interval left between the peritoneum and the fascia transversalis, at the reflection of the former from the iliac fossa to the anterior wall: upon this wall it encloses the epigastric vessels, the umbilical ligament, and the spermatic vessels, and not only does it extend universally over the interior of the abdominal walls but it is prolonged through their several apertures upon the parts which pass through them, as in the case of the spermatic vessels.

From the anterior wall of this region it passes to the posterior, where it lines the iliac fossa, and connects the peritoneum or the viscera to the iliac fascia; at the outer part of the fossa it is remarkably free, soft, and easily lacerated, so that the peritoneum can be detached, probably with greater facility at this than at any other situation; at its inner part it is even more abundant, thicker the nearer to the crural arch, forming the investment by which the iliac vessels are inclosed, and descending thence into the pelvis.

Lastly, the peritoneum of the anterior wall is continuous inferiorly with that of the iliac fossa, being reflected from the one to the other at the distance of five or six lines above the crural arch—a fact deserving of much attention, since it permits the external iliac artery to be secured without disturbing the membrane. In its reflection from one wall of the region to the other it leaves immediately above the crural arch, between itself, the fascia transversalis, and the fascia iliaca, a triangular interval of some lines, occupied by the fascia propria, and at times at least by one or more lymphatic glands; this space is widest at the iliac artery and diminishes as it extends outward; this fact also deserves attention, inasmuch as it points out where the fascia transversalis may be divided, if necessary, in the operation of exposing the external iliac with least danger to the peritoneum, viz. on the outside of the deep inguinal ring and close as possible to the crural arch. The peritoneum of the anterior wall of the fossa is weaker toward the middle line than externally; it presents toward the abdomen two depressions or recesses denominated by Velpeau "fossettes inguinales," internal and external; these depressions vary very much in their depth, sometimes hardly perceptible, at others of considerable depth and capacity, more especially the external, which is much the larger; they are produced by the projection of the umbilical ligament from the interior of the abdominal wall, and the reflection of the peritoneum round the ligament, by means of which a triangular fold, wide in proportion to the degree to which the ligament projects, is formed, the base of which is below, the apex above toward the umbilicus, and in the free edge of which the ligament is contained; this fold separates the depressions, one being external to it, the other internal, between it and the urachus; the external one, the bottom of which tends forward and inward, corresponds to some point of the posterior wall of the inguinal canal, but its precise relation to it is uncertain, because of the irregularity of the position of the umbilical ligament; at times it is identical with another slight depression situate on the outside of the epigastric vessels, which marks the situation of the deep inguinal ring, the ligament in such case being behind these vessels; at others it corresponds to the wall of the canal, to the superficial inguinal or the deep femoral rings, the ligament being in these latter cases internal to the epigastric vessels.

The branches of the external iliac artery deserving of particular attention are usually two, the anterior or circumflex iliac and the epigastric arteries; throughout the superior part of its course the artery gives only minute branches to the peritoneum, the cellular tissue, the psoæ muscles, and the lymphatics; the other two, which have been mentioned, are given off immediately before the artery escapes from the abdomen. They arise at a very short distance above the crural arch, sometimes so high as three-fourths of an inch from it, at others at it, and sometimes again below the arch from the femoral; they proceed one from the outer and the other from the inner side of the vessel, sometimes opposite to each other, at others indifferently one above the other; occasionally they are given off from a trunk common to both; they are nearly of equal size, but for the most part the epigastric is larger than the circumflex.

1. The *anterior or circumflex iliac artery*, (*arteria circumflexa iliaca* or *ilii;* Fr. *artere circonflexe iliaque*, ou *iliaque* ou *antericure*,) arises from the outer side of the external iliac on a level with or somewhat lower than the epigastric; it runs outward and upward above and parallel to the crural arch as far as the superior anterior spinous process of the ilium; during this course it lies upon the fascia iliaca superficial to the psoas and iliacus muscles and the anterior crural nerve, and it is inclosed in a triangular canal, formed behind by the fascia iliaca, below and above by laminæ of the fascia transversalis, which divides at its union with the former, in order to inclose the artery. When the anterior abdominal wall has been thrown down, and the peritoneum with the fascia propria removed from the iliac fossa, the course of the vessel may be traced by a white line, which marks the union of the two fasciæ, extending from the middle of the crural arch upward and outward within about three-fourths of an inch of the spinous process of the ilium; by the division of the fascia transversalis along this line the artery will be exposed.

During its course toward the spinous process the artery gives branches to the psoas and iliacus, the transversalis and oblique muscles, and to the inguinal glands; near the process it gives upward a considerable branch, which ascends in the anterior wall of the abdomen between the internal oblique and transversalis muscles, in front of the spinous process, serving with its accompanying veins as a guide in dissection by which to distinguish between the two muscles; it divides into branches, which are distributed to the muscles, as also to the structures, which cover and line them, and communicate with branches of the epigastric, lumbar, and intercostal arteries.

The circumflex artery pursues its course and runs backward around and within the crest of the ilium, internal to the transversalis muscle; during its course it gives branches inward to the iliacus muscle which anastomose with similar branches from the iliolumbar, and upward to the lateral abdominal muscles, which are partly distributed to them, partly turn over the crest of the ilium and communicate with the gluteal artery, and in part communicate with the lumbar or intercostal arteries. Finally, the artery, very much reduced in size, anastomoses freely with the termination of the iliolumbar, which pursues a similar course in a contrary direction around the interior of the crest of the ilium.

The circumflex artery has been found by Monro to present an irregularity deserving of notice; he has seen a branch from it, nearly as large as the epigastric, pass under the crural arch, about two inches from the symphysis pubis, and there divide into branches, which were distributed upon the symphysis and the fat and skin over the arch.

2. The *epigastric artery*, (Fr. *artere epigastrique, A. sus-pubienne)* arises from the internal and rather anterior part of the iliac artery, near to the crural arch; the distance of its origin from the arch, however, is liable to variety; for the most part it occurs about half an inch above it, but it is frequently nearer to it, or even at it, and occasionally it is below it, arising from the femoral artery; it is given off, as has been stated, from that part of the iliac, which is left uncovered by peritoneum, and its point of origin is posterior to, sometimes above, sometimes on a level with, and at others below the reflection of the mem-

brane from the posterior to the anterior wall of the abdomen. Its course is tortuous; it passes forward and inward; when its origin is low, or very near to the arch, at once upward; but when its origin is high, at first downward in front of the external iliac vein, and then changing its direction, when it has reached the reflection of the peritoneum, it ascends inward toward the outer margin of the rectus muscle, in front of the membrane, between it and the fascia transversalis; it reaches the margin of the muscle from one and a half to two inches above the pubis, and then passing behind it enters its sheath, and continues its course upon the posterior surface of the muscle toward the umbilicus, and terminates by dividing into branches, which anastomose freely with descending branches of the internal mammary artery; the main course of the vessel is therefore oblique upward and inward; and it may be defined by a line drawn from the junction of the middle and inner third of the crural arch to within half an inch upon either side of the umbilicus.

The artery, when its origin is high, is situate, at its outset, behind the peritoneum, posterior to the deep inguinal ring; in the rest of its course it is at first beneath and then before it, in immediate contact with it from the crural arch to the edge of the rectus, and enclosed in the fascia propria, but in the remainder separated from it by the back of the sheath of the muscle; it therefore forms in this case a curve in which the reflection of the peritoneum is contained, and through which the vas deferens forms a similar curve,—the aspect of the curves being however different, the convexity in the former directed downward, and in the latter outward and somewhat upward—the two cords hooking round each other; in its ascent from the crural arch it is contained in the posterior wall of the inguinal canal, between the fascia transversalis and the peritoneum, crossing the canal nearly at right angles, and intermediate to the two rings, being distant from the outer part of the superficial one, according to the size of the aperture, from half an inch to an inch and a half, and in its relation to the deep ring varying from the margin of the aperture itself to four or five lines distance from it. It is accompanied sometimes by one, at others by two veins; in the former case the artery is always external and next to the margin of the ring; in the latter, one of the veins is at times between it and the aperture.

The relation of the artery to the inguinal rings indicates at once that which it must hold to the neck of the sac in the two original forms of inguinal hernia; in the oblique or external inguinal hernia it is, as a matter of course, placed beneath and on the inside; and in the direct or internal inguinal, upon the outside of the neck; but in the former it must, in consequence of its natural vicinity to the ring, and the dilatation of the latter, be close to and surround the neck upon the two sides mentioned, while in the second, unless the aperture be much enlarged, it will be at a greater or less distance from it; the risk of danger to the vessel from cutting to the side, at which it lies, in a strangulation at the neck of the sac, must therefore be much greater in the former than in the latter. In the case of a hernia originally oblique and become direct by long continuance, the artery carried inward along with the deep ring, from the displacement of which the hernia assumes the character of the direct form, the artery is of course situate still upon the inside of the neck, which at the same time it surrounds to a greater extent than in the former instances; this third, though secondary, form of inguinal hernia presents another case, in which the relation of the vessel to the neck of the sac demands attention the more that the true nature of the case being obscure and the hernia originally and secondarily direct, being thence liable to be confounded, it is most important that it should be borne in mind that the artery may be to the one side or the other, according as the hernia has been originally or secondarily direct. The epigastric artery is also situate, in its ascent, external to the deep femoral ring; its distance from it, in the natural state, is about half an inch; but when hernia is present, and the neck at all large, the epigastric vessels are close to its outer and anterior side, the vein, however, being between the artery and the ring; when the obturator artery arises from the epigastric, the propinquity of the latter to the ring is increased.

The branches of the epigastric artery are numerous, and some of them important. Its first branches are two given off between its origin, and the deep inguinal ring, higher or lower, according to the situation of the origin of the epigastric itself; they arise, in some instances separately, in others by a single origin, and they run over to the posterior surface of the pubis, the other to anastomose with the obturator artery; the former, the pubic branch, runs inward above Gimbernat's ligament, sometimes along its anterior, sometimes along its posterior margin, to the back of the pubis, and according to its course is liable to be situate before or behind the neck of a femoral hernia. The second, the obturator branch, runs backward, downward and inward toward the superior aperture of the pelvis, i.e. in the direction, which the obturator artery when arising from the epigastric takes; having descended into the pelvis it joins the obturator at a variable distance between the origin of that vessel from the internal iliac and the subpubic foramen; frequently it divides at the brim of the pelvis into two, of which one joins the obturator and the other runs backward along the brim and anastomoses with the ilio-lumbar artery. This branch holds precisely the same relation to femoral hernia which the obturator when arising from the epigastric does; it is very variable in size, and it is upon its development as compared with that of the origin of the obturator from the internal iliac that depends, whether the former shall seem a branch of the latter, or of the epigastric; when the origin of the obturator from the iliac has become wanting, this branch takes its place and becomes the obturator.

2. The epigastric artery in passing the deep inguinal ring gives a branch, which goes out through the ring in company with the spermatic process, descends to the scrotum and is distributed to the structures of the cord, to the tunica vaginalis, and to the cremaster, and anastomoses with branches of the spermatic artery; it is denominated by some *the inferior spermatic artery*.

3. As the artery ascends in the abdominal wall it gives to either side numerous branches, which are distributed among the structures of the wall, anastomosing externally with branches of the circumflex iliac, of the lumbar and the inferior intercostal arteries, and internally with those of the artery of the other side; many of these branches ultimately become superficial, passing through the muscles, and through apertures in the aponeurosis of the external oblique; they terminate in the superficial structures, anastomosing with the other superficial vessels.

4. Finally, the epigastric artery terminates by two or more long ascending branches, which meet and anastomose with branches from the internal mammary artery.

Methods of operation for the ligature of the iliac arteries.—The methods of operation for the internal and primitive iliacs being but modifications of those adopted for the external, I propose to detail the latter first.

The operation in each case may be resolved into three stages, viz. 1, the division of the structures of the abdominal wall; 2, the displacement of the peritoneum with the intervening viscera; 3, the management of the artery and the parts immediately related to it. Several plans have been proposed for exposing the external iliac artery; these may be regarded as, all, modifications of the same; yet their number, the existence of points of difference leading to results of some importance, and the advantage to be derived from a clear apprehension of them, render it desirable to distinguish them so far as they present distinctive characters deserving notice. I propose, therefore, to particularize five methods, between which operators may have occasion to select. In the first the line of incision is straight, and corresponds to the course of the artery. In the second the line of incision is also straight, and inclines away from the course of the artery toward the superior anterior spinous process of the ilium. In the third the line of incision is curved, convex downward toward the thigh, and crosses the course of the vessel. In the fourth the line of incision is straight, and transverse to the artery's course. The fifth, which I would specify, is a modification of the third, by which that plan may be rendered more generally applicable. The first is, that which was adopted by Abernethy, by whom the artery was first tied, A.D. 1796, and is now generally known as his method, of which the following is his own account:—"I first made an incision, about three inches in length, through the integuments of the abdomen, in the direction of the artery, and thus laid bare the aponeurosis of the external oblique muscle, which I next divided from its connection with Poupart's ligament, in the direction of the external wound, for the extent of about two inches. The margins of the internal oblique and transversalis muscles being thus exposed, I introduced my finger beneath them for the protection of the peritoneum, and then divided them. Next, with my hand I pushed the peritoneum and its contents upwards and inwards, and took hold of the artery."*

The second method seems due to several, and first also to Abernethy. This may seem doubtful, from the account of his second operation originally given by himself, in which he says merely that "an incision of three inches in length was made through the integuments of the abdomen beginning a little above Poupart's ligament, and being continued upwards; it has more than half an inch on the outside of the upper part of the abdominal ring, to avoid the epigastric artery."† But in his collected works‡ of different dates it is expressly stated of this and his subsequent operations that the incision "began just above the middle of Poupart's ligament, and consequently external to the epigastric artery, and was continued upwards, but *slightly inclined towards the ilium.*" The plan adopted by Frere differed not much from this. This method appears however more particularly attributable to Roux, who seems to have been the first to give specific instructions for it, recommending that the beginning of the incision should never be further than half an inch from and a very little higher than the anterior superior spine of the ilium, and that it should be carried very obliquely downwards to the middle of Poupart's ligament.§

The third method is that of Sir A. Cooper, in which the incision is begun just above the abdominal ring, and is extended downward in a semilunar direction to the upper edge of Poupart's ligament, and again upwards to within an inch of the anterior superior spinous process of the ilium. This incision exposes the tendon of the external oblique muscle: in the same direction the above tendon is to be cut through, and the lower edges of the internal oblique and transversalis muscles exposed: the centre of these muscles is then to be separated from Poupart's ligament: the opening by which the spermatic cord quits the abdomen is thus exposed, and the finger passed through it is directly applied upon the iliac artery above the origin of the epigastric and circumflex ilii arteries: the next step of the operation consists in gently separating the vein from the artery by the extremity of a director or the end of the finger; the aneurismal needle is then passed under the artery.‖

The fourth is that of Bogros, in which the line of incision is, as I understand it, straight, from two to three inches long, immediately above the crural arch, and has its extremities

* Surgical Works, 1830, v. 1, p. 292.
† Surgical Observations, 1804, p. 214.

‖ Cooper's Lectures by Tyrrell, v. 11.

equidistant, the external from the spine of the ilium, and the internal from the symphysis of the pubis. The aponeurosis of the external oblique muscle having been laid open in the direction of the crural arch upon a grooved director, the spermatic cord with the cremaster is to be drawn upward beneath the superior lip of the wound; the deep ring dilated with the point of the finger; the epigastric vessels, if a guide be necessary, followed toward their origin; the cellular structure and lymphatic glands situate above the arch upon the artery separated; and the vessel exposed and isolated.*

In the fifth method, which is but a modification of Cooper's, the outer extremity of the incision as directed by him is prolonged to, or beyond the superior spinous process of the ilium in proportion to circumstances.

Before these methods be contrasted with each other, a few additional remarks seem required in reference to the operation however performed.

1. The posture of the patient should be such as will most relax the abdominal muscles in order to prevent as much as possible their pressure upon the viscera, and to allow the more easy separation of the edges of the wound. The shoulders should be raised and the legs bent upon the pelvis.

2. It seems desirable that unless the superficial wound be longer than has been stated, the division of the aponeurosis of the external oblique should be of equal extent.

3. The recommendation to divide that aponeurosis upon a director appears judicious as a means both of facility and safety.

4. Where it can be used the finger seems a safer instrument with which to separate the internal oblique and transversalis muscles from the structures beneath, for it will be readily understood that the extremity of a director might be easily thrust through the peritoneum in the execution of this step.

5. It must be borne in mind that between the muscles and the artery there are to be expected beside the peritoneum two other structures: 1. the fascia transversalis; 2. the immediate investment of the vessels. The fascia transversalis may either be treated in the manner directed by Cooper, viz. by dilating the deep ring, or be lacerated with the nail, as recommended by Guthrie, but it is to be recollected that a prolongation of the fascia descends upon the spermatic cord, and that therefore there exists no opening, and that the fascia varies in strength, and may at times be found so strong as to require more force to lacerate it than it may be deemed proper to exert. In such case an opening may be made through it with the knife, and enlarged upon a director if necessary. This may be effected by either of two methods, viz. either by dividing the prolongation of the fascia, which descends upon the spermatic process, "having been first raised with a forceps, to a sufficient extent to admit the forefinger to pass upon the cord into the internal abdominal ring,"—a proceeding adopted by Mott, and which offers a safe mode of opening that structure; or by cutting the fascia upon the outside of the ring, in the direction toward the superior spine of the ilium, to such an extent as may allow the introduction of the director or the finger: the section cannot be attempted safely inward, because of the vicinity of the epigastric artery, which is so near to the inner side of the deep ring that it must in such case be exposed to imminent danger, situate as it is between the fascia and the peritoneum; on the other hand the more close attachment of the fascia to the latter membrane in proportion as it recedes from the crural arch forbids the section of the fascia directly upward; while the existence of the triangular interval, which has been described, between the fascia and the peritoneum immediately above the arch renders the membrane safe from injury in a division outward near to the arch: it must however be recollected that in approaching the arch the circumflex ilii artery is also approached and endangered, so that the incision should not be brought too near to that part, but made in the direction mentioned, nor in any case be larger than will suffice for the introduction of the finger or the director.

6. The immediate investment of the vessels frequently opposes great resistance to the separation of the artery and vein, and to the isolation of the former; this impediment is due not merely to the strength of the investment, but also to the absence of a resisting support behind the vessel as it recedes from the pubis, in consequence of which it yields to the pressure exerted to separate it. In such case the nail, the director, or the knife has been recommended for the division of the expansion; Abernethy made a slight incision on either side of the artery. The nail does not seem the best instrument in this instance, because, by the use of it the vessel must be a good deal disturbed, a circumstance to be avoided whenever it can be; the knife again must be attended with risk unless used with great caution and in steady hands, and the risk is the greater when the incision is made at one side of the artery, since the vein is thereby endangered; it would seem a safer proceeding and one less likely to disturb the artery unnecessarily, if, when it can be done, the investment were pinched up with a forceps over the middle of the artery and then divided to the extent to which it may have been raised, after which, with the director or the blunt aneurism-needle, the artery may be isolated with facility while the investment is drawn to either side with the forceps.

7. It is to be borne in mind that one or more lymphatic glands usually lie in front of the artery imbedded in the cellular structure which forms its investment, and that these may be to be displaced.

8. In operations upon the iliac arteries, more particularly when performed after the method of Abernethy, or upon the internal or primitive vessels, a protrusion or bearing down of

* Archives Générales de Méd., t. iii. p. 408.

the abdominal viscera is to be expected which has been found a great obstruction to the operation: this will be most effectually prevented by the use of purgatives previous to the operation; by posture, the abdominal muscles being thereby relaxed as much as possible; and during the operation, if it occur, by the use of curved spatulas of considerable width and curve, as used by Mott, with which the viscera may be supported.

9. In the passage of the ligature it will always be necessary to be assured that the genito-crural nerve is not included; but it may be avoided without difficulty, and can seldom require to be divided. Its situation should be borne in mind, viz. above external to the artery, below external or anterior.

Lastly, it would seem the safer plan to pass the needle and ligature from within outward, inasmuch as the vein is internal to the artery. In Cooper's Lectures edited by Tyrrell, it is directed to pass the needle from without; by so doing there is less risk that the genito-crural nerve shall be included, and in high operations, since the vein is situate so much beneath the artery at the superior part of their course, it will not be thereby much endangered, but at the lower part the vein must certainly be more exposed by that mode of passing the ligature than by the contrary one, while the nerve may be avoided without difficulty.

We shall next consider the comparative merits of the several plans of operation. In the method of Abernethy the direction of the line of incision is attended with the following consequences. 1. It requires a more extensive division of the oblique and transversalis muscles, and hence is more likely to be followed by weakness of the abdominal wall. 2. Falling, as first performed by him, nearly upon the course of the epigastric artery, it exposes that vessel to be divided, though in the method adopted by him in his latter operations this risk must be very much diminished, if not removed. 3. The extent to which it is necessary to divide the internal oblique and transversalis muscles must expose the peritoneum lining the anterior wall of the abdomen to be lacerated or divided during their separation. 4. The parallelism of the vessel and the wound must render it necessary to expose a greater length of the former, in order to effect its separation from the contiguous parts and to pass a ligature round it. 5. It is therefore necessary to detach the peritoneum in all cases, and to a greater extent than may be necessary or required by a different method. 6. The peritoneum must be detached to an equal extent from both walls of the abdomen—from the anterior as much as, or it may be more than, from the posterior. 7. The protrusion of the viscera must be more likely to occur.

It is asserted by some* that the spermatic cord is more exposed to injury in this method; but it appears to me that it cannot be more so than in others, and that it ought to be more safe.

* Velpeau.

The second method is free from many objections to which others, and especially the first, are exposed. 1. It does not endanger any vessel but the superficial epigastric. 2. It does not endanger the spermatic cord. 3. Probably it does not tend to weaken the abdominal wall as much as the first method. 4. It renders necessary a much less extensive detachment of the peritoneum, since the line of incision falls so much nearer to the inferior reflection of the membrane. Add to these that by it the artery may be reached at as high a point as by the first, and no doubt can remain that it is to be preferred to it; and in cases requiring a high ligature of the vessel there is none, save the modification of Cooper's method, which can be considered equally eligible. It is still, however, subject to the same conditions with the first, only in less degree. In the method of Cooper, on the contrary, the internal oblique and transversalis muscles are divided to but an inconsiderable extent, and the division of the aponeurosis of the external oblique approaches more to the course of its fibres. The direction of the incision being transverse to that of the artery, the vessel may be exposed, and a ligature passed round it without stripping it to a great extent and with little disturbance of it. Again, for the same reason and because of the vicinity of the incision to the crural arch, the vessel may be exposed either without displacing the peritoneum at all, or displacing it but little; and when it is necessary to displace the membrane, that may be effected with the least possible disturbance of it, inasmuch as, because of the propinquity of the line of incision to the reflection of the membrane, it is not necessary to detach the latter from the anterior wall of the abdomen. It must also be less exposed to the protrusion of the viscera, and when the vessel is tied below, the reflection of the peritoneum must be exempt from it. This method permits the artery to be reached at from an inch to an inch and a half above the crural arch.

On the other hand this method endangers the epigastric artery and spermatic cord more than the others; the former because the line of incision crosses the vessel's course, commencing internal to it, and the latter because the line of incision crosses and sweeps over the cord in describing its curve. Velpeau considers that there is greater danger to these parts in the method of Abernethy, but I cannot concur in this opinion, for the lower extremity of the incision alone can fall upon the situation of the cord, and in the mode adopted by him in the majority of his operations, the line of incision was external to that of the epigastric artery. Experience too proves that there is greater danger of dividing the epigastric artery in the method of Cooper, since the accident has occurred more than once in it, and in the most dexterous hands; thus Averill relates that the artery was wounded by Dupuytren, and Guthrie also states that he has seen the artery divided in the performance of this operation, while I am not aware of an instance in which the trunk of the artery has been divided in the method of Abernethy. But these objections to the method of Cooper, however serious in themselves, seem of insufficient weight when contrasted with those to which the plan of Abernethy is subject, more especially since they only require caution to be effectually obviated, while the others are inseparable from the plan to which they apply. And hence the preference has been given to his method, by the greater number of those* who have had opportunities of experimentally testing the comparative claims of the two in all cases where it is applicable; i. e. in those instances in which the aneurismal tumour has so little encroached upon the crural arch, or in which there is so much reason to consider the artery in a healthy condition immediately above the arch, that it may be with propriety tied near to that part. Sabatier is of opinion that the method of Abernethy should be preferred in every case; but the number of authorities in favour of the other is so great, that we must consider its greater eligibility as a decided question. And the method of Cooper possesses the additional and great recommendation that it may at any time be so modified by the prolongation of the upper extremity of the incision, as to be adapted to every case, so that in instances, in which it may be found necessary to tie the artery at a greater distance from the arch than the original plan will permit, this modification of it may be adopted even in the course of the operation: for the most part surgical writers recommend a preference of Abernethy's first plan in such circumstances; but to this all the same objections which have been already stated, apply, and forbid its adoption, while another less subject to them and not less efficacious presents for selection. Abernethy's plan certainly promises one advantage, viz. that the line of incision being nearer to that of the artery the depth of it from the surface is likely to be less, unless where the abdomen is very prominent, than in the latter, in which the obliquity of the direction must increase the depth of the wound, and for the same reason it may be more easy to obtain a view of the vessel, and to direct the operation by the sight, which must be more difficult in the latter, and in proportion as the point at which the operator aims is higher; yet, notwithstanding this circumstance in favour of the method of Abernethy, and the preference given by several to it in such cases, the method of Cooper, modified as has been explained, appears to me still preferable, inasmuch as the greater disturbance of the peritoneum, the risk of injuring it in front, and the greater debility of the abdominal wall likely to be the consequence of Abernethy's method, seem to outweigh its advantages: there is beside another disadvantage attending the latter and a corresponding advantage attending Cooper's plan, which must be experienced when an aneurismal tumour occupies the iliac fossa, viz. that, by the former the peritoneum must be detached from all the front of the tumour, while in the latter the lower and inner part of it may be left undisturbed, and this I consider a matter of some importance.

* Norman, Todd, Velpeau.

The method of Bogros has been proposed as an improvement upon that of Cooper, under the impression that in the latter the incision, which makes nearly a right angle with the artery, corresponds to the vessel only by its internal extremity, while in the one which Bogros proposes the middle of the incision corresponds directly to the artery; by this plan he further maintains that greater facility in the operation is obtained, and the artery may be exposed nearly an inch above the crural arch without disturbing the peritoneum, while in Cooper's the membrane must be always displaced, and the ligature can be applied at only a very short distance from the arch. Bogros plainly understands Cooper's incision to commence at the internal abdominal ring, and in such case his objections would be well founded. It is certainly to be regretted that Cooper has used an ambiguous expression, which has led others beside Bogros to mistake his meaning; but if reference be made to his description of the anatomy of hernia it will be found that by the "abdominal" he intends the superficial inguinal ring, and if so, that the sole difference between his and Bogros' plan is that in one the line of incision is straight while in the other it is curved, whence the comparative results must be the reverse of those inferred by Bogros, so far as the facility of securing the artery and of reaching it at a greater distance from the crural arch is concerned. If however it be desired to secure the artery immediately above the crural arch, between it and the reflection of the peritoneum, as may occur in cases of femoral aneurism, the method of Bogros furnishes a plan fully adequate to the intention, free from the necessity of disturbing the peritoneum and easy of execution; at the same time that it is subject to the objection, that, unless care be taken to prevent it by tracing the vessels to their origin, which must render the operation more complicated and delicate, the artery is more likely to be tied below the origin of the epigastric and circumflex arteries by this than by any other plan, and this upon two accounts had better be avoided, so that all things considered this plan appears to me not so eligible as that of Cooper, in which it is altogether optional with the operator whether he shall disturb the peritoneum or not, or whether he shall tie the vessel immediately above the arch or farther from it, the one method being applicable to all cases, and not requiring, perhaps during the operation, a transition to another, after that the first has been found insufficient.

The modification of Cooper's plan, which has been enumerated as a fifth method, can be required only in those cases, in which it may be necessary to reach a very high point of the external or the primitive iliac. In such it will be a question whether to adopt Abernethy's original method, the second method, or the one under consideration: for myself it appears to me that the first ought to be abandoned in operations upon the external or primitive iliacs, unless there be something peculiar in the particular case to justify its adoption. The advantages of the second method have been partly stated; to these is to be added that the line of incision will be made to correspond more to that of the artery than by the last method, and consequently the wound will be less oblique in depth, whence probably there will be less difficulty experienced in holding aside the parts which intervene between the surface and the vessel; and certainly the operator, who may be apprehensive of injuring the epigastric and circumflex iliac arteries or the spermatic process, will do well to adopt it. Still for some reasons I feel disposed to prefer the last, for 1, it requires less disturbance of the peritoneum; 2, it appears to me that the exposure of the vessel must be greatly facilitated by carrying the lower extremity of the incision across the course of the artery to its inner side, which is not accomplished by the second method; 3, a semilunar line of incision furnishes a wound of greater length, and capable of being more widely opened than a straight one, while caution will secure the spermatic process and the epigastric artery from injury; and if a branch of the circumflex ilii be, as it is likely to be, divided, it may be tied with ease. This was the method adopted by Mott in the operation, in which he tied the primitive iliac artery; a case which sufficiently establishes the adequacy of this plan for the high ligature of the vessel, at the same time that it displays in a strong light the difficulties for which the operator must be prepared. In such cases the method of dividing the internal oblique and transversalis used by Mott may be adopted with advantage, viz. after having opened the fascia transversalis to insinuate the finger between it and the peritoneum, and guided by it to divide both muscles at once from within. It must not be forgotten that it is not uncommon to find the ureter crossing the internal iliac artery, upon the right side, near its origin.

Operations for the ligature of the internal iliac artery. — The method adopted in this operation by Stevens, by whom the artery was first tied, and that recommended by the majority of writers, is similar in principle to the first plan of Abernethy for the external iliac, and differs from it only in the length of the incision, which, according to Guthrie, should be five inches, beginning about half an inch above Poupart's ligament and about the same distance to the outside of the inner ring; it should be nearly parallel to the course of the epigastric artery, but a little more to the outside, in order to avoid it and the spermatic cord, and have a gradual inclination inwards toward the external edge of the rectus muscle: according to Hodgson the centre of it should be nearly opposite the superior anterior spinous process of the ilium. The aponeurosis of the external oblique, and the internal oblique and tranversalis muscles having been divided with the same precautions to avoid the peritoneum, as in the other case, the fascia transversalis is to be torn through at the lower and outer part, so that the fingers may be passed outward towards the ilium, and the peritoneum detached from the iliac fossa, and turned with its contents inward by a gradual and sidelong movement of the fore and second finger inwards and upwards, until passing over the psoas muscle the external iliac artery is discovered by its pulsation. This is then to be traced upward and inward toward the spine, where the origin of it and the internal iliac from the common iliac trunk will be felt. The artery is to be traced downward from its origin and separated with care from its connections, and more especially the vein. The sides of the wound should now be separated and kept apart with curved spatulæ in order that the surgeon may, if possible, see the artery, and have sufficient space for passing the ligature. Great care must be taken to avoid every thing but the artery; the peritoneum which covers, and the ureter, which crosses it, must be particularly kept in mind; the latter may be separated with ease, and usually accompanies the former as it is being detached from the artery. The situation of the external iliac artery and vein, which have been crossed to reach it, must be always recollected, and, if possible, they should be kept out of the way and guarded by the finger of an assistant.* This method has in this case a recommendation, which it does not possess for the other iliacs, viz. that, as it is necessary in tying the internal iliac to descend more or less into the pelvis, it is desirable that the external wound should be as near as possible to the aperture of the cavity, but the danger to the peritoneum must be even greater because of the greater extent to which it must be separated, and the closer attachment of it to the tendinous than the muscular structure of the abdominal wall. It, therefore, seems to me a question whether even in this case the line of incision here recommended should be adopted, and whether it would not be better to have recourse to that either of Roux or Cooper. Of the two perhaps the former may be best adapted to the internal iliac for the reason just assigned; though, if the inferior extremity of the incision be not carried beyond the middle of Poupart's ligament, difficulty must be experienced in exposing the vessel and passing the ligature; therefore here again I am disposed to prefer the semilunar line of Cooper, only not brought so close to the crural arch as for the external iliac, and prolonged, as directed by Velpeau, two inches at its external extremity.

It is recommended to pass the ligature from within outward because the internal iliac vein is posterior to the artery; this appears to me, however, not the most judicious plan, by it the point of the needle must be first carried outward and then forward and inward in order to pass round the vessel: now the external iliac vein is immediately external to and crossed by the artery; the junction of the two iliac veins is also external to the artery, and the internal one, though posterior, is at the same time rather external to it. In such a case the course

* Guthrie on Diseases of Arteries, p. 371-2.

to be pursued must be very much influenced by the convenience of the moment; but it would seem the better plan, where a choice can be made, to pass the needle first backward between the artery and the external iliac vein, and then inward behind the artery toward the pelvis, by which plan the veins will be more surely avoided, and more space will be obtained for seizing the ligature.

In this as well as every operation upon the iliac arteries, the spermatic vessels must be kept in mind, inasmuch as they require attention as much as the ureter; they are usually, however, like it, removed with the peritoneum. Velpeau suggests the possibility of rupturing the ilio-lumbar artery in isolating the internal iliac, and the risk ought not to be overlooked.

Ligature of the primitive iliac artery.—Any of the methods recommended, whether for the internal iliac or the external at a high point, will answer for the ligature of the primitive iliac. Guthrie gives the preference to that upon Abernethy's first plan in this as in the case of the internal iliac; but it appears to me that here, at all events, the method of Roux or the modification of Cooper's operation is to be preferred; for, beside that there does not exist in this case the reason for approximating the line of incision to the aperture of the pelvis, which applies to the internal iliac artery, the situation of the aneurismal tumour in front must render the direct line of incision less convenient than a lateral one, and by the adoption of the former there must be incurred a great exposure of the peritoneum without a commensurate advantage; the necessity also of stripping the membrane from all or a great part of the front of the aneurism, incurred by this plan, must be very objectionable. The length of incision recommended by Guthrie is five inches at the least, and may be required of even greater extent; thus Mott was obliged to extend it in his case upward and backward, about half an inch within the ilium, to eight inches: he adopted the principle of Cooper, commencing his first incision " just above the external abdominal ring, and carrying it in a semicircular direction half an inch above Poupart's ligament until it terminated a little beyond the anterior superior spinous process of the ilium, making it in extent about five inches." It is likely that a longer incision may be necessary in this method when applied to the primitive iliac than in that recommended by Guthrie; the greater length of the external incision is doubtless an objection of secondary importance; but it is probable that, when the primitive artery is to be tied, little will be gained by commencing the incision so low as was done by Mott, and that it would be more advantageous to carry it upward rather than downward; such appears to have been the design of Crampton in the operation performed by him for the ligature of the primitive iliac, in which the line of incision was curved, concave toward the umbilicus, and extended from the anterior extremity of the last rib downward beyond the superior anterior spinous process of the ilium, and since unnecessary division of the abdominal parietes is of course to be avoided, and the leaving them entire at the lower part must be attended with two good results, viz. avoidance of the aneurism and less subsequent danger of pecuniary protrusion, I cannot but regard this plan as a desirable addition to the methods of proceeding when the primitive iliac is the vessel to be tied. In passing the ligature the difference of the relation between the vein and artery of the opposite sides is to be borne in mind, the former being external to the artery on the right and internal on the left, on both sides however being upon a posterior plane.

The obstruction to the course of the operation caused by the protrusion of the viscera is to be expected; in that of Mott it is described as very great, while no mention is made of it in Crampton's. This difference was probably the consequence of the difference in the site of the wounds. The separation of the artery and vein is more easily effected than in the case of the external iliacs, because their investment is less thick and resisting.

The diversity presented by the arteries of the opposite sides suggests a difference as to greater practicability and probability of success on one as compared with the other; the artery of the right side being longer than the left presents greater room for the application of a ligature at a sufficient distance, whether from the seat of the disease or from the origin of the vessel, while that of the left being more perpendicular in its course and nearer to the left side of the body ought to be more easily exposed; but it is to be recollected that this disposition is not uniformly present.

Before undertaking an operation upon any of the iliac arteries it will be advantageous to determine, so far as possible, the relation of the vessel, which is to be the subject of it, to the superficial points of the abdominal wall. This must be understood to be intended only as an approximation, but by attention to the following circumstances it will prove sufficiently close to serve the desired purpose. The mean point, at which the aorta divides and the primitive iliac commences, is half an inch below the umbilicus at its left side, and that at which the external iliac terminates is midway between the symphysis pubis and the superior anterior spinous process of the ilium: of course a line connecting these points will define the general course of the primitive and external iliac arteries. The length of the primitive iliac being from two to three inches, the extent of its course may be determined by the subdivision of this line. The point of demarcation between the primitive and external iliacs, and which will serve to mark the origin of the internal and external, as well as the termination of the primitive, may be further determined by a line extending from the crest of the ilium about one inch and a half behind its anterior superior spinous process to a similar point on the other side; such a line will traverse the sacro-vertebral articulation posterior to the division of the primitive iliac, and by its decussation with that before mentioned will mark more particularly the point of division of the vessel,* which will also correspond nearly to the centre of a line drawn from the anterior superior spinous process of the ilium to the umbilicus.†

The practicability and success of these operations have been so long established that they do not now require to be insisted upon.

When the external iliac has been tied below the origin of the epigastric and circumflex ilii branches, the circulation of the limb is maintained through the communications of the branches of the internal iliac with those of the femoral, of which the principal have been ascertained by Sir A. Cooper‡ to be the gluteal with the external circumflex, the obturator with the internal circumflex, and the ischiatic with the profunda, and through those of the circumflex iliac with the same. (See FEMORAL ARTERY.) When the ligature has been applied above the origin of these branches, the circulation is established also through their communications with the internal iliac, the internal mammary, the inferior intercostal and lumbar arteries.

The ligature of the internal iliac artery can cause little interruption of the supply of blood to the parts to which it is distributed; its communications are so numerous and free, externally and inferiorly with the external iliac and femoral arteries; inward with that of the other side, and upward with the aorta through the middle sacral and hemorrhoidal arteries, that the obstruction of the main trunk can affect it but little.

When the primitive iliac has been tied the circulation must be restored by means of the communication which exists between the arteries of the upper and lower extremities through the internal mammary and epigastric arteries, of that between the aorta and the iliac arteries, through the intercostal, lumbar, middle sacral, hemorrhoidal, and the branches of the latter, and of that between the iliac arteries of both sides.

For BIBLIOGRAPHY, see ANATOMY and ARTERY.

(B. Alcock.)

ARTERIA INNOMINATA, (in human anatomy) Fr. *Tronc brachio-cephalique.*

The innominata or brachio-cephalic artery is situated to the anterior and right side of the thorax, extending from the arch of the aorta to the sterno-clavicular articulation.

Of the three large vessels proceeding from the arch of the aorta, the innominata is the most anterior, the shortest, but of the largest calibre; it takes its origin at a point corresponding and very nearly parallel to, the upper edge of the cartilage of the second rib almost immediately from that part of the arch of the aorta where it alters its direction from the right towards the left side, or rather from the commencement of what is termed the transverse portion of the arch, and hence the cause of its being at this point not only to the right side but also anterior and rather superior to the other two, which arise from the remainder of the transverse division of the arch, the left carotid and subclavian arteries. It immediately ascends obliquely upwards, outwards, and very slightly backwards, to opposite the right sterno-clavicular articulation, where it divides into the right sub-clavian and carotid arteries, the latter of which, although the smallest in diameter, appears from direction to be its continuation. The innominata, therefore, is but a short trunk, rarely exceeding from an inch and a half to two inches in length. Nevertheless instances are upon record in which it has attained above two inches and a half; but these may be considered more in the light of anomalies than regular occurrences.

We now proceed to consider the various relations which this vessel bears to the several important organs in its neighbourhood, and we shall then the more readily be able to account for the many distressing symptoms usually accompanying its enlargement. At its origin, it lies upon the trachea and at its division corresponds, although at a considerable distance, to the longus colli muscle separated from it by glands and cellular tissue. Internally, or on its left side from below upwards, are the commencement of the left carotid artery and the trachea, the latter, however, lying upon a plane posterior to the artery, a quantity of cellular tissue and glands being usually met with between them. Externally or to its right the relations are more complicated and consist of parts of very great importance. It is here connected to the right pleura and the middle and inferior cardiac branches of the great sympathetic nerve; the internal jugular vein lies above it and on its right side, whilst the right brachio-cephalic vein is to its right but somewhat anterior. Behind this vein and crossing the subclavian artery at right angles very close to its origin, we find the pneumo-gastric nerve entering the thorax and giving back its recurrent branch which winds round the subclavian artery; still more externally is the phrenic nerve conducted into the thorax upon the anterior border of the anterior scalenus muscle, and between the two latter the internal mammary branch of the subclavian artery. The parts covering the vessel are studied with greatest advantage from the integuments backwards; and the best method of effecting this is as follows, as it enables us at the same time to take a clear view of the attachment of the various layers of the cervical fascia to the first bone of the sternum and the inter-clavicular ligament.

Having placed the subject with a block underneath the shoulders, and the head hanging down, thus drawing the vessel as much as possible out of the thorax, carry an incision of about five inches upwards, commencing at the middle of the sternum opposite the cartilage of the second rib. Through this incision carry another of the same length at right angles, commencing at the left sterno-clavicular articulation, and extending along the right clavicle as far as its centre. This crucial incision should merely divide the skin, the triangular flaps of which are next to be raised and re-

* Guthrie.

† Harrison.

‡ Medico-Chirurgical Transactions, vol. iv.

flected to the right and left, thus exposing a layer of fascia separating the skin from the platisma muscle; this fascia is thin externally, but where it corresponds to the interval between the two sterno-mastoid muscles it becomes dense and more or less loaded with fat; reflect this fascia and the platisma will next appear, behind which is that usually described as the superficial fascia of the neck covering the sterno-mastoid muscle, containing the external jugular vein, and increasing considerably in density above the sternum, over which it passes down in front of the pectoral muscles. Like the previous layer its thickness is augmented by fat. If this be raised the sterno-mastoid muscles and the first layer of the deep cervical fascia, extending between their two anterior margins, are brought into view, together with some small superficial vessels and nerves. This latter fascia should be carefully examined above the sternum to the anterior margin of which it strongly adheres; it is very dense, so much so that if we endeavour to force a finger into the thorax at this point, it effectually resists our efforts. Behind this fascia is a space corresponding in depth to the thickness of the upper edge of the first bone of the sternum, containing fat and usually a gland, and in addition a vein rather larger than a crow-quill, extending across the neck about half an inch above the sternum; this communicates with a vein on either side of the neck running down on the anterior margin of the sterno-mastoid muscle, and should be carefully avoided by the surgeon in the operation for tying the innominata, as it is of sufficient size to cause embarrassment if wounded. If the fat and gland be now removed we come down upon the second layer of this fascia, which is also very dense and adheres to the inter-clavicular ligament. Having examined these parts and the triangular space existing between the sternal and clavicular insertions of the sterno-mastoid muscles, the sternal insertions of the latter should be detached and the first bone of the sternum removed; this will expose the remains of the thymus gland and the sterno-hyoid and thyroid muscles, which being cut through and reflected upwards are found to cover the deep or third layer of the cervical fascia, which may be traced from the anterior scalenus muscle to its union with its fellow of the opposite side, binding down the cervical vessels, &c. Upon removing this fascia we come down upon the arteria innominata covered by the following parts; inferiorly the left brachio-cephalic vein passes nearly horizontally across the root of the artery to form the vena cava superior by uniting with the corresponding vein of the right side. Although the commencement of the vena cava, strictly speaking, has a closer relation to the arch of the aorta than the innominata, it is nevertheless sufficiently near the latter to render it of considerable importance in operations performed upon that vessel. Superiorly the first or upper cardiac nerve in its course towards the thorax crosses the innominata opposite its bifurcation; we next observe the right inferior thyroid vein, which, emanating from the lower portion of the thyroid gland, and having formed with its fellow of the opposite side the thyroid venous plexus runs, obliquely downwards from the gland towards the right side directly in front of the innominata artery, and empties itself into the vena cava superior between the two brachio-cephalic veins. The middle thyroid artery, when it exists, may now be seen ascending in front of the trachea. These several objects, viz. the left brachio-cephalic and thyroid veins with the cardiac nerve, are all enveloped in a quantity of loose cellular tissue and glands serving to connect them to the vessel, which may now be fully exposed and its different relations studied; when we shall observe that on its right side there is a space bounded superiorly by the right subclavian artery, inferiorly by the left brachio-cephalic vein, to the right by the right brachio-cephalic vein, and to the left by the innominata artery itself; this is the situation where the aneurismal needle should be introduced in the operation for tying this vessel, as we thus run less risk of wounding the veins.

From the above description it is evident that the coverings of the innominata may be arranged into ten layers, which, enumerated from the surface, consist of

1. The skin. 2. Layer of superficial fascia. 3. Platisma myoides muscle. 4. Superficial fascia. 5. First bone of the sternum, sternal extremity of the right clavicle, sterno-mastoid muscle, with its accompanying vein the sterno and inter-clavicular ligaments and anterior layer of deep cervical fascia. 6. Cellular tissue, fat, containing large vein and a gland; the second layer of deep cervical fascia. 7. Sterno-hyoid muscle. 8. Sterno-thyroid muscle. 9. Third layer of deep cervical fascia. 10. Cellular tissue containing the first cardiac nerve, right inferior thyroid, and left brachio-cephalic veins, glands, &c.

Arrivéd opposite to the right sterno-clavicular articulation and to the interval between the sternal and clavicular insertions of the sterno-mastoid muscle, the arteria innominata usually divides into the right carotid and subclavian arteries. It rarely gives off any branches antecedent to its division, but a small third branch is frequently observed proceeding from it to distribute itself in front of the trachea, and terminate in the thyroid gland. Mr. Harrison, in his work on the Surgical Anatomy of the Arteries, has named it the "middle thyroid artery." The French anatomists give M. Neubauer the credit of discovering it, and consequently term it "l'artère thyroidienne de Neubauer" It is, however, as frequently given off from the aorta between the arteria innominata and left carotid.

When we consider the relation which the innominata bears to the important organs surrounding it, we can scarcely be at any loss to account for the apparently remote symptoms present in aneurism of this vessel; such, for instance, as œdema and blueness of the upper extremities, head and neck, cough, difficulty of breathing and swallowing, vertigo, failure of sight, &c. Where the tumor extends towards the right side it presses upon the right brachio-cephalic vein, preventing the return of blood from the right arm and side of the head and neck; if upwards in that direction the carotid and subclavian arteries become implicated, and consequent interruption to the circulation ensues; if forwards, the passage of blood is stopped through the left brachiocephalic vein and the inferior thyroid venous plexus; if to the left, it encroaches upon the left carotid artery and trachea, whilst by enlarging backwards it acts immediately upon the trachea and mediately upon the œsophagus.

Although the above facts are interesting, as serving to elucidate the various phenomena occurring in this malady, I fear that we must not attach too much importance to them as means of diagnosis, inasmuch as many, if not all, of the above symptoms may result from enlargement of other vessels and other causes, indeed we have only to turn to the admirable work of Mr. Allan Burns on the Surgical Anatomy of the Head and Neck, to be at once aware of the probability of deception in this respect.

Anomalies.—There are perhaps few arteries in the body which present so many varieties and anomalies as the innominata, whether studied with respect to its extent, course, situation, or the number of branches which it gives off. In the first place, it is frequently met with extending up into the neck as high as the thyroid cartilage before it divides into its ultimate branches, and sometimes lying in front of the trachea. It is scarcely necessary to remark in how great a degree this anomaly increases the difficulties and dangers attending the operation of tracheotomy. Secondly, the most remarkable variety occurring in the course of this artery is described by M. Velpeau, who, in his Elémens de Médecine Opératoire, mentions three instances in which it passed to the left side in front of the trachea, and subsequently wound from before backwards over this organ, returning between the œsophagus and vertebral column, to its usual points of division opposite the right sterno-clavicular articulation. Thirdly, the innominata is also occasionally irregular as to situation. It has been found arising from the centre of the transverse portion of the arch of the aorta instead of its commencement, and dividing into right and left carotid arteries, the right subclavian taking its origin from the spot usually occupied by the innominata. Again, instead of being placed on the right it has been met with given off from the left or posterior part of the arch dividing into the right and left carotids and left subclavian, in other instances into left subclavian and left carotid. Cases are also on record in which the innominata was altogether absent, the right carotid and subclavian arteries arising directly from the arch of the aorta. Fourthly, it is frequently anomalous in the number of branches it gives off. Occasionally the left carotid arises from it in addition to its usual branches, sometimes it divides into the two carotids instead of the subclavian and carotid; and Tiedemann mentions an instance where it gave off the right internal mammary.

The considerations of the functions, size, and situation of the innominata, as well as its relations not only to the heart and aorta but also to the surrounding parts, at all times rendered the study of this vessel a subject of interest and importance in the eyes of the operative surgeon; but it is comparatively of later years since Mr. Allan Burns first directed the attention of the profession to the fact that circulation through this vessel might be suddenly arrested without the functions of the brain, and power of the superior extremity being of necessity destroyed, that surgeons have been found bold enough to attempt placing a ligature upon it.

There are three cases upon record in which a ligature has been placed upon the trunk of the innominata itself. The first operation was performed by Professor Mott, of New York, on the 11th of May, 1818. The patient died on the 26th day after the operation from repeated hemorrhage resulting from ulceration and yielding of the vessel.

The second was by Professor Graeff on the 5th of March, 1829. The patient died on the sixty-seventh day after the operation from repeated hemorrhage.

The third was by Mr. Lizars at the Edinburgh Royal Infirmary, on the 31st of May, 1837. The patient died on the twenty-first day after the operation, likewise from hemorrhage.

This artery was likewise tied by Mr. Bland on the 25th March, 1832. The patient died on the 13th of April, three weeks after the operation.

The following are the steps of the operation. The patient being placed in the horizontal position with the shoulders raised and the head thrown back, make an incision of about two inches upwards along the anterior margin of the sterno-cleido-mastoid muscle of the right side, commencing at the upper edge of the sternum: from the inferior extremity of this carry another of similar extent outwards upon the right clavicle; these should divide the skin and subcutaneous tissue: next dissect this flap from below upwards and reflect it, exposing the platisma muscle; cut through this muscle and the superficial fascia beneath it, and then carefully detach the sternal insertion of the sterno-mastoid muscle and anterior layer of deep fascia, and should there not be sufficient space a portion of the clavicular fibres of the muscle. Having proceeded thus far, cut through the second layer of deep fascia, avoiding the vein already described as crossing this space, and subsequently divide the sterno-hyoid and thyroid muscles upon a director; this will expose the third layer of deep fascia covering the vessel; a portion of this should be pinched up by forceps and an opening very cautiously made in it, after which, with the handle of a scalpel, clear the artery of its surrounding cellular tissue, draw the thyroid veins to the left side, the right pneumo-gastric nerve and internal jugular vein to the right, and pressing the left brachio-cephalic vein downwards, carry the ligature obliquely upwards and inwards, or from the right to the left side, keeping it close to the vessel to avoid implicating the cardiac nerves.

Other plans of operation have been recommended, but the above appears to me to be the best, as it gives the surgeon room and opportunity to see the state of parts through which he cuts, and enables him, if necessary, to tie either the subclavian or carotid, or both, without further trouble or inconvenience.

It has been recommended to remove a portion of the first bone of the sternum; but the idea will scarcely be entertained by any surgeon possessing a proper knowledge of the parts, or who is competent to perform the operation.

In the year 1827 Mr. Wardrop introduced a new method for treating aneurisms of the innominata in imitation of Brasdor's plan of tying the vessel beyond the aneurismal tumour. He tied the subclavian artery, having found that the circulation through the carotid was very weak if not quite obliterated.

The patient was a Mrs. Denmark. The results of this case have been recorded as favourable, but erroneously so. Mrs. Denmark died in the year 1829 of the same malady on account of which she underwent the operation.

Altogether his example has been followed in six cases, with various results.

In the first, Mr. Evans, of Belper in Derbyshire, in the year 1828, tied the carotid for aneurism of the innominata and commencement of the carotid. The patient recovered.

In the second, M. Dupuytren, on the 12th of June, 1829, tied the subclavian for aneurism of the innominata. The patient died nine days afterwards.

In the third, Professor Mott tied the carotid for aneurism of the innominata on the 26th of September, 1829. The patient recovered.

In the fourth, Dr. Hall, of Baltimore, tied the carotid for aneurism of the innominata on the 7th of September, 1830. The patient died five days afterwards.

In the fifth, M. Morrisson, of Buenos Ayres, tied the common carotid for aneurism of the innominata on the 8th of November, 1832. The patient died twenty months afterwards.

In the last, Mr. Fearn, of Derby, tied the carotid for the same complaint in the year 1836, the circulation through the subclavian being almost obliterated. Subsequent to the operation the patient suffered from repeated attacks of bronchitis, with difficulty of breathing and cough upon the slightest exertion, so much so that on the 26th of July, 1838, she was again placed under Mr. Fearn's care. That gentleman concluding, after a careful examination, that, in consequence of the circulation having been renewed through the subclavian artery, the previous operation had not cured the aneurism (which he now found implicated the commencement of the subclavian artery) determined upon placing a ligature upon this vessel where it passes over the first rib, and performed the operation on the 2d of August, 1838, apparently with complete success.

Here then are the results of the two plans of operation hitherto performed in connection with the innominata. In Hunter's all the patients were lost from repeated hemorrhage, although, as we have seen in one instance, the individual survived the operation above two months. Mr. Pattison, in his account of Mr. Mott's case, appears to attribute the loss of the patient to the fact of that gentleman's having commenced by exposing the subclavian artery, thereby depriving the vessel of nourishment by the unnecessary destruction of the vasa vasorum; this might in some degree have led to the result; but I am more inclined to believe that it occurred from other causes over which the surgeon unfortunately has no controul, I allude to the situation, origin, and direction of the vessel itself. We have already observed that it arises from the commencement of the transverse portion of the arch of the aorta, and is consequently in a direct line with the aorto-ventricular opening, being in point of direction the continuation of the ascending portion of the arch of the aorta. It thus receives the undiminished impetus bestowed upon the blood by the contraction of the ventricle at a distance, barely of three inches; hence, when a ligature is placed upon it, the force of the ventricle is directed more immediately upon this part of the artery, a coagulum can scarcely, if at all, be formed here, and the ligature being subjected to the constant efforts of the blood to overcome it, instead of ulcerating its way out, cleanly dividing the vessels, produces inflammation and ulceration in its neighbourhood by constant friction, and thus gives rise to the fatal results.

If I have here taken a correct view of the causes which have led to the fatal termination in all the cases where Hunter's method has been adopted, (and I have no reason to doubt having done so, as we learn from the accounts of the post-mortem examinations both in Mott's and Lizars' cases, that the coagulum was very imperfectly formed, and that extensive ulceration of the vessel had ensued in the neighbourhood of the ligature,) I am quite justified in adding that it is an operation which should never be performed unless in those cases where it presents the only chance of lengthening the patient's existence.

This remark, however, does not apply to the plan introduced by Mr. Wardrop in imitation of Brasdor. Out of the seven cases in which it has hitherto been employed, and which I have here cited, three were successful, and of the other four one lived for a period of twenty months, and another (Mrs. Denmark) for about two years after the operation.

(H. Hancock.)

INSECTA.—(εντομα; Fr. *Insecte;* Germ. *Insecten.)* A class of Invertebrate animals, which, as constituted by Linnæus, formerly included several remarkable groups, which are now arranged as distinct classes. Besides the true Insecta these were Crustacea, Arachnida, and Myriapoda. Modern naturalists have been almost unanimous in separating these groups from Insects, which, in their perfect state, differ from them in being constantly Hexapods. Besides this very marked character, Insects differ from Crustacea in respiring atmospheric air by means of ramified tracheæ—from Arachnida in the body being constantly divided into a distinct head, thorax, and abdomen—and from Myriapoda, in the body being composed in general of thirteen segments.

Insects, therefore, may be characterized as a class of hexapodous invertebrate animals, which possess antennæ, and have the body composed of several segments, united into three and sometimes four distinct parts, articulated together, consisting of head, thorax, and abdomen. They breathe atmospheric air by means of lateral spiracles and tracheæ, and pass through a succession of changes of form, or shed their external covering before they arrive at their perfect state. They also possess other characters in common with the Myriapods and Arachnidans, as the circulation of the nutritive fluids by means of a pulsatory dorsal vessel, divided into distinct chambers or compartments, and the respiration of atmospheric air by means of spiracular orifices, and with the Crustaceans in being in general oviparous.

Anatomically considered, Insects, as remarked by Professors Grant* and Owen,† bear a remarkable analogy amongst invertebrated animals to Birds amongst the vertebrated. They constitute the most beautiful, most active, and most highly organized of any of the Invertebrated classes. Like Birds, they are inhabitants of the air, the earth, and the waters, and the dominion of some of them is even extended to the bodies of other animals. Physiologically considered, they also resemble "the feathered tribes of air." Like them they have a more voluminous and extensive respiration, and a greater power of generating and of maintaining a higher temperature of body than any other class in the division of animals to which they respectively belong. The number of species is greater than is known in any other division of the animal kingdom, and is only exceeded, as in Fishes, by the almost countless myriads of individuals which every species produces. The metamorphoses which most of them undergo before they arrive at the perfect state, and are able to fulfil all the ends of their existence, are more curious and striking than in any other class, and in the greater number of species the same individual differs so materially at its different periods of life, both in its internal as well as external conformation, in its habits, locality, and kind of food, that it becomes one of the most interesting investigations of the physiologist to ascertain the manner in which these changes are effected,—to trace the successive steps by which that despised and almost unnoticed larva that but a few days before was grovelling on the earth, with its internal organization fitted only for the reception and assimilation of the grossest vegetable matter, has had the whole of its external form so completely changed as now to have become an object of admiration and delight, and able to "spurn the dull earth" and wing its way into the open atmosphere, with its internal parts adapted only for the reception of the purest and most concentrated aliment, now rendered absolutely necessary for the support and renovation of its redoubled energies. But this condition of insect life is greatly modified in the different families. Thus the most active species are diurnal insects, and are those which have the greatest development of the organs of locomotion, accompanied, as in birds of flight, by a more voluminous respiration, and a greater force and rapidity of circulation, and consequent muscular energy and necessity for a constant supply of food, as is well exemplified in the hive-bee and its affinities. But although many species are furnished with wings for flight, these organs are not universally met with in the species of every order, neither are they constant in the two sexes of the same species. In these instances it is always the male individual that is furnished with them. These exceptions occur among the beetles, as in the glow-worm (*Lampyris*, *fig.* 335 & 336), in the *Blattæ* or cock-roaches (*fig.* 343), in some species of of moths (*Bombycidæ*), and in the plant-lice (*Aphides*), while in other species, the ants, the individuals are furnished with wings only at a particular season of the year, and lose them immediately after the fulfilment of certain natural functions. In each of these instances, as noticed by Mr. Owen* in the ostrich and other birds unaccustomed to flight, the extent to which the respiratory organs are developed is in proportion to the habits of the species, being greatest in those of flight and least in those which reside constantly on the ground. Indeed, so varied are the forms, so different the habits and modes of life, that the division of Insects into families and tribes has afforded no small amount of difficulty to the scientific naturalist in arranging them according to their most natural affinities, and hence a great variety of systems have been proposed for this purpose, all of which perhaps are open to many objections.

But it is not in the mere division of Insects into families and tribes that the philosophic naturalist meets with the greatest difficulty, but in assigning the situation which the whole class ought to occupy in the animal kingdom, both in regard to Insects themselves, and in their relations to other animals. Whether naturalists adopt as the basis of arrangement the development and perfection of the nervous system or that of the skeleton, with the organs of circulation and digestion, as compared with similar parts in other classes, they have usually been led to admit that while Insects are superior to many groups, which have been placed above them, in the former respects, they are inferior to them in the latter; and hence, although that portion of the animal body which is so all-important to active existence, the nervous system, is employed without hesitation as the fundamental type and principle of arrangement, and in the vertebrated classes is scarcely ever departed from, it has become in the hands of many naturalists only of secondary importance in the invertebrated, and the greater perfection

* Lectures on Comp. Anatomy, Lancet, 1833-34.
† See AVES, vol. i. p. 246.

* See AVES, vol. i. p. 341.

of the circulatory and digestive organs in the molluscous classes has induced them to place these, which in other respects are inferior in development, above the Articulated. We cannot, however, agree with those who consider the organs of nutrition alone of sufficient importance to allow of this deviation from the fundamental principle of arrangement, neither can we admit with others that the nervous system of the higher Articulata is inferior to that of the higher Mollusks, the Cephalopoda, while we ourselves claim for the higher Articulata the most decided superiority in the next essential character of arrangement—the development of the skeleton and organs of locomotion.

Without entering further upon this difficult subject, we will simply state our conviction with Carus, Burmeister, and others, that the articulated ought to stand at the head of the invertebrated classes, seeing that they contain among them some of the most completely organized of invertebrated animals. We shall reserve for the present our explanation of the steps by which we propose to pass from the lowest vertebrated forms to these, in our estimation, the highest of the invertebrated, and proceed to consider the arrangement of Insects, as a class, as proposed by different naturalists, before we enter upon an examination of the peculiarities of these animals.

The principles upon which naturalists have attempted to arrange this interesting class have been almost as various as the systems proposed. Aristotle among the ancients arranged Insects with reference to the presence or absence of the organs of flight; and although he was far more successful than many of his successors in separating from Insects the Crustacea, as a distinct class, his arrangement of Insects is not entirely natural, since it separates some of the most nearly connected families. Among the moderns, Aldrovandus, in the beginning of the seventeenth century, divided them into *land* and *water* Insects, and subdivided these groups into families according to the structure of their wings and legs. Swammerdam many years afterwards first proposed to arrange Insects with reference to their *metamorphoses;* first, those which undergo only a partial or incomplete metamorphosis, and, secondly, those which undergo a true or complete one. The latter he again divided into those which undergo a slight change of form, but are active during the pupa state; secondly, those which have distinct limbs but are inactive in that condition; and, lastly, those which have no external development of wings or legs, but remain as inactive ovate pupæ. This was the first step towards arranging Insects upon a truly natural system; since, as Messrs. Kirby and Spence have justly observed,* although the employment of the metamorphoses taken alone leads to an artificial arrangement, it is of the greatest use in connexion with characters taken from the perfect Insect, in forming a natural system. Our illustrious countryman Ray, in the beginning of the eighteenth century, followed the example of Swammerdam in arranging Insects primarily according to their metamorphoses; and Lister, in 1710, followed with a modification of Ray's classification, after which nothing further was proposed until Linnæus published the first edition of his Systema Naturæ in 1735. His arrangement was based upon the form and structure of the wings. By these he divided Insects into three groups. First, those with *four* wings, in which he included in three divisions those Insects which now constitute his orders Coleoptera, Hemiptera, Lepidoptera, Neuroptera, and Hymenoptera. In the second group he placed Insects with two wings, his single order Diptera; and in the third, Insects without wings, his order Aptera. In this arrangement, founded partly upon that of Aristotle, Linnæus was particularly successful in establishing some very natural series, although in including the Crustacea among his Aptera, like Swammerdam and Ray, he receded a little from a natural system. After Linnæus, Degeer and Geoffroy each proposed a new arrangement, but it was not until an entirely new set of organs had been selected by Fabricius that Insects began to be arranged upon truly natural principles. The parts from which Fabricius drew his characters were those of the mouth, by which he divided Insects primarily into two sections, the *Mandibulated*, or those furnished with jaws for comminuting their food, and the *Haustellated*, or those which take their aliment by means of a flexible elongated proboscis, without distinct manducatory organs. But the difficulty of forming a strictly natural system still existed, so long as the characters employed were derived only from particular sets of organs, and not from a consideration of the whole. Cuvier, by founding his arrangement upon an examination of *all* the external organs, and thereby establishing natural families, advanced very far towards the object desired, and was followed by Latreille, Lamarck, Dumeril, Leach, Kirby and Spence, and MacLeay, who continued to improve the arrangement of the class. These have been followed by Messrs. Stephens and Curtis, and very recently by Mr. Westwood, the indefatigable Secretary of the Entomological Society, each of whom has proposed a different arrangement. But none of the systems hitherto proposed are entirely satisfactory, so great indeed is the difficulty of discovering the connecting links of families, which, distributed over the whole globe, are believed to include from 100,000 to 150,000 distinct species; and this difficulty will probably continue until the internal as well as the external organization is better known in a greater number of insects than it is at present, and applied to their arrangement, as has lately been done by Burmeister. In the succeeding pages we shall adopt the arrangement of Mr. Stephens, giving a synoptical view of the families, with the addition of some of the recently established foreign ones, and shall also add particular descriptions of some of the most remarkable, referring our readers for more minute descriptions of them to Mr. Stephens's admirable

* Introd. to Entomol. vol. iv. p. 442.

" Illustrations," and also to the valuable work " An Introduction to the Modern Classification of Insects," now in course of publication by Mr. Westwood, from which work we shall in part derive the characters by which the different tribes are distinguished.

Table of the Arrangement of Insects according to the System of Mr. Stephens.

CLASS *INSECTA.*

SUB-CLASS I.

MANDIBULATA.

COLEOPTERA.

- Sectio 1. Pentamera.
  - Tribe 1. Adephaga. *(Gluttons.)*
    - Sub-tribe 1. Geodephaga. Predaceous ground-feeders.
      - Cicindelidæ *Tiger-beetles.*
      - Brachinidæ
      - Scaritidæ
      - Carabidæ, *fig.* 329, *Ground-beetles.*
      - Harpalidæ
      - Bembidiidæ
      - Elaphridæ
    - Sub-tribe 2. Hydradephaga. Predaceous water-feeders.
      - Diticidæ *Water-beetles.*
      - Gyrinidæ *Whirlgigs.*
  - Tribe 2. Rypophaga. *(Cleansers.)*
    - Sub-tribe 3. Phylhydrida. Water-lovers.
      - Heteroceridæ
      - Parniidæ
      - Limniidæ
      - Helophoridæ
      - Hydrophilidæ, *fig.* 330, *Water-beetles.*
      - Sphæridiidæ
      - Anisotomidæ
    - Sub-tribe 4. Necrophaga. Carrion-feeders.
      - Scaphididæ
      - Silphidæ, *fig.* 331, *Carrion-beetles.*
      - Nitidulidæ
      - Engidæ
      - Paussidæ, *West.*
      - Dermestidæ
- Sectio 2. Pentamera.
  - Helocera 1.
    - Byrrhidæ *Sand-beetles.*
    - Histeridæ *Dung-beetles.*
  - Lamellicornes 2.
    - Lucanidæ *Stag-beetles.*
    - Scarabæidæ
    - Geotrupidæ, *fig.* 332, *Dung-beetles.*
    - Aphodiidæ
    - Trogidæ
    - Dynastidæ, *fig.* 333, *Rhinoceros-beetles.*
    - Rutelidæ
    - Anaplognathidæ
    - Melolonthidæ *Cockchaffers.*
    - Glaphyridæ
    - Cetoniadæ *Sun-beetles.*
  - Subsectio 3. Macrosterni, *West.* Sternoxi. *Lat.* (pointed sternum).
    - Buprestidæ *Gold-beaters.*
    - Eucnemidæ, *West.*
    - Elateridæ, *fig.* 334, *Springing beetles.*
  - Sub-sectio 4. Aprosterni, *West.* Malacodermi, (soft skin.)
    - Cebrionidæ
    - Cyphonidæ
    - Lampyridæ *figs.* 335 & 336 *Glow-worms*
    - Telephoridæ
    - Melyridæ
    - Tillidæ
    - Ptinidæ *Death-watches.*
    - Lymexylonidæ
    - Bostricidæ *Wood-borers.*
    - Scolytidæ

Pseudo-Tetramera, *West.*	Sectio 3.		Rhinchophora 1.	Curculionidæ *fig.* 337 *Hog-beetles.* Attelabidæ, *West.* Salpingidæ

		Aphidæ	*Plant-lice.*
		Coccidæ	

CLASS INSECTA, (Insects.)

Animal Invertebrated, hexapodous, undergoes metamorphoses.

Body in general winged, and composed of segments divided into three distinct regions.

Skeleton external, formed of the dermal coverings.

Antennæ two, respiration aerial, sexes distinct.

Sub-class 1. MANDIBULATA.

Order I. *COLEOPTERA.*

Wings four, anterior ones (elytra) hard, coriaceous, covering the abdomen, divided by a longitudinal suture, not employed in flight; posterior ones usually jointed, with their apex acute. Metamorphosis complete.

The *Beetles* constitute by far the most numerous and varied tribes in any order, and differ as much in habits and size as in general form. They include every variety of conformation and bulk from the minute but rapacious *Staphylinidæ*, to the gigantic phytophagous *Dynastidæ* and *Cetoniidæ*. So numerous are the species that, according to Burmeister,* there are 28,000 in the Berlin collection alone, while the whole that is known is supposed to exceed 36,000. In Mr. Stephens's arrangement they have been divided into families which amount to more than one-third of the whole class, and these families are grouped into six sections. The first section includes most of the predaceous beetles, and is divided into two tribes, *Adephaga* and *Rhypophaga*, and these are divided into four *sub-tribes*.

* Manual of Entomology (Translation), p. 583.

The first sub-tribe, *Geodephaga*, includes the predaceous Ground-beetles, which are characterized by the elegance of their form and alacrity of their movements. They have six projecting palpi,* their mandibles are strong, curved, and pointed, and their legs slender and formed for running, (*fig.* 329.) Some of

Fig. 329.

Carabus monilis, (Ground-beetle, male.)

* The third pair of palpi are maxillary, and are the analogues of what we shall hereafter describe as the *Galea*.

this division, the *Cicindelidæ*, are extremely voracious, and most of them feed upon dead animal substances, although some of the *Harpalidæ* are known to be vegetable feeders. The second sub-tribe, *Hydradephaga*, includes the predaceous water-beetles, and the third, *Philhydrida*, a variety of families allied to each other by similarity in general structure, by inhabiting water or damp situations, and by subsisting upon decaying animal and vegetable substances, fungi, &c. Amongst the aquatic species is one of the largest British beetles, *Hydröus piceus* (*fig*. 330).

Fig. 330.

Hydröus piceus, (Great water-beetle, male.)

All the water-beetles are characterized by their four posterior legs being formed peculiarly for swimming; they are ciliated along the tarsal joints, the last of which is furnished with a very minute claw. The insects of the third sub-tribe, the predaceous water-beetles, *Dyticidæ*, are distinguished from those of the second by the latter having long and slender instead of clavated antennæ, and by their possessing *six* instead of only *four* palpi. The males of both sub-tribes have one or more joints of their anterior tarsi (*fig*. 330, A.) very much dilated, by means of which they attach themselves strongly to the females. Their larvæ are active

Fig. 331.

Necrophorus vespillo, (Burying-beetle).

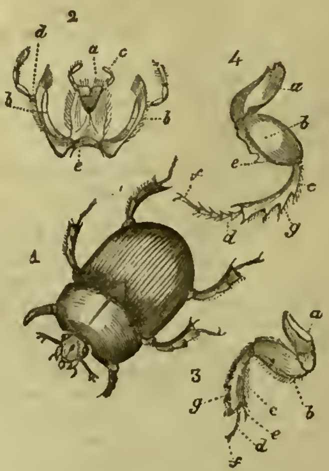
and voracious. The fourth sub-tribe, *Necrophaga*, includes the carrion and burying-beetles (*fig*. 331), so called from their habit of burying small dead animals in the ground, by digging away the earth from beneath them, and thus allowing them to sink down, and then depositing their eggs in the bodies. The genera of this division differ considerably from each other, but may be characterized as in general possessing abruptly clavated antennæ, an oval or oblong body, with the elytra often truncated, and the legs strong and formed for running.

The second section is also divided into four tribes, which include insects of different habits and conformation.

In the first tribe, *Helocera*, the insects are of an oval shape, and have the antennæ geniculated, and terminated by an oval club. Their legs are flattened, broad, and formed for burrowing, and are terminated by very minute tarsi. Their bodies are exceedingly hard; they feed upon decaying animal matter, and when touched simulate the appearance of death.

The second tribe, *Lamellicornes*, are a very natural group. They are distinguished by the club of the antennæ being divided into plates or lamellæ. Their legs are thick, strong, and deeply notched, and the tarsi of the anterior pair in some families are very minute. They are either stercoraceous or vegetable feeders, subsisting, like the common dung-beetle, *Geotrupes stercorarius** (*fig*. 332), upon decomposing vegetable substances, or like the chaffer-beetles, *Melolonthidæ*, upon the foliage of shrubs or trees, or like the *Dynastidæ*†

Fig. 332.



Geotrupes stercorarius, (Dung-beetle).

* This drawing is of a specimen captured by the writer of the present article in the summer of 1829, and affords a curious instance of malformation of the anterior extremities with the tibiæ lunated and acuminated, without dentations, the tarsi entirely wanting. It is now in the cabinet of the Rev. F. W. Hope.

† It is asserted that the *Dynastes Hercules* grasps

(*fig.* 333) upon the sap that flows from the wounded bark or roots.

Fig. 333.

Dynastes Hercules.

a, the epicranium; *b*, the clypeus; *c*, labrum; *d*, mandibles; *e*, maxilla and palpi; *f*, labial palpi; *g*, antennæ; *h*, the eye; *i*, prothorax and horn; *k*, scutellum; *l*, elytra; *m*, abdomen; *n*, femur; *o*, tibia; *p*, the tarsus; *q*, unguis.

The third tribe, *Macrosterni*, Westw. includes a family of insects, *Elateridæ*, (*fig.* 334),

Fig. 334.

Elater noctilucus, (Click beetle, female.) West-Indian fire-beetle.

or springing-beetles, which are commonly known in their state of larvæ, as the *wire-worm*, and are often exceedingly injurious to meadows and corn-fields. In some counties many acres of meadow-land have occasionally been destroyed by these insects attacking the roots of the grass, which then quickly perishes.* They are characterized in their perfect state by having an elongated body, with the head sunk deeply into a notch in the prothorax; by their fan-shaped or serrated antennæ, and by a long spine or process directed backwards from the pro-sternum or under-surface of the prothorax, and received into a groove in the meso-sternum. By means of this spine they are enabled, on bending the body and then suddenly retracting it, to spring to a considerable distance. From this act they have derived their name. Some species of the family are remarkable for shining brilliantly at night, and are the noted fire-flies of the West Indies.

In the fourth tribe, *Aprosterni*, Westw., there are insects equally curious and destructive as in the preceding. The true Aprosterni are distinguished chiefly by their soft flexible elytra, by an entire absence of any process from the sternal surface of the prothorax, and by the dilatation of the margins of the pro-

the branch of a tree between its frontal (*a*) and thoracic horn (*i*), and then whirls itself round to cut through the bark and occasion a flow of sap, upon which the insect is said to subsist. Improbable as the statement appears, from the circumstance that the thoracic horn is wanting in the female, we were once assured of its correctness, by a gentleman who affirmed to us he had witnessed the fact. A similar act is attributed to the male stag-beetle, *Lucanus cervus*, which is furnished with mandibles nearly half the length of its whole body, while in the female they are not larger than in other insects of the same size.

* The Rev. F. W. Hope has ascertained that the larvæ of this family were exceedingly destructive to the potato crops in the West of England during the summer of 1838, an account of which was read at the meeting of the Entomological Society, April 1st, 1839.

thorax, which anteriorly covers the base of the head. Some exceptions exist to these characters in the *Bostricidæ* and their congeners, which ought perhaps to be removed to another tribe. In the *Lampyridæ* (glow-worms), (*figs.* 335 and 336), there is an example of a circum-

Fig. 335. *Fig.* 336.

Male. *Female.*
Lampyris noctiluca, (Glow-worm).

stance not uncommon among insects, the possession of wings by the male sex and their entire absence in the female. The *Ptinidæ* or death-watches, and other Xylophagous insects of this tribe, although small, are exceedingly destructive to furniture and the wood of houses; and the *Bostricidæ* aud *Scolytidæ* to living trees. It is an insect of this family, *Scolytus destructor*, that of late years has occasioned incalculable mischief to the elms in St. James's Park and Kensington Gardens, and in the park at Brussels. So lately as the summer of 1836 nearly eighty fine elms were cut down at the latter place and its neighbourhood, in consequence of decay occasioned by this pest.* Another species *S. pygmæus*, which attacks the oak, has destroyed many thousands of young trees in the *Bois de Vincennes.*† Another genus, *Tomicus typographus*, was so destructive in the Hartz Forest in Germany during a series of years from the beginning of the last century to 1783, that the number of trees destroyed by it in that forest alone was calculated at a million and a half.‡

In the third section, *Pseudo-tetramera*, WESTW., the species have one false and four distinct tarsal joints to their legs, with pulvilli or hairy cushion on their under surface, and the ante-penultimate joint is bilobed and broader than the others. The section is divided into two tribes.

In the first tribe, *Rhynchophora*, (*fig.* 337), the head is elongated in the form of a snout or rostrum, at the extremity of which is the mouth, and at the sides are inserted the antennæ which are usually geniculated and club-shaped. The larvæ of these insects are generally apodal, and many species are exceedingly injurious to the blossoms of the apple, pear, and other fruit-trees. Both the larva and perfect individual of one minute species, well known as the "weevil," *Calandra granaria*, closely allied to *fig.* 337, occasion immense losses in the storehouses of the factor by attacking and destroying his corn. The parent insect not

Fig. 337.

Calandra longipes, male.

only feeds upon the corn itself, but deposits a single egg in every grain, and the larva when hatched devours the whole excepting the husk.

The second tribe, *Longicornes*, (*fig.* 338),

Fig. 338.

Cerambyx latipes.

are known chiefly by the great length of the antennæ, which usually exceeds that of the whole body. Their mandibles are strong and pointed; the body elongated and depressed; and the prothorax, which is often tuberculated or spined, is narrower than the abdomen. Their larvæ are short, thick, and apodal, and are furnished with strong mandibles, and live beneath the bark or in the wood of trees.

The third tribe, *Phytophaga*, KIRBY, is also composed of pseudo-tetramerous insects, with pulvilli on their tarsi, and is divided into two sub-tribes. In the first, *Eupoda*, the body is of an elongated oval form, the head is sunk deeply into a narrow prothorax, and the thighs of the posterior legs are greatly enlarged. In the second sub-tribe, *Cyclica*, the body is of a rounded or oblong oval (*fig.* 339), the base of the prothorax is narrower than that of the elytra, and the antennæ, which are of moderate length, are inserted widely apart from each

Fig. 339.

Timarcha tenebricosa.

other. It is an insect of this tribe, *Haltica nemorum*, that often occasions so much injury to the agriculturist by destroying his crops of turnips immediately after the young plant appears above ground. The perfect beetle, scarcely larger than a millet-seed, deposits its eggs upon the under surface of the first leaves, and the larva when hatched penetrates into the substance of the parenchymatous tissue, between the cuticle of the upper and under surface of the leaf, where it lives until it is ready to undergo its transformations in the ground.* In some years the plants are attacked by such prodigious numbers of these insects that many thousand of acres are destroyed in a few days. The loss sustained by the devastations of this insect in Devonshire in 1786, is said to have been not less than £100,000.†

In the fourth section, *Pseudo-trimera*, West. the insects have only three distinct joints in their tarsi, although a fourth one, exceedingly minute, and which like the additional one in the Tetramera was first noticed by Messrs. Kirby and Spence,‡ exists at the articulation of the last joint, as in the insects of the third section. The *Pseudo-trimera* are distinguished by their tarsi, by their oval or hemispheric shape, and by the antennæ ending in a three-jointed club. The larvæ are hexapodous and active; those of the common lady-cow, *Coccinella*, feed upon aphides, and other genera upon fungi.

In the fifth section, *Heteromera*, there are five joints in the first and second pairs of legs, but only four in the third, (*fig.* 340). The palpi, four in number, are large and projecting, and the antennæ, usually filiform or moniliform, are never terminated by a pectinated club. It includes many genera of dissimilar habits, the darkling-beetles, *Blapsidæ*, the meal-beetles, *Tenebrionidæ*, and the *Cantharidæ*, the oil-beetles and blister-flies.

Fig. 340.

Blaps mortisaga, (Darkling-beetle).

In the sixth section, *Brachelytra*, (*fig.* 341),

Fig. 341.

Creophilus maxillosus, (Rove-beetle).

the body is elongated, and terminated by two exsertile papillæ, the elytra short, quadrate, and often covering only the meso- and metathorax; the true or posterior wings, folded beneath the elytra; head broad and flattened, mandibles large, hooked, and pointed, antennæ often enlarged towards their extremities, and the tarsi of all the legs five-jointed. The larvæ are active and voracious, and undergo a complete metamorphosis.

The situation assigned to this group of insects by different systematists has varied considerably. Many authors have placed them with the pentamerous insects, unto which from their habits and number of joints in their tarsi they appear to belong. Thus Dejean assigned them a position between the *Hydradephaga* and *Phylhydrida*; Dr. Leach* between the *Silphidæ* and *Dermestidæ*; Mr. Kirby, in his recent work,† between the *Adephaga* and *Necrophaga*; and, lastly, Mr. Westwood‡ between the *Dermestidæ* and *Byrrhidæ*. On the other hand Mr. Stephens, after Linné and Fabricius, has placed them at the end of his Coleoptera, thinking, probably, as Mr. Kirby has remarked, that they are connected with the following orders, *Dermaptera* and *Orthoptera*, by their abbreviated elytra, and by their anal papillæ or styles; as they are also, probably, by the shortness and structure of their alimentary canal, which in many respects as much resembles that of the *Forficulidæ* or *Blattidæ*, as the *Adephaga* or *Necrophaga*.

Order II. *DERMAPTERA*.

Wings four, anterior ones (elytra) crustaceous, quadrate, and divided by a straight suture; not employed in flight; posterior ones membranous, folded longitudinally and transversely, only partially covered by the elytra; *anus* armed with large moveable forceps. *Larva* active, resembles the perfect insect. Metamorphosis incomplete.

The single family of this order, *Forficulidæ*, (Earwigs) are readily distinguished from the

Brachelytra by the forcipated anus, the great length of the antennæ, and the breadth and circularity of the wings when expanded, compared with the narrow and acute ones of the latter insects.

Order III. *ORTHOPTERA.*

Wings four, anterior ones coriaceous, reticulated, and overlapping each other, posterior ones partly coriaceous partly membranous, reticulated, and folded longitudinally; head vertical; mandibles, thick, strong, and dentated; *palpi* four, maxillary ones in most genera five-jointed. Metamorphosis incomplete. The larvæ are active, and resemble the perfect insect.

In this Order are included many remarkable families. The *Locustidæ*, Locusts; the *Achetidæ*, the House and Mole-crickets (*fig.* 342);

Fig. 342.

Gryllotalpa vulgaris, (male). Mole-cricket.

the *Mantidæ*, or praying insects; and the *Blattidæ* (*fig.* 343), or destructive Cock-roaches.

Fig. 343.

Blatta Orientalis (male.) The Cock-roach.

Order IV. *NEUROPTERA.*

Wings four, linear, naked, membranaceous, and minutely reticulated; all employed in flight; head large, eyes projecting; body linear.

This Order is divided into five sections.

In the first section, *Panorpina*, or Scorpion-flies (*fig.* 344), the head is produced anteriorly

Fig. 344.

Panorpa communis (male). Scorpion-fly. (Samouelle.)

into a short rostrum, at the extremity of which is the mouth, as in some of the *Curculionidæ;* the antennæ are long and filiform, and the body is slender, and terminates in the female in an acute ovipositor, and in the male in an articulated claw (*a*) like the tail of the Scorpion, from which the insect derives its name. The larva is unknown, but is supposed to undergo a complete metamorphosis. The pupa or nymph is inactive.* The perfect insect is predaceous.

In the second section, the *Anisoptera* or *Ephemeridæ*, May-flies (*fig.* 345), are distinguished

Fig. 345.

Ephemera vulgata. May-fly. (Samouelle.)

by the smallness of their posterior wings, by the shortness of the antennæ, and by the long setæ at the extremity of the abdomen. The larvæ are active, and much resemble the perfect insect. They reside constantly beneath stones, or in burrows at the bottom of running streams,† and undergo an incomplete metamorphosis. The pupa is active like the larva. In the perfect insect, which takes no food, and is proverbially noted for the shortness of its existence, which is seldom more than a few hours, the parts of the mouth are almost entirely obliterated.

In the third section, *Libellulina*, Dragon-flies, all the wings are of equal size, eyes large and prominent, antennæ minute, body slender,

* Westwood, Introduction to Entomology, vol. ii. p. 53.

† Ibid. vol. ii. p. 29.

and tarsi with only three joints. The larva and pupa are active, voracious, and aquatic, and like those of the Ephemera, resemble the perfect insect. Metamorphosis incomplete.

The fourth section, *Termitina*, have large and nearly equal sized wings, either disposed horizontally or erect, with the antennæ rather long and filiform, as in *Hemerobidæ*, lace-winged flies, or club-shaped, as in the ant-lions, *Myrmelionidæ*. The larvæ are active and predaceous. The ant-lion lives at the bottom of a minute pit-fall, which it digs to entrap other insects. The *Hemerobius* lives among crowds of *Aphides*, plant-lice, upon which it feeds, while the larvæ of the *Termites*, or white ants, live in societies of almost innumerable individuals. The first two of these families undergo a complete metamorphosis, and the insects in the condition of nymphs are inactive in the earlier stages of the pupa state. In the latter family the larva and pupa greatly resemble the perfect insect, and are active at every period of existence.

The fifth section, *Megaloptera*, have the posterior wings rather larger than the anterior, the head and pro-thorax large and quadrate, and the antennæ long and setaceous. Metamorphosis incomplete. According to Mr. Westwood * the larva and pupa are active, and not inclosed in a case, are aquatic, and greatly resemble the perfect insect.

Order V. *TRICHOPTERA*.

Wings four, deflexed, hairy, not reticulated; texture slightly coriaceous; posterior pair plicated, broader than the anterior; antennæ very long, setaceous; ocelli three; maxillary palpi long; "mouth unfitted for mastication; mandibles rudimental." Metamorphosis complete.

The perfect insects of this Order, called by fishermen "stone-flies," † are found on water-plants, stems of trees, and palings by the side of rivers. The larvæ, the caddis, or case-worms, are aquatic, and reside in little cases which they carry about with them, and construct by uniting bits of wood, minute shells, and fragments of stones, which are woven together with threads of fine silk. The pupa is semi-complete, and quiescent during the greater part of its period, but becomes active, and creeps out of the water upon the stems of plants before changing to the perfect insect.

Order VI. *HYMENOPTERA*.

Wings four, membranous with large areolar cells; posterior pair smaller than the anterior; antennæ longer than the head; eyes large; ocelli three. Mandibles strong, and generally dentated; maxillæ largely developed; labium and ligula together forming a long proboscis sheathed by the maxillæ. Female armed either with a borer or sting. Metamorphosis complete.

This Order is divided into four sections.

In the first, *Terebrantia*, borers, the abdomen is sessile or united to the thorax by its whole breadth. In one family, the saw-flies, (*fig.* 355, B), the abdomen is armed with two serrated partially concealed plates, with which the insect cuts through the bark or pierces the leaves of plants to deposit her eggs. In another family, *Uroceridæ*, the true borers, the abdomen is armed with a strong projecting cylindrical spiculum, which is grooved on its under surface, and contains two smaller dentated spicula, analogous to the plates of the saw-fly, with which the insect bores into timber-trees and deposits its eggs. The larvæ are active and extremely voracious. Those of the saw-flies, *pseudo-caterpillars* (*fig.* 355, A,) devour the leaves of plants, and are sometimes exceedingly injurious to the agriculturist, as has been the case with those of *Athalia centifoliæ* to the turnip crops during the last few summers,* while the larvæ of *Uroceridæ* are said to be equally destructive to living trees.†

In the second section, *Pupophaga*, the ichneumon flies, the body is long and slender, and the abdomen is petiolated, or connected only by a constricted neck with the thorax, and the antennæ are long and setaceous. The larvæ are apodal, and are parasitic on other insects.

In the third section, *Aculeata*, the body is short and pedunculated, and furnished with a true aculeus, which is used as a weapon of defence. The larvæ are apodal, are fed by the parent or by sterile females, and generally reside in cells. Some species are solitary, and feed their young with the bodies of other insects, *Crabronidæ*; others live in society, and are either omnivorous, as the *Formicidæ*, ants, and *Vespidæ*, hornets (*fig.* 346) and wasps, or

Fig. 346.

Vespa crabro. The Hornet. (Samouelle.)

mellivorous, as the humble and hive bees, (*Apidæ*), which feed their young upon a mixture of pollen and honey.

In the fourth section, *Tubulifera*, the body is short, slightly convex, and often compressed laterally; the posterior wings are almost entirely destitute of nervures, and the abdomen is

* Introduct. to Entom. vol. ii. p. 23.

† Yarrell's British Fishes, vol. ii. p. 84.

* Prize Essay of the Entomological Society on the Anatomy, Habits, and Economy of Athalia centifolia, 1838, by G. Newport.

† Westwood, Introd. &c. vol. ii. p. 119. Mr. Ruddon in Trans. Entomological Society, vol. i. p. lxxxv.

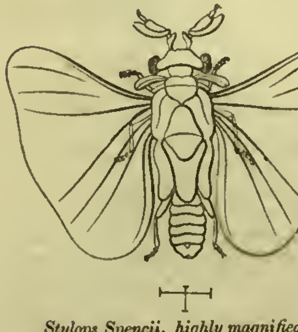
furnished either with a telescopic, jointed tube, as in the *Chrysididæ*, golden wasps, or with a spiculiferous ovipositor, which is partly retractile within the abdomen, as in the *Cynipidæ*, gall-flies. The former of these insects deposit their eggs either in the cells of other Hymenoptera or in the bodies of active Lepidopterous larvæ, before their change to the pupa state, and thus resemble in habits the true *Ichneumonidæ*. The *Cynipidæ* puncture the leaves or bark of trees and plants, and deposit their eggs, at the same time injecting into the wound a fluid which occasions the growth of galls or excrescences, the interior of which is both food and habitation for the young larva. In their habits, as Mr. Westwood has well observed, the *Cynipidæ* very closely approach the *Terebrantia*, and seem to form a link of communication between them and the true *Ichneumonidæ*.

Order VII. *STREPSIPTERA*.

Wings four, the anterior ones (pseudelytra) very minute, twisted, and projecting transversely from the sides of the meso-thorax like little scales; posterior pair very large, fan-shaped, with radiating nervures, and plicated when folded. Body linear, abdomen compressed, metathorax very large; meso- and prothorax very short; head transverse, broader than the pro-thorax; eyes slightly pedunculated; antennæ inserted into an excavation in the front, and terminated by two branches; mouth unfitted for taking food; maxillæ minute, projecting, stiliform; labial palpi very large.* Metamorphosis complete.

These insects, *Stylopidæ*, are parasitic and exceedingly minute; they undergo their transformations in the bodies of perfect wasps and bees, and pass out between the abdominal segment. Latreille has aptly designated them the Œstri of insects. It is entirely unknown where the eggs are deposited, whether in the body of the wasp or bee, or in that of its larva. Four distinct genera of these minute parasites have already been discovered. *Stylops Spencii (fig.* 347) is one of the largest species, but is scarcely more than two lines in length, while the smallest species yet known, *Elenchus Templetonii*, West.* is not more than two-thirds of a line, or scarcely a line in breadth with its wings expanded.

Fig. 347.



Stylops Spencii, highly magnified. Westwood, Ent. Trans.

The anomalous structure of these insects has been a matter of great difficulty to entomologists. Rossi, who first discovered an insect of this order, placed it with the Hymenoptera. Mr. Kirby at first thought that it ought to follow the Coleoptera, on account of its elytra and kind of metamorphosis; Mr. Mac Leay† placed it between the Coleoptera and Hymenoptera, to both of which, as Mr. Kirby had remarked, it is connected by its metamorphosis. Dr. Leach placed it between the Coleoptera and Dermaptera, while Mr. Newman, who at first thought it belonged to Hymenoptera,‡ afterwards placed it with the Diptera,§ between which two Orders it was also placed by M. Samouelle.‖ It has, however, been satisfactorily shown by Mr. Westwood¶ that it is an imperfectly mandibulated insect, and that if the structure of its oral apparatus, the shortness of its first thoracic segments, and its kind of metamorphosis be considered, it ought to be placed between the Hymenoptera and Lepidoptera, at the end of the *Mandibulata*, which situation it occupies in Mr. Stephens's arrangement.** But the existence of elytra, and the peculiar structure of its wings, ought not to be disregarded, and should any species sufficiently large for minute dissection be hereafter discovered, it is not improbable that an examination of its internal organs may lead to a different opinion.

Sub-Class II. HAUSTELLATA.

Order VIII. *LEPIDOPTERA*.

Wings four, covered with minute scales; mouth proboscidal, formed of two elongated organs, approximated laterally to form a tube; when at rest spirally convoluted. Labial palpi large, hairy. Metamorphosis complete.

The Order is divided into six sections.

First the *Diurna*, day-fliers or butterflies, are distinguished by their long clavated antennæ, which in a few are also slightly hooked at the apex. The wings are large and erect when the insect is at rest. The larva or caterpillar has sixteen feet. Pupa quiescent and complete.

In the second section, *Crepuscularia*, (*fig.* 348,) the sphinges or hawk-moths, the antennæ are prismatic, and generally thickest in the middle, the body large, and tapering towards its extremity, which is often bearded, and the wings are elongated and slightly deflexed when at rest. The pupa is smooth, and inclosed in a cocoon,

Deilephila elpenor, the Elephant Sphinx.

or in a cell of the earth. The perfect insects fly very swiftly, and are mostly abroad at twilight.

In the third section, *Pomeridiana*, which includes the silkworm-moths, the body is short and thick, proboscis in general very short, antennæ tapering, and much pectinated or feathered in the males, and the wings, when at rest, deflexed and horizontal. The larva before changing incloses itself in a case, which in the *Bombycidæ* is composed entirely of fine silk.

In the fourth section, *Nocturna*, night-moths, the antennæ are setaceous, the proboscis long and spirally convoluted, the palpi compressed and terminated abruptly by a minute joint, and the wings, when at rest, folded horizontally upon the abdomen. It is a larva of this section, *Agrotis segetum*, that of late years has been almost as injurious to the agriculturist by attacking the full-grown turnip as that of the saw-fly, *Athalia*, or the beetle, *Haltica*, by attacking the plant in the earliest stages of its growth.

In the fifth section, *Semidiurna*, the body is slender, the antennæ in general setaceous, the proboscis short, and the wings broad and expanded horizontally, as in the *Geometridæ*, or deflexed and forming an angle with the body as in the *Pyralidæ*.

The sixth section, *Vespertina*, is composed of minute species, among which are the destructive clothes-moths, *Tineidæ*.

Order IX. *DIPTERA*.

Wings two, membranous, naked, and situated anteriorly to two minute pedunculated bodies *(halteres)*, the analogues of the posterior wings in the preceding orders;* mesothorax very large, and forming nearly the whole of the thoracic region; head rounded, distinct from the thorax; mouth rostriform; metamorphosis complete; pupa coarctate.

Among the families of this extensive order are the *Culicidæ*, gnats, the *Asilidæ (fig.* 349) and *Tabanidæ*, bloodsuckers, the *Œstridæ*, gad-flies, and *Muscidæ*, common house-flies. In most of the families the larvæ are active and

Fig. 349.

Asilus crabroniformis (Samouelle).

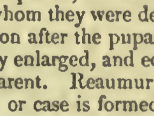
apodal, or are furnished only with abdominal feet. It is doubtful whether any of them cast their skins during their growth. In most species it becomes the outer covering of the pupa.

Order X. *HOMALOPTERA*.

Wings two, or entirely absent; head sunk into the anterior part of the thorax, or divided from it only by a suture; abdomen flat, broad, and obtuse; anus notched; claws large, bidentate or tridentate; metamorphosis complete: pupa coarctate.

In this remarkable order, the forest-flies *(fig.* 350) and ticks, the larva is nourished, and un-

Fig. 350.



Hippobosca equina, the Forest-fly (Samouelle).

dergoes its change into the pupa state within the abdomen of the parent, as was first noticed by Reaumur, by whom they were designated "spider-flies." Soon after the pupa is deposited, it becomes greatly enlarged, and equals in size the body of the parent. Reaumur found that its outer envelope or case is formed of the skin of the larva, as in the true Diptera, and he also succeeded in detecting within it the proper covering of the nymph. The type of the order, the forest-fly *(fig.* 350) is exceedingly troublesome to horses in the summer, and abounds in the New Forest in Hampshire.

Order XI. *APHANIPTERA*.

Wings none; body oval, compressed; head small, rounded, and compressed; eyes simple, orbicular; thighs strong; posterior legs the longest; tarsi five-jointed.

The *Pulicidæ*, fleas, undergo a complete metamorphosis. The larva is an active elongated worm, which spins itself a case or coccoon, in which it becomes a nymph, and at the end of a few days assumes the perfect state. One species, *Pulex penetrans*, is exceedingly troublesome in the West Indies by introducing itself beneath the toe-nails or under the skin, where it occasions malignant ulcers. Most of the species are of diminutive size, and seldom exceed a line in length. Mr. Kirby,

* Kirby and Spence, Introduction, &c., vol. ii. p. 354.

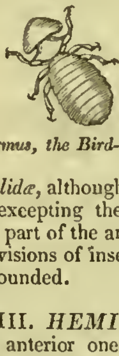
however, has recently described one species, *P. Gigas*,* which is two lines in length.

Order XII. *APTERA.*

Wings none; body ovate, flattened; head distinct from the thoracic segments, which are narrower than those of the abdomen; mouth either haustellated or mandibulated; metamorphosis incomplete.

This order, which is formed of the *Pediculi* of Linnæus, and is based upon the entire absence of the wings and an incomplete metamorphosis, affords a striking proof that we ought not in our arrangements to place too much dependance upon the presence or absence of any one particular set of organs, or kind of metamorphosis; else, as well remarked by Burmeister, we ought to include among the Aptera the female Blatta and the common Cimex, insects which evidently belong to different orders. But it may be further observed that dissimilarity in the structure of *one* particular kind of organs is not alone sufficient to authorise the separation of genera which in other respects are closely united; otherwise the *Nirmidæ (fig.* 351) ought to be separated

Fig. 351.



Nirmus, the Bird-louse.

from the *Pediculidæ*, although resembling them in every thing excepting the structure of the mouth, the very part of the animal upon which the two great divisions of insects in the present arrangement is founded.

Order XIII. *HEMIPTERA.*

Wings four, anterior ones partly leathery, partly membranaceous, decussating each other at the apex; posterior wings entirely membranaceous; pro-thorax and scutellum very large; mouth rostriform, composed of elongated setæ; ocelli three; metamorphosis incomplete.

Fig. 352.

Nepa cinerea, the Water-scorpion (Samouelle).

This order is divided into two sections, *Terrestria* and *Aquatica.*

The larva and pupa are active, and most species subsist upon the juices of other animals. The *Terrestria* are distinguished chiefly by the length of the antennæ, which exceeds that of the head, and by their three-jointed tarsi. The *Aquatica* have the antennæ in general shorter than the head (which in some species *(fig.* 352) is sunk into the pro-thorax), the eyes are large, the rostrum short, and the tarsi with only two joints.

Order XIV. *HOMOPTERA.*

Wings four, anterior pair either entirely coriaceous or membranaceous, not decussating each other; pro-thorax very short; head large and transverse; antennæ shorter than the head in most genera; abdomen in some furnished with a compound serrated ovipositor; metamorphosis incomplete.

This order is considered by many authors as only a section of the preceding. It is, however, composed of several distinct families. The types of the order, the *Cicadiidæ (fig.* 353), tree-hoppers, in possessing a serrated

Fig. 353.

Cicada hæmatodes (female). (Samouelle).

ovipositor seem to approach to the *Terebrantia*, while the *Thripidæ*, which in the structure of the mouth resemble mandibulated insects, have recently been formed into a distinct order,* and have been placed by Mr. Westwood before the Neuroptera. Perhaps a closer examination of the remaining families, *Aphidæ* and *Coccidæ*, the plant-lice, &c., might lead to a similar removal.

In the preceding remarks we have closely adhered to the arrangement proposed by Mr. Stephens, but it cannot be denied that much remains to be done before the entomologist will be able to form an arrangement so far natural as to be free from serious objections. The principal divisions of the last two orders, in possessing ocelli, in the size of the thorax, the connexion of the wings during flight (which we shall hereafter show exists in some of the *Cercopiidæ*,) and in the serrated terebral ovipositor, seem to be more nearly connected with the Hymenoptera than with the wingless and less perfectly developed Aphanïptera and Aptera.

From the above remarks on the orders it will

* Fauna Boreali-Americana, 1837, p. 318.

* Thysanoptera. Haliday, in Entom. Magazine, vol. iii. & iv.

be seen that a large majority of insects have four states of existence,—the egg, the larva, the pupa, and the imago or perfect state. Until very lately, it was supposed that this peculiarity of existing at different periods under such different forms belonged only to this class of the Invertebrata, but recent observation,* as shown in the article CIRRHOPODA, &c.,† has made it appear that there are other classes also which undergo metamorphoses, although in no instances do the animals continue so long in their preparatory states, nor undergo such remarkable changes of form in passing from one state to another, as insects.

The egg.—In the egg, or earliest stage of extra-uterine existence, the insect continues for a longer or shorter time according to external circumstances. We have at present only to notice the external form, markings, and colour of the egg, which vary as greatly in the different species as the locality in which it is placed by the parent. The greatest variety of these occurs among the Lepidopterous insects. In some, as in the butterfly, *Pontia brassicæ*, the egg is of an obtuse conical figure, like a Florence flask, and is beautifully ribbed and beaded on its exterior surface; in others, as in one of the night-moths, *Acronycta Psi*, it is ribbed, and is flattened like a lens;‡ in the small but beautiful butterfly, *Thecla betulæ*, it is shaped like a turban;§ in *Clisiocampa neustria*, which glues its eggs together like a ring around the small branches of fruit-trees, it is cylindrical, and flattened at both ends, and in the puss-moth, *Cerura vinula*, its form is compressed and lenticular. Among the Neuroptera, Hemiptera, and Diptera there are other forms equally curious. The lace-winged fly, *Chrysopa perla*, suspends its egg in the air upon a long pedicle;|| the egg of the water-scorpion, *Nepa cinerea* (*fig.* 352), is encircled at one extremity by a coronet of rays or processes,¶ while in one of the dung-flies the egg has two projecting appendages which have somewhat the appearance of ears. The *color* and *markings* of the egg are not so various as its form. In the common green grasshopper, *Acrida viridissima*, it is green, like the seeds of some plants. In *Pedicia rivosa* and *Tipula oleracea* it is perfectly black, and in other instances, as in *Odonestis potatoria*, it is beautifully encircled with bands of white and green, or is speckled with darker spots, like the eggs of birds, as in *Lassiocampa quercus*. The prevailing colours, however, are yellow, as in the cylindrical eggs of the oil-beetles, the *Meloe* and *Proscarabæi*; or white as in the flesh-flies, *Musca vomitoria* and *domestica*; or perfectly translucent, as in the saw-fly of the turnip, *Athalia centifoliæ*. The external markings and sculpture on the egg are not less remarkable than its general form and colour. Sometimes the egg, as above stated, is ribbed and beaded, sometimes excavated over its whole surface into regular cells like a honey-comb, at others it is imbricated like the tiling of a house, but in the greater number of instances it is smooth as in other animals.

These peculiarities of form and color appear in many instances to have relation to the circumstances under which the egg is deposited by the parent, to its preservation, or to the locality in which it is placed. The egg of *Scatophaga stercoraria*, KIRBY, is only partially inserted into recent cow-dung,* with its auricular processes, through which it is supposed to respire, exposed to the influence of light and air; that of *Chrysopa perla*, K., the lace-winged fly, is attached by its pedicle in the midst of crowds of Aphides, upon which the young larva is to subsist;† while the coronetted eggs of *Nepa* (*fig.* 352) are inserted into the stems of water-plants, with their processes only exposed,‡ probably for the purposes of respiration, until the enclosed germs are stimulated into active existence by the vivifying influence of light and air, without which perhaps they would perish. This indeed happens with the eggs of the great water-beetle, *Hydröus piceus* (*fig.* 330) which, according to Lyonet, are deposited in a little nest that floats upon the surface, and from which the larvæ escape into the water immediately they are developed. We have found that if the eggs of this insect be allowed to fall to the bottom of a vessel of water, and remain there for some days, organisation proceeds in them for a day or two, after which they perish. For a similar purpose the eggs of *Athalia centifoliæ* (*fig.* 355), which require a high atmospheric temperature for their speedy development, are inserted into little spaces between the cuticle and parenchymatous tissue of the leaf of the turnip. In each of these instances the object to be insured is the safety of the egg itself; either its preservation from external injury, or its full exposure to atmospheric influence to accelerate its development. It may be remarked as a general rule, that those eggs from which the larvæ are most rapidly developed are those which require the highest temperature and fullest exposure to the atmosphere. These are the external circumstances which greatly influence the development of the germ into the state of larva.

The larva.—Immediately the insect is liberated from the external coverings of the egg it is called a larva. It is so designated from its then being as it were under a *mask* or in disguise, and unable to fulfil one of the principal objects of its existence, the continuation of its kind. In some species, as among the Aptera, it has at this period the form of the parent, from which it differs in nothing externally but size, being always very much smaller. Instances of this kind occur in the *Pediculi* and *Nirmi* (*fig.* 351). In other species, examples of which are seen in the *Cimices*, *Blattæ* (*fig.* 343),

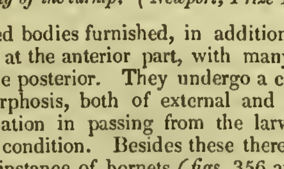
Forficulæ, and *Cicadæ* (*fig.* 353), the insect is very much smaller, but has the general form of the parent, without any rudiments of wings or elytra. Another description of larva is that in which the insect comes from the egg either as a fat sluggish grub, or as an active and voracious one, with an elongated body very different in form from that of the parent, and is furnished with but six legs, which are attached to the anterior part of the body, in addition in some instances to two processes employed as legs at its posterior extremity. Examples of the last of these occur in the voracious water-beetles, *Dyticidæ*, in the *Carabidæ* or ground-beetles (*fig.* 354) and many others; and of the

Fig. 354.

Larva of Calosoma Sycophanta (Burmeister).

first, in the Chaffer-beetles *Melolonthæ*, and stag and dung-beetles, *Lucanidæ* and *Geotrupidæ* (*fig.* 332). Other kinds of larvæ, to which the term is more strictly applicable, are known to every one, as the caterpillars of butterflies and moths. These and the *pseudo-caterpillars*, the larvæ of the saw-flies, *Tenthredinidæ*, (*fig.* 355, A), are active and have

Fig. 355.



A, *larva, and* B, *perfect state of Athalia centifoliæ, the saw-fly of the turnip*. (*Newport, Prize Essay.*)

elongated bodies furnished, in addition to the six legs at the anterior part, with many others along the posterior. They undergo a complete metamorphosis, both of external and internal conformation in passing from the larva to the perfect condition. Besides these there are, as in the instance of hornets (*figs.* 356 and 357) and bees, larvæ which are entirely destitute of organs of locomotion, and exist simply as elongated maggots; and others, as some of the flesh-flies, *Muscæ*, and the tailed maggots that inhabit the most noisome puddles, *Eristalis tenax*, which are entirely destitute of the true or anterior legs, and have only those which are attached to the abdomen.

These kinds of larvæ were formerly referred by Fabricius, under special designations, to different kinds of metamorphoses, which those designations were supposed to indicate; but, as remarked by Burmeister,* neither were the terms employed in strict accordance with the conditions of the larvæ themselves, nor always indicatory of the metamorphoses they were about to undergo. We fully agree, therefore, in the opinion expressed by Burmeister, that the different kinds of larvæ are referable to only two kinds of metamorphoses; the one a *metamorphosis incompleta*, which consists simply in the insect shedding its skin and increasing in size, and in some cases acquiring new organs, but in all stages of its existence continuing active, and having the form of the parent, as in the instances above noticed; and the other a *metamorphosis completa*, including all insects which in the larva state have a form different from the parent, and undergo a complete change, both of external and internal conformation, before they arrive at the perfect state.

But whatever be the form or changes of the insect, the larva state may be looked upon as its most voracious period of life. In many species it is also its longest period. Those which do not hybernate in the perfect state exist but for a very short time as larvæ; while those which continue for a long period in the larva state, as the *Lucanidæ* and *Melolonthidæ*, some of which are said to continue for four years, pass but a little while in the perfect. But these periods are not always equally long in different species of the same families. Thus among the *Apidæ*, the *Bombus terrestris*, or common humble-bee, exists but for a short period in the larva, but a long one in the perfect state; while in a closely allied genus *Anthophora retusa*, one of the solitary bees, that form separate nidi in vertical sections of dry banks exposed to the sun, the insect often continues through the whole winter in the larva state, and only exists for a few weeks of the following summer in the perfect. On the other hand the numerous species of *Muscidæ* exist but a short time as larvæ, or maggots, but a very long time as active flies.

External anatomy of the larva.—The body of a larva is in general composed of thirteen distinct segments, or divisions; the first constitutes the head, with the organs of manducation, the second, third, and fourth, and, as we shall hereafter see, in part also the fifth, together form the thorax of the future *Imago*, while the remaining ones form the third division of the body, the abdomen. In most insects in the larva state, the whole of these segments from the second to the thirteenth are equally developed, and differ but little from each other in their general appearance. The second, third, and fourth segments have each a pair of short scaly feet, the rudiments of the future limbs, and the segments of the abdomen are often furnished with soft membranaceous ones, which disappear entirely when the larva undergoes its metamorphosis. On each side of the body there are in general *nine* oval apertures, the

* Manual, Trans. p. 34.

spiraculæ, or breathing holes. These are situated in the true larva, or caterpillar, in the second, fifth, sixth, and following segments to the twelfth. This is the general structure of the larva, but there are modifications of it in every particular. Thus, in the larva of those *Hymenopterous* insects which are entirely destitute of feet, there are fourteen distinct segments in the body, besides an anal tubercle, and ten spiraculæ on each side (*fig.* 356). These are

Fig. 356.

Lateral view.

Fig. 357.

Inferior view.

Larva of Vespa crabro, magnified.

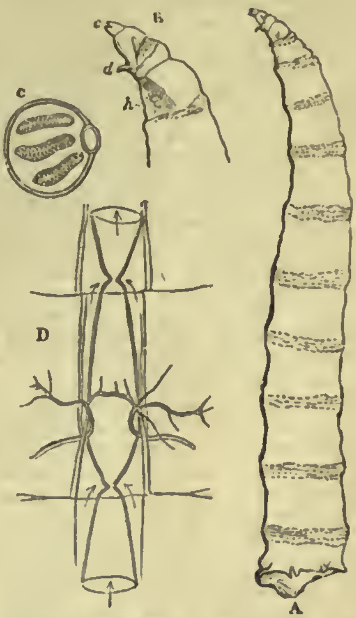
situated in the second, third, fourth, and remaining segments to the twelfth, so that in these insects the thoracic portion of the body contains an additional spiracle, while the abdomen has one additional segment. This fact is particularly interesting from the circumstance of its apparently disturbing the opinions hitherto advocated by naturalists respecting the normal number of segments, which has been thought to be constantly thirteen in this class of invertebrata, while it derives a greater importance from the additional segment belonging to the abdomen, as we shall hereafter prove. This additional number of segments, as constantly occurring in apodal Hymenoptera, was first pointed out by Mr. Westwood,* and has been observed by ourselves in every instance in the larvæ of *Vespa Crabro*, (*fig.* 356.) *Bombus terrestris*, *Anthophora retusa*, *Ichneuman Atropos*, and other species. In the common maggots or larvæ of the flesh-flies, *Muscidæ*, the body is elongated, and tapering at its anterior extremity, and consists of fourteen segments.† In the larva of a species of *Musca* which infests bacon and other dried provisions, and in that of the common flesh-fly, *Musca vomitoria*, we have distinctly

* Trans. Ent. Soc. vol. ii. p. 124.

† *Fifteen*, if we include the anterior portion of the third segment, which appears like a distinct part. Since these observations have been in print the XII. and XIII. Parts of Mr. Westwood's "Introduction" have been published, and it is gratifying to observe that he has found fifteen segments, including the head, in the larva of *Odynerus*, *Colletes*, and *Anthidium*.

noticed fourteen (*fig.* 358). The first four of

Fig. 358.



A, *Apodal larva of Musca*; B, *head of do.: a, mandibular hooks; b, the anterior branchia; c, the labrum;* C, *organs of respiration;* D, *a portion of the dorsal vessel.*

these appear to constitute the head of the larva, since in them are contained the palpi and oral apparatus, besides two remarkable orange-coloured organs, which project from the sides of the fourth segment, and on a cursory view appear to be the organs of vision, but are in reality the branchiæ of the future pro-thorax (B *h*). In the larva of the sheep-bot, *Œstrus ovis*, which resides for many months in the frontal sinuses and roots of the horns of that animal, there are thirteen segments, but the terminal one is very indistinct, while the anterior one, which is exceedingly minute, is proved to form a large proportion of the head, by its containing the oral apparatus, and by the existence in it, at its anterior part, of two very distinct eyes. These larvæ respire by means of two sets of branchiated organs, (*fig.* 358, c) situated at the posterior part of the body, and not by lateral spiracles. The apparently anomalous condition of the head in these insects, like the additional segment in Hymenoptera, is a circumstance of much interest, but is not without its parallel in perfect individuals of other classes, as in *Myriapoda*, in which the head is most distinctly composed of at least three segments. We must not conclude, however, with Dr. Ratzeburg, as noticed by Mr. Westwood,* that in *Hymenoptera* the head of the *Imago* corresponds to the first two segments of the larva, because at the latter period of the larva state, just before the insect becomes

* Trans. Ent. Soc. vol. ii. p. 125.

a nymph, or pupa, the head is found to occupy the anterior part of the second segment. The true head of the hymenopterous larva, before its changes have commenced, is in reality the first segment; since, as remarked by Mr. Westwood, it has not only the usual conformation of the head, but contains also the rudiments of *all* the manducatory organs, and the antennæ. In addition to this, we may state that before the larva has discontinued to feed, and has begun to prepare itself for transformation, we have invariably found on dissection, that the first cerebral mass, the supra-œsophageal ganglion or brain is situated in the superior part of the first segment, and the first sub-œsophageal ganglion in the posterior part of the inferior surface; so that it is not until after the changes into the nymph state have commenced, beneath the skin of the larva, that the head becomes so greatly enlarged as to encroach upon the second segment.

Of the head. The head of a larva, excepting in Dipterous insects as above noticed, is usually of a rounded or oval figure, and of a harder texture than other parts of the body. At its inferior surface are situated the organs of manducation, and at its lateral and anterior the rudiments of the eyes and antennæ. In all true larvæ it is divided longitudinally into two halves, by a suture which extends from the vertex or *epicranium* to the face, the front of which is formed by a convex plate, the *clypeus*, or shield (*fig.* 359, *b*). This is generally of a

Fig. 359.

Head of larva of Athalia centifoliæ.
a, the epicranium ; b, the clypeus ; c, labrum ; d, the mandibles ; e, maxillæ and palpi ; f, the labium and labial palpi. (Newport, Prize Essay.)

semicircular, or a quadrangular form, but varies considerably in different species. Immediately beneath this plate is situated another, the *labrum* or upper lip (*c*). This also is of an elongated, quadrangular, and sometimes heart-shaped form, and constitutes the anterior boundary of the mouth. Beneath this plate are a pair of strong horny jaws, *mandibulæ* (*d*), which are in general thick, curved, and strongly indented or toothed, and are placed one on each side of the head. Beneath these are a pair of lesser jaws, *maxillæ* (*e*), placed in a similar manner, and with the mandibles form the lateral boundaries of the mouth. The maxillæ are soft, membranaceous and adapted for holding, rather than for comminuting the food like the mandibles. They are in general also furnished, as in the larva of *Athalia*, with two other jointed organs, *palpi* or feelers which are employed by the insect entirely as tactors. Behind these parts is situated a second transverse plate, the *labium* (*f*), or inferior lip, which bounds the posterior part of the mouth. This also, like the maxilla, is furnished with a pair of jointed palpi. The motions of the mandibles and maxillæ differ from those of the jaws in vertebrated animals, being always from side to side, and meeting, or passing across each other like the blades of a pair of scissors. Besides these parts, there is in many larvæ a projecting papilla situated within the mouth upon the soft membrane of the labium. This is conical and jointed, and is called by Messrs. Kirby and Spence the *spinneret*. It is the common excretory duct of the glands which secrete the materials with which the insect spins its coccoon, previously to undergoing its transformations. In all larvæ the *antennæ* (*g*) are but slightly developed. They are situated a little above the base of the mandibles, on each side of the clypeus, and are of a conical form, jointed, and usually terminating in a point. In some species they are three, but rarely more than five-jointed. The *eyes* in all larvæ are single, or *sessile*, and not compound, or aggregated together, as in perfect insects. In the pseudo-caterpillars, *Tenthredinidæ*, as in *Athalia centifoliæ*, there is only one large stemma on each side of the head (*h*), situated above the antennæ; but in the true caterpillars, *Lepidoptera*, as in the *Sphinx ligustri*, there are always six very minute ones, placed at a little distance from each other, in the form of an arc near the base of the mandibles and antennæ, at the lateral part of the head. In the apodal hymenopterous larvæ which constantly reside in the dark, the oral apparatus is developed, but the eyes are in general entirely absent.

The form of the oral apparatus in the maggots, or larvæ of the Dipterous insects, is entirely different from that of the insects we have just described. In the larva of *Œstrus ovis* instead of mandibles and maxillæ crossing each other transversely, the mouth is formed by two fissures, the one anterior and longitudinal, and the other posterior and transverse, the two meeting each other in the form of the letter T inverted thus ⊥ (*fig.* 360). In the anterior fissure (*c*) are situated two longitudinal powerful hooks, the mandibles (*d*) directed forwards and downwards, and employed by the insect both as organs of progression and nutrition. At the base of these in the transverse fissure (*e*), are two other hooks, maxillæ, of a similar description, directed both to the median line, but jointed like the mandibles in Myriapoda, and crossing each other like the mandibles of the true larva. The hooks thus include between them the cavity of the mouth, in this manner adapted both for wounding and tearing as well as suction, and it is curious to observe that we have here in the larva of a true insect an approach to the vermiform type of the permanent condition of the oral apparatus of the leech. In the maggot of the larder-flies and flesh-flies above alluded to, the mouth is formed somewhat differently. Behind the transverse hooks the mouth is bounded by a membranaceous labium, while at its anterior part it is furnished with a proboscidal lip (*fig*. 358, B *c*), divided into four very minute palpiform organs. There are also two processes situated one on each side of the mouth in the second segment. At the base of the fourth segment are the two projecting orange-coloured organs of a semicircular form, divided into what appear like single pedunculated eyes, but which are in reality external branchiæ, and correspond to the spiracles of the pro-thorax of the perfect insect (*h*). In the *Œstrus ovis* (*fig*. 360) the two sides of

Fig. 360.

2, 3, 4, *segment; a, optic nerve; b, epicranium; c, labium; d, mandibles; e, maxillæ.*

the fissure that forms the anterior part of the mouth are developed into very distinct organs of vision (*h*), in which may be traced the nerves of two separate but nearly approximated eyes. The existence of distinct eyes in this larva is the more remarkable, from the circumstance that the larva resides in the frontal sinus of the skull of the sheep, where we sought for, and found the identical specimens upon which our observations have been made.

Organs of locomotion. We stated above that the true organs of locomotion are six in number, both in the larva and perfect state, and that they are always attached to the second, third, and fourth segments of the body. They are distinguished from the false, or abdominal legs by their possessing distinct articulations or joints, by the strength and hardness of their texture, and by their general pointed form. In Coleopterous larvæ they are of considerable length, and the parts of which they are composed are readily distinguished. These

Fig. 362. *Fig*. 361.

are (*figs*. 361, 364 ***), as in the perfect insect, the *claw* (*f*), the *tarsus* (*d*), the *tibia* (*c*), the *femur* (*b*), and *coxa*, or hip (*a*). In all terrestrial larvæ the legs are attached to the inferior parts of the segments; but in one remarkable genus of water-beetles the great *Hydröus piceus*, they were supposed by Frisch to be attached so much nearer to the dorsal than the sternal surface as to have the appearance of being actually placed on the back. But this is erroneous, the mistake having arisen from the peculiar formation of the head, which is flat on its upper, but convex on its under surface. The whole of these thoracic legs, in all larvæ which possess them, are nearly equally developed, and do not present any marked difference of form or size, as is often subsequently found in the perfect insects. In the larvæ of Lepidoptera they are exceedingly short and pointed, and in many *Hymenoptera* and *Diptera* are entirely absent. The false or abdominal legs are totally different in appearance and structure from the true or thoracic ones. Although varying in number in different species, they are universally present in the Lepidoptera (*fig*. 364, †††) and in many Hymenoptera and Diptera. In some instances, as in many of the *Geometridæ*, there is only a single pair at the anal extremity of the body; while in others, as in some of the *Tenthredinidæ*, there are as many as eight pairs. In every instance they are soft and membranaceous, without distinct joints or articulations. In some of the Lepidoptera their structure is exceedingly curious, and has been beautifully illustrated by Lyonet (*fig*. 362), in his anatomy of the larva of *Cossus ligniperda*. In that insect their shape resembles an inverted cone, with its apex truncated to form a flat sole, or foot, upon which the caterpillar walks. The sole in its middle can be rendered concave at the will of the animal, while around its margin are several rows of minute hooks, directed outwards, and when the sole of the foot is pressed firmly upon any surface in walking these hooks attach themselves, and are released again when the sole of the foot is contracted, previously to the caterpillar's raising it to make another step forwards. In the *Sphingidæ* the abdominal feet are formed of two parts, the external one, broad, semicircular, and edged with minute hooks, directed inwards like a claw, and the internal one smaller, with its hooks directed outwards, so that two parts of the foot are opposed to each other, and grasp the surface upon which they are walking like the foot of a bird. It is with these that the Sphinx attaches itself so firmly to the stems and branches of plants, that it is often almost impossible to remove it without injury. In the Sphinx there are four pairs of these legs, attached to the seventh, eighth, ninth, and tenth segments, besides one pair at the thirteenth, or anal extremity. In some Dipterous larvæ the abdominal legs are the only organs of locomotion—as in the rat-tailed larva of *Eristalis tenax*.

In every instance these abdominal legs are only processes of the exterior covering of the insect, furnished externally with peculiar developments of the cuticle, in the form of hardened spines or hooks like the claws and nails of vertebrated animals, and internally with a greater development of certain portions of the muscles of the abdomen. We have full proof of this in those numerous apodal larvæ which are capable of locomotion, as in most of the *Muscidæ*, the common maggots. In all these, in which both the true and false legs are entirely absent, the whole external surface of the body is modified for this purpose. In the maggot of the flesh-fly the whole anterior part of every segment is surrounded and beset with numbers of very minute hooks, with their apices directed backwards. With these the larva attaches itself to the surface over which it moves, and carries itself along by the alternate contraction and relaxation of the longitudinal muscles of its body. A beautiful adaptation of these dermal hooks to the peculiar habits of the individual is observed on comparing their form and position on the bodies of the larvæ of two very distinct species of *Œstrus*, the one *Œstrus ovis*, parasitic in the head of the sheep, the other beneath the skin on the backs of oxen, *Œstrus bovis*. In the first of these larvæ, which moves about freely in its habitation, the hooks (*fig.* 360) are all directed backwards around the posterior margin of each segment, a direction rendered necessary for their employment as organs of locomotion; but in the latter insect, which is confined to one spot for many months, in the tumour occasioned by it on the back of the ox in the cellular tissue beneath the skin, the hooks are not required as organs of progression, but yet are rendered necessary for the purpose of retaining the larva in its nidus unaffected by the varied muscular movements of the parts around it. To accomplish this object each segment of the larva is provided with two sets of hooks. One of these is arranged around the anterior part of the segments, and consists of very numerous minute sharp-pointed spines, directed forwards, while the other is composed of strong flattened scales with curved points, very much larger but less numerous than the preceding. These are disposed around the posterior part of the segments, and have their points directed backwards. The effect of the spines thus placed in opposite directions evidently is that of retaining the larva in exactly the same position among the cellular tissue in the back of the animal, while the greater strength of the posterior spines enables it at will to penetrate deeper beneath the skin of its victim.

We have thus seen that in apodal larvæ endowed with powers of locomotion the place of the true organs of progression is supplied by peculiar developments of the cuticular covering of the body, analogous to the scales on the bodies of Ophidian Reptiles, and these are employed by the larvæ in all their progressive movements in the same manner as the scales on the body of the snake. But in those apodal larvæ which remain in the same locality until they have passed through all their changes, as the larvæ of the bee and wasp, these developments of the cuticular surface do not exist, but the body is perfectly smooth.

It is not always, however, that the spines on the bodies of larvæ are employed as organs of locomotion since they exist on many larvæ which possess both true and false feet, and are then either merely ornamental appendages or a means of defence. But whatever be their use in the economy of the larva, they are only developments of its external covering, and generally disappear when the insect undergoes its change into the pupa state, being thrown off with the skin.

Growth and changes of the larva.—The life of an insect that undergoes a true metamorphosis is one continued series of changes from the period of its leaving the egg to that of its assuming the perfect state. These are not merely from the larva to the pupa and from that to the perfect animal, during which the insect gradually acquires new organs, but consist also of repeated sheddings of its skin, which occur at certain intervals before the larva has attained its full size. These changes and the circumstances connected with them have been more particularly watched in Lepidopterous insects, and have been carefully noted by many naturalists, especially by those of the last century, Redi, Malpighi, Gœdart, Merian, Ray, Swammerdam, Reaumur, Lyonet, Bonnet, De Geer, and others, who concur in their statements respecting the manner in which these changes are effected.

Almost immediately after the insect is liberated from the egg it begins to feed with avidity, and increases much in size. According to the observations of *Count Dandalo** the common silk-worm, *Liparis mori*, does not then weigh more than one hundredth of a grain, and is scarcely a line in length, but at the expiration of about thirty days, when it has done feeding and has acquired its full size, its

* Count Dandalo on Silk-worms (Eng. Trans.) p. 326.

average weight is about ninety-five grains, and its length sometimes as much as forty lines. During this period, therefore, it has increased nine thousand and five hundred times its original weight, and has eaten sixty thousand times its weight of food. But observations on the larva of the privet hawk moth, *Sphinx ligustri*,* lead us to believe that this estimate of the amount of food eaten is a little too great. The larva of the sphinx at the moment of leaving the egg weighs about one eightieth of a grain; at about the ninth day it casts its second skin and then weighs about one-eighth of a grain: on the twelfth day it changes its skin again and then weighs rather more than nine-tenths of a grain. On the sixteenth day it casts its fourth skin and weighs three grains and a half, and on the twenty-second day enters its sixth and last skin and weighs very nearly twenty grains; but on the thirty-second day, when it has acquired its greatest size, it weighs nearly one hundred and twenty-five grains, so that in the course of thirty-two days this larva increases about nine thousand nine hundred and seventy-six times its original weight. At this period it is sometimes more than four inches in length. But this is not the greatest weight that the larva attains. One specimen which was bred in its natural haunts weighed one hundred and forty-one grains and seven-tenths, so that in this instance the insect had increased at the rate of eleven thousand three hundred and twelve times its original weight. But great as is this proportion of increase, it is exceeded by some other larvæ. Lyonet found that the larva of *Cossus ligniperda*, which remains about three years in that state, increased to the amount of seventy-two thousand times its first weight.† This amazing increase is occasioned chiefly by a prodigious accumulation of fat which exists in a greater quantity in this than in most other larvæ. We have ourselves removed forty-two grains of fat from one specimen, which was more than one-fourth of the whole weight of the insect. The occasion for this prodigious accumulation is chiefly to supply the insect during its continuance in the pupa state, while the muscular structure of the limbs and other parts of the body are in the course of development; and also to serve, perhaps, as an immediate source of nutriment to the insect at the period of its assuming the perfect state, and more particularly during the rapid development of its generative functions; since, when these have become perfected, the quantity that remains is very inconsiderable. But all larvæ do not increase in these amazing proportions, although their actual increase may be more rapid. Those in which the proportion of increase is the greatest are usually those which remain longest in the pupa state, as in the species first noticed. Thus *Redi*‡ observed in the maggots of the common flesh-flies a rate of increase amounting to about two hundred times the original weight in twenty-four hours, but the proportion of increase in these larvæ does not at all approach that of the sphinx and cossus. From observations made on the larva of one of the wild bees, *Anthophora retusa*, we believe that this is also the case with the *Hymenoptera*. The weight of the egg of this insect is about the one hundred and fiftieth part of a grain, and the average weight of a full-grown larva six grains and eight tenths, so that its increase is about one thousand and twenty times its original weight; which, compared with that of the sphinx of medium size, is but as one to nine and three-quarters, and to a sphinx of maximum size only as one to a little more than eleven.

The changes of skin which a larva undergoes before it enters the pupa state are more or less frequent in different species. In the generality of Lepidopterous insects it occurs about five times, but in one of the tiger-moths, *Arctia Caja*, according to Messrs. Kirby and Spence,* ten times. A few hours before the change is to take place the larva ceases to eat and remains motionless, attached by its abdominal legs to the under-surface of the twig or leaf upon which it has been feeding. Many species spin a slight web or carpet of silk in which they attach their posterior legs, as observed by Dr. Pallas of *Apatura iris*,† and in this manner await their change, which appears to be attended with much uneasiness to the insect. The whole body is wrinkled and contracted in length. In the sphinx this contraction occurs to so great an extent in some of the longitudinal muscles of the anterior and middle part of the body that the larva assumes that peculiar attitude from whence the genus derives its name. In this attitude the larva remains for several hours, during which there are occasionally some powerful contractions and twitchings of its whole body, the skin becomes dry and shrivelled, and is gradually separated from a new but as yet very delicate one which has been formed beneath it, and the three or four anterior segments are greatly enlarged on their dorsal but contracted on their under surface. After several powerful efforts of the larva the old skin cracks along the middle of the dorsal surface of the second segment, and by repeated efforts the fissure is extended into the first and third segments, and the covering of the head divides along the vertex and on each side of the clypeus. The larva then gradually presses itself through the opening, withdrawing first its head and thoracic legs, and subsequently the remainder of its body, slipping off the skin from behind like the finger of a glove. This process, after the skin has once been ruptured, seldom lasts more than a few minutes. When first changed the larva is exceedingly delicate, and its head, which does not increase in size until it again changes its skin, is very large in proportion to the rest of its body. In a few hours the insect begins again to feed most voraciously, particularly after it has entered its last skin, when its growth is most rapid. Thus a larva of *Sphinx ligustri*, which at its last

* Phil. Trans. 1837, part ii. p. 315.

* Vol. i.
† Trans. Ent. Society, vol. ii. part ii. p. 138.

change weighed only about nineteen or twenty grains, at the expiration of eight days when it was full-grown weighed nearly one hundred and twenty grains. Most larvæ immediately after changing their skins remove to fresh plants, but some, as the larvæ of a beautiful moth, *Episema cæruleocephala*, devour their old skins almost immediately they are cast, and sometimes one another when deprived of food.

But it is not merely the external covering which is thrown off during these changes; the whole internal lining of the alimentary canal also comes away with the skin, as was formerly noticed by Swammerdam,* and repeatedly observed by ourselves and others. The lining of the mouth and pharynx with that of the mandibles, is detached with the covering of the head, and that of the large intestines with the skin of the posterior part of the body, and besides these also, the lining of the tracheal tubes. The lining of the stomach itself, or that portion of the alimentary canal which extends from the termination of the œsophagus to the insertion of the so called biliary vessels, is also detached, and becomes completely disintegrated, and appears to constitute part of the *meconium* voided by the insect on assuming its Imago state. Herold, however, has denied that this change ever occurs in the alimentary canal, and says that in the trachea it takes place only in the larger stems. But Swammerdam states that he saw it in the larva of the rhinoceros beetle, *Oryctes nasicornis*, which shed both the lining of the colon, and of the delicate as well as larger branches of the tracheæ,† and Bonnet‡ had witnessed a similar occurrence. Burmeister§ has also seen it, both with respect to the colon and tracheæ, in some of the Libellulæ, and we now add our own testimony to the fact of its occurring, not simply at the extremities of the canal, but throughout its whole extent, as we have distinctly seen during the changes of the nettle-butterfly, *Vanessa urticæ*.|| It is more distinctly observed when the larva is changing into the pupa state than at any other period, although we believe that it really does take place at every change of skin. Hence these changes are of the greatest importance to the larvæ, which often perish during their occurrence. They are undergone by all larvæ which possess the true organs of locomotion, but it has been questioned whether they are common also to the apodal larvæ, more particularly those which constantly remain in the same locality until they have changed into pupæ or nymphs. Reaumur and Huber¶ state that the larva of the common hive-bee does not change its skin, but only grows larger; Swammerdam,** on the contrary, asserts that it does, and also that he has observed the same thing in the alimentary canal of the hornet.* Burmeister† believes that it does not take place, and states positively that the larvæ of Diptera do not moult. We have watched for these changes in the larvæ of the wild bee, *Anthophora retusa*, but have been unable to observe them, although we believe they do really occur. But the universally acknowledged accuracy of most of Swammerdam's observations, supported as they are in this instance by analogy, fully warrants us in considering this subject as still open for enquiry.

When a full-grown larva is preparing to change into the pupa state it becomes exceedingly restless, ceases to eat, and diminishes much in weight. Many species spin for themselves a covering of silk, termed a *coccoon*, or case, in which they await their transformation. Others prepare little cavities in the earth and line them with silk for the same purpose, (*fig.* 363), and others suspend themselves by their anal prolegs to the under surface of a leaf. In each of these instances this important change takes place in the same manner. Before the larva thus prepares itself for metamorphosis its alimentary canal is completely evacuated of its contents, its body, as at the previous changes of skin, becomes dry and shrivelled, and much contracted in length, and certain enlargements at the sides of the anterior segments indicate the now rapidly developing parts of the future pupa. These changes take place in all insects in a similar manner, but have been most frequently watched in Lepidoptera, upon which also our own observations have been made. We have also observed the same changes in Hymenoptera. The larva of the sphinx, when it is ready to undergo its changes, penetrates the earth to the depth of a few inches, and there forms for itself a little chamber, in which it awaits its transformation. But the butterfly either fastens itself by a little rope of silk, carried across its thorax, to the under surface of some object, as a ceiling, &c., or suspends itself vertically by its prolegs, with its head directed downwards. as is the case with the common nettle butterfly, *Vanessa urticæ*. We have watched these changes with much care in

this insect, which frequently remains thus suspended more than ten or twenty hours before the transformation takes place. During this time the four anterior segments of the larva become greatly enlarged, and the segments assume a curved direction, occasioned by the contraction, or shortening of the muscles of the under surface of those segments, which are repeatedly slowly extended and shortened, as if the insect were in the act of laborious respiration. This generally takes place at short intervals during the two hours immediately preceding the change, and increases in frequency as that period approaches. When the period has arrived, the skin bursts along the dorsal part of the third segment, or *meso-thorax*, and is extended along the second and fourth, while the coverings of the head separate into three pieces. The insect then exerts itself to the utmost to extend the fissure along the segments of the abdomen, and in the meantime pressing its body through the opening gradually withdraws its antennæ and legs, while the skin, by successive contortions of the abdomen, is slipped backwards and forced towards the extremity of the body, just as a person would slip off his glove or his stocking. The efforts of the insect to get entirely rid of it are then very great; it twirls itself in every direction in order to burst the skin, and when it has exerted itself in this manner for some time, twirls itself swiftly, first in one direction, then in the opposite, until at last the skin is broken through and falls to the ground, or is forced to some distance from it. The new pupa then hangs for a few seconds at rest, but its change is not yet completed. The legs and antennæ, which when withdrawn from the old skin were disposed along the under surface of the body, are yet separate, and do not adhere together as they do a short time afterwards. The wings are also separate and very small. In a few seconds the pupa makes several slow but powerful respiratory efforts; during which the abdominal segments become more contracted along their under surface, and the wings are much enlarged and extended along the lateral inferior surface of the body, while a very transparent fluid which facilitated the slipping off of the skin, is now diffused among the limbs, and when the pupa becomes quiet dries, and unites the whole into one compact covering.* Exactly the same thing occurs in the changes of the sphinx. The limbs at first are all separate, each one inclosed in its distinct sheath, but within a very short period after the change they become agglutinated together by the fluid effused between them, and form the solid exterior of the pupa case. The body of the insect is now divided into three distinct regions, head, thorax, and abdomen. The first step towards this division is the contraction which takes place in all the longitudinal and diagonal muscles of the body, soon after the larva (*fig.* 364) has acquired its full size, by means of which each segment of the insect forms a slight intussusception, the anterior margin of one segment being drawn

under the posterior margin of the one which immediately precedes it. This occurs in all the segments which form the abdominal region of the future moth, the nine posterior ones of the larva. When the period of changing into the pupa state has arrived, a much greater shortening takes place in the muscles of the fifth and sixth segments, and in some insects this is carried to so great an extent that the whole body becomes constricted in the fifth segment like an hour-glass, and is thus divided into two distinct regions, thorax and abdomen. The same change takes place also in the muscles of the first and second segment, by means of which the region of the head is divided from that of the thorax (*fig.* 365). These duplicatures of the external covering are carried to a greater extent on the under surface of the first four segments than on the upper,

and form the divisions between the legs of the perfect insect,—the bony processes of the sternal surface to which some of the principal muscles are attached. On the upper surface of the same segments they in like manner become the *phragmata*, or bony partitions of the dorsal surface. The fifth segment becomes almost entirely atrophied, and the sixth very much shortened. A part of the fifth segment forms a portion of the posterior surface of the thorax of the perfect insect, (*fig.* 366) while the remainder constitutes the petiole or neck which connects the abdomen with the thorax, the sixth being the first true segment of the abdominal region. Exactly the same changes take place in Hymenopterous insects, and in every other species in which we have had opportunities of watching them. We have before alluded to the opinion of Dr. Ratzeburg that the head in Hymenopterous insects is composed of two segments of the larva, because just before the change into the nymph or pupa state a portion of the head is found beneath the integuments of the second segment. The fact is indisputable, but the explanation of it appears to be this. The true head of the Hymenopterous larva consists of but one segment, which is provided with the organs of manducation and sensation the same as in the Lepidopterous. But the head in this larva ceases to become larger after a certain period, while the other segments of the body continue to grow, and ultimately acquire a diameter more than double that of the head. Now the parts which are to form the head of the future nymph continue also to grow beneath the unyielding cranium, from which, as the change approaches, they become detached, and are gradually developed backwards, and encroach upon the anterior portion of the second segment. This, in accordance with the laws of development, as established by Geoffroy St. Hilaire, that in proportion as one part of an organized body is increased beyond its ordinary size, the part or parts in its immediate vicinity are in a corresponding degree arrested in their development, becomes so much reduced, that in the nymph, this second segment, which in the larva is of the same size as the third and succeeding ones, has not half its original extent, and being still further reduced in that state constitutes at length the atrophied, and almost obliterated *pro-thorax* of the perfect insect. But while the second segment is thus encroached upon by the first it is in like manner encroached upon from behind by the third, the immense *meso-thorax*, which supports the chief organs of flight in the perfect insect. The fourth segment from the same cause is developed backwards, and the fifth, diminished to a very small size, exists only as in the sphinx as the petiole which connects the thorax with the abdomen, thus leaving the nine posterior segments of the larva to the latter region, as stated when alluding more particularly to the number of segments in hymenopterous larvæ. The necessity for this additional segment in the abdomen of these larvæ is a matter of much interest, and appears to be connected with the development of an *apparently* additional organ in the females of this class, a circumstance to which we shall return in our description of the skeleton of the perfect insect.

The Pupa.—We have seen that after leaving the larva or feeding condition, the insect assumes one of a very different form, which is called the *pupa*, *nymph*, *aurelia*, or *chrysalis* state. The two latter terms were applied by the older entomologists to this stage of transformation in butterflies and moths. The term aurelia was used, as expressive of the beautiful golden colours or spots with which many species are adorned, as *Vanessa urticæ*, *v. atalanta*, and others. The term *chrysalis* had a similar signification. Linnæus, desirous of employing a term that would be applicable to this stage of transformation in all insects, adopted that of *pupa*, because in a large majority of the class the insect is as it were *swathed* (*fig.* 367) or

Fig. 367.

Pupa of Deilephila Elpenor. Elephant hawk-moth.

bound up, as was formerly the practice of swathing children. This kind of pupa, in which the future limbs are seen on the outside of the case, is called *obtected*. The term *nymph*, which is sometimes employed, is applicable only to those species in which the limbs remain free, but are folded up, as in the pupæ of the butterfly and moth, and are not covered with a hard uniform case; as in many Coleopterous and most Hymenopterous insects (*fig.* 368). When the pupa is in-

Fig. 368.

Nymph or pupa state of Vespa crabo. Hornet. Magnified.

closed in a smooth uniform case, but no signs of the limbs or other parts of the body are visible, as in *Diptera*, it is called *coarctate*. In these insects the skin of the larva is not cast off at the period of changing, but becomes the covering or coccoon of the included pupa, which is also inclosed in its own proper skin within it. In all insects which undergo a complete metamorphosis, this is the period of quiescence and entire abstinence. Many species remain in this state during the greatest part of their existence, particularly the true pupæ of moths and sphinges, which often continue in it for nearly nine months of the whole year. But in most of those insects which assume the particular condition of nymph, in which the body remains soft and delicate, as the hornets, ants, and bees, the pupa state is the shortest period of existence, being often scarcely more than a week or ten days. In every species the length of this period is much affected by the influence of external circumstances. Thus if the larva of the common nettle-butterfly, *Vanessa urticæ*, change to a chrysalis in the hottest part of the summer, it will often, as we have found, be developed into the perfect insect in eight or nine days;* whilst if its change into the chrysalis takes place at the beginning of summer, it is fourteen days before the perfect insect appears; and if it enters the chrysalis state at the end of summer, it remains in that condition through the winter until the following spring. On the other hand, as was proved by Reaumur, if the chrysalis be placed in an ice-house, its development into the perfect insect may be retarded for two or three years. Again, if the chrysalis be taken in the midst of winter into a hot-house, it is developed into the perfect insect in from ten to fourteen days. This period of quiescence is absolutely necessary in all those species which undergo an entire change of form and habits, for the completion of those structural metamorphoses by which the creature is not only adapted to the performance of new functions, but is equally incapacitated for the continuance of some of those which it has previously enjoyed. During this period it is that new parts are developed, and the insect's mode of life is in consequence entirely changed. Whilst these alterations are taking place in the organic structures, the functions of the organs themselves are in a great measure suspended, and the condition of the insect becomes that of the hybernating animal. Respiration and circulation are reduced to their minimum,† and the cutaneous expenditure of the body is then almost unappreciable even by the most delicate tests.‡ Thus a pupa of *Sphinx ligustri*, which in the month of August, immediately after its transformation, weighed 71.1 grains, in the month of April following weighed 67.4 grains, having thus lost only 3.7 grains in the long period of nearly eight months of entire abstinence. The whole of this expenditure, therefore, had passed off

* Phil. Trans. 1834, part 2, p. 416.
† Phil. Trans. 1836, part 2, pp. 555-6.
‡ Idem. 1837, part 2, p. 323.

by the cutaneous and respiratory surfaces. But when the changes in the internal structures are nearly completed, and the perfect insect is soon to be developed, the respiration of the pupa is greatly increased, and the gaseous expenditure of its body is augmented in the ratio of the volume of its respiration, which is greatest the nearer the period of development. Thus in the same insect in which the diminution of weight was so trifling during eight months' quiescence and abstinence, it amounted in the succeeding fifty-one days to nearly half the original weight of the pupa, since the perfect insect, immediately after its appearance on the 24th of May, weighed only thirty-six grains.

This increased activity of function is attended with a correspondent alteration in the general appearance of the pupa. In the sphinx all the parts of the future *Imago* become more and more apparent on the exterior of the pupa case, the divisions into head, thorax, and abdomen are more distinctly marked, the eyes, the antennæ, and the limbs appear as if swollen and ready to burst their envelope, and the pupa gives signs of increasing activity by frequent and vigorous contortions of its abdominal segments. The naked pupa or *nymph*, in which, as we have seen, all the parts of the body are free, and encased only in a very delicate membrane, acquires a darker colouring and a firmer texture, while the species which undergo their metamorphoses into nymphs in the water, *Trichoptera*, the caddis-flies, acquire a power of locomotion as the period of their full development approaches, to enable them to creep up the stems of plants, and leave that medium in which it is impossible for them to exist as perfect insects.

In every instance the assumption of the perfect state is accompanied by a slipping off of the external covering. Before this can be effected, many Lepidoptera, like the Trichoptera, have first to remove themselves from the locality in which they have undergone their previous metamorphoses. When this happens to be in the interior of the trunks of trees, or in other situations from which it is difficult to escape, the abdominal segments of the pupa are often beset with minute hooks (*fig.* 367), similar to those on the feet of the larva. By means of these, by alternately contracting and extending its abdominal segments, the pupa is enabled to force an opening through its silken coccoon, or to move itself along until it has overcome the obstacles which might oppose its escape as a perfect insect.

The imago or perfect state.—Immediately after the insect has burst from the pupa case it suspends itself in a vertical position with its new organs, the wings, somewhat depending, and makes several powerful respiratory efforts. At each respiration the wings become more and more enlarged by the expansion and extension of the tracheal vessels within them, accompanied by the circulatory fluids. When these organs have acquired their full development the insect remains at rest for a few hours and gains strength, and the exterior of the body becomes hardened and consolidated, and forms, what we shall presently consider, the *Dermoskeleton*. This is what takes place in Lepidopterous insects. Some of the Coleoptera, as in the instance of *Melolontha vulgaris*, the common chaffer-beetle, remain for a greater length of time in their nidi before they come abroad after entering the imago state. This is also the case with the Humble-bees. When these insects first come from their cells they are exceedingly feeble, their bodies are soft, and covered with moisture, their thick coating of hairs has not acquired its proper colour, but is of a grayish white, and they are exceedingly susceptible of diminished warmth. They crowd every where among the cells, and among other bees, where there is most warmth. In a few hours this great susceptibility is diminished, and their bodies acquire their proper colours, but they do not become sufficiently strong to be capable of great muscular exertion, and undertake the labours of the nest until the following day.

When an insect has once entered its perfect state, it is believed to undergo no further metamorphosis or change of covering. But there exists an apparent exception to this general law in the *Ephemeridæ*, which are noted for the shortness of their existence in the imago state. When these insects have crept out of the water, and rid themselves of the pupa covering, and their wings have become expanded, they soon take flight, but their first movements in the air are performed with some difficulty, and they shortly alight again and throw off a very delicate membrane with which every part of the body has been covered, and then resume their flight with increased activity. The condition of the insect previously to this final change has been called by Mr. Curtis the *pseudimago* state. It was noticed long ago by Swammerdam, and has usually been thought to be peculiar to the *Ephemeridæ*, but occurs also in the *Lepidoptera* and *Diptera*,* but in them takes place at the same time with the change from the pupa state. Swammerdam thought the change peculiar to the males of the *Ephemeridæ*, but Mr. Westwood has seen it also in the females.

Many insects, of which the *Ephemeridæ* and *Bombycidæ* are known examples, take no food in the perfect state, and exist only for a few hours, or at most only a few days, the business of life being almost entirely devoted to the propagation of the species. In every instance of the entire abstinence of a species in the perfect state there is a corresponding atrophy of the parts of the mouth. This we shall find is the case in the Ephemera, in the gad-fly, *Œstrus*, and in the silk-worm moth. In the latter instance the parts of the mouth are simply so much diminished in size as to be unfitted for taking food; in the former they have almost disappeared. On the other hand, when the life of the imago is continued for a long period, all the parts of the mouth are fully developed. The duration of life in these species often extends for many weeks, or in some even months, and the quantity of food taken is consequently greater than is taken by the larva. In those

* Westwood's Introduction, &c. vol. ii. p. 28.

instances in which the life of the imago is extended beyond the usual period, it appears to result from one of the great objects of existence being unaccomplished; the insect is always in a state of celibacy, in which condition the life of an ephemera may be extended to several days, and perhaps even to two or three weeks.*

1. *Dermo-skeleton.*—The skeleton of insects is formed of a modification of the external coverings of the body, together with certain ossified portions situated within the head and thorax, to which some of the most important muscles are attached. Hence it is called a *dermo-skeleton*. The true organs of support are thus placed on the exterior instead of the interior of the body, and the solid skeleton, impacting the whole, as it were, in a coat of mail, gives additional strength to the delicate limbs by affording a larger surface for the attachment of muscles, while it more securely protects the bodies of these diminutive, but exquisitely formed little creatures, from the injuries to which they are constantly exposed. Thus, then, in the strength and position of the skeleton, insects have as striking affinities with the Chelonian Reptiles as they have, as we shall hereafter see, with Birds in the extent, distribution, and activity of their respiratory organs; and with the hibernating Mammalia in their maintaining an elevated temperature of body only when in a state of activity. Some naturalists, however, have contended that the analogies which were traced, first by our illustrious countryman Willis in the year 1692, and subsequently by Geoffroy St. Hilaire and other comparative anatomists, between the dermo-skeleton of insects and the proper skeleton of vertebrated animals, are incorrect, and that the structure ought rather to be regarded as the analogue of the skin than as that of the osseous system, and hence they have compared it only with the nails, horns, and other appendages of the epidermis. These objections receive additional weight and importance from the circumstance that one set of organs, the elytra, which form part of the hardened coverings, are actually derived from the respiratory structures. But it may be remarked in reply, that the skeleton of insects, both in its office and ultimate composition, resembles more the bones of Chelonian Reptiles, which, like it, are covered with a thin cuticular lamella, and placed on the exterior of the body, than the true skin or the epidermis. Hence we shall continue to regard and describe it as subservient to the same purposes in these diminutive creatures as the osseous system in vertebrata. This view of its real nature is justified, as we shall presently see, by analyses of its chemical constituents. The peculiar characteristic of bony structure is the presence of a large proportion of a particular kind of earthy matter, and this is also one of the great characteristics of the coverings of insects, which become consolidated during the changes, by the deposition of a quantity of the same kind of earthy matter within them. But we cannot regard the coverings thus formed as merely exsiccated non-vascular structures; on the contrary, we believe them to be nourished by the circulatory fluids, perhaps to as great an extent as the external skeleton of Chelonia. In support of this opinion it may be remarked that those internal processes which exist in the perfect state, and are developed during the metamorphoses from duplicatures of the external tegument, perform most important offices in the body as organs of support and attachment for powerful muscles. It can hardly be imagined that these internal processes are not nourished by the circulatory fluids like the muscles that are attached to them, while it is well known that every part of the external covering is penetrated by ramifications of the air-vessels, the course of which in the wings has recently been shown to be always indicative of the passages along which the blood circulates.* Hence it is fair to infer that every part of the animal supplied with tracheæ is also nourished by the circulatory fluid, as well in the exterior skeleton of the thorax and abdomen as in the hardened elytra and wings, in which the presence of the fluid has been actually detected by its movements.

Chemical composition.—The peculiar substance that constitutes the hard portion of the dermo-skeleton is called *chitine* by Odier, and *entomoline* by Lassaigne. The most generally received name is chitine. M. Odier, who first analysed the coverings of insects, and discovered this substance,† found that it constitutes about one-fourth part of their whole weight, and that the remaining three parts consist of albumen, extractive matter soluble in water, a coloured oil soluble in alcohol, and a brown animal substance soluble in potass, but insoluble in alcohol. The latter substance, which exists in considerable quantity, was found by Lassaigne to be analogous to the peculiar animal matter of cochineal, *coccine*, and that it forms the basis of the colouring matter of the skeleton. The composition of chitine has been differently stated by chemists, but by all it has been shown to be perfectly distinct from horn, the nails, and other appendages of the epidermis, in being quite insoluble in a hot solution of caustic potass, and in not fusing or swelling up like horn when burnt at a red heat, but leaving a white ash, which retains the original form of the part. This sufficiently proves that the coverings of insects cannot properly be compared with the mere epidermis or its appendages. According to Odier, chitine is obtained by digesting the hard parts of the skeleton in a hot solution of caustic potass, renewed several times, until it has ceased to have any action upon them. The solution, by removing the colouring matter and other constituents, becomes of a deep brown, and leaves the chitine nearly as transparent as horn, without any change of form. This substance, as we have before stated, constitutes about one-third or fourth of the weight of the whole skeleton, and was believed by Odier to contain no nitrogen,

† Mémoires de la Societé d'Hist. Natur. de Paris, tom. i. Zoological Journal, vol. i. p. 101, Mar. 1824.

on which account it was compared by him to lignin, the basis of woody fibre. He believed also that it contains no carbonate of lime, the earthy salts being chiefly phosphate of lime, with carbonate of potass and a little phosphate of iron. Mr. Children, however, by a more careful and different mode of analysis, proved that chitine is composed of carbon, hydrogen, nitrogen, and oxygen, in about the following proportions, the mean which we have deduced from his details of two careful analyses:

	Grs.
Carbon	46.08
Hydrogen	5.96
Nitrogen	10.29
Oxygen	37.41
	99.74

and that, in addition to the earthy salts mentioned by Odier, there are also small proportions of silica and magnesia, and a slight trace of manganese; and it has since been stated that there is likewise a trace of carbonate of lime.* Some authors still imagine that chitine contains no nitrogen;† but in the careful experiments of Mr. Children, who was assisted by Professor Daniell,‡ the formation of prussic acid, which took place during the analysis, was decisive of the fact of its existence.

Thus, then, in the distinctness of its chemical composition from that of horn and other dermal appendages, and in its similarity to that of true bone, in the greater proportion of its earthy matter being phosphate of lime, may we not venture to infer that chitine, the basis of the insect skeleton, is intermediate in its chemical condition between the ossific and dermal structures; or, in other words, is an imperfectly developed condition of bony matter, so modified that, while it is subservient to the great purpose of animal life, in affording strength and solidity to the parts in which it exists, it at the same time admits of their performing all the organic functions of the true skin?

If such be not the case, it will be difficult satisfactorily to account for the solidification of those internal processes which, in insects, occupy the position and perform the office of the true bones in vertebrata, but which are originally derived from the external teguments. Thus we shall find that in the cranium of some of the Coleoptera, the most perfect insects, the cerebral ganglia are protected on either side by more or less perfectly developed laminæ of this bone-like structure; that the first subœsophageal ganglion actually lies in a cradle of the same, and that the nervous cord itself, before passing out of the cranium, is not only protected laterally by continuations of these laminæ, but is often inclosed in a distinct bony ring. But it may be said that the exuviation of the coverings of insects during the early period of life, when undergoing their metamorphoses, and a like condition in other articulata, is opposed to this opinion. To this we reply, that in all true insects exuviation of the skeleton takes place only during the growth and metamorphoses of the individual, and that when these are completed, and the insect has arrived at its adult condition, when its body no longer continues to be enlarged, the then perfect skeleton is persistent throughout the remainder of life, which, as in the hive-bee, may continue for many months, and under some circumstances, as has been known among the Coleoptera, even for two or three years. The exuviation of the skeleton of Crustacea, which are said to continue to grow throughout the whole period of their existence, is similar to that of insects, and perhaps in both is induced, not alone, as usually supposed, by the mere incasement of the animal in a covering which prevents the further growth of its body, but by changes in the actual condition of the skeleton itself, dependent upon the same laws of existence which regulate the removal of the old and the deposition of new matter in the bones and other structures of the vertebrata.

Of the manner in which chitine is deposited in insects we have no direct information. Latreille considers it to be a solidification in the mucous tissue, and Dr. Grant affirms it to be a deposition upon the true skin. This appears also to have been the opinion of Odier, who found chitine in the exuviable skeleton of Crustacea, in which he says it exists in the form of lamellæ.* In whatever form it is deposited, it is intimately connected with the true corium, into the composition of which it appears to enter. It is covered by the colouring matter, and also with a distinct epidermis like the horny cuticle on the carapace of Chelonia. On comparing the experiments of M. Odier and Mr. Children the quantity of chitine appears to vary a little in different insects.† A curious circumstance mentioned also by Odier is that it appears to enter into the composition of the tracheæ of the wings, but not into that of their connecting membranes. If this be the case, it is a further proof that the skeleton ought not to be compared to the epidermal appendages of vertebrata.

The skeleton consists of thirteen distinct segments, which are believed to be its normal number in all insects. But recent observations on the larvæ of Hymenoptera and Diptera, before alluded to, render it probable that this is not the full amount, and that the number is at least fourteen, at all events in some species. Mr. Westwood has already shown this to be the case in Hymenoptera, and that in the perfect state of *Forficula*‡ there are thirteen distinct segments in the male, and, also in a rudimentary state, in the female, besides the anal forceps. We have ourselves invariably found fourteen in the apodal larvæ of Hymenoptera and in some of the Diptera; but we

were not prepared to meet with anything like an approach to the same number in a perfect insect. In the female of the *Gryllotalpa vulgaris* we have found nine distinct segments in the abdomen, besides the post-scutellum, which resembles a tenth one in a rudimentary condition on the dorsal surface between the meta-thorax and base of the abdomen. In the male of the same species there are also nine distinct segments, but the penultimate and ante-penultimate are in a rudimentary condition, corresponding to those in the female Forficula. The post-scutellum at the base of the meta-thorax is as much developed as in the female, and is very distinct as a portion of the meta-thorax. We have also found the same number in a foreign species, *Gryllotalpa didactyla*. The similarity in the number of segments thus appears to connect the *Gryllotalpæ* with the *Forficulæ*. These variations in perfect insects lead us to hesitate in admitting *thirteen* to be the normal number of segments, especially as we shall presently endeavour to show that the head itself is composed of more than one. The varied forms of the body in the different classes are entirely dependent upon the extent to which these primary segments are developed, whatever be their true number, and chiefly upon the greater or less development of parts of the first four segments. But whether the changes in these segments be greater or less, they are always in reference to the habits or economy of the individual. Thus in the Coleoptera and Orthoptera the parts of the mouth are nearly equally developed, and are admirably fitted for all the purposes of manducation. In the Lepidoptera some of these parts are developed to their greatest possible extent, the consequence of which is that the neighbouring parts become atrophied, and leave scarcely a trace of their former existence. This is the case with the mandibles and lips, the most conspicuous parts of the mouth in the larvæ of this order. In the *imago* the maxillæ are greatly elongated, and altered in shape, to form a flexible tube, because the perfect insects are destined to take their food in a liquid state, and because still further, the food is produced in situations where it would be inaccessible to the insect, were the mouth of the same form as in those the food of which requires to be comminuted by the jaws, before it is passed into the stomach.* Then again in the same segment in which the oral organs are nearly equally developed, other parts are often enlarged, and in like manner encroach upon those which are in immediate connexion with them. In the rapacious Neuroptera which obtain their food solely by means of the organs of vision, and are constantly hawking in search of it in the brightest light, the corneæ of the eyes are expanded over nearly two-thirds of the whole surface of the head, and in consequence reduce to their minimum of development those parts which are most conspicuous in the head of Coleoptera, which usually obtain their food by the aid of other senses. The causes which regulate the development of the segments of the thorax are exactly those which influence the development of the head. In the mole-cricket, which burrows in the earth for its food, the second segment, or pro-thorax, with its appendages the anterior extremities, is enlarged to its greatest extent, because it is necessary that nearly the whole strength of the insect should be concentrated in this segment, to enable it to dig its way with ease and rapidity through a resisting medium, while the third and fourth segments, which bear the organs of flight, in this species of minor importance, are smaller than in most other insects. In the Coleoptera, *Geotrupidæ*, which not only burrow in the earth, but require to be transported from place to place in quest of food, the pro-thoracic, and the wing-bearing meta-thoracic segments are largely developed, and form a great proportion of the body, and the intermediate segment, the meso-thoracic, encroached upon by both, is almost atrophied between them. On the other hand, in the Hymenoptera, Lepidoptera, and Diptera, in which the principal organs of locomotion are the anterior wings, the meso-thoracic segment is enormously enlarged, and the pro-thorax and meta-thorax are reduced to a size of comparative insignificance.

These important modifications of structure, by means of which every part of the body is beautifully adapted to the habits and wants of the individual, and the insect itself becomes an agent employed by nature to work certain necessary effects on other parts of Creation, are accomplished during the metamorphoses by certain changes in the form of parts of the external teguments. By this means many insects which in their naked larva condition scarcely at all differ in their general external appearance, are made to assume forms, when they have undergone their metamorphoses, so totally distinct from each other as to be instantly recognisable by the most unpractised observer. The primary division of the body into segments is effected simply by a duplicature of the external covering. One margin of the fold is carried over the other, and a simple telescope articulation is produced. In this way the body of the larva in its earliest condition is first divided into its normal number of segments, and by a continuation of the same process, as we have before shown, into distinct regions.

The articulations of the limbs and organs of manducation are as much the result of changes in the form of the external surface as the division of the body into segments or regions. The folding, the intussusception, the depression, or the extension of certain portions of the integument, when solidified, at the completion of the metamorphoses, serve all the offices, and become parts of the different kinds of articulations, which in principle are precisely similar in insects to some of the more important ones in the Vertebrata. In the simple approximation of two surfaces, completely solidified, and allowing of no motion between them, we discover the common *sutural* connexion of some of the

* See Newman on the External Anatomy of Insects, p. 13.

bones in man. An instance of this occurs in the upper surface of the cranium of every insect, in the union of the clypeus posterior with the epicranium. In another duplicature, one surface of which is rendered concave, and the corresponding one opposed to it convex, and allowing of motion between them almost wholly in one plane, we perceive the true *ginglymoid* or hinge-like articulation; while the small intervening portion of tegument, by means of which the margins of these surfaces are connected, becomes thinned and atrophied, and forms their proper connecting ligament. Instances of this kind of articulation occur also in the head of most insects in the articulation of the mandibles with the cranium, as well as in the limbs of almost every species. Again, when a portion of the tegument which covers the developing organs of locomotion becomes constricted at the base of the organ, that surface of the duplicature which is nearest the body forms a hollow or cup-shaped cavity, into which the other surface of the duplicature, rendered convex, is inserted, and in this way a true *enarthrodial* or cotyloid articulation is developed, the connecting ligament between the two surfaces forming the internal ligament of the joint, which is thus rendered capable of most extensive rotation. The ligament thus formed in every instance is hollow, to allow a passage for the muscles and other structures of the limb. Examples of this kind of articulation occur in the coxæ or basial joints of the legs, in the *Cerambycidæ* and *Curculionidæ*. Lastly, where the tegument is simply reflected upon itself, and a sliding motion allowed of, we have the simple *squamous* articulation. In all cases the development of one portion of tegument takes place at the expense of another, as in the development of the segments themselves, and not by the introduction of a new element in the composition of the part. In this manner, in accordance with the law of *centripetal development* as pointed out by M. Serres in the vertebrated classes, every part of the body is formed in the so-called invertebrated.

We thus recognise *four* distinct kinds of articulation, although several more have been described by Straus-Durckheim in his excellent work on Melolontha,* but all of them appear to be reducible to these primary ones.

These principles will enable us to understand the cause of the presence or absence of those structures which form the internal skeleton, and also the manner in which the limbs of the imago are developed from the soft and uniform body of the naked larva. They may also tend to elucidate one of those hidden and mysterious processes of nature by which the exterior organization of the queen or female inmate of the hive is caused so materially to differ from that of the so-called neuter or sterile female, influenced as it is said to be in its whole system by the different quality of the food supplied to the larva during the first few hours of its existence.

According to the investigations of the most careful observers, Savigny, Audouin, Macleay, Kirby, Carus, Straus-Durckheim, Newman, and others, every segment of the perfect insect is made up of distinct parts, not always separable from each other or developed to the same extent, but existing primarily in all. It is also believed that the head itself is formed of two or more segments, but the exact number which enter into its composition is yet a question. So uncertain are the opinions held upon this subject, that while Burmeister recognizes only two segments, Carus and Audouin believe there are three, Macleay and Newman four, and Straus-Durckheim, even so many as seven. These different conclusions of the most able investigators appear to have arisen chiefly from too exclusive examinations of the head in perfect insects, without reference to the corresponding parts in the larvæ. It is only by comparing the distinctly indicated parts of the head in the perfect insect with similar ones in the larva that we can hope to ascertain the exact number of segments of which it is composed. In the head of the perfect insect there ought to be found some traces of all the segments which exist in the larvæ of the same species, and in that of the more perfectly developed larvæ that undergo a true metamorphosis, there ought in like manner to be found the rudiments of all the segments in the least perfectly developed. Now the common larva of the Dipterous insect, the maggot of the flesh-fly, is one of the lowest forms we have yet examined, and we have already seen that its head appears to be formed of four, and perhaps even of five segments. This is the greatest number yet noticed in the head of the larva of any species. If, therefore, we can trace the like number in the head of a perfect insect, we may fairly conclude that this is the normal number of segments throughout the class. The head of the great water-beetle, *Hydröus piceus*, is remarkably well-fitted for exemplifying the number of segments of which the head is originally composed, the remains of four of the segments being distinctly marked; and it also affords us a proof of the correctness of the opinions advanced by Savigny and others, that the organs of manducation are the proper articulated members of distinct segments, and are perfectly analogous to the proper organs of locomotion.

We shall first describe the parts of which the head is composed, and then endeavour to explain the manner in which these parts have been developed from separate segments to form the perfect cranium and its appendages. It has hitherto been customary with naturalists to designate the head the first segment of the body, and as every change in the nomenclature of a distinct part ought always to be avoided, unless positively required, through fear of creating confusion, we shall not deviate on the present occasion from the established mode, but when speaking of it as a whole shall consider it the first segment, while the aggregation of segments of which it is composed we shall designate individually *sub-segments*, distinguishing them numerically in the order in which they appear to exist in the earliest condition of the fœtal larva.

The above table exhibits the whole of the parts yet found in the cranium in the most perfect order of Insects, the *Coleoptera*; but it must be remembered that many of these parts are less perfectly developed in the other Orders, and in some of the species have not yet been discovered.

Commencing our examination of the head at the posterior part of its upper surface, we observe that the *occiput* (*a*, *fig.* 369) is that portion of its base which is articulated with the anterior margins of the prothorax. It is perforated by a large foramen, through which the organs of the head are connected with those of the body. It is very distinct in the Hydröus and most Coleoptera, and in some, the *Staphylinidæ*, *Carabidæ*, and *Silphidæ*, is constricted, and extended backwards so as to form a complete neck; but in others, as in the *Curculionidæ*, it is short and hardly distinguishable from the *epicranium* (*b*), of which it is the continuation and posterior boundary. The *epicranium* is the whole of the posterior and upper surface of the head, bounded posteriorly by the occiput, laterally by the corneæ and sides of the gula, and anteriorly by a triangular suture which extends from the anterior margin of the corneæ to the middle of the head between the eyes, where its apex unites with a longitudinal suture which extends along the median line to the occiput. This triangular suture is a marked character in the head of many insects, both in the larva and perfect state, and is of great importance in determining the number of the *sub-segments*. It is very distinct in the larvæ of Lepidoptera, and is as marked in the *Melolonthidæ* and the *Staphylinidæ* as in the *Hydröus*. In some of the beetles it is indistinctly marked on the upper surface, but forms elevated ridges on the interior surface. This is particularly the case in the Hydröus. In the *Dyticus* it is more distinctly marked by a lighter colour of the skull, while in the common dung-beetles, *Geo-*

trupidæ, its existence is indicated by a slightly elevated ridge. This suture divides the epicranium from the posterior portion of the *clypeus* (*d*), the most conspicuous portion of the head. The proper boundaries of this part have been ascertained with tolerable precision in Coleoptera, but do not appear to have been traced correctly in some of the other orders, particularly in *Orthoptera*. The *clypeus* or shield, in Coleoptera, is that broad cover of the anterior surface of the head, bounded posteriorly by the epicranium and anteriorly by the labrum, with which it is freely articulated. It is the part called by Mr. Kirby the nose, and by Straus Durckheim *chaperon*. It appears originally to be formed of two portions, which we have called *clypeus anterior* and *posterior*, and which are completely united in some families, as in the *Lamellicornes*, without trace of their previous distinction, but in others with slight traces of their former separation, as in *Hydröus*, while both parts are distinctly articulated in some of the *Dyticidæ*, in which its anterior portion appears to be moveable, and has probably been mistaken for the whole clypeus, as has been the case in Orthoptera.* In some species the shield is curiously excavated, tuberculated, or armed with a long horn, as in *Copris*, *Typhæus*, and *Dynastes*, (*fig.* 333,) or is minute and inconspicuous as in the *Cantharidæ*. The original division of the shield into two portions in *Hydröus* appears to be indicated by two rough excavations situated between the triangular suture, its posterior boundary, and the anterior lip. The *labrum* or upper lip (*e*) is the most anterior portion of the upper surface of the head, bounded only on its posterior margin by the clypeus. It is usually a narrow transverse piece which has been confounded by some writers, particularly by Fabricius, with the clypeus. In some families, *Scarabæidæ* and *Lucanidæ*, it is very minute, but, as remarked by Mr. Newman,* cannot be considered to be in any case entirely wanting, as was supposed by Olivier. In those cases in which it appears to be absent it is concealed beneath a largely developed clypeus. In many families it is large and projecting, and often notched, as in the *Carabidæ* and *Silphidæ*. It is also very distinct in the water-beetles. It forms the anterior boundary of the mouth.

The *corneæ* constitute a great portion of the fixed parts of the head. The principal of these (*c*), the corneæ of the true or compound eyes, are situated on the lateral external surface of the cranium, bounding the basilar piece below, and the epicranium above. They are two large convex surfaces, generally of a nearly circular, but sometimes of a kidney-shaped form, divided into a great number of very minute facets, perfectly distinct from each other, each of which is the proper cornea of a distinct eye. They are more or less numerous in different insects, amounting in some to no more than fifty in each compound eye, but in others to so many as thirty-six thousand. Thus Lyonet reckoned eleven thousand three hundred in the eye of the goat-moth, and Geoffroy more than thirty-six thousand six hundred in the eye of a butterfly. Each compound cornea is usually situated immediately behind the external angles of the triangular or epicranial suture, and is more or less protuberant in different species, as in Hydröus and its affinities. This is particularly the case in the ground-beetles, as noticed by Dalman,† especially in those which reside near water or in sandy situations, as the *Cicindelidæ*, &c.; and, as remarked by Mr. Westwood, these protuberant eyes occur mostly in insects of rapacious habits. But it must further be observed that they occur also in insects which are not of rapacious habits, but require for some other purpose an extended field of vision. This is the case with the males of many species, and most remarkably so in the male of *Lampyris noctiluca*, the common glow-worm, in which the corneæ cover almost the whole lateral and under surface of the head. This insect is well known to be attracted by the light of the female. The like occurs in the male of the hive-bee, and in that of some Diptera, as in the *Empidæ*, which seek their females, and are constantly found *in copulâ connexos* on the wing in the open air. Again, in the sun-beetles, *Cetoniidæ*,

* Newman, p. 9.

* Paper on the Nomenclature of the Parts of the Head in Insects, p. 18.

† Entomologist's Text-book, p. 236.

which live on the pollen of flowers, the eyes are very protuberant. From these circumstances it may be inferred that all those insects in which the eyes are either protuberant or very large are directed by sight alone to some particular object of their search, whether this be the female of the species, as with the glow-worm, &c. or the active living prey, as with the rapacious beetles; and consequently in these instances a more extended field of vision is required than in those whose object of search is more easily discovered, or whose means of subsistence is less precarious. In many Coleoptera each eye is divided anteriorly by a process of the epicranium, the *canthus*, as is particularly the case in the Lamellicornes (*fig.* 333). The extent to which this is developed in different insects varies considerably, and seems to be greatest in those species which are constantly engaged in burrowing. Thus, while it is extended only a little way into the eye in *Cetoniidæ*, it is carried half way across it in *Copris*, and in the female of *Lucanus cervus*, but less than half in the male; in the genera *Ateuchus* and *Dorcas* more than half way across; while, according to Kirby and Spence,* in another genus, *Ryssonatus*, it completely divides the eye into two. In other instances the canthus is not produced, but the eye is encroached upon anteriorly by a portion of the epicranium or by the base of the antenna, which sometimes, as in the *Cerambycidæ*, appears as if inserted into the eye itself. In other families, as in the *Gyrinidæ*, the middle of the eye is excavated across its whole surface by a deep furrow, which gives the appearance of two distinct eyes on each side of the head. In some insects the eyes are entirely absent, an instance of which occurs in one of the *Xylophagi*, *Annomatus terricola*, recently discovered by M. Robert, near Liege, and an account of which was read before the Royal Academy of Sciences of Brussels by M. Wesmael, in Oct. 1835. This insect, whose habits are believed to be entirely subterraneous, is without any external organs of vision.†

The *ocelli*, *stemmata*, or single eyes, are simple, convex, hemispheric lenses, varying in number from one to three. They are always situated, in those insects in which they exist, on the superior part of the epicranium, posteriorly to the triangular suture. They are entirely absent in Hydröus and all Coleoptera except the *Dermestidæ*, in which there is a single ocellus situated on the centre of the epicranium, a little posteriorly to the true eyes; in one of the *Paussidæ*, and in some of the smaller Brachelytra;‡ but they almost invariably exist in some of the other orders, as in the Hymenoptera, Neuroptera, &c.

The under surface of the head is formed chiefly by the posterior and lateral parts of the *gula* (*fig.* 369, *n*), which unite with the lateral parts of the epicranium and occiput. It is bounded anteriorly by an indistinct suture, and laterally by the inferior portions of the corneæ. In *Melolonthidæ* it is of great extent, and is the *pièce basilaire* of Straus Durckheim. In *Hydröus* it is excavated in the middle line, on each side of which are two elevated ridges, the remains of the basilar parts of the mandibles (*o*), the proper appendages of the fifth sub-segment, or basilar portion of the head, with which they have become consolidated. The *sub-mentum* (*m*), *pièce pre-basilaire* of Straus, is the most posterior of the parts that form the under lip. Straus Durckheim and others appear to have considered this part as a process of the immoveable structure of the head, with which at first it appears to be firmly united. Mr. Westwood remarks, that although it appears to be articulated in some beetles, it is immoveable, and forms part of the under surface of the head.* We have but little doubt that it is a distinct piece, and is part of the third sub-segment of the head, however it may become anchylosed to the *gula* by the obliteration of the fourth in some instances, or be itself entirely obliterated in others. In Melolontha it is exceedingly short, but of great width. In Hydröus it is very distinct, and the maxillæ are articulated to the skull on each side of its base, as is the case also in Melolontha and most other instances. It is a little narrower posteriorly than anteriorly, and its length is not more than one-half its breadth. It is articulated anteriorly with the *mentum* (*l*); this is a short transverse plate, in *Hydröus* somewhat lunated on its anterior margin, rather broader than long, but not so short as the sub-mentum. In *Dyticus* it is excavated at its anterior margin, the sides being carried forward like separate lobes. In this genus it forms with the sub-mentum, from which it is separated only by a slight transverse articulation, a broad plate, rounded on its edges, and covering nearly the whole of the under surface of the mouth; in some of the *Staphylinidæ* it is exceedingly short and broad, in *Melolonthæ* it is nearly of a square form, but its anterior margin is acute; in *Cetonia aurata*, on the contrary, its anterior margin is much wider than its posterior, or articulation with the sub-mentum. In *Amphimalla* it is quadrate as in Melolontha, and forms with the *palpiger* a nearly square plate. The *palpiger*, first described by Mr. Newman,† is not developed in the lip of *Hydröus*. In those genera in which it is found, as in *Dyticus*, it is an articulation which, as its name implies, bears the labial palpi, and is situated between the mentum and ligula, of which it seems to be only a portion. It is subject to great diversity in size and shape, and in consequence is often confounded with the ligula itself. It is said to be very distinct in most of the *Carabidæ*, and in *Cychrus rostratus*, as remarked by Mr. Newman, it seems at first to have entirely taken the place of the ligula. In the *Staphylinidæ*, *Göerius*, it is much narrower and longer than the mentum, with which it forms as it were a cone. In one of the *Endomychidæ*, *Lycoperdina*

bovistæ, according to the figure by Mr. Curtis,* it is a broad oval plate, much larger than either of the other parts of the labium. This irregularity in its size is very perplexing in examining the parts of the mouth, since in those cases in which it is developed to a great extent the ligula is often so much reduced in size as to appear entirely absent, and to render it a matter of consideration whether it would not be better to consider the palpiger in all cases as only the inferior portion of the true ligula, since, in a great number of instances in which the palpiger is large, the ligula is very small; and, as in the instance of *Cychrus*, is formed only of minute linear lobes, situated upon and almost hidden by the palpiger. The *ligula* (*i*) is the most anterior portion of the under lip. It varies as much in shape and size as the palpiger. In Hydröus it is divided into two lobes by a slight fissure in its anterior margin, which is membranous, and covered, as well as its internal surface, with short smooth hairs. It is the part which properly represents the true lip, its internal surface being continuous with the soft membrane of the mouth. In most of the Geodephagæ it is divided into three linear lobes, not very unlike in their appearance to the true palpi. This division into lobes occurs in most of the predaceous land-beetles. In *Cicindelidæ* the ligula is very minute, and this is the case also in some of the *Staphylinidæ*. In the predatory water-beetles, as Mr. Newman has observed, the ligula is of considerable size, and this is particularly the case in Hydröus.

The *mandibles* (*fig.* 369, *f*, *fig.* 370, A), the true organs of manducation, are two exceedingly large and strong arched jaws opposed to each other, and sometimes decussating like the blades of a pair of scissors. This is the case in the most rapacious insects, *Cicindelidæ*, *Staphylinidæ*, *&c.* In the Hydröus they do not decussate. They are situated immediately beneath the clypeus and labrum on each side, and are connected by a ginglymoid articulation with the upper and under surface of the head. The *superior external condyle* moves in the articulating surface of the small bone (*fig.* 372, *q*), a little anterior to the bone of the antennæ (*r*) and the *inferior external condyle* (*fig.* 370, *f.* 3) in the articulating surface (*fig.* 372, *y*) of the *os transversum*. In this insect their form is somewhat like that of a sickle or garden knife. They are thick and strong at their base, and hooked at their apex, and are armed with three projecting, notched, or double-pointed teeth. The internal margin of the apex of the mandible is excavated or grooved, as also are the teeth along their posterior surface. The object of this has reference, probably, to the habit of the insect, the structure of the jaws being somewhat similar in this respect to that of the jaws of the more rapacious Dyticus, which is said to prey upon small fishes and water-insects. The under surface of the internal margin of each mandible is covered with soft villi, and there are four condyles to each mandible. Those just described perform the

chief motions; the others are the middle external condyle (1), which gives attachment to the tendon of the great extensor muscle, and is situated between the superior and inferior condyles; and the *internal condyle* (*b*) is situated on the internal posterior margin of the mandible, and gives attachment to the flexor muscles of the jaw. The internal margin of the mandible is also rendered concave, and forms part of the lateral boundary of the epipharynx. From the general structure of the mandible we at first are lead to suppose that the habits of the insect are entirely carnivorous, but it is said to subsist chiefly upon aquatic plants, although it feeds with avidity on dead larvæ and aquatic mollusca.* In the truly carnivorous Coleoptera, the *Cicindelidæ*, *Carabidæ*, and others, the mandibles are acutely pointed; but in those which feed upon vegetable matter, leaves of trees, &c., they are thick and obtusely dentated, as in *Melolonthidæ*. In the generality of species the mandibles are always strong dentated organs, but a few exceptions occur in the *Cetoniidæ*, which feed on the pollen of flowers, and in the *Aphodiadæ*, which subsist on the recent excrement of cattle, in which their margins are soft and flexible. They are always the most conspicuous parts of the mouth, and differ from

* Westwood, Introduct. Entomology, vol. i. p. 127.

the lesser jaws, *maxillæ*, in being articulated both with the upper and under surface of the head.

The *maxillæ*, or lesser jaws (*fig.* 370, B,C), are of very compound structure. They are situated between the mandibles and labium, and are employed by the insect to hold its food, and to convey it to the posterior part of the mouth. They are each formed of four primary and three or more accessory parts, when most completely developed. The primary parts are the *cardo* or hinge, the *stipes* or footstalk, the *palpifer*, and the *lacinia* or blade. The accessory parts are the *galea* or *lobus superior*, the *lobus inferior*, and *unguis*. The *cardo* (*fig.* 370, B, C, 1) is the joint upon which nearly all the motions of the maxilla depend. In Hydröus it is a minute trapezoid or irregularly triangular corneous plate, with an elongated curved process by which it is articulated with the *os transversum* on the under surface of the cranium, and over which the cardo is articulated like a hinge. In some genera, as in *Staphylinus*, it is more elongated, and this is particularly the case in *Melolontha*, whence it was called *branche transversale*. In most instances it is as it were wedged in between the sub-mentum and mandible. It is articulated at its anterior margin with the second piece of the maxilla, the *stipes* (2), which forms the outer surface of the organ, being considered its primary part. It is an elongated corneous plate, broadest at its articulation with the *cardo*. It is approximated along its anterior margin to the *squama palpifer* (3), a broad plate which covers the superior external surface of the maxilla. Immediately beneath the anterior margin or apex of the *squama* is inserted the palpifer (4), a short cylindrical appendage, which is usually considered part of the squama, the whole being together called the *palpifer*. It supports the proper maxillary or true palpus, which is remarkable for its length in the Hydröus. The *lacinia* (5), sometimes improperly called *maxillo*, forms the internal portion of the organ, and, as we shall hereafter see, appears in its earliest condition in the embryo to constitute a separate organ or appendage, belonging to the mentum—as the stipes appear to belong to the sub-mentum—but which in the course of development becomes approximated to the stipes to form part of the maxilla of the perfect insect. Like the stipes, it is a broad corneous plate, which forms the greater portion of the under surface of the maxilla, and is articulated with the cardo only by a small portion of its base. On its upper surface, which forms a great part of the sides of the mouth, it is soft, membranous, and covered with fine hairs. It gives origin at its anterior truncated extremity to the accessory parts of the maxilla, the *lobus superior* and *inferior*. The *lobus superior*, or *galea*, is a thick, double-jointed organ (6), densely covered at its anterior margin with stiff reddish hairs. It is articulated with the external angle of the lacinia, and covers the lobus inferior, which is articulated with the internal angle, and on this account, more particularly in *Orthoptera*, is called the *galea* or helmet. It is used by this and other insects as a palpus, or feeler, to touch and convey food to the mouth. The *lobus inferior* is a short quadrate joint (7), articulated with the internal angle of the lacinia, of which it forms the proper continuation. At its superior extremity is a minute articulated claw (8), densely covered on its upper surface with long stiff hairs, as is also the whole of the internal margin of the lacinia itself, which forms the lateral boundary of the mouth, and is continuous with the soft lining of the pharynx. The *maxillary palpi* (*h*) are two very long flexible organs, composed each of four joints. The *palpifer*, upon which they are situated, is a short joint or tubercle, inserted at the anterior external angle of the maxilla, between the angle of the lacinia and the plate which covers the superior surface of the maxilla (3), and of which it forms a part, but from which in this insect it appears quite distinct. The first joint of the palpus is exceedingly short, so as to allow of extensive motion to the organ in every direction, while the second is much longer than in most other insects, and, when the palpus is retracted, forms with the third joint a distinct elbow or bend. The third and fourth joints are also of great length, so that the insect is enabled to protrude the organ to a great distance. The *labial palpi* (*fig.* 369, *k*) are much shorter than the maxillary. The first two joints are very minute, the second being partly hidden within the first, but the third and fourth are long and projecting, but not so long as those of the maxillary palpi.

From all we have been able to observe, the office of the maxilla appears to be of a two-fold kind, and of greater importance to the insect than that of the mandibles themselves. The chief office is that of seizing and retaining the food within the mouth; and the secondary that of assisting the mandibles in comminuting it before it is passed on to the pharynx. Consequently all the parts of the maxilla are subject to great variation of form; and in the different tribes of Coleoptera, as in the other orders of insects, each particular form is adapted to the kind of food on which the insect subsists. In *Melolontha*, in which the four primary parts, the *cardo*, *stipes*, *palpifer*, and *lacinia*, were first accurately distinguished by Straus Durckheim,* the maxilla is a thick obtuse organ, with the cardo, which is less completely developed in Hydröus than in most other insects, forming a broad transverse piece, the stipes a short and triangular one, the palpifer also nearly triangular, and the lacinia, which, as Straus has remarked, is always continuous with the pharynx, nearly also of a triangular form, and together constituting a thick compact organ, with its inner angle, the lobus inferior in other insects, forming a strong projecting inarticulated tooth, and its external, articulated with a short thick galea, armed with three obtuse points, which probably serve the office of teeth for masticating the parenchymatous food of this species. This form of

* Considerations Générales sur l'Anatomie Comparée des Animaux Articulés, par Hercule Straus-Durckheim, 1828, p. 68, pl. i. fig. 8.

the maxilla and galea seems more peculiarly adapted to the phytophagous feeders, since in the true carnivorous insects, *Cicindelidæ*, tiger-beetles, and the larger *Carabidæ*, ground-beetles, the maxilla is more elongated, the internal lobe, or apex of the lacinia, is more acute, and often armed with a sharp hook, and the galea assumes the form of a distinct palpus, shorter but similar in appearance to the true maxillary palpus. This is more manifestly the case in the tiger-beetles, in which the galea is a distinctly double-jointed palpus, placed on a feeler-bearer, and the lacinia is armed with a long sharp hook, evidently more adapted for seizing and piercing its living food, like the canine teeth of carnivorous quadrupeds, than for comminuting it like the strong tuberculated galea of the vegetable-feeding Melolontha, or the tuberculated teeth of herbivorous quadrupeds. The office then of the galea, in distinctly carnivorous insects, is simply that of a palpus or feeler, and in accordance with this view we find that in the tiger-beetles it is longer than the inferior lobe, or hooked portion of the lacinia. In the ground-beetles Mr. Newman has remarked that it is shorter than the lacinia, but, in the generality of the tribe, we have also found it longer, as in the rapacious Cicindelidæ, particularly in the larger *Carabidæ*, and this is also the case in some of the *Harpalidæ*, particularly in one species, *Zabrus gibbus*, which is known to be a vegetable feeder. This form of the galea, however, seems more peculiarly to belong to the carnivorous insects, as it is also found in the Dyticidæ, but not, as we have seen, in the nearly allied but far less rapacious *Hydrophylidæ*. On the other hand, in most insects which feed entirely on vegetable matter, the galea is of a more obtuse form, and is less distinct from the other parts of the maxilla than in the rapacious insects. Thus in the greater number of the true vegetable feeders the galea is short, thick, and densely covered with hair. This is the case not only with the maxillæ, but also with the mandibles in those insects whose food is the pollen and perhaps also the honey of flowers, as in the *Cetoniidæ*, and also in the *Geotrupidæ* and other *Scarabæidæ*, which feed upon soft decaying vegetable matter. In the *Cerambycidæ*, as in the rare insect *Monochamus sartor*,* in the *Lepturidæ*, which are found upon umbelliferous plants feeding on the pollen and honey; and in the stag-beetle, *Lucanus cervus*, which subsists on the sap that flows from the wounded bark or roots of trees, the galea is always densely covered with hair, and sometimes elongated to a considerable extent, as in the stag-beetle. In those species which are purely phytophagous, as many of the *Galerucidæ* and *Chrysomelidæ*, which feed on the parenchymatous structure of leaves, both the *galea* and *lobus inferior* are short, obtuse, and covered with stiff hairs, while in the *Coccinellidæ* that very much resemble the latter insects, but are carnivorous feeders, the galea is longer and distinctly jointed, and resembles the same part in Hydröus, being still covered with hair.

* Curtis's British Entomology, pl. 219.

This is also the case in the common meal-beetle, *Tenebrio molitor*, which belongs to a family of less distinctly vegetable feeders. From these facts we are inclined to believe that the structure of the maxilla has much closer connexion with the kind of food and habits of the insect than that of either the labium or the palpi. The latter organs, however, are subject to great variation in the form of the terminal joint, which in some species is much dilated and shaped like a hatchet, as in the common lady-bird, *Coccinella*, while in others it is acute or obtuse. The number of joints is usually four, and it has been supposed that there are never more, either in the maxillary or the labial palpi, in any Coleopterous insect, but the Rev. Mr. Kirby* has mentioned an instance in which there appeared to be an anomalous condition of the maxillary palpi, in this respect, in one of the Geodephaga, *Sericoidia bembidioides*, K. In one of the palpi in this insect there was a fifth joint, retractile within the fourth. Mr. Kirby suggests that since the fifth joint was not apparent in the other palpus, it may perhaps have been a false joint, produced by an effort of nature to repair a mutilated organ, but at the same time observes that if this were the case it is the only instance he has met with in true insects of the reproduction of a lost organ.

The *antennæ* constitute the remaining moveable parts of the head (*fig.* 369, A). They are occasionally absent in the larva, but never in the perfect state in any insects. They are two jointed organs, attached to the head by a distinct and freely moveable articulation, in some insects near the middle of the front part of the head, but in Hydröus and most Coleoptera on each side immediately anterior to the corneæ, at the extremity of the epicranial suture, but never, so far as we are aware, in the epicranium itself. They are subject to much diversity of form, on which account they have been employed by naturalists as affording characteristic distinctions of different families. They have been divided into several parts, only three of which appear to be generally applicable. These are the *scapus*, (*fig.* 371, M 1), *pedicella* (2), and *clavola* (3).† The *scapus*, or basial joint, is usually very long, and often the most conspicuous part of the antenna. It is connected with the *torulus*, or part upon which it moves, by means of a ball and socket articulation, beneath the external margin of the clypeus. The second joint, *pedicella*, in Hydröus, as in almost every species, is a minute and nearly globular articulation, which allows of the freest motion, and supports the remaining portion of the antenna, the *clavola*, which forms the chief part of the organ, and is that which varies most in general structure. When each succeeding joint of the clavola is gradually diminished in size from the base to the apex of the organ, as in the *Gryllidæ*, *Achetidæ*, and *Blattidæ*, *fig.* 342 and 343, the antenna presents its simplest condition, and is

called *setaceous* (*fig.* 371, A), but when, as in some of the *Locustidæ*, each joint is much smaller than the preceding and is angulated at its sides, the whole forming a sword-like organ, it is called *ensiform* (B). When all the joints of the clavola are of uniform thickness, as in the *Carabidæ*, (*fig.* 329,) the antenna is said to be *filiform* (*fig.* 371, C), but when the joints are of equal size, but are globular or rounded, as in the *Tenebrionidæ* (*fig.* 340), it is called *moniliform* (*fig.* 371, D). When the joints, as in some of the *Elateridæ*, (*fig.* 334,) appear like inverted triangles, with the inner margin more produced than the outer, they are said to be *serrated* (*fig.* 371, E), and when, as in the *Prionidæ*, the acute base of each joint is inserted into the middle of the broad apex of the joint behind it, *imbricated* (F). When every joint is developed on one side into a spine or process, the organ is said to be *pectinated* (G); and when a spine or process is developed on each side of the joints, *bipectinated* (H). In like manner it is called *plumose* (N) when each joint produces one or more rami which are themselves minutely pectinated, as in many of the *Bombycidæ*; and when, as in *Hemirrhipus flabellicornis* and other *Elateridæ*, each process from a joint is flattened, and is nearly as long as the whole of the succeeding joints taken together, and the whole form a fan-shaped organ, the antenna is called *flabellate* (I). But when, as in the true beetles, Pentamera, the clavola ends in a true *capitulum* or knob, it is said to be *clavate* (K), or *capitate* (L), according as the knob is gradually or suddenly formed at the extremity of the organ. In Hydröus the capitulum exists in that form which is designated *perfoliate*, in which the joints of the club are separated a little from each other by a minute foot-stalk. This form exists also in the *Necrophori*, and in a less degree in the clavated antennæ of other *Silphidæ*. It is in some of the *Lamellicornes*, the *Scarabæidæ*, *Geotrupidæ*, *Dynastidæ*, and *Melolonthidæ*, that the antennæ reach a degree of completeness which seems to indicate the real use of the organs. Thus in the *Melolonthidæ* (M), the capitulum is divided into seven laminæ, which may either be applied closely together, or be widely expanded at the pleasure of the insect. In the *Dynastidæ* and *Geotrupidæ* the capitulum is formed of only three laminæ, the two outer ones being convex externally, but flat on their internal surface, while the intermediate one is flat on both surfaces, the flat surfaces of each being more delicately organized than the hard corneous exterior. A similar structure exists also in the *Scarabæidæ*. When the insect is in motion the antennæ are stretched out, and the laminæ are expanded to their fullest extent, but by many species are immediately retracted on the occurrence of any loud or sudden noise.

These are the usual forms of the antennæ, but in some species they are subject to much greater variation. Thus, in the remarkable order *Strepsiptera* (*fig.* 347), each antenna has a distinct lobe at its base. This is also the case in some of the *Muscidæ* (N), in which the filamentous portion of the antenna represents the true *clavola*, and the club-shaped portion of the organ is simply an appendage. A similar deviation from the usual structure occurs in some Coleoptera, more particularly in the smaller water-beetles. Thus, in the *Gyrinidæ*, the true *pedicella* is developed into a large ear-shaped cup, which nearly covers the *clavola*. In another insect, *Globaria Leachii*, LATR. very beautifully figured in the recent work of the Rev. F. W. Hope,* the pedicella, (O, 2) instead of being a small rounded joint, is elongated like the scapus (1), while the clavola (3) ends in a large capitulum, attached laterally to the base of the fifth joint and directed backwards. These are a few of the variations which occur in the form of these

* The Coleopterist's Manual, part ii. tab. 3, fig. 6. 1838.

curious organs, the necessity of which it is difficult to understand.

The function of the antennæ has been a subject of much dispute amongst naturalists, some contending that it is simply that of *feeling*, others that of *smelling*, others again that of *hearing*, and lastly others that of a *sixth* sense unknown to vertebrata. Our own observations lead us most decidedly to the conclusion that the primary function of the antennæ is that of *hearing* or feeling the vibrations of the atmosphere, while an additional function possessed by the antennæ of many insects is that of common feeling or *touch*. We have endeavoured to support this opinion by facts and experiments detailed in a paper on the use of the antennæ, which was read before the Entomological Society of London in the beginning of 1838, but which has not yet been printed. First as regards the employment of the antennæ as olfactory organs, there seems in their anatomical structure the most decided evidence that they cannot be designed for such purpose. In every instance in vertebrata, the faculty of smelling is situated in a delicate mucous or soft surface, and in no animal that we are aware of has it ever been found to reside in a dry horny covering, or in a tense membranous structure, while, on the contrary, that of hearing is constantly dependent upon an elastic membrane, or other part sufficiently delicate to be affected by the vibrations of the atmosphere. If therefore the sense of smelling be dependent, as it appears to be, upon a moist or lubricated surface, it cannot reside in the antennæ, since the exterior surface of these organs is in every instance formed of a dry hardened covering. On the other hand, if the perception of sound be dependent upon the elasticity of a part, and its capability of being affected by the vibrations of the air, the structure of the antennæ is in no instance unadapted for the performance of this function. It seems improbable that the office of the antennæ is simply that of *touching* or feeling other objects, by direct contact, as supposed by some naturalists, from the circumstance that in certain insects these organs are much too short to be so employed, being in many species, as in the *Libellulidæ* and *Cicadiidæ* (*fig.* 353), shorter than the head itself. But that they are so employed by some insects is indisputable, particularly by the *Blattidæ*, *Gryllidæ*, and most of the Hymenoptera. The Gryllidæ, when sipping water from the channelled surface of a moistened leaf, constantly feel about with the antennæ; and the honey-bee, when constructing its cells, ascertains their proper direction and size by means of the extremities of these organs, while the same insect, when evidently affected by sounds, keeps them motionless in one direction, as if in the act of listening. Another circumstance which favours the opinion that they are auditory organs is their greater development in the males of some species than in the females, as in the bipectinated antennæ of many moths, and the lamellated ones of the *Melolonthidæ*. The structure well known to exist in the Crustacea,* the bony tubercle covered externally by a tense membrane, and communicating internally with a membranous vesicle, situated at the base of the antennæ, sufficiently proves that in those animals the antennæ are organs of hearing, and is not an inadequate reason for regarding them as ministering to the same function in insects. But the fact of the existence of a small circular space discovered by Treviranus, at the base of each antenna in the *Blattidæ*, (*fig.* 373, †) which are noted for extreme acuteness of hearing, and which space, as in Crustacea, is covered by a membrane, is an additional reason for considering the function of the antennæ in insects analogous to that of the corresponding organs in those animals. Thus then almost every circumstance connected with the antennæ leads us to the conclusion that these are the proper organs of hearing, while their occasional employment as tactors or cerebral feelers is not incompatible with the exercise of that function, hearing being in reality only a more exquisite sense of feeling.

Internal parts of the head.—On the interior surface of the superior portion of the cranium of *Hydrous piceus* (*fig.* 372), the insect we have selected for our purpose, is a thick horny ridge (*p*), extending along the middle line from the

* See vol. i. p. 768, art. CRUSTACEA.

occipital foramen to about midway between the corneæ, where it becomes much thickened and expanded, and then divides into two portions, which pass forwards and outwards in a diagonal direction, to the anterior margin of each cornea. These ridges on the internal surface exactly correspond to the faint indication of the epicranial suture on the external. They serve for the attachment of muscles, and divide the epicranium from the clypeus posterior. At the external angles of these ridges, immediately anterior to the corneæ, are two articulating apophyses, the most external of which, the *torulus* (*r*), is smooth and rounded on its anterior surface, and articulates with the broad concave extremity of the scapus] or basial joint of the antennæ, and the external one (*q*), (*cavité cotyloid*, STRAUS,) is smooth, rounded, and constricted in its middle, and articulates anteriorly with the superior external condyle of the mandible, and posteriorly with a process of the *laminæ squamosæ* (*s*), which support and protect the brain, and are united with other laminæ (*v*) (*lames laterales*, STRAUS,) which arise from the inferior surface of the cranium. The torulus (*r*) is attached externally to the most anterior portion of a thin broad lamina, the *orbital plate* (*w*), which extends backwards to the posterior angle of the cornea, in an arched direction, separating the cavity of the orbit from the interior of the cranium, with which it communicates only by means of a round foramen for the passage of the large optic nerve and its tracheæ. The superior half of this plate consequently belongs to the epicranial, and the inferior to the basilar portion of the skull. Immediately anterior to the epicranial suture is situated the clypeus (*d*), the middle portion of which is smooth and slightly concave, and forms the covering of the anterior part of the head. On either side it has a smooth broad inflected margin, which is not included within the interior region of the head. At the anterior margin of the clypeus is articulated the freely moveable labrum (*e*), the under surface of which is smooth and shining, and gives no attachment to muscles, excepting along its posterior margin. The ridge of the epicranial suture is developed to a greater extent in the head of *Hydröus* than in any other species we have yet examined. Its perfect correspondence with the faint indication of the suture on the exterior of the head clearly indicates the boundary of the epicranium, and is of very great importance, as we shall hereafter see, in enabling us to determine the number of segments of which the head is composed. This suture exists in every species we have examined, more or less developed in different individuals. Its existence appears to have been entirely overlooked by Straus-Durckheim in the head of *Melolontha*, in which, indeed, it is almost obliterated externally, but when the cranium is well cleansed, and then examined by means of transmitted light, a trace of it may still be observed, and its situation internally is indicated by a shallow triangular furrow, which extends backwards from the anterior portion of each orbital plate to within a short distance of the occipital foramen in the middle line, the longitudinal portion being exceedingly short. But in the larva of the same insect the suture is very distinct on the exterior of the epicranium, and the ridges corresponding to the suture are developed on the interior. Anterior to this suture in the same larva is a triangular piece, which is bounded in front by a freely articulating plate, the anterior clypeus. It is the part corresponding to this, and which is consolidated with the true clypeus in the head of Hydröus, as indicated by the diagonal depressions before noticed on the external surface of the head, which we shall distinguish in all insects as the *clypeus anterior*.

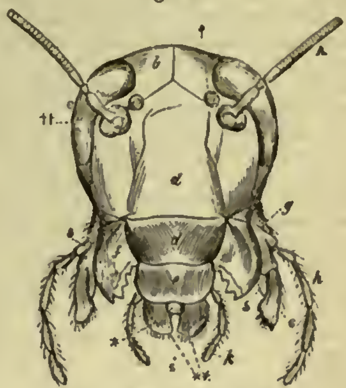
It will thus be found that in some insects the clypeus anterior and posterior have hitherto been confounded under one name, and in others the clypeus posterior and epicranium. We believe, however, that these are distinct parts in all insects, but are less readily distinguished in some than in others. The upper surface of the head is thus shewn to be formed of at least four clearly indicated portions, both in the larva and perfect insect. In the larva of melolontha there is also a slight indication of a *fifth* segment, of which the antennæ, or anterior prolongations of the spinal columns, are in reality the proper appendages. The indication of this segment exists in a triangular line, parallel with, but a little anterior to, the suture behind the clypeus posterior, and in the space included between it and the epicranial suture the antennæ seem to be inserted. But although we believe in the existence of the fifth segment in all insects, it must be acknowledged that it is not easily demonstrated. Four segments are, however, readily detected, yet in some species one of these has almost disappeared. Thus in *Geotrupes stercorarius*, the epicranial suture has become very indistinct on the upper surface of the head, and the ridges are entirely absent on the interior, as in melolontha, while the clypeus posterior exists only as a narrow triangular space, bounded by the suture posteriorly, and anteriorly by a ridge corresponding to the boundary of the proper anterior clypeus on the exterior of the head; the labrum also, as in all insects, being quite distinct. In *Lucanus cervus*, in which the head has reached its maximum of development, and is much broader than the pro-thorax, there is no indication whatever of the triangular suture in the male, all the parts of the head being firmly consolidated together. But in the female there is a faint depression internally, as in melolontha, and the trace of a corresponding line is apparent in some specimens externally. In some specimens of *Meloë cicatricosus* there is a distinct indication of the suture externally, extending from the occipital foramen to near the middle line between the eyes, while internally the ridge is distinctly elevated; but we have not been able to trace the clypeus posterior, which may be supposed to have merged in the largely developed epicranium. In *Blaps mortisaga* the epicranial suture is usually distinct on the upper surface of the head, posterior to the corneæ, but the ridge is absent, while the transverse ridges between the two portions of the clypeus are distinct, and also their corresponding sutures on the exterior. On the other hand, in the large *Buprestis chrysis*, the longitudinal portion of the epicranial suture is very distinctly marked on the upper surface, and extends as far forward as the middle between the corneæ, while internally the ridge is so largely developed that it extends downwards into the cavity of the head, like the ossified falx in the head of some Carnivorous Mammalia, partially dividing the posterior region of the head into two halves. But the clypeus anterior and posterior are so solidified together, and united with the epicranium, that they are not easily distinguished. This is also the case in the rapacious ground-beetles, *Cicindelidæ*, in which all the parts of the cranium are completely united, and the true clypeus is reduced to a narrow transverse plate, with which the labrum is freely articulated. But in the rapacious water-beetle, *Dyticus marginalis*, although the ridge of the epicranial suture is wanting, as in *Cicindelidæ*, the suture itself is remarkably distinct, and the anterior and posterior clypeus are well marked, and are very clearly seen owing to their thinness and translucency, when examined by transmitted light.

The inferior surface of the head affords us equal reason with the superior, for believing that this part of the insect is formed of an aggregation of several segments. We shall examine them more particularly when speaking of its development. On its interior surface are parts which tend much to confirm the opinion. In *Hydröus piceus* on each side of the occipital foramen there arises a strong bony plate, lamina posterior (t), which, bending a little towards the median line, extends across the basilar portion of the skull, as far as the *os transversum* (x), with which it is united. At a short distance from the occipital foramen the lamina of one side is connected with its fellow of the opposite by a narrow bony arch (u), which has been called by Straus *l'arcade*, and by Burmeister, who has described it in Dyticus, the *tentorium*. The two laminæ beyond this are expanded upwards and laterally, and uniting anteriorly by a thin process form a cradle, or bed, which, as Straus and Burmeister have remarked, supports the first subœsophageal ganglion, while the two *laminæ posteriores* inclose between them, as in a canal, the anterior portion of the spinal cord, which passes under the tentorium in its exit from the cranium through the occipital foramen. Each of these expanded portions of the laminæ are united by their superior angles with a narrow process (s), which articulates, as before noticed, with one of the apophyses of the upper surface or vault of the cranium. The orbital plates (w) above described are continued around the margin of the corneæ, and form the inferior lateral boundary of the basilar portion of the cranium. Between the anterior margins of the corneæ, extending across and dividing the basilar part of the skull from the sub-mentum, is a thick elevated ridge, the os *transversum* (x). On its anterior border the os transversum is connected with a minute bony ridge, which extends forwards on each side of the sub-mentum, and it has also two articulating surfaces. The first and most internal of these (x) is situated close to the base of the sub-mentum, and is that with which the hinge of the maxilla is articulated. The second is situated more externally, between this and the margin of the cornea. It is a deep smooth cotyloid cavity (y), which receives the external inferior angle of the mandible, and is separated from the articulation for the hinge of the maxilla by an elevated tubercle. Externally the base of the skull is connected only by an indistinct suture with a quadrate plate, the *sub-mentum*, which was supposed by Straus-Durckheim to form a process only of the basilar piece in melolontha, and was called by him the *pre-basilaire*. We have already seen that it is part of a distinct segment, and seems to correspond to the clypeus posterior of the upper surface. At the anterior margin of the sub-mentum, or rather extending backwards upon that segment from the mentum, are two broad diverging laminæ (z), which support the fleshy pharynx and tongue, in which respect they are similar in office to the proper hyoid bones of vertebrata. They serve as means of attachment for some of the muscles of the pharynx, and are connected with similar laminæ that cover the upper surface of the pharynx, and seem to be connected with the clypeus, as in the *Lucanus cervus*. The *mentum*, like the sub-mentum, to which it is attached, is broad, quadrate, and supports the diverging laminæ which form the floor of the mouth, and it also affords an attachment for some of the muscles of the tongue and labial palpi. The *ligula*, or most anterior portion of the labium, is densely covered on its upper surface with hairs. It is divided in the median line into two halves, which, when developed to a much greater extent, as in some other insects, take the name of *paraglossæ*.

The general structure of these parts is similar in most Coleoptera, but in some species there is considerable variation of form and relative size, owing to the greater development of one part than of another. Thus in *Lucanus cervus*, (*fig*.388,) in which the whole head is developed to its greatest extent, and the epicranial and basilar regions, with the mandibles (f'), have very far exceeded their usual proportions, the labrum is very minute, and soldered to the clypeus (d), and the maxillæ (g) are reduced to small palpiform organs. Internally, the posterior laminæ (t) do not extend forward to an *os transversum*, but are short, strong, triangular plates, which, instead of being connected, as in Hydröus and Melolontha, by an *arcade*, or tentorium (u), support a double ring, or *annulus*, like the ring of a vertebra, through which the nervous cord passes before it arrives at the occipital foramen. In *Geotrupes stercorarius* there is a like annular form of the same parts, but the *laminæ squamosæ*, which are absent in Lucanus, are thick and strong, and form a complete cradle for the supra-œsophageal ganglion. In like manner a similar change in the form and relative size of parts of the head occurs in the hog-beetles, *Curculionidæ* (*fig.* 337), in which the head is elongated forwards, and the mouth is situated at the extremity of a long rostrum or beak. This is occasioned by the narrowing and extension forwards of the clypei, and the parts corresponding to them, the mentum and sub-mentum. This change is carried to such an extent in some species, as in *Liparis Germanus*, that the antennæ are also carried forwards, and appear as if situated at the sides of the mouth. That this is the manner in which the change of form is effected is proved by the circumstance, that the basilar and epicranial regions in this insect do not exceed a fair proportion, as compared with other insects; while the triangular suture, which always divides the epicranium from the posterior clypeus, exists in its usual situation on the part between the eyes; and the labrum, which is very distinct, is freely articulated with the anterior margin of the clypeus. The effect of this elongation of some parts of the head and mouth is the necessarily small size of others, and consequently we find that the mandibles, which are so enormously large in *Lucanus*, are reduced almost to their minimum in the *Curculio*; because, although the elongated form of the head is admirably adapted to the habits of the insect, in boring deeply into hard substances, it is insufficient for the support of large and powerful organs, and its extent of surface is too limited to afford adequate room for the muscles necessary for their employment. Wherever large and powerful organs exist, the parts to which they are attached are enlarged in like manner. Thus we invariably find that in those insects in which the mandibles are large, the whole head is either short and wide, or its posterior portions, the basilar and epicranial regions, to which the muscles of the mandibles are attached, greatly exceed those of the anterior.

The parts observed in the head in Coleoptera are equally apparent in Orthoptera. In this order the head is placed vertically on the pro-thorax, without any constricted portion or neck, so that the extent of the occipital region is greatly reduced. The *epicranium* in some species, *Locustidæ*, *&c.* is broad behind, but narrowed in front, where it is bounded, as in other insects, by the *clypeus posterior*, and laterally by the corneæ and sides of the head, of which it forms a part. In this order the *ocelli*, or single corneæ, which are found only in a few solitary instances in Coleoptera, exist in most of the families. They are situated in the anterior portion of the epicranium, and form part of its surface, whether placed on the vertical portion of the head, or more anteriorly near the clypeus. In the osculant family, *Blattidæ*, the epicranium is exceedingly shortened, but retains along its vertex a trace of the epicranial suture, which is scarcely ever absent in the insects of this order. It is very distinct in the common house-cricket and mole-cricket, *Achetidæ* (*fig.* 342), in the *Gryllidæ* and *Locustidæ*. In the mole-cricket it sometimes appears as if wholly obliterated, but is always seen in the pupa if care be taken to remove the down with which it is sometimes covered. Its apex is situated in the middle line between the ocelli, and on each side it passes down to the insertion of the antennæ. It is in this order that the suture is particularly useful in indicating the boundary of the posterior clypeus, the extent of which in Orthoptera appears hitherto to have been overlooked.

Fig. 373.



Head of Blatta Americana.

A, antenna; †, tympanum; † †, socket for the antenna, covered with membrane; *dd*, clypeus, anterior and posterior; *, lingua; *i***, paraglossæ. (*Other letters and figures as in Hydrous.*)

In the epicranium of *Blatta* (*fig.* 373), the suture is almost obliterated, being only discoverable by aid of the microscope, but on careful inspection it is seen to end at a point opposite to the middle of the superior portion of the corneæ, where it forms the apex of the triangle, which enters, on each side, the anterior margin of a circular space covered with a tense membrane, the *tympanum* (†), which is situated, as observed by Treviranus, a little behind the insertion of the antennæ. These organs are also inserted in a rounded space covered by a membrane. From these points the suture becomes obliterated, but seems to pass in the direction of the anterior boundary of the corneæ to the base of the mandibles. The *clypeus posterior* (*d*) thus appears to form the greater portion of the front or *face* of the insect, and is united by a transverse freely articulating membrane, extending across from the base of each mandible with a short transverse plate, the *clypeus anterior* (*d*), which has hitherto been looked upon as the true clypeus. In the common green grasshopper, *Acrida viridissima*, the boundary of the posterior clypeus is at the most anterior part of the head immediately between the antennæ, the suture extending, as in other insects, to their base. The clypeus anterior is a short transverse moveable plate, and is articulated with the *labrum* (*e*), which is also short, transverse, and freely moveable upon the clypeus anterior. This moveable condition of the anterior clypeus and lip has not a little puzzled entomologists. Mr. Newman* has remarked that "the lip and *shield* move simultaneously

* Op. cit. p. 9.

with the mandibles in mastication," and that "this is a departure from a general law of nature, and its occurrence is well worth remarking; as the motion of the *shield* might induce an observer to suppose it the lip, which would consequently become a new and supernumerary elementary part." Thus, then, the motion of this part in Orthoptera is considered as an anomalous condition, but the same thing occurs in Coleoptera. In *Dyticidæ*, the clypeus is freely moveable, as well as the labrum, and probably this mobility has reference to the rapacious habits of the insects.

The inferior surface of the head in Orthoptera varies a little from the type of the Coleoptera, although it is formed, as in that order, of four distinct parts. The *gula*, or basilar region *(m)*, which includes part of the occipital foramen, is a broad transverse plate, rounded at its lateral, and concave at its anterior and posterior margins. In the mole-cricket, as in most of the beetles, the true gula is well developed between the occipital foramen and sub-mentum, and in that insect is of a triangular shape, with its apex directed backwards.

Fig. 374.

Under surface of mouth of Blatta. Figures as before.

But in the *Blattidæ (fig.* 374, *m)*, the sub-mentum and gula appear to have been closely united, without trace of their former distinction, and the mentum *(l)* is short, transverse, and articulated with the *palpiger* and *ligula (i)*. From the complexity of parts into which the ligula is divided, we consider it better, as before remarked, to omit any particular description of the palpiger, which, Mr. Newman states, is situated between the proper ligula and mentum. In Blatta the ligula is divided into six distinct parts. To two of these (*i*) are attached the labial palpi, and they appear to be the palpiger as described by Newman. From the upper anterior margin of these, nearest the median line, arise two short lobes, covered partly on their exterior margins by two larger ones, the *paraglossæ* (* *), which become of much importance in the mouth of Hymenoptera. In the mole-cricket the ligula is divided only into four lobes, all of which are exceedingly narrow, and very much resemble palpi. In some of the *Locustidæ*, the labium is simply divided in the median line as in Hydröus. The true *ligula* or tongue *(fig.* 374*) in most of the Orthoptera is a soft projecting fleshy body, like the tongue of other animals, and is situated above the mentum and sub-mentum, within the mouth of which it forms the floor and passage to the pharynx. In *Blatta* it is narrow and elongated, and projects as far as the middle of the ligula, and it is even more largely developed in the *Locustidæ* and *Achetidæ*. In the *maxillæ* we recognise the same parts as in Coleoptera, with but little variation of form except in the *galea* and *lacinia*. The *lacinia* (5) is usually elongated, and furnished with a sharp hook bipid at its apex. In *Achetidæ* and most of the vegetable feeders it is strong and much bent at its extremity, but in the omnivorous *Blattidæ* it is also sharpened to a cutting edge along its inner margin. It is in this order of insects that the secondary appendage of the maxilla, the *galea* (6), is most fully developed, and covers the lacinia so completely as to serve the office of a shield or helmet. In the vegetable-feeding *Locustidæ*, this part is sometimes three-jointed, as observed by Newman* in *Acrydium*, but usually it is simply an obtuse double-jointed organ, hollowed on its inner side; but in the *Blattidæ* it is expanded at its extremity into a thick oval bulb, or soft cushion, encircled with fine hairs, evidently well adapted for *touching* or *feeling*. In all the Orthoptera, but more particularly in the *Blattidæ*, the articulation of the maxilla with the sub-mentum is less compact than in the Coleoptera; and this appears to be referable to the same circumstance as before noticed with regard to the mobility of the anterior clypeus, the voracious habits of the insect. Thus, to allow of very extensive motion to the parts, the stipes (2) is articulated at an angle with the *cardo* (1), and a broad muscular structure, attached along the inner border of the lacinia, as far as the base of its sharp articulated apex, upon which it acts, is interposed between the maxilla and sub-mentum, and forms part of the inferior boundary of the mouth. The *mandibles* in this order of insects, as remarked by Marcel de Serres,† are more perfectly constructed than in any other. In those which masticate their food, and devour large quantities of vegetable matter, as the *Locustidæ*, the mandibles are furnished both with cutting and grinding surfaces. The anterior or apical margin is developed into acute cutting teeth, somewhat like the canine teeth of vertebrata, while the inner and posterior part of the mandible is broad, flattened, and covered with elevated irregular ridges, like the teeth of some Herbivora, and is admirably adapted for grinding or chewing. This complicated structure does not exist in the more carnivorous species, the *Blattidæ*, in which the mandibles are arched, and indented with sharp triangular teeth *(fig.* 373, *f)*, very closely resembling the cutting teeth of Carnivora, and are articulated by strong condyles at the side of the head, on a line with the articulation of the clypeus anterior, and not so far back as that of the maxilla. The eyes in Orthoptera are usually exceedingly prominent and round, but not large, except in *Blatta*, in which they

* P. 32.

† Annales des Muséums, No. xvi. p. 56.

are kidney-shaped, and are spread over a great part of the sides of the head. The *ocelli*, which are found in most of this order, do not exist in *Blatta*. They are very distinct in the *Gryllidæ* and *Locustidæ*, and also in the mole-cricket; but it is remarkable, as Mr. Kirby formerly observed, that they are not met with in the pupa or larva state of these insects. In the pupa of the mole-cricket there are simply two slightly elevated tubercles, in the situation in which the ocelli are afterwards developed. They thus appear to have reference to some particular condition of the perfect insect, although the habits of the three states appear to be similar. The *antennæ* are organs of much importance, and are usually of considerable length, except in the carnivorous *Mantidæ*, or praying insects, in which they are very short. These insects, which take their living food by sight alone, have the shortness of their antennæ, the supposed organs of. hearing, compensated for by the immense size of their large globular corneæ, situated at the superior angles of the head, so as to enable the insect to see in every direction. But in those which reside in the dark, or which seek their food by the aid of other senses, the antennæ are exceedingly long, and formed of an immense number of joints, especially in the *Gryllidæ*, *Achetidæ*, and *Blattidæ*, which are noted for acuteness of hearing. In the interior of the head the *laminæ squamosæ* are thick and strong, and are articulated, as in Hydröus, with the angles of the epicranial suture superiorly, and inferiorly with the *laminæ posteriores*, and the *tentorium* forms a distinct ring, as in *Lucanus*.

In the Neuroptera we recognise the same elementary parts in the head and mouth as in the preceding Orders, but in this they are developed into new forms. The *epicranium*, so conspicuous in the former, is reduced to its minimum in this Order, owing to the immense development of the organs of vision, which, attaining their greatest extent in *Œshna grandis*, are expanded over the whole of the upper and lateral surfaces of the head, and are approximated together in the median line, leaving only the epicranial suture between them. A small portion only of the epicranium exists anterior to these great corneæ, but in that portion, as usual, are situated the *ocelli;* while the minute antennæ, reduced also to their minimum of size in these *Libellulidæ*, the most rapacious and insatiable of all insects, are still situated, as in Coleoptera, at the external angles of the suture. In the dilated anterior portion of the head we distinctly recognize the *clypeus posterior* and *anterior*, and below these the transverse cordiform *labrum*, separated by sutures, but freely articulated together as in Orthoptera. At the lower concave margin of the clypeus anterior in *Œshna grandis* is a short triangular plate intervening between the clypeus and labrum, and articulating with both like a distinct segment; it is probably only part of the labrum. On the under surface of the head the *gula* and *sub-mentum* are indistinct, and merged as it were in the construction of three immensely dilated, doubly articulated plates, which cover the whole lateral and under surface of the mouth. The anterior portion of the middle plate, which in *Œshna* is rounded at its anterior margin, is the true *ligula*, while the articulation behind it, from which arise the lateral plates, is the analogue of the *mentum*. The two lateral plates, composed each of two articulations, and in some species also of a third very minute one in the form of a short spine at the apex, we regard, with Brullé,* as the proper labial palpi immensely dilated. The *mandibles* concealed within the mouth are short, strong, and, in *Libellula quadrimaculata*, arched. At the apex they are bifid, and armed with two sharp triangular teeth, and at their base with four sharp-pointed ones, excavated, and placed in different directions, adapted for crushing and cutting rather than for masticating the food. Within the head they are articulated with portions of the epicranial and basilar regions, as in Coleoptera. The *maxillæ* are long and prehensile. The true palpi are entirely absent, but the *galea* exists as an oblong articulated lobe, and the *lacinia*, which is articulated at its base and sharpened along its inner margin, as in the *Blattidæ*, is armed at its apex with four crooked sharp-pointed teeth, while the *cardo* is long, and articulated with the base of the maxilla at an angle, to allow of extensive motion, as in the maxilla of Orthoptera. In other families of the Neuroptera, as in the *Panorpidæ*, the organs of manducation are small, but the anterior part of the head is elongated into a rostrum, occasioned by the narrowing and extension of the clypei, as we have before noticed in the *Curculionidæ*, while in the *Phryganidæ*, which take no food in their perfect state, the parts of the mouth are almost atrophied.

In Hymenoptera the mouth assumes an entirely new form, but the changes in it are confined to the maxillæ and labrum, which are soon to become its chief organs. The head, placed vertically on the thorax, is still well developed. The *epicranial* region is large, and extends very nearly to the insertion of the antennæ on the front. In most species it is densely covered with hairs, and the *ocelli (fig.* 375, *b*,) which are constant in this class, are usually arranged in a triangle on its most vertical part. The *corneæ* (*c*) are large and kidney-shaped, and cover part of the lateral surface of the head, leaving between them a broad front, occupied by the clypei (*d*) and part of the epicranium. But in the males of the hive-bee, which come abroad only in the brightest sun-light in quest of the female, this space is diminished, and the corneæ are expanded over part of the front, and the whole of the epicranial region, as in the *Libellula;* the most extensive vision being required by these insects, to enable them to discover the object of their solicitude, as by the other in the pursuit of its prey. In some of the pollenivorous and pre-

daceous genera, the *Tenthredinidæ* and *Vespidæ*, the clypeus posterior seems to have become entirely obliterated, unless we regard the broad clypeus in these insects, as in the Hornet, the posterior one, and the plate concealed beneath it, within the mouth, to which the labrum is attached, as the anterior. But we are not inclined to do this, because in some of the *Ichneumonidæ* and *Sphecidæ* a trace of the clypeus posterior remains a little anterior to the antennæ. In *Ichneumon Atropos* the clypeus is narrowed and depressed in its middle, as if originally formed of two parts, while in *Ammophila vulgaris* the clypeus posterior is clearly indicated as a minute triangular plate situated in the middle line, immediately beneath the insertion of the antennæ, and it exists in a similar form in some of the *Apidæ*, as in the large female *Bombus lapidarius*, and in some specimens of *Anthophora*, the clypeus posterior being in all instances bounded by a trace of the triangular suture. The *labrum* (*c*) is always distinct, but variously formed. In *Vespidæ* it is narrow, acute, and hidden beneath the anterior clypeus; in the leaf-cutting bees, *Megachile*, it is narrow and quadrate; but in the hive and humble-bees it is large, and rounded at its anterior margin. The *mandibles* are subject to considerable variation of form.* In some, as in *Ammophila*, which burrows in the sand, they are long, hooked, and furnished with but a single tooth at the apex, without cutting edges; and they are of somewhat the same form in *Anthophora* (*fig.* 375, *f*), whose habits of life in this respect are similar. In the *Vespidæ*, which gather the materials for their nests by rasping off little packets of fibres from decaying wood, they are broad, triangular, and armed along their edges with strong teeth; and such is also their structure in *Anthidium manicatum*, which scrapes off the down from the woolly stems and leaves of plants for the same purpose; while, in the hive-bee, which employs them in moulding the soft wax in the construction of the combs, they are shaped at the apex like a spoon, without indentations; their form in each instance being thus distinctly referable to the habits of the insects. In the gregarious species there is also a difference in their form in the two sexes, those of the males being often smaller and less curved than of the females, or workers, and they are always, particularly in the *Bombi*, more densely covered with hairs.

In the whole of the Terebrantia, Pupophaga, and some of the Aculeata the mandibles are still the chief cibarian organs; the *Athalia* employs them in masticating the pollen of flowers, and the maxillæ and labium in sipping the honey; while the omnivorous *Formicidæ* and *Vespidæ* employ them in tearing and masticating their food, whether it be the pulpy substance of fruits, or the muscles and hard coverings of other insects. In the *Apidæ* the chief use of the mandibles is in constructing the nest, while the maxillæ and labium are the only organs employed in taking food. In the strictly carnivorous families the *maxillæ* are not longer than in the preceding Orders. In most of these, as well also as in the *Terebrantia* and *Chrysididæ*, the extremity of each maxilla is obtuse, and divided into a distinct lacinia and galea, and the palpi are long and six-jointed. In the *Formicidæ* and *Vespidæ*, which subsist upon fluid as well as solid aliment, their length is increased; but in the true *Apidæ*, which subsist entirely upon honey, they are drawn out to a great length, and, with the labium beneath, form a tube through which the aliment is conveyed to the mouth, as in the hive and humble-bees. In these species the *cardo* (1) is long, slender, and formed of two parts, which conjointly articulate with the stipes (2). The longest of these, the basilar portion, has two apophyses at its extremity, and is articulated with the anterior part of the base of the cranium, at the inner side of the articulation for the mandibles, exactly as in Coleoptera; and its muscles in like manner are attached to the lateral and inferior parts of the head and orbital plates. It is the *lora*, or lever of Kirby, which enables the insect, by the additional articulation of its second part with the sub-mentum, to thrust out the maxillæ and labrum together to a great distance. The part that articulates with the sub-mentum, the proper *cardo* of Kirby, is very short in *Bombus lapidarius*, but of consi-

* See Essay on Fossorial Hymenoptera, by W. E. Shuckard, p. 12, et seq.

Fig. 376.

Lateral view of the mouth of Anthophora. Letters and figures as before. 12, the lingua, or tongue.

derable length in *Anthophora.* In each instance it is broadest at its articulation with the stipes, and, passing backwards diagonally, unites at its extremity with a corresponding part of the opposite side, and the two thus joined articulate with the narrow sub-mentum, the *fulcrum* of Kirby. The *stipes* forms the lateral basilar part of the maxilla, and is shorter in Anthophora than in Bombus, in which it is about one-third of the length of the maxilla. The *palpifer* is also distinct (3). The lacinia (5) is of great length, and gradually tapers to its extremity. Internally it is slightly concave, and externally is covered with a few scattered hairs. It is articulated freely with the stipes and palpifer, upon which it is inflected in a state of rest to form a sheath for the labium, when the parts of the mouth are folded. When the maxillæ are extended to form the sucking tube with the labium, they are a little separated at their base, and inclose between them the cavity of the mouth, within which is a soft fleshy body, the *lingua* (12) or true tongue, situated anterior to and serving as a valve to the pharynx. The *sub-mentum* (*m*) is articulated by a single joint with the united extremities of the two cardines (13). It is long and narrow in *Anthophora*, but short and triangular in *Bombus*. It is attached at its sides by a fine membrane to the under surface of the head and throat. The *mentum* (*l*) articulates with the sub-mentum, and is an elongated rounded plate, which forms internally a channelled passage to the pharynx. Within it are inserted the muscles of the labial palpi (*k*). These organs are long and styliform, and arise from a space at the base of the ligula, the part described as the palpiger by Newman. Their great length is occasioned by an excessive elongation of the second basial joint, which is sometimes as long as the whole maxilla itself, and is furnished at its distal extremity with a minute brush of hairs, and also articulates with the remaining short joint of the organ. The remaining portion of the labium is divided into three parts. The two lateral ones are short styliform processes, the *paraglossæ* (**), and the central one, commonly called the *tongue* of the bee, is the part employed by the insect in gathering honey. In *Apis, Bombus*, and *Anthophora* it is a long tapering muscular organ, formed of an immense number of short annular divisions, and densely covered throughout its whole length with long erectile hairs. It is not tubular but solid, and when actively employed is extended to a great distance beyond the other parts of the mouth, but when at rest is closely packed up and concealed between the maxillæ. The manner in which the honey is obtained when the organ is plunged into it at the bottom of a flower, is by lapping, or a constant succession of short and quick extensions and contractions of the organ, which occasion the fluid to be accumulated upon it, and ascend along its upper surface, until it reaches the orifice of the tube formed by the approximation of the maxillæ above, and the labial palpi and this part of the ligula below. At each contraction a part of the extended ligula is drawn within the orifice of the tube, and the honey with which it is covered ascends into the cavity of the mouth, assisted in its removal from the surface of the ligula by the little brush of hairs with which the elongated second joint of each labial palpus is furnished. From the mouth the honey is passed on through the pharynx into the œsophagus by the simple act of deglutition, as in other animals. In *Anthidium* the ligula is not longer than the labial palpi; while in the *Andrenidæ* all the parts of the mouth are much shortened, and resemble similar parts in the *Vespidæ* in being divided into four lobes.* In the latter insects the ligula is quadrifid, and is dilated at its apex, and each lobe is terminated by a minute gland.† The two lateral lobes, *paraglossæ*, are shorter than the middle ones. In *Tenthredinidæ* the ligula is also short, but is divided only into three lobes.

We have thus seen that the head and its appendages are most perfectly developed as a whole in the Coleoptera, and that in passing through the succeeding Orders of Mandibulata certain parts are more or less developed in each Order, in accordance with the general habits and mode of life of the insects; that in the carnivorous and omnivorous families, and in those whose habits of life require a great amount of strength, either in procuring their food or in the construction of their nests, the mandibles are the most important of the oral organs, and are most largely developed. But as we pass from insects with these habits to the Haustellata, whose food and modes of life are of an entirely different description, the mandibles lose their importance, and become atrophied, and their office, now altered in its character, is performed by the maxillæ and labium,

* Newman. Paper on the Head of Insects, p. 22.

† Curtis. Westwood.

the development of which, in the higher forms of insects, is only of secondary importance, compared with that of the mandibles, but is now carried to so great an extent that these organs become almost or entirely the sole means of taking food. Not only do these changes take place in the parts of the mouth, but the whole head undergoes a similar alteration in the relative form and size of its parts, occasioned by the excessive development of the organs of vision. Thus in the Lepidoptera, (*fig.* 377,) the

Fig. 377.

lateral and a large portion of the inferior surface of the head is entirely occupied by the corneæ (*c*), which are also extended far forwards upon the anterior. The occipital region is confined to the flat surface that is approximated to the prothorax. The epicranium (*b*) is distinct, and, as in the preceding Orders, extends as far anteriorly on each side as the base of the antennæ between the corneæ, but the suture that separates it from the clypeus posterior (*d*) is almost transverse. The *clypeus posterior* is very large, and occupies the whole of the space between the corneæ, on the front of the head. It is convex as in Neuroptera, and is narrowest at its inferior part. The *clypeus anterior* appears to exist in the form of a minute transverse plate, a little elongated in its middle on the hinder part, and separated by a transverse groove on its anterior from a much smaller plate, the *labrum* (*e*), with which it is consolidated. This part, which was first detected in Lepidoptera by the accurate Savigny,* is also a small convex transverse plate with a little triangular scale at its anterior margin, fitted closely to the front of the maxillæ. In *Sphinx ligustri*, (*fig.* 377,) the separation of the labrum by suture from the part which we regard as the clypeus anterior, is distinct, but it appears to have been overlooked by Savigny and others. On each side of the labrum are the rudiments of the mandibles (*f*). They are two minute, triangular plates, attached in part to the labrum and margin of the clypeus, to which, as Savigny has remarked, they appear to be soldered. They are applied to the base of the maxillæ, and in *Sphinx* appear each to be formed of two parts, and are covered along their inner margin with stiff hairs. They are the remains of the large corneous mandibles of the larva. We are indebted for their discovery to the indefatigable researches of Savigny, who first traced their identity. The *labium*, which forms so conspicuous a part of the mouth in the preceding Orders, like the mandibles, is reduced to insignificance in this. It is a small triangular plate, closely attached to the under surface of the head, at the base of the maxillæ, and its division into parts, so distinct in other insects, is now scarcely perceptible. The *labial palpi* (*k*) arise one on each side of the labium. They are usually long, hairy, and three-jointed, and are reflected on the front of the head. Next to the maxillæ they are the most conspicuous parts of the mouth, particularly in *Pyralidæ* and *Tortricidæ*, in which they are long and pointed. The *lingua* has been supposed to be entirely absent in Lepidoptera. It was not detected by Savigny. Latreille believed it to exist in the suture at the floor of the mouth, but Mr. Newman has observed a small mammiform protuberance in *Sphinx ligustri* which he regards as the analogue of the tongue in this Order. The labrum, mandibles, and labium are entirely concealed by the reflected labial palpi and a dense clothing of scales, and are only observed when the anterior part of the head is completely denuded of these coverings. Their atrophied condition affords a beautiful illustration of the law that in proportion as the functions of an organ become suspended, or are rendered unnecessary by the employment of other parts, the organ itself becomes wasted and utterly useless, and perhaps entirely disappears. Thus in those Lepidoptera whose food is liquid honey produced in the deep chalices of flowers, the short mandibles of the voracious herbivorous larva would be entirely useless to the perfect insect, and its food would be inaccessible to it. Accordingly we find that the mandibles are now unimportant organs, and the office of conveying food to the mouth is performed solely by the maxillæ (*g*), which are extended in the shape of a long sucking tube. Each maxilla is composed of an immense number of short, transverse, muscular rings. It is convex on its outer surface, but concave on its inner, and the tube is formed by the approximation of the two organs. When at rest they are rolled up like a watch-spring, between the large labial palpi, but are capable of being darted forth in an instant. They are the so-called tongue, or proboscis of the butterfly and moth. Each maxilla has usually

* Mémoires sur les Animaux sans Vertèbres.

been described as being hollow in its interior, or forming " in itself a tube,"* which appears to have arisen from the circumstance of there existing in each, one or more large tracheal vessels, (*fig.* 378, 6, *e*,) connected with the tracheæ of the head, and which are divided, as they approach the extremity of the organ, into a great number of minute ramifications, but which have no communication with the external surface, their distribution being precisely similar to that of the tracheæ in other parts of the body. The maxilla is composed of elementary parts, as in the preceding Orders, but they are not easily distinguished. The long extensile portion is the proper *lacinia*, which is constricted at its base, immediately beyond which is situated, in *Sphinx ligustri*, a minute three-jointed hairy palpus (*h*). Mr. Newman could not detect this maxillary palpus in Sphinx,† and hence concluded that it was obsolete in this family. It is indeed exceedingly minute and easily overlooked, but is distinctly three-jointed, and densely covered with long hairs. The structure of the maxillæ in different genera and species is particularly interesting, and their length is exceedingly various. Thus in the *Sphingidæ*, in *Smerinthus ocellatus*, which takes no food, they scarcely exceed one-eighth of an inch, while in *Sphinx ligustri*, which continues hovering on the wing while extracting the sweets from a flower, they are nearly two inches in length, and this is also the case in the humming-bird moth, *Macroglossa stellatarum*. In the butterflies, and in many of the *Noctuidæ*, they are often about equal to the length of the body. The inner or concave surface which forms the tube is lined with a very smooth membrane, and extends along the anterior margin throughout the whole length of the organ, as in the transverse section, (*fig.* 378, 6, *b*.) At its commencement at the apex it occupies nearly the whole breadth of the organ, and is rather smaller than at its termination near the mouth, where the concavity or groove does not occupy more than about one-third of the breadth. In some species the extremity of each maxilla is furnished along its anterior and lateral margin with a great number of minute papillæ, but in others these parts are entirely absent. They are extensively developed in some of the butterflies, as in *Vanessa atalanta*, (*fig.* 378, 1, 2, *c*,) in which they are little elongated barrel-shaped bodies, (4, *c*,) terminated by three smaller papillæ, arranged around their anterior extremity, with a fourth one a little larger than the others placed in their centre. These papillæ are arranged in two rows along the lateral and anterior surface of each maxilla, near its extremity, for about one-sixth part of its whole length, as at 1, and 5, *c*, *d*. There are seventy-four in each maxilla, or half of the proboscis. To judge from their structure, and from the circumstance that they are always plunged deeply into any fluid when the insect is taking food, they may probably be regarded as organs of taste. They are largely developed in this genus of insects, but in *Pontia*, the common white butterflies, and in *Sphinx ligustri* they are scarcely perceptible. There are also some curious appendages arranged along the inner anterior margin of each maxilla, in the shape of minute hooks, which, when the proboscis is extended, serve to unite the two halves together. They were first noticed by Reaumur,* and subsequently by Mr. Kirby.† In many insects, as in *Sphinx* and *Pontia*, they have more the appearance of cilia, like the barbs of a feather, than of hooks, but in *Vanessa* they are falcated, and furnished with an additional tooth (3, *d*) a little beyond the apex. They are so exceedingly minute, and arranged so closely together, that their true form is with difficulty distinguished. They lock across each other like the teeth in the jaws of some fishes, and we are inclined to believe that the points of the hooks in one-half of the proboscis are inserted, when the organ is extended, into little depressions between the teeth of the opposite side, so that they form the anterior surface of the canal, but of this we are not con-

fident. That they really form the anterior surface of the canal or tube seems evident from the distinctness with which coloured substances are observed to pass along the tube when the insect is taking food.

There are various opinions with regard to the manner in which the food ascends the tube to the mouth. Some have imagined that it is simply by capillary attraction, and others, the chief of whom was Lamarck, that it is forced along by successive undulations and contractions of the sides of the tube, occasioned by the action of the transverse muscles. Kirby and Spence* believe that these undulatory motions, which certainly do exist to a considerable extent, are not sufficiently powerful to carry along the food with the rapidity with which it usually ascends, but that the lateral canals, which, as we have just shewn, are the proper tracheæ of the organs, assist in producing the phenomenon by occasioning a vacuum in the mouth and tube which facilitates the conveyance of the food more rapidly along it. That something of this kind does in reality occur is proved by the following observation. We gave sugared water, coloured with indigo, to two specimens of *Pontia napi*, and on attentively examining the front of the organ with a microscope while the insects were busily employed in partaking of the fluid, observed the particles of indigo disseminated in it ascend along the tube, not in a gradual and regular succession, as must have been the case had the ascent of the fluid been occasioned simply by capillary attraction, but pumped up, as it were, sometimes in a full stream in quick succession for one or two seconds, as if the insect was then sipping a full draught, while at others a few particles only ascended quickly, followed by still fewer with a much slower motion; thus indicating distinct intervals between each draught or ascent of fluid. From these circumstances we are led to offer the following explanation of the manner in which the food ascends the tube to the mouth. The instant an insect alights upon a flower, it makes a forcible expiratory effort, by which the air is removed both from the tracheæ that extend through the proboscis, and from those with which they are connected in the head and body, some of which we shall hereafter see are distributed over the œsophagus and alimentary canal, and at the moment of applying its proboscis to the food makes an inspiratory effort, by which the tube is dilated, and the food ascends it at the instant to supply the vacuum produced, and is carried onward by the same act to the mouth, and from thence by the action of the muscles of the pharynx into the œsophagus and stomach, without any interruption of the function of respiration, the constant ascent of the fluid into the mouth being assisted by the action of the muscles of the proboscis, which continue in action during the whole time the insect is feeding. By this combined agency of the acts of respiration and the muscles of the proboscis, we are enabled to understand the manner in which the humming-bird sphinx extracts in an instant the honey from a flower while hovering over it without alighting, and which it certainly would be unable to do so rapidly were the ascent of the fluid dependent only upon the action of the muscles of the organ.

In Diptera there is the same irregularity in the development of certain parts of the head as in Neuroptera and Hymenoptera. The shape of the head is usually that of a flattened hemisphere, with its base or occipital region concave, and approximated to the prothorax, as in the common house-flies, *Muscidæ*, the blood-suckers, *Tabanidæ*, and the gad-flies, *Œstridæ*. But in others, as in the gnats, *Culicidæ*, the long-legs, *Tipulidæ*, and the *Asilidæ*, (*fig.* 349,) it is either convex at its occipital surface or extended in the form of a short neck. In the latter instances the *occipital* and *epicranial* regions are large and distinct, and the *corneæ* are protuberant, and situated a little anteriorly at the sides of the head, but do not much encroach upon the epicranium. This is not the case in the *Tabanidæ*, &c. in which they occupy nearly the whole of the epicranial region. But in most of the genera in which the eyes are thus expanded, there is usually, as in Neuroptera, some portion of the epicranial region still existing in the form of a small triangular space anterior to the inner margin of the corneæ. On this space the longitudinal portion of the triangular suture is often distinctly marked, and extends backwards between the corneæ to the occiput, as is well seen in *Tabanus bovinus*. Anteriorly it extends as far as the middle line behind the antennæ, where it terminates, thus distinctly indicating the proper boundary of the *clypeus posterior* in this order. The whole front of the head or face is formed of the two clypei, which are so united together as to be scarcely distinguished as originally separate parts. They together form a broad and somewhat lozenge-shaped plate, at the upper portion of which are situated the antennæ, and at the lower or anterior, which is notched, the labrum, freely articulated with it, and which is usually concealed beneath it. In some genera, as in the *Tabanidæ*, the antennæ are inserted on each side of the middle line, into little fossæ close to the triangular suture; while in others, as in *Chrysotoxum* and *Conops*, the place of these fossæ is occupied by little elevations, upon which those organs are seated, sometimes nearly close together, as in *Sargus*. The face thus formed of the two clypei is developed laterally on each side of the corneæ, and is gradually narrowed from its upper part to its lower, where it is articulated with the labrum. In *Rhingia rostrata* the posterior clypeus is elongated, and forms the long projecting front: it is deeply notched at its interior margin, where, as also in *Volucella*, is a very minute plate, apparently the analogue of the clypeus anterior. The *corneæ*, as above stated, are usually the most conspicuous parts of the head in Diptera, and form

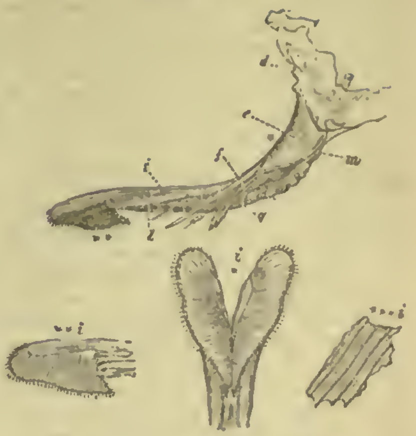
* Introduction, vol. iv. p. 470.

its lateral regions. They are always largest, as in Neuroptera, in those species which are most constantly abroad in the brightest light, and are expanded over nearly the whole of the epicranial region, as in *Tabanus*, *Chrysotoxum*, and *Doros*. But although the corneæ of the compound eyes are so largely developed, the *ocelli* also are almost invariably present in this order. They are generally three in number, placed on the most vertical part of the epicranium, immediately behind the proper corneæ. This is their situation in *Musca*, *Helophilus*, and *Stratiomys*, and also in the gnat, *Culex annulatus*, but we have not observed them in a neighbouring genus, *Pedicia*. Professor Muller* believes that the *ocelli* are designed chiefly for observing near objects, and the fact of their existing, as just stated, in many insects in which the corneæ of the proper eyes are exceedingly large, seems to favour this opinion. Their presence, as in Hymenoptera, is most remarkable in the males, as in the male *Empidæ*, in which, although the proper corneæ cover the whole surface of the head, yet there are also three large ocelli situated in the triangular space immediately behind the corneæ, and even elevated upon a pedicle. In *Tabanus* there appears at first to be only a single ocellus, situated in the median line between the corneæ at the anterior part of the head; but on close inspection it is found to be divided into two by the longitudinal suture which passes through it, so that the two ocelli from their close approximation appear but as one.

In the organization of the mouth the same parts exist in Diptera as in the preceding orders, but modified in form to adapt them to a different mode of use. Thus we have seen that in Hymenoptera and Lepidoptera it was simply necessary that the parts should be elongated, to enable the insects to obtain the liquid food already prepared for them; but in Diptera not merely was it necessary that this should be the case, but also that their form should be materially altered, to adapt them to a mode of employment different from that of analogous parts in other insects. Thus in *Tabanidæ*, the labrum and mandibles are used like lancets, to pierce the integuments of other animals, before these parasitic blood-suckers can obtain the living fluid they are in quest of; while in other species, as in *Eristalis floreus*, (*fig.* 379,) which subsists both on the pollen and honey of flowers, the mandibles and maxillæ are employed to scrape off the pollen from the anthers, before it is conveyed along the tube formed by the united parts of the mouth to the pharynx. In other Diptera, of which the food is entirely fluid and easily accessible, as in the common house-flies, *Muscidæ*, all the parts of the mouth are soft and fleshy, and simply adapted to form a sucking tube, which in a state of rest is closely folded up in a deep fissure, on the under surface of the head, formed by the two sides of the clypeus.

* Elements of Physiology, by J. Muller, M.D., (translated by W. Baly, M.D., part v. p. 1116.

Fig. 379.



Mouth or proboscis of Eristalis floreus.

d, front beneath the clypeus; *e*, labrum; *f*, mandible; *g*, maxilla and palpus; *i*, labium; *i**, labium dilated; ***i*, inner surface of paraglossa; ****i*, the rows of hairs on the inner surface; *l*, ligula; *m*, cardo and submentum.

On the other hand, in the *Œstridæ*, which, as we have seen in the *Phryganidæ*, *Bombycidæ*, and others that take no food in their perfect state, all the parts of the mouth have entirely disappeared. It is in *Tabanidæ* that the oral organs of Diptera are most perfectly developed, and approach nearest to those of Hymenoptera, and are easily distinguished; while in the soft fleshy proboscis of *Muscidæ* their identification is a matter of considerable difficulty. According to Savigny* the proboscis of Diptera is formed solely by the labium, or under-lip, divided into its primary parts as in other insects; while Desvoidsy† on the contrary believes that it is *not* formed by the labium, but, as in Lepidoptera, solely by the maxillæ. Now we have seen, that although in Lepidoptera the maxillæ alone form the tubular mouth or proboscis, yet that in Hymenoptera the labium is the part chiefly employed in gathering the honey, which is conveyed to the cavity of the mouth and pharynx only by the maxillæ assisting to form a tube of which the labium constitutes the inferior portion. Analogy therefore would lead us to expect a somewhat similar conformation of the mouth in Diptera, and that since these insects have either to pierce the coverings of other animals before they can obtain their food, or to gather their nourishment by employing the proboscis as a prehensile organ, the maxillæ may fairly be supposed to enter into its formation, and accordingly we find, on a careful examination, that such is actually the case, and that the proboscis is formed of the maxillæ and labium united. We have been led to this conclusion by a care-

* Mém. sur les Anim. sans vertèbres.

† Essai sur les Myodaires, par le Docteur J. B. Robineau Desvoidsy, 4to, 1830, tom. x. Mémoires de l'Institut de France.

ful examination and comparison of the parts of the mouth in *Volucella*, *Echinomyia*, and *Musca*, with those in *Tabanidæ* and *Asilidæ*. To commence our observations with the most perfect form of mouth, we find in *Tabanidæ* that the *labrum* is an elongated, acute, corneous plate, freely articulated to the margin of the clypeus, and marked along its middle line with a raphé. It is concave on its under surface, and is as long as the mandibles and maxillæ, which it partially covers, and somewhat resembles in appearance. In *Culex* it is longer than these parts, and is more sharp-pointed. In *Asilus crabroniformis* it is much shorter than either the mandibles or maxillæ. It is narrow, triangular, and rounded at its apex, with a slight indentation, and is not used by the insect as a lancet, as in the preceding instances, but merely forms the anterior covering of the mouth. In *Eristalis floreus* (*e*) it is a short mitre-shaped plate, which covers the base of the mandibles and maxillæ, and articulates freely with the clypeus. In *Volucella bombylans* it is reduced to a very narrow short plate, articulated with, and, in a state of rest, inflected beneath a small triangular one, which is inserted into a deep cleft of the clypeus, and which appears to be the proper analogue of the clypeus anterior. In *Rhingia rostrata* it has almost entirely disappeared, so likewise has the part that we are inclined to regard as the clypeus anterior, which is inserted into the cleft at the extremity of the elongated rostriform anterior part of the head. In *Echinomyia* it still exists as a very narrow corneous plate articulated with the clypeus, inflected beneath the head when the proboscis is retracted, but forming the anterior portion of its base when the organ is extended. In *Musca* it has entirely disappeared as a distinct piece, but seems to have become the union of two corneous plates, which together form an arch on the front of the mouth, or base of the proboscis, and represent the mandibles, the intervening space being covered by a strong membrane. The *mandibles*, which had almost disappeared in Lepidoptera, still exist in the rapacious Diptera, and in those which pierce the skin of other animals. In *Tabanus* they are long, and somewhat lancet-shaped plates, situated immediately beneath the labrum. They are slightly curved, like a cutlass, and sharp-pointed. They are not employed in crushing or cutting solid food, as in proper mandibulated insects, but in puncturing or piercing with a horizontal motion from behind forwards, and not from side to side. In this genus, however, their motion appears to be not simply that of thrusting or piercing, but also that of cutting vertically with a sweeping stroke, like the lancets of a cupping instrument, for which motion they are well adapted by their cotyloid form of articulation. In the common gnat, *Culex*, they are very slender, and sharp-pointed. The pain occasioned by the piercing, or supposed biting of the insect, arises from the act of thrusting these instruments through the skin. In these instances the mandibles are equal in length to the other parts of the mouth, but in *Eristalis*, in which they have still the same acute form, they are somewhat shorter. In the rapacious *Asilus crabroniformis* the mandibles of the two sides are united to form a single, strong, sharp-pointed barb, very acute, and ciliated at the apex on its upper surface, and projecting beyond the other parts of the mouth. In *Rhingia rostrata* they still exist as delicate elongated setæ, approximated at their apex; but in the neighbouring genus, *Volucella*, we have been unable to detect them, except as two flat plates, approximated to the anterior part of what we regard the proper *cardines* of the maxillæ and labrum, and by which the parts of the mouth are thrust forwards. In *Echinomyia* the mandibles have also disappeared as distinct organs, and seem to be united to the base of the cardines within the mouth, as in *Volucella*, and there is a similar condition of these parts in *Musca*, in each instance the anterior part of the mouth being covered by a strong membrane, which supplies the place of the horny labrum. The *lingua* exists in most Diptera. It is largely developed in *Tabanus*, in which it is a single horny seta situated between the mandibles in the centre of the mouth. It was distinctly pointed out by Savigny, and subsequently by Latreille. It was called by the former the *hypopharynx*. The *maxillæ*, like the mandibles, undergo a gradual diminution of size. In *Tabanus* they are straight, and as long as the mandibles, but narrower and less acute. In *Asilus*, (*fig.* 380, *g*) they are very acute and

Fig. 380.

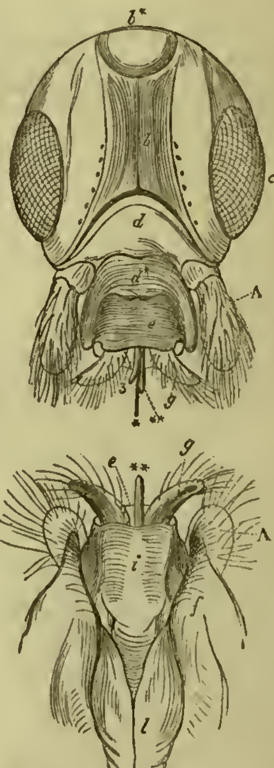
m, submentum; 1, cardo; 2, stipes; 3, palpifer; 5, lacinia: *h*, maxillary palpus; *l*, mentum; *i*, ligula.

strong, with sharp cutting edges. They are shorter and narrower than the mandibles, and are usually inclosed within the sheath or proboscis formed by the labium. In this family some of their primary parts are easily distinguished. Thus the blades (5) that lie within the sheath of the labium, are the true laciniæ in other insects. These are articulated at their base with the palpifer (3), a small triangular plate, which bears the maxillary palpus and is situated most externally,—and also with a broad squamous plate (2), which is united at its base to its fellow of the opposite side, and appears to be analogous to the *stipes* and *cardo* (1) united. This plate, with its fellow, forms the anterior boundary of the throat, and is closely united to the proper *gula* that bounds the anterior margin of the occipital foramen. The muscles attached to the posterior margin of the mentum and submentum pass over this plate to be attached, one set to the anterior margin of the gula, and the other to the posterior. In *Volucella bombylans* the maxillæ have lost much of their importance, but are still easily distinguished, and, with the other parts of the mouth, are beginning to be merged in the united fleshy proboscis. The *cardines*, upon which all the motions of flexion and extension in this kind of mouth depend, are very largely developed. They are two elongated plates, approximated to each other along their inner margins, and to two triangular plates, the remains of the mandibles, at their anterior and lateral. The cardines thus form the posterior, or basilar part of the proboscis, and the plates which, from being articulated within the margin of the clypeus posterior, we regard as analogous to the mandibles, the lateral. At their inferior portion, which forms the joint or elbow of the proboscis, the cardines are freely articulated with the *stipes*, which is a short plate not easily distinguished from a part of the mandible with which it is also in apposition. Between the stipes and cardo is a short triangular plate, the *palpiger*, rounded at its most inferior part, and, with its fellow of the opposite side, assisting to form the elbow or joint of the proboscis. The maxillary palpus, which aises from its external border, is long and slender, and appears to be formed of three short joints and one very long one. At the inner and anterior margin of the palpifer and stipes is articulated the *lacinia*, which, as in *Asilus*, is of considerable length. It is interesting to remark, that in this insect, which is parasitic in its habits, insinuating itself into the nests of humble-bees to deposit its eggs, the mandibles, as just shewn, are atrophied, and the two laciniæ of the maxillæ, although distinct from each other, are approximated in the middle line to form the anterior or upper surface of the tube to the mouth, as in Hymenoptera, the sides and lower portion of the tube being formed by the labium, and all the motions of extension and flexion in the proboscis being dependent upon the cardines, as we have before seen in Hymenoptera. In this genus therefore we discover one of the transitionary forms of mouth from that of the blood-sucking insects to those of the more omnivorous feeders, all the parts of the mouth being less and less distinct in proportion as the act of taking food is less complicated. Thus we have seen that in *Tabanus* distinct mandibles are required to pierce the skin of an animal, before the food is accessible; but in the *Muscidæ*, whose fluid aliment is every where present, a complicated form of mouth is unnecessary, and accordingly we find it reduced to a simple sucking tube. In *Eristalis* the *maxillæ* are present, as in *Asilus* and *Volucella*, as also are their palpi, which are nearly equal to them in length. In *Echinomyia* they are less distinct than in *Volucella*. The anterior part of the proboscis at its base is formed simply by a broad membrane united to the anterior margin of the atrophied mandibles, while the laciniæ, which were distinct in the preceding genera, are united in this genus to form the front of a lower portion of the organ. That this union has taken place is shewn in the presence of the maxillary palpi, which invariably exist in Dipterous insects. In all the *Muscidæ* the palpi arise from a distinct *palpifer*, which appears to be connected with a proper *stipes*, but the remaining parts are not easily distinguished. It seems evident, however, that at least the basilar portion of the proboscis is formed by the union of the laciniæ above and the labium below, as in Hymenoptera, and that the labium forms the chief portion of the organ, contrary to the opinion of Desvoidsy, who believed that the proboscis of Diptera was formed of the maxillæ alone, and to that of Savigny, who regarded the proboscis as formed only of the labium. The principle therefore upon which the proboscis of Diptera is constructed, is precisely analogous to that of Hymenoptera, but there are important differences in the form of similar parts in the two orders. The *labium* includes the same primary parts as in Hymenoptera, but the labial palpi are almost invariably absent. The *submentum* is usually indistinct. In *Asilus* the part we regard as such is a small triangular plate, (*m*,) distinguished only when the parts are examined by transmitted light. It is situated between the anterior portions of the two cardines. In *Volucella* it is that part of the proboscis which is nearest to the cardines, close to the articulation. In *Culex*, in which the cardines are short, it is situated very close to the under surface of the head; in other Diptera it is frequently very indistinct. The *mentum* on the contrary is always a conspicuous part. In *Asilus* it is the broadest part of the proboscis (*l*). It is a strong horny plate, deeply channelled on its upper surface to form a canal to the mouth, and receive within it the mandibles and maxillæ. It is articulated with the ligula, or extremity of the proboscis (*i*), which is distinctly formed of two halves approximated together, and narrowest at the apex, with three slight lateral dilatations. In *Volucella* the mentum in like manner is a strong deeply channelled plate, covered above by the laciniæ. There is a similar structure of the proboscis in *Eristalis*. The submentum is the part in which the flexion of the organ takes place; the mentum, as in the preceding instances, is a strong horny plate, almost closed on its upper as well as its under surface, and the ligula is horny, but terminated by soft dilatable lips. The *ligula* is always articulated by a distinct joint with the mentum, and appears to be constantly present in this order. In *Asilus*, as we have just remarked, it is strong and corneous, but in the less rapacious insects, as in *Eristalis*, and the *Muscidæ*, it is terminated by two dilated fleshy lips, which we regard as the analogues of the *paraglossæ (fig.* 379, * *i.*) In *Tabanus* these are exceedingly large and broad, and are widely expanded to encompass the wound made by the insect with its lancet-like mandibles in the skin of the animal it attacks. The structure of these paraglossæ is curious. On their outer surface they are fleshy and muscular, to fit them to be employed as prehensile organs, while on their inner they are more soft and delicate, but thickly covered with rows of very minute stiff hairs (*** *i*) directed a little backwards, and arranged closely together like the teeth of a comb. There are very many rows of these hairs on each of the paraglossæ, and from their being all arranged in a similar direction are easily employed by the insect in scraping or tearing delicate surfaces. It is by means of this curious structure that the busy house-fly often occasions much mischief to the covers of our books by scraping off the albuminous polish, and leaving traces of its depredations in the soiled and spotted appearance which it occasions on them. It is by means of these also that it teases us in the heat of summer when it alights on the hand or face to sip the perspiration as it exudes from and is condensed upon the skin. The manner in which the fluid ascends the proboscis is similar to that of its ascent in other Haustellata, it being dependent partly upon the sucking action exerted by the application of the proboscis, assisted by the muscular action of the paraglossæ, as any one may readily convince himself on watching the motion of the parts in the common house-fly, when sipping a drop of fluid, or moistening the stolen grain of chrystallized sugar between its paraglossæ.

The *palpi* yet remain to be noticed. Those of the maxillæ appear to be constant throughout the whole order. In *Culex* they are very conspicuous parts, covered with hairs and as long as the proboscis; they are formed of three short basial joints and three very long ones, the fourth joint being more than twice the length of either of the others. In *Tipula* and *Empis* they are also six-jointed, but of moderate length. In *Tabanus* also they are very conspicuous, and appear to be formed of two short and one very long joint densely covered with hairs, and serve as a cover to the base of the proboscis. In *Asilus* they are short, three-jointed, and slightly hairy (*fig.* 380, *h*), and they are equally conspicuous in most of the *Muscidæ* and *Syrphidæ*, in which they are formed in general of two short joints and one very long one. In the common *Musca* they are long and club-shaped, but in *Eristalis (fig.* 379, *g*, *h*) and *Volucella* they are long, slender, and sometimes covered with hairs. The *labial palpi* do not appear to exist in Diptera. Savigny believed that he had observed at the base of the ligula in *Tabanus* a pilose excrescence which he considered the analogue of the labial palpi; but although, as Mr. Newman has remarked, the spot which Savigny pointed out is exactly that at which they ought to be situated if they really did exist, we have been unable to detect them or to confirm his opinion.

In Homaloptera the head resembles that of Diptera. It is rounded but flattened on its upper surface, and is so closely approximated to the anterior margin of the prothorax into a notch in which it is inserted, as to appear as if separated from it only by a suture. All the primary parts found in the head in other insects appear to be developed in some species of this order. Thus the *epicranium* in *Oxypterum* is broad, distinct, and channelled along the median line into a deep groove (*fig.* 381, *b*),

Fig. 381.



The upper and under surface of the head in Oxypterum.

and the triangular suture, particularly the anterior portion, which divides the epicranium from the clypeus posterior (*d*), is very distinct. At the anterior external angle of this part of the clypeus, as in Coleoptera, are situated the *antennæ* (A), two short and thick porrected organs, covered with a few long hairs, and which, although apparently composed each of two joints, appear to be rigid and motionless. Immediately anterior to the clypeus posterior, and divided from it by a distinct suture, is a short lunated plate (*d**), the *clypeus anterior*. The cornua of this part are extended laterally at the sides of the mouth, and are continuous with a portion of the under surface of the head (*f*) that bounds the labium. Between the two cornua of the upper surface is extended a strong and somewhat horny membrane (*e*), the proper *labrum*, which is continuous with a similar membrane on the under surface (*i*), the labium, which thus forms the orifice of the mouth, the parts of which do not appear to have been sufficiently examined in this order. Thus, although the entrance to the mouth is indicated by a distinctly marked labrum and labium, scarcely more developed than in Coleoptera, the habits of the insect require that it should also be furnished with a strong sucking tube. Accordingly we find that within this membranous mouth are situated two curved horny plates, a little convex on their external, but concave on their internal surface, and capable of being protruded to some distance. They are directed downwards, and when approximated form a tube analogous to that of Lepidoptera. These parts have been described by Curtis as the *maxillæ* (*g*), of which they seem to be the proper analogues, so that in the Homaloptera the maxillæ form the sheath or outer part of the sucking tube. At the base of these parts, within the cavity of the mouth, are two horny margins fringed with dark hairs, which are probably rudimental maxillary palpi. In the centre of the mouth is situated an elongated slender organ (*), which is folded at an angle like the proboscis of Diptera, but is retractile within the mouth, and extends backwards to the entrance to the œsophagus. It consists of three parts, an inferior one which is strong, horny, and forms a groove or canal, the upper surface of which is covered by another smaller piece, and the two inclose between them a third setiform organ. Upon the precise nature of these parts we do not offer a positive opinion; the inferior one, which is continuous with the inflected portion of the labium, seems to represent an elongated portion of that organ, and the middle one probably is the lingua, in which case the upper one would answer to a similarly elongated portion of the labrum.

The under surface of the head is divided by a deep incisure anteriorly, the margins of which are covered with stiff hairs and form the lateral boundary of the mouth. The *mentum* (*l*), described as such by Curtis, is a strong convex plate, divided also at its anterior part by a continuation of the incisure just noticed. The *corneæ* (*c*), of an oval convex shape, are situated more on the upper than on the lateral part of the head, but the ocelli in this insect are entirely wanting, unless we regard as a large ocellus a convex plate situated in the middle of the most posterior part of the epicranium (*b**). In the other genera of this order, as in *Hæmobora*, the head is more orbicular and less flattened; the epicranium is broad and distinct, and the suture between this part and the clypeus posterior is strongly marked. In *Melophagus*, the tick or sheep-louse, the maxillæ are of considerable length, and the retractile portion of the labium inclosing the lingua is of considerable strength. The ocelli are present, inserted in little excavations in *Hæmobora*, but absent in *Melophagus*. In *Nycteribidæ* the head offers a most anomalous condition of parts, its form being, as described by Latreille, that of a reversed cone. We have had no opportunities of examining for ourselves either the head or parts of the mouth, which, according to Messrs. Curtis* and Westwood,† are styliform, and analogous to those of *Hippoboscæ*.

In Aphaniptera the head is compressed from side to side, but we have not yet identified its primary parts. Its chief characteristics are its extreme narrowness, the situation of its antennæ, and the peculiarity of its organs of vision, the corneæ of the proper eyes being each simple and not compound as in other insects. The mouth is formed upon the same general principles as in the blood-sucking Diptera, being composed of six primary parts adapted for piercing the skin, and occasioning the pain which distinguishes the puncturing of these troublesome insects.

In Aptera, all of which, like the insects of the two preceding orders, are parasitic upon the bodies of other animals, the mouth in one family, the true *Pediculidæ*, is formed for sucking, but in the other, the *Nirmidæ*, it is distinctly mandibulated, and approaches the usual type of mandibulated insects.

In Hemiptera the head is often flattened and somewhat triangular, and the mouth is rostriform as in some of the Diptera, but the sheath of the organ is formed entirely by the labium (*fig.* 382, *k*). The corneæ are usually very prominent, and are placed at the posterior angles of the head. The epicranium is distinct, but its occipital portion is sunk into a notch in the prothorax. The ocelli are usually two in number, placed on the most posterior part of the epicranium, and are constant throughout the order in the perfect state, but are not developed in the larva or pupa. The division of the head into its primary parts is very distinct in some genera. In *Coreus marginatus* the epicranial suture is strongly marked along the middle line as far as the space between the corneæ, where it joins the triangular suture which passes outwards immediately behind the insertion of the antennæ, bounding the clypeus posterior. In some specimens, but more particularly in the pupa, a faint longitudinal suture extends forwards over the clypeus as far as the

* British Entomology, pl. 277.

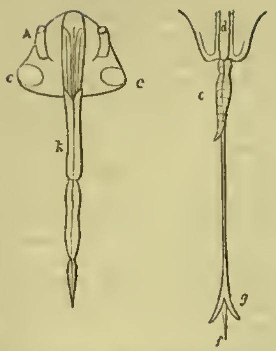
Fig. 382.



Head of Pentatoma rufipes (Savigny).

most anterior portion of the front of the head, where it joins with a second triangular suture which passes outwards on each side anterior to the insertion of the antennæ, and thus divides the clypeus anterior from the posterior. The proper triangular suture between the epicranium and clypeus passes backwards from behind the insertion of the antennæ along the sides of the head as far as the margin of the cornea, thus clearly indicating the extent of the epicranial region, as in Coleoptera. The *clypeus anterior* is distinctly marked at the front of the head (*d*) as a narrow elongated plate, a little widened at its lower portion, where it is articulated with the *labrum* (*e*), which is narrow, lengthened, and ends in a point, and covers the front of the proboscis (*k*), which is formed of four joints or articulations, and is believed by Savigny to represent the true *labrum.* This part, which, in a state of rest, is concealed beneath the under surface of the head and prothorax, forms a cylindrical tube throughout nearly its whole length, from its apex to its base, where it is covered by the labrum. It incloses four distinct setæ, which have been shewn by Savigny to be the proper mandibles and maxillæ. We are satisfied of the correctness of this opinion from our own examination of these parts, the insertion of the muscles belonging to them being in the basilar portion of the head, as in all the preceding orders. But it is in *Reduvius* that the parts of the head are most distinctly marked. The occipital portion is so much elongated backwards as to form a very distinct neck, narrower considerably than the other parts of the head, and the corneæ are large and protuberant and stand out from its broadest part, while the *ocelli,* two in number, are also exceedingly large and are placed on short pedicles almost on the constricted neck-like part of the epicranium, far behind the *corneæ,* and with their axis directed posteriorly. Between this portion of the head and that which contains the true corneæ is a deep transverse impression, which seems to indicate that the corneæ and ocelli are derived from distinct segments. But one of the most marked characteristics of the epicranium in this insect is the existence of a triangular elevation or ridge, which commences in the usual situation of the suture in the middle line between the corneæ, and extending outwards marks the course of the antennæ. The posterior margin of this ridge is in the usual direction of the triangular suture, posterior to the insertion of the antennæ. Anterior to this is a lozenge-shaped plate, the clypeus posterior, which is elevated along its middle line, and which is continuous with a similar elevation on the clypeus anterior. The labrum is short, and terminates in a triangular process, that covers the base of the proboscis as in the preceding species. We have thus five clearly indicated segments in the head of a perfect insect,—the occipito-basilar segment bearing the ocelli, the proper epicranial with the corneæ and antennæ, the two clypeal, and the labial. The proboscis consists, as in *Coreus,* of four distinct articulations, which form the labium, and correspond to the segments of the upper surface of the head, but which are extended forwards and form a sheath for the setiform mandibles and maxillæ. In the *Hydrometridæ,* which connect the terrestrial with the aquatic Hemiptera, the head is elongated forwards, and the corneæ, which are large and kidney-shaped, are very protuberant. In *Gerris paludum* the epicranial region is short, but the suture is still very distinct. It divides as usual at a point opposite to the middle of the corneæ, and passes outwards to their anterior margin. The clypeus posterior is broad and lengthened, and seems to have become united with the anterior, and the antennæ are moved forwards to the base of the proboscis. The *Nepidæ* have a form of head similar to that of the Hydrometridæ, but the epicranial region (*fig.* 383, *d*) is of greater extent. In

Fig. 383.

the figure which we have copied from Savigny the parts of the head are not distinguished, but they are distinct in the insect. The epicranial suture, the proper guide to a correct determination of the primary parts of the head in every species, bounds the corneæ anteriorly and the clypeus posteriorly, which is reduced to a small triangular plate (*d*) with its apex directed backwards. It is divided by a transverse suture from the clypeus anterior, which forms a chief part of the front of the head. The labrum (*e*), as in the preceding species, is short and pointed, the mandibles (*f*) are long and setiform, but larger than the maxillæ (*g*), and the lingua (*), according to Savigny's observations, forms a short trifid process within the cavity of the mouth, at the base of the maxillæ, the covering or sheath to the parts being formed, as in the other species, by the labium.

In Homoptera, which are considered by many naturalists as constituting only a division of the Hemiptera, the general form of the head is that of a triangle, the lateral and basilar angles of which are occupied by the protuberant corneæ. In the *Cicadiidæ* the epicranium is short but exceedingly wide, bearing at its sides on distinct pedicles the large projecting corneæ similar to the pedunculated eyes of *Diopsis*, one of the Diptera. The epicranial suture is most distinctly marked. It passes outwards from the middle line on each side behind a large, convex, transversely striated protuberance on the front, which is the proper *clypeus posterior*, as far as the base of the pedunculated corneæ, where the antennæ are inserted immediately in front of it. The *ocelli*, three in number, arranged in a triangle, are placed on the most vertical part of the epicranium, and the suture passes through the anterior one. The clypeus anterior is a short triangular plate, united by suture to the anterior margin of the clypeus posterior. It has usually been described as the labrum. The proper *labrum* is a small pointed corneous plate, which covers the base of the proboscis in front, and is freely articulated to the margin of the clypeus. It has been figured by Messrs. Kirby and Spence* as an appendage to the labrum *(appendicula)*, which, as just shown, is the clypeus anterior. It is often partially concealed beneath the clypeus. The mandibles and maxillæ are usually strong corneous setæ, contained within the sheath formed by the labium. At the base of the maxillæ, concealed by the labium, are two short membranaceous appendages, which are probably the rudimentary maxillary palpi. They are attached to the external under surface of the maxillæ, and are entirely concealed by the labium. In the *Fulgoridæ*, as in *Fulgora candelaria*, the epicranial region constitutes the greater portion of the head. The large curved process or horn on the front is derived entirely from the epicranium. The *corneæ*, which are remarkably protuberant, are included within the same region at the sides of the head, as also are the two *ocelli*, which are placed one on each side immediately before the corneæ. The *antennæ* present a remarkable character, being formed of three short thick joints, terminated by a minute setaceous one. The third joint, which is nearly globular, is covered with minute protuberances, somewhat resembling the structure of the corneæ, or rather that of the antennæ in the males of *Eucera longicornis*. These organs are situated in deep fossæ, into which the triangular suture enters. The clypeus posterior forms the chief portion of the front, as in the preceding family, the clypeus anterior a narrow plate united to the latter by suture, and the labrum a small triangular appendage.

* Introduct. vol. iii. pl. 6, fig. 7, *a*.

We have entered thus minutely into an examination of the parts of the head and mouth in the different orders of insects, in consequence of the uncertainty which has hitherto existed among naturalists with regard to the number of segments of which the head is normally composed, and also because it was necessary that we should first show the analogous parts of the head in the different orders before stating our opinions with regard to the manner in which they are developed; and further, because from the minuteness of the subjects and consequent difficulty of investigation, the most ample elucidation was necessary upon which to base our opinions.

In our examination of the remaining parts of the skeleton the same minuteness will be of less consequence, because the parts are more easily examined, and have already been identified through the excellent and elaborate investigations of Audouin, Macleay, and others.

Developement of the head.—We have seen in our examination of the perfect insect, that the head is normally composed of four, and apparently even of five sub-segments, as is proved by the existence of the parts we have described, which correspond to the superior and inferior arches of that number. The first, or most anterior of these sub-segments, is formed by the labrum above and the ligula below; the second, by the clypeus anterior and the mentum; the third, by the clypeus posterior and submentum. But the fourth, which has become entirely atrophied, is represented above only by the little bones of the antennæ, within the cranium, and perhaps also the corneæ; and below by that reduplicature of tegument which forms in some insects, as in Hydrous, the large transverse bone, or ridge between the submentum and anterior margin of the gula; while the fifth is formed by the epicranial region above, and the gula and broad basilar region below, the greater size of this sub-segment being the result of its confluence with the preceding one, the fourth, which has disappeared. The number and position of these parts are precisely similar in the larva and the perfect insect, as seen in Coleoptera, Hymenoptera, and the vermiform larvæ of Diptera. In each of these instances the greater or less distinctness of the parts is in an inverse ratio to the more or less perfect organization of the individual. Thus, if we take, for example, the head of the larva of the common Chaffer-beetle, *Melolontha*, the first, second, third, and fifth sub-segments are very distinct, and the antennæ, inserted at the angles of a strongly marked triangular suture, indicate the situation of the fourth atrophied sub-segment. But in the perfect beetle, as we have formerly seen, not only have all these separate parts of the larva become confluent, but their previous existence as distinct pieces is scarcely to be detected. A similar condition of parts exists in the heads of other Coleoptera. The disappearance of one segment of the head thus early in the larva state is in perfect accordance with that progressive developement which we know takes place in every part of the body, and hence it was to be expected, that those parts in which the changes first occur are those which first entirely disappear. Hence the disappearance of the fourth subsegment, which we believe exists in the earliest stages of the larva, and of which the antennæ are the superior appendages. If we turn from this transitory larva state of the insect to the permanent vermiform condition of the Annelida, the lower Articulata, we find in the common *Nereis* a condition of the head apparently analogous to that of the vermiform larva. It is elongated forwards, and formed of distinct segments, of which the posterior ones, as in insects, support the organs of vision. But these remarks on the relations of the different parts of the head are offered with much hesitation, because, in Myriapods, which have usually been compared with the larvæ of insects, the form of the head seems to be opposed to this mode of viewing its development in Articulata, since the antennæ and organs of vision are situated on the most anterior part of a large and broad shield, which has been considered the first segment. But if this be correct, it will be difficult to explain the circumstance of the antennæ and corneæ of hexapodous insects being constantly situated posteriorly to the first three sub-segments of the head, the labrum and clypei.

The appendages of the head, which form part of the organs of manducation, correspond in number to the number of sub-segments. These parts are analogous to those which constitute the organs of locomotion, when attached to other segments of the body, as in Myriapoda, and Crustacea. In the head of an insect the mandibles are the proper appendages of the fifth or basilar sub-segment, while a small but freely articulated lobe, which sometimes exists, as in some of the *Brachelytra*, at the inner side of the mandible, appears to represent that of the fourth. The stipes, or external portion of the maxilla, which at its base articulates with the cardo, and at its distal extremity is connected with the palpus, seems to be the proper appendage of the submentum, while the inner portion of the maxilla, which originally appears to be a distinct part, and which at its distal extremity supports the galea, seems to be the proper appendage of the second sub-segment, and the labial palpi in like manner represent those of the ligula or first. It has been shewn by Savigny and others, that these analogues of the organs of locomotion undergo a very gradual change of form and use in the different classes. In Myriapoda the appendages that belong to the basilar segment of the head, which constitute the mandibles, are greatly enlarged, and are directed forwards as organs of prehension, like the chelate organs of Crustacea and Arachnida, but are jointed and retain the exact form of true legs. In insects the mandibles are in like manner directed forwards, and are placed above those of the preceding segments, but are compressed, and materially altered in size and shape, their terminal portions, the tarsal joints, being undeveloped, and the tibia alone enormously enlarged, constituting the whole jaw or manducatory organ, while the basilar joints, the femur and coxa, are lost in the under surface of the segment, with which they have become confluent. That this is really the case is proved by the fact that all the muscles that belong to these powerful organs are attached to the basilar and postero-lateral parts of the head, in the very situations which they must have occupied had the organs remained free for the purposes of locomotion or prehension, as in Crustacea, Arachnida, or Myriapoda. That this confluence of parts has in reality taken place is further proved by the circumstance, that the outlines of the portions that become united with the skull are distinctly marked in *Lucanus cervus*, and still more clearly in that of the great Hydröus (*fig.* 369, o). There is a remarkable illustration of the principle upon which the change of form in the adaptation of these organs to a new function depends, in that curious instance of monstrosity in an individual of *Geotrupes stercorarius*, described in a former page (860), in which the tibiæ of the pro-thoracic legs have been arrested in their development, and are lunated like the proper mandibles, the tarsi being entirely absent. In a remarkable insect, *Onitis aygulus*, to which our attention was directed by Mr. Shuckard, there is a further illustration of this principle, in the permanent condition of the pro-thoracic legs of that species, in which the tarsi are entirely absent, and the tibiæ are lunated and terminated each by a sharp hook. There is also a similar condition of the same parts in other species, *O. Olivierii*, *O. serripes*, and *O. chinensis* and *Apelles*, while in a species of a neighbouring genus, *Bubos bison*, the tibiæ are considerably narrower than in the preceding, and approach much nearer in shape to the instance of monstrosity in *Geotrupes*, thus distinctly indicating, not only that the form of parts depends either upon excessive or deficient developement, but also that the abnormal conditions occasionally met with in some species are permanent normal conditions in others.

From the manner in which the appendages of the cranial sub-segments are arranged to form the parts of the mouth, it necessarily follows that the most posterior pair, the mandibles, are carried upwards, and become the superior lateral organs; while the maxillæ obtain the next place beneath them, and the whole are covered in by the inferior arches of their respective sub-segments, which constitute the labium.

In all insects, the whole of the parts of the head in the perfect individual exist in the head of the larva, the changes which take place being only those of size and relative position. When the head of the larva is smaller than that of the future imago, as in the Hymenoptera, its increase of size just before the insect changes into a nymph, and when a great portion of the head is found beneath the skin of the second segment, does not depend upon its having become confluent or united with a portion of that segment, but upon the development of those parts which already existed in it in the larva, so that the diminution which the second or prothoracic segment undergoes is simply an atrophied condition, which results from the developement of the adjoining parts, and not from an actual union or coalescence with them; since in every instance in which a part becomes confluent with an adjoining one, it loses its distinctness of form and character, and does not remain free as when simply atrophied, or arrested in its developement. But when the head of the perfect insect is smaller than that of the larva, as in the Lepidoptera, the extent of the pro-thoracic segment is not diminished, unless encroached upon from behind by the enlargement of the meso-thorax.

The thorax is that region of the body which immediately follows the head, and bears all the organs of locomotion in the perfect insect. It is always composed of three very distinct segments, first, the *pro-thorax*, which bears the first pair of legs; second, the *meso-thorax*, which bears the first pair of wings and second pair of legs; and third, the *meta-thorax*, which bears the second pair of wings and third pair of legs. Besides these segments, which are analogous to the second, third, and fourth in the larva state, there is also another, the fifth segment of the larva, which enters in part into the composition of the thorax of the perfect insect, and forms its connexion with the abdominal region. We have already alluded to this in our account of the changes of the larva, (p. 877, 8,) during which we have shewn that at least one segment of the body always becomes atrophied, and very frequently almost disappears, and that this segment is the fifth. But we have not there sufficiently explained that this segment belongs partly to the thoracic and to the abdominal regions, on which account we propose to designate it the *thoracico-abdominal* segment, and consequently the number of segments of which the abdomen is composed will depend upon whether or not we include this in that region. For our own parts we prefer to consider it as forming a most distinct part, for reasons which we shall presently explain. Now it has been shewn by M. Audouin, in an admirable and elaborate series of investigations, that each segment of the thorax is normally composed of four sub-segments, which sub-segments or annuli are each formed of distinct parts, one upper or dorsal, one lower or pectoral, and two lateral. The four annuli thus formed are easily demonstrable on the upper surface of each thoracic segment, but are less readily detected on the pectoral or under surface, in consequence of the parts having there become confluent, in order to afford a greater degree of solidity to the skeleton; and in consequence also of the diminished extent of the pectoral as compared with the dorsal surface, which, as before explained, (page 877,) is dependent upon the greater extent of change that takes place on the pectoral than on the dorsal surface during the metamorphoses of the insect. The parts capable of demonstration in each segment, according to the views of Audouin, are, on the upper or dorsal surface, the *præscutum*, *scutum*, *scutellum*, and *post-scutellum*; on the inferior or pectoral surface a single piece, the *sternum*, and on the lateral two pieces, the *episternum* and *epimeron* on each side; in addition to which there are also two evanescent pieces, which are of considerable size in some species, but scarcely distinguishable in others. These are the *paraptera*, portions of the thorax not articulating with the sternum, but with the episternum, anterior to each wing, and the *trochantin*, articulating with the epimeron and coxa of the leg, the paraptera of the pro-thorax being, according to Audouin, absent. Hence the number of pieces he describes as forming the external thorax are ten for the pro-thorax, twelve for the meso-thorax, and a like number for the meta-thorax, making in all thirty-four pieces. These are parts capable of being demonstrated, if we regard each sternum as formed of two transverse pieces united, and corresponding to the episterna and epimera. But as remarked by Mr. Macleay,* each sternum at the maximum of development ought to be regarded, like the dorsal surface of each segment, as composed of four transverse sub-segments united longitudinally, and the sides of the same number. If then the four portions on the dorsal surface of each segment, and the sternum on the under, be also divided in the median line, the number of pieces in the thorax will amount to seventy-two. But this number, as Mr. Macleay has well remarked, can never appear together in any insect, owing to the great extent to which some parts are developed, and the consequent atrophy of others. At the same time it must be observed, that if we adopt this, which appears to be the correct theoretical mode of considering the subject, the number of pieces which enter into the composition of the thorax is in reality greater than that given by M. Audouin, who has not described any parts belonging to the pro-thorax as analogues of the paraptera of the meso- and meta-thorax, but which we think may be found in a pair of those little detached plates that exist in the articulating membrane between the head and pro-thorax in Coleoptera, and which have been described by Straus Durckheim† as *pièces jugulaires*, and conceived by him to represent the remains of two distinct segments, situated originally between the head and pro-thorax, but which have disappeared during the transformations. But we are more inclined to consider them as detached portions of the pro-thorax than as remains of distinct segments, since we are totally unaware that any such disappearance of segments ever takes place between the head and pro-thorax; the head or first segment of every Coleopterous larva being the proper representative of the head of the perfect insect; and the second segment of the larva being in

* Zoological Journ. vol. i. p. 177.

† Considerations Gén. &c. p. 75.

like manner that of the pro-thorax, the change which takes place between these two segments during the metamorphoses being chiefly a shortening of the sternal surface of the pro-thorax, or second segment, occasioned by a reflexion inwards of a portion of the external tegument, to form the articulation as in other insects. If, therefore, we include the jugular pieces of Straus as the analogues of the paraptera, the external surface of each of the three thoracic segments will be found to consist of twelve primary and readily demonstrable pieces, making in all thirty-six, the number which we believe always enters into the composition of the thorax, as formerly stated by M. Jurine. But it is probable that the parts described by M. Audouin, and recognised by ourselves, are not identical with those of that author, since the scutum of the meso-thorax in Hymenoptera, as will presently be seen, and as formerly pointed out by Mr. Macleay,* is not only divided in the median line, but its two sides are also separated by a deep longitudinal fissure each into two parts, the outermost of which Mr. Macleay designates *parapsides.* This division of the scutum of the meso-thorax, if constant in the other orders, would raise the number of distinct pieces to thirty-eight. M. Audouin, who adopts the name given to these parts by Mr. Macleay, states that although he was previously well acquainted with this division of the scutum in Hymenoptera, he did not assign names to the pieces because he considered them rather as mere divisions of the scutum itself than as distinct parts of the skeleton. The existence of these pieces, therefore, in Hymenoptera, is a circumstance connected with the number and identification of the normal parts of the skeleton, which, it must be acknowledged, offers not a little difficulty, because if it be ultimately found that these, which are so distinct in some genera, the *Chrysididæ*, be in reality normal parts of the mesothorax which are thus shown to exist as such only by this segment being developed to its maximum extent in this Order, it must be admitted that they also exist primarily in all other insects, not merely in the mesothorax, but in the pro- and metathorax, so that the dorsal surface of each thoracic segment must be regarded as formed not of four but of sixteen parts, the præscutum, scutellum, and post-scutellum being each divided in the same manner as the scutum into four pieces, first by a median line into two halves, and these again divided laterally into two others. The two middle pieces would then constitute the *notum*, or dorsal surface of each segment, and the two lateral the *parapsides.* An equal number of parts must then be recognised as entering into the formation of the ventral arch of each segment. Each middle or sternal piece, formed of four consecutive pieces, analogous to those of the dorsal arch, and divided in the median line, would correspond to the middle series of dorsal pieces, the proper *notum*, and a like number on each side of the sternum would correspond to the lateral portions of the dorsal arch, the parapsides. Of these lateral pieces of the ventral arch, three are already known in each segment, as we shall presently find, the *parapteron*, *episternum*, and *epimeron.* But since there has never yet been actually found even an approximation to this multitude of pieces in the dorsal surface or arch of the thorax, we prefer for the present to follow the views of M. Audouin, and with him to regard the parapsides as only detached portions of the scutum in Hymenoptera, in which the development of the mesothorax is carried to its greatest extent. It must be acknowledged, however, that in admitting the parapsides to be only detached portions of the scutum, and not primary parts, the same thing may be urged with regard to some of those which, according to M. Audouin's views, are believed to be normal structures. But this objection seems to be replied to by the fact that the pieces described by M. Audouin are almost always found to exist most distinctly marked, whether developed to a greater or less extent, in the generality of insects. Thirty-six, therefore, we regard as the number of the distinct external parts of the thorax. Yet even this is more than has been recognized by others who have attended to this subject. Thus Knoch describes only twelve, Chabrier and Burmeister, eighteen; Kirby and Spence, twenty; Straus Durckheim, twenty-two; and Macleay, fifty-four. But whatever be considered the exact number, they are never all distinctly developed in every insect, owing to the causes before explained with reference to the greater developement of some parts than of others, although some trace of the existence of the atrophied pieces usually remains. It is owing, also, to the same causes, that the actual position of the parts becomes altered in different insects, although their relative position continues the same.

Very much confusion has arisen in the descriptions of the parts of the thorax, in consequence of various authors applying different names to the same parts in different insects, and also from the uncertainty which, as above shewn, exists in the opinions of authors with regard to the exact number of pieces that enter into the composition of the thorax. In order, therefore, to obviate as much as possible this serious inconvenience and difficulty in recognizing the parts, we shall add a table of the names given to them by Audouin, with references to the delineations of them by that author, and also the synonyms used by other writers. In doing this we shall also adopt Burmeister's very convenient names for the upper and under surface of each thoracic segment, which are equally simple, and distinctive of the parts to which they are applied.

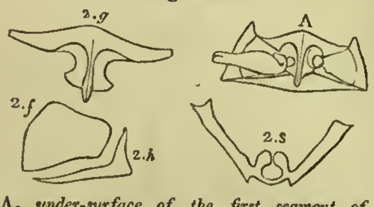
						Post-furca, *Macleay*; Ento-thorax, *Audouin*; Apophyse epistern post, *Straus*	

The *pro-thorax*, as we have stated, is composed of four sub-segments, which on its upper surface, or *pro-notum*, are generally confluent, more particularly in Coleoptera, and form a smooth, uniform, and often very broad surface. In shape, the pro-notum is usually more or less quadrate and convex, with its sides arched and dilated. In many species, as in some families of Coleoptera, Orthoptera, and Homoptera, the pro-notum is larger than the corresponding part of any segment of the body, being considerably broader and longer than the head. This is the case more especially in those insects which are much employed in burrowing, as in *Gryllotalpa*, *Geotrupidæ*, *Copridæ*, and *Silphidæ*. Sometimes, as in the *Cercopidæ*, it is enormously enlarged. In *Membracis foliata* it is developed in the median line into an elevated crest like that of a helmet, which is not only extended forwards so as completely to conceal the head, but also laterally and backwards over the whole body. In others of the same family, as in *Ledra*, it resembles an acute triangle, its sides being developed into two obtuse processes, while it is elongated backwards like an acute spine, which completely covers the abdomen. In other instances, as in *Dynastidæ*, (*fig.* 333,) it is developed into a strong horn or process, which is as long as the whole body. In each of these instances, the abnormal form and size depend either upon the excessive development of the whole of the sub-segments, as in *Gryllotalpa*, or upon one or more of them, as in *Dynastes*, since in those species in which the parts of the pro-notum are all nearly equally developed, and are of moderate size, their lines of separation are very distinctly marked, as in the common green grasshopper, *Acrida viridissima*. The *pro-sternum*, or under surface of the pro-thorax, is considerably shorter than the pro-notum. In *Dyticus circumflexus* (*fig.* 384 A), the species selected by Audouin

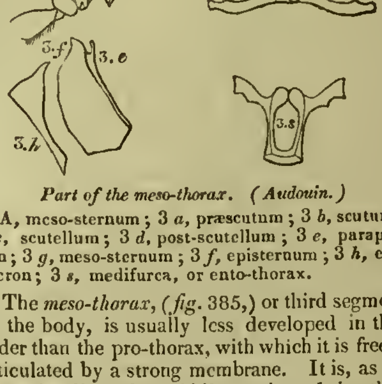
Fig. 384.



A, under-surface of the first segment of the thorax or pro-sternum of Dyticus circumflexus, (Audouin); 2 *g*, pro-sternum; 2 *f*, episternum; 2 *h*, epimeron; 2 *s*, ante-furca or ento-thorax.

for the purpose of illustrating the anatomy of the thorax in Coleoptera, it is divided into three distinct pieces. The *sternum*, or largest piece, (2 *g*,) is situated in the middle line, and is of a triangular form. It is extended on each side, at the anterior part of the segment, into two processes, which articulate at their extremities by a distinct suture with the produced margins of the pro-notum. Posteriorly to these it is developed in the median line into a spine or crest, on each side of which it is hollowed out to form part of the *acetabula*, into which the coxæ of the anterior legs are inserted. External to each acetabulum is a broad and somewhat triangular-shaped plate, the *episternum* (2 *f*). This part is united by suture at its anterior margin to the extended part of the sternum, by its superior border to the dilated margin of the pro-notum, and by its posterior to the *epimeron*. It is a very distinct piece, and does not enter at all into the formation of the acetabulum, as it appears to do on a cursory examination. The third piece, the *epimeron* (2 *h*), is that which is always connected with the *coxa*, or basial joint of the leg. In this species it is a narrow plate, situated posteriorly to the episternum, and forms the posterior margin of the sternal surface of the pro-thorax. At its sternal end it has a short process, that forms the outer margin of the acetabulum, and articulates both with the sternum and episternum. It is probable that a portion of this process is the proper *trochantin* of the leg on each side, since the part, which has been described by Audouin as the trochantin in the meso- and meta-thoracic segments, has not been delineated in his drawing of the pro-thoracic. In *Dyticus marginalis* there is a mark upon the process which resembles a suture, and which still further induces us to believe that this part is the analogue of the trochantin. Within the cavity of the pro-thorax, extending upwards from their attachment to the pro-sternum, are two bony rami, which at their inferior extremity are developed into two rounded plates (2 *s*), that form a collar, or leave a circular hole between them for the passage of the spinal cord. They constitute the *ante-furca*, the *ento-thorax* of Audouin. These are the parts that enter into the formation of the pro-thorax, exclusive of the anterior pair of legs, the only appendages of this segment.

Fig. 385.

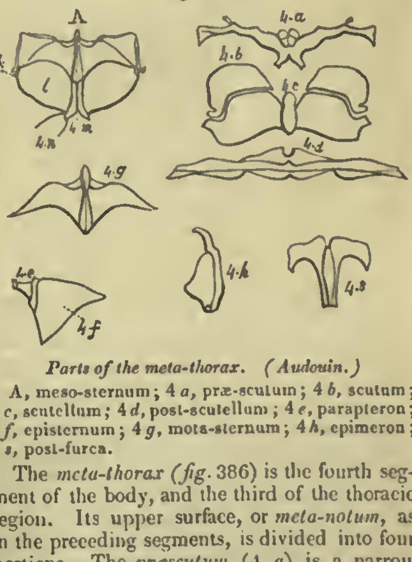


Part of the meso-thorax. (Audouin.)

A, meso-sternum; 3 *a*, præscutum; 3 *b*, scutum; 3 *c*, scutellum; 3 *d*, post-scutellum; 3 *e*, parapteron; 3 *g*, meso-sternum; 3 *f*, episternum; 3 *h*, epimeron; 3 *s*, medifurca, or ento-thorax.

The *meso-thorax*, (*fig.* 385,) or third segment of the body, is usually less developed in this order than the pro-thorax, with which it is freely articulated by a strong membrane. It is, as its name implies, the middle portion of the thorax, and in most instances its division into four sub-segments is distinctly marked on its dorsal surface, or *meso-notum*. It is the segment that bears the elytra and middle pair of legs. The first piece, the *præscutum* (3 *a*), is in general narrow and transverse; it is very readily overlooked, being in most cases bent downwards to form the *meso-phragma*, the anterior boundary of the segment. The second piece, the *scutum* (3 *b*), is a much broader and very distinct corneous plate, and may be regarded, perhaps, as the most important division of the meso-notum, since it is to this that the anterior pair of wings, the elytra, are articulated. It is followed by the *scutellum* (3 *c*), which also is a very important division. Like the scutum it is a broad piece, that covers the posterior part of the meso-notum, and extends on each side to the base of the elytra, the *alulæ*, which are continuous with them, being attached to its margin. It is developed in the middle line into a remarkable elevated plate, that is shaped like an armorial shield, and is so exceedingly large in some species, that it covers nearly the whole of the body. In *Dyticus*, and most of the Coleoptera, it is the small triangular plate which is situated between the elytra, at their base, and is supposed to be of use in keeping these organs steady during flight. The fourth and last piece of the meso-notum, the *post-scutellum* (3 *d*), like the præ-scutum, is narrow and inconspicuous. It is situated immediately behind the scutellum, and is the posterior boundary of the meso-notum. These parts together form the dorsal surface of the first wing-bearing segment, which is developed to as great an extent on its under as on its upper surface. The meso-notum is most fully developed in those insects in which the anterior pair of wings are the largest, as in the Lepidoptera, Hymenoptera, and Diptera, while in those in which the chief organs of flight are the posterior wings, as in the Coleoptera, it is the smallest of the three thoracic segments. The *meso-sternum (fig.* 385, A), like the pro-sternum, is formed by a strong middle piece, the proper sternum of the segment, (3 *g*,) which is developed laterally into two processes, behind which the coxæ of the middle pair of legs are articulated, and anteriorly and laterally the episterna (3 *f*) and epimera (3 *h*). Each *episternal* piece is a broad elongated plate, which forms the anterior part of the meso-sternum. It is attached to the anterior margin of the lateral sternal process, so that its actual position is a little altered, the corresponding part of the pro-thoracic segment being situated behind the process of the sternal piece. This is a circumstance which occasionally takes place in the development of every part of the skeleton, the actual position of one part being altered by the greater or less developement of another, while the relative position of each part always continues the same. Thus, although the episternum is situated more anteriorly in the meso- than in the pro-sternal surface, it still continues to be articulated with the sternum. The epimeron (3 *h*) is situated behind the episternum. It is a narrow elongated plate, that forms the posterior portion of the meso-thorax, and is united to the anterior of the meta-thorax. At its superior extremity it is much broader than at its inferior, which is articulated with the extremity of the sternal process, and also with the coxæ of the middle legs. At the anterior border of the episternum there is a very narrow but distinct plate, the *parapteron* (3 *e*). This piece, which is connected especially with the wings, undergoes a great change of form and size in the different orders. In the Coleoptera it is narrow and evanescent, but as we shall hereafter see, is largely developed in the Lepidoptera. It is evidently a normal portion of the skeleton, but has only been described by Audouin as found in the meso- and meta-thoracic segments. We have before alluded to the existence of two detached pieces in the connecting membrane of the pro-thorax and head, which we regard as the analogues of these pieces of the meso- and meta-thorax. If this be correct, the relative position of these to the other parts of the pro-sternum is precisely similar to that of the same parts of the meso-sternum. The *medifurca*, (3 *s*,) or ento-thorax of this segment, is attached to the internal surface of the sternal piece, as in the pro-thorax. It is formed by two ascending rami, which are larger and longer than those of the pro-thorax, but like them are developed into two expanded portions, which are approximated together and form an arch, under which the nervous cord passes in its course to the meta-thorax.

Fig. 386.



Parts of the meta-thorax. (*Audouin.*)

A, meso-sternum; 4 *a*, præ-scutum; 4 *b*, scutum; 4 *c*, scutellum; 4 *d*, post-scutellum; 4 *e*, parapteron; 4 *f*, episternum; 4 *g*, meta-sternum; 4 *h*, epimeron; 4 *s*, post-furca.

The *meta-thorax (fig.* 386) is the fourth segment of the body, and the third of the thoracic region. Its upper surface, or *meta-notum*, as in the preceding segments, is divided into four portions. The *præscutum* (4 *a*) is a narrow transverse plate, which is bent down at its anterior margin like the præscutum of the meso-notum, to form the meta-phragma, and is extended on each side as far as the paraptera, bounding the insertion of the wings. In the middle line it is extended backwards upon the dorsal surface as far as the scutellum, thus dividing into two parts the second piece, the *scutum*, (4 *b*,) which, like the corresponding part of the meso-notum, is connected with the wings of the segment. This connexion is the great characteristic of the scutum in all insects. The next piece, the *scutellum*, (4 *c*,) is a much broader plate, and is extended across the whole surface of the meta-notum. Like the corresponding piece of the meso-notum, it bears on the middle line an excavated shield-shaped plate, and is connected at its external margin with the borders of the wings. The last piece, the *post-scutellum*, (4 *d*,) which, although narrow like the præscutum, is a strong horny plate that extends on each side, and like the scutellum, is connected with the wings. Its posterior margin is bent down to assist in forming the division between the thorax and abdomen, and is connected with the remains of the atrophied fifth segment. The *meta-sternum* (A) is frequently the most developed portion of the meta-thorax, particularly in those insects which, as Audouin has observed, are especially walkers. In *Dyticus*, the middle piece, the proper *sternum* (4 *g*), is a smooth expanded plate, which is produced at its anterior part into a spine, that articulates with the emarginated extremity of the crest of the meso-sternum. On each side of the spine it is developed into a broad, smooth, triangular plate, to the anterior border of which is articulated the episternum, (4 *f*,) also of a triangular form. This piece occupies the anterior lateral region of the meta-sternum, and the *parapteron*, (4 *e*,) which is situated immediately beneath the insertion of the wing, is articulated with its superior border. The *epimeron* (4 *h*) of this segment is exceedingly small, and appears at first to be removed from its proper situation, being carried upwards to the side of the body by the enormously expanded *coxa* (*l*). But although removed from its usual situation, and reduced in size, it still retains its characteristic distinction, that of articulating with the coxa, and also with the *trochantin* (?), (*k*,) which, although minute, is in connexion both with the coxa and epimeron. The *meta-furca*, or ento-thorax of this segment, (4 *s*,) is an exceedingly large and important piece, shaped like the letter Y. It is attached at its posterior extremity to a thin vertical plate, which is situated between the united coxæ of the legs of this segment, and it is also articulated with the posterior part of the internal surface of the meta-sternum. From this attachment it is extended upwards and forwards into the middle of the meta-thorax, where it is expanded on each side into two broad curved plates, to which the muscles of the posterior legs are attached. In the middle line it is grooved, and at its anterior part forms a partially covered canal, along which the nervous cord is transmitted in its course to the abdomen. Besides the parts now described, there are also two curved plates reflected inwards from the posterior margin of the meta-sternum, where it is articulated with the coxæ, and also one central vertical one, which arises in the median line from the interior surface of the sternum, and which appears to be the proper interior sternal ridge. Each of the posterior coxæ is also furnished with a broad plate, which is situated within the meta-thorax, on each side of the attachment of the post-furca. These parts afford attachments for the muscles of the legs.

Fig. 387.

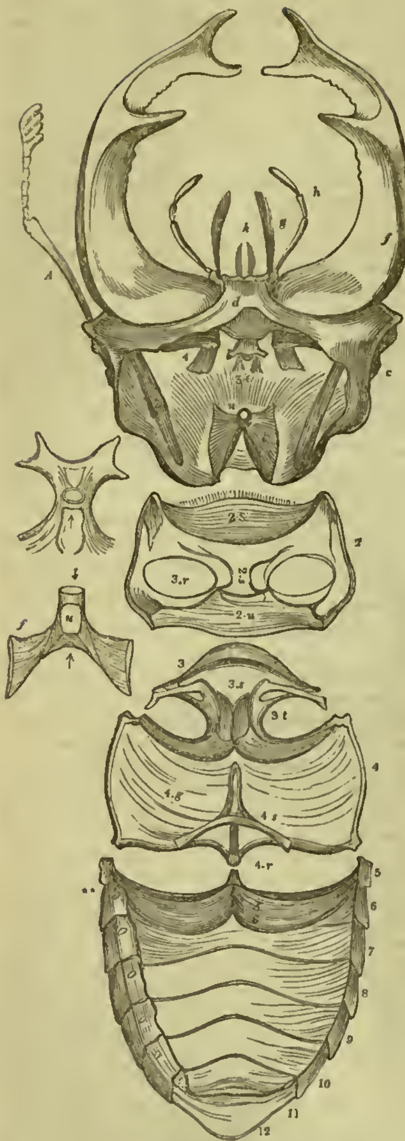
notum; 3 *a*, præscutum; 3 *b*, scutum; 3 *c*, scutellum; 3 *d*, post-scutellum; *meso-sternum*; 3 *g*, sternum; 3 *h*, episternum; 3 *f*, epimeron; 3 *i*, crest of the meso-sternum; 3 *e*, parapteron; 3 *k*, trochantin; 4, *meta-notum*; 4 *a*, præscutum; 4 *b*, scutum; 4 *c*, scutellum; 4 *d*, post-scutellum; 4 *e*, parapteron; *meta-sternum*; 4 *f*, episternum; 4 *g*, meta-sternum; 4 *h*, epimeron; 4 *i*, crest of meta-sternum; 4 *k*, trochantin (?); 4 *l*, coxa; 4*m*, trochanter; 4 *n*, femur; *o*, tibia; *p*, tarsus; *q*, unguis.

These segments constitute the proper thorax of the insect, and the parts we have described are found in nearly all the Coleoptera, the most perfect species; although, as before stated, they are sometimes greatly modified in shape, and varied in size and position, in order that the body of the insect may be adapted to its peculiar habits. Thus in the great water-beetle, *Hydröus piceus*, (*fig.* 387,) which in its general appearance and mode of life very nearly resembles the *Dyticus*, and not only burrows deeper into the mud at the bottom of stagnant waters, but is also accustomed to float among the weeds on the surface to bask in the sun, the form of the sternum is admirably adapted to its habits. The sterna of the meso-thorax and meta-thorax are not only both armed with a strong keel like a boat, but the two are firmly articulated together, which enables the insect more securely to float on the surface of the water, and thus afford additional strength to its whole body for the accomplishment of its object. But in the *Dyticus*, to which it is of the utmost consequence to be able to swim with the greatest rapidity, and turn with facility in the water, in the pursuit of its living prey, the pro-sternum and meso-sternum only are slightly keeled, while the meta-sternum is smooth, and the sides of the body are acute, and offer the least possible resistance to its movements. In addition to this, to afford sufficient strength to the body, together with facility of motion, the sternum of the meta-thorax is produced in front into a short spine, which is inserted into a notch in the posterior part of the meso-sternum; while the coxæ of the posterior pair of legs upon which the chief efforts in swimming depend, although enormously enlarged to afford sufficient space for the insertion of the muscles, are flat and smooth like the rest of the under surface of the body, in order that they may not oppose the slightest impediment to the motions of the insect. The different forms of the coxæ (*l*) and of the acetabula (4 *k*), into which they are inserted, have also a reference to the habits of the species. The large posterior coxæ of the *Dyticus* are immoveably united by suture to the posterior margin of the meta-sternum, because, in this insect, the posterior pair of legs being especially designed for swimming, and their motions consequently being almost wholly in one direction, additional strength is afforded to these organs by the immobility of the coxæ. In the Hydröus, in which all the legs are employed in walking, as well as in swimming, the coxæ are freely articulated in their respective acetabula, and each one is supported in part by the *trochantin* (?), (*k*), which is more developed than in the other insect.

The strength of the body depends much upon the size of the thoracic segments, and the firmness of union which exists between them. Thus in those species which are more especially employed in walking, in flying, or in swimming, the meso- and meta-thoracic segments are the largest. If the insect be aquatic, the largest parts, as we have seen, are the sternal surface of the meta-thorax, and its coxæ; but if, on the contrary, the habits of the insect be aerial, then the dorsal surface of the segment is larger than the sternal. In those insects which are mostly employed on the ground in running or walking, as the *Carabidæ*, *Geotrupidæ*, *Copridæ*, and *Lucanidæ*, the meso- and meta-thoracic segments are often anchylosed together, to give greater strength to the whole body. This is particularly the case in *Lucanus cervus* (*fig.* 388), in which the small sternum of the meso-thorax (3 *g*) is firmly anchyclosed to the enormously enlarged sternum of the meta-thorax. The reason for this is not merely to afford greater stability to the meta-thorax and its wings, upon which entirely devolves the labour of supporting this unwieldy insect during flight, but also to give greater strength to the whole body, during the efforts of the insect to strip off the bark from the smaller roots and branches of trees, to obtain a flow of the juices upon which it subsists. That such is the reason for this anchyclosed condition of its segments is evident from the circumstance, that it occurs not only in those insects which require great muscular power during flight, but also in those which are much accustomed to laborious efforts in tearing, in burrowing, or in running. In these, also, the acetabula (2 *r*, 3 *r*), are exceedingly deep, and almost entirely enclose the coxæ within them, so that while the limb can be rotated freely in almost every direction, a dislocation of it is utterly impossible. The acetabula are situated on each side of the posterior part of the sternum, in each of the three thoracic segments, and in general are formed by an approximation of the sternum and epimeron, and sometimes, also, of the episternum, as in the *Dyticus* (*fig.* 384, A). When, as in this instance, the episternum enters largely into the formation of the acetabulum, the epimeron is carried backwards, and forms the postero-lateral boundary, the episternum the antero-lateral, and the sternum the anterior boundary, so that the acetabulum is formed by the junction of three articulating sutures, and completely surrounds the coxa. This consolidation of parts gives an amazing increase of strength to the segment in which it occurs, and is one of the circumstances which enables the insect to exert a degree of muscular power which is sometimes truly astonishing. It occurs in general in the pro-thoracic segment, as in *Lucanus*, (388, 2,) *Geotrupes*, *Ateuchus*, and other *Lamellicornes*. A similar condition of the acetabula of the meso-thorax exists also in the same insect (3 *r*). But instead of the posterior wall of the cavity being formed by the epi-

Fig. 388.



Internal skeleton of Lucanus cervus.

meron, it is formed by a reflection inwards of part of the anterior margin of the meta-sternum, (4 *q*,) with which the meso-sternum has become anchylosed, and the episternum and epimeron form the lateral boundary of the cavity. The great strength of limb required by insects for other purposes than those of locomotion, belongs especially to the first and second pair of legs, and consequently the articulations of these with the body are required to be most secure. We have seen that in the aquatic insects the posterior pair are almost solely employed in swimming, and in the terrestrial insects they are in like manner employed chiefly in locomotion. The necessity, therefore, for a consolidation of the walls of the acetabula, into which they are inserted, is not so great as in the preceding instances, and consequently we find that those for the posterior pair (4 *r*) are formed by the posterior margin of the expanded meta-sternum in front, and the consolidated margin of the inferior surface of the fifth or thoracico-abdominal segment behind, reflected inwards and upwards, and loosely articulated in the median line with the sternum, thus allowing of the freest motion to the coxæ, the sides of each being formed by the epimeron. But in insects which move with a sudden effort, as in jumping, and in those that employ the hinder legs as prehensile organs, like the *Copridæ, Ateuchi*, and others, these legs, like the anterior ones, are inserted into deep acetabula.

The *abdomen*, or third division of the body, is entirely destitute of organs of locomotion. It contains the chief part of the digestive, respiratory, circulatory, and generative systems, and, like the thorax, is composed of distinct segments. These are nine in number, if the fifth segment of the body, which almost disappears during the change to the perfect state, be included. This segment, however, we prefer to consider as a distinct part, so that the abdomen consists certainly of eight segments, besides the anal appendages. Each segment is formed of one dorsal and one ventral plate, connected at the sides by a distinct membrane. Only five of these plates are in general to be observed on the under surface, but some trace of the whole number is always seen on the upper, and also at the sides (*fig*. 388). This arises from the circumstance that a portion of the ventral surface of the first three segments of the larva is employed in forming the under surface of the anterior part of the abdomen of the perfect insect, the change in Coleoptera, as in other insects, being carried to a greater extent on the under than on the upper surface of the body. One segment, also, the anal one, becomes partly removed from the others at the posterior part, and is retractile within the abdomen, so that there are only five connected segments to the ventral surface, but nine on the upper. The form of the abdomen is in general somewhat triangular or oval in Coleoptera, its basial part being of the same width as the thorax. Each segment is freely moveable, the anterior part of one being retractile within the posterior of another. At the external margin of each dorsal plate, in the membrane that connects those of the upper with the under surface, there is an oval corneous ring, the *spiraculum*, or breathing orifice, which communicates internally with the organs of respiration. In most of the Coleoptera the abdomen is covered by the elytra, but in some species it is exposed, as in the oil-beetles, rove-beetles, and ear-wigs. In the latter instances it is furnished at its extremity with strong forceps, which appear to be analogous to parts which we are about to consider more particularly in other insects.

In Orthoptera the structure of the thorax is similar to that of the Coleoptera, but it is unnecessary to describe it more minutely at present, a greater interest being attached to the whole skeleton of those insects which undergo metamorphoses, more particularly the Hymenoptera and Lepidoptera, than to those in which these interesting changes do not take place.

The structure of the thorax in Hymenoptera merits considerable attention, from the circumstance that it is scarcely yet decided whether it be composed only of three distinct segments of the larva, or whether a fourth one enters in part into the composition of it. We have seen that in the larva state in this order there are fourteen distinct segments, besides an anal tubercle, and that during the transformations the body is constricted in the fifth segment, which seems to form the connexion between the thorax and abdomen. According to the usually received opinions, the true thorax is always composed of but three segments, but M. Audouin believes that this is not strictly the case in Hymenoptera, and has endeavoured to shew that in this order the posterior portion of the thoracic region is part of a segment that belongs to the abdomen. Mr. Macleay, on the contrary, contends* that this is not an additional segment, but is in reality part of the fourth or meta-thoracic segment of the larva. In this opinion he is supported by Burmeister and Westwood, while the views of Audouin are advocated by Latreille and Kirby and Spence.

The *pro-thorax*, which is a large segment in the larva state, is greatly reduced in size in the perfect insect, owing to the operation of causes which take place during the metamorphoses. But it is not so much reduced as in the Lepidoptera and Diptera. The boundaries of this segment in Hymenoptera, like those of the meta-thorax, are a subject of dispute among naturalists, owing to the segment in the perfect state being divided into two distinct parts, the first of which is articulated with the head, and freely moveable upon the other, which is attached firmly to the meso-thorax. The piece articulated with the head is believed by Kirby and Spence to represent the entire pro-thorax, or second segment of the larva. It bears the first pair of legs, and in the winged species is readily detached from the other, which is the *collare* of those authors, who, on account of its being attached to the great meso-thorax, believe it forms a part of that segment. This, as Mr. Macleay has shewn, is not the fact, as is proved by the circumstance that in the Ants and other walking Hymenoptera it is readily removed from the meso-thorax, and is united to the anterior piece, which bears the first pair of legs; while he suggests that the reason for its being attached to the meso-thorax in the flying species, is to give strength to that segment, and support the wings.† We have convinced ourselves of the correctness of this view of the subject by an examination of the parts in *Ichneumon atropos*, (*fig.* 389, 390,) in which the

2, pronotum; 3 *b*, scutum of meso-thorax; 3 *c*, scutellum; 3 *e*, parspteron; *, wing; 4 *b*, scutum of meta-thorax; 4 *d*, frenum; 4 *c*, scutellum; **, spiracle; *l*, coxa.

two pieces are freely separable. The *præ-scutum* and *scutum* of the *pro-notum* are exceedingly short and evanescent, as described by Mr. Macleay in *Polistes*, the præ-scutum being merely a ligamentous membrane that unites this segment to the head. The scutum is a short plate that forms the upper surface of the anterior portion of the segment, the sides being formed, as we shall see, by the epimera and episterna (2 *g*). The posterior piece, the *scutellum*, is of considerable size laterally (2 *h*), but it is short on the upper surface (2), and is deeply notched to fit it to the anterior part of the meso-notum, its two sides being produced into a somewhat triangular shape, and wedged in between the scutum of the meso-thorax and the episternum on each side. The *post-scutellum* exists only as a rudimentary membrane, which assists to mark the proper boundary of the pro-thorax, this being, as Mr. Macleay has observed, one of the proofs that the scutellum now described does not belong to the meso-thorax, while the non-existence of a similar membrane, or *phragma*, between the two portions of the pro-thorax itself, affords an additional reason for considering these but as parts only of one segment.

The *meso-notum* is the most largely developed portion of the thorax in this order, as in Diptera and Lepidoptera. It is a convex elongated plate that covers nearly the whole of the dorsal surface of the thorax. The præ-scutum is a vertical piece, developed inwards to assist in the formation of the pro-phragma that divides the collar from the scutum. The *scutum* (3 *b*) is broad, convex, and lozenge-shaped. At its sides are developed the anterior pair of wings, and at its base, which is slightly truncated, is an elevated *scutellum*. It is marked on the median line by a longitudinal suture, and in some genera by two others, one on each side of this. In the *Chrysididæ*, these lateral markings completely divide the scutum into three distinct pieces, the two outermost of which are those to which Mr. Macleay has given the name of *parapsides*, and which he somewhat curiously suggests may probably be a third pair of paraptera,* those of the prothorax, pushed out of their proper place. But, as remarked by Audouin,† in his notes to Mr. Macleay's paper, were this the case, it would indeed be a most singular displacement; at the same time we are compelled to acknowledge that we hesitate to admit the explanation which M. Audouin has given of the nature of these pieces. He regards them as mere divisions of the scutum, and not as elementary parts. If this be the case, other parts that are considered as distinct pieces may with equal justice be regarded as only occasional divisions of more important ones. They seem rather to indicate the division of the skeleton into a much greater number of parts than are at present recognized in it. We are led to this opinion from the circumstance that these markings exist more or less distinct in very many species. We have found them very distinctly in the dried skeleton of *Bombus terrestris*. The *scutellum* (3 *c*) is of large dimensions in most of the Hymenoptera, and is usually considerably elevated above the level of the scutum. It is in general of a triangular figure, and in many species of this order, as well as in some Diptera, is a marked character of the thorax being often armed with spines. The post-scutellum is not developed externally, but its position is indicated by an elevated ridge, which is extended forwards on each side from the hinder part of the scutellum very nearly to the base of the anterior pair of wings, as in the Diptera and Lepidoptera, and indicates the boundary of the segment. It forms the *meso-phragma*, and as Mr. Macleay has remarked in *Polistes*, is connected with the scutum only at the sides, being deficient in the middle line. The pectoral surface of this segment, the *meso-sternum*, is larger in *Ichneumon Atropos* (*fig.* 390) than in many other species. In form it is nearly quadrate (3 *g*). It covers the whole under surface of the segment, and is divided by a deep fissure into two halves. At its anterior margin it is united by an indistinct suture to a thin plate, the *episternum*, (3 *f*,) that covers the front of this part of the segment, and is almost hidden behind the pro-thoracic legs, and it has sometimes been considered as forming part of that segment. Its lateral portion passes upwards posteriorly to the collar of the prothorax, and forms a process that projects beneath the anterior pair of wings, and above the *epimeron*, (3 *h*,) which is the chief portion of the side of this segment. At its inferior margin this piece is united by an indistinct suture to the sternum, at its anterior to the episternum, and at its posterior it is articulated with the coxa of one of the middle pair of legs.

Fig. 390.

The next segment, the meta-thorax, is an exceedingly interesting portion of the body, owing to the varied extent to which it is developed in the different Orders of Insects; and on account more particularly of the question that has been started, as to whether this portion of the thorax in Hymenoptera is formed entirely by the fourth segment of the larva, or whether a portion of the fifth also enters into the composition of its posterior part, as believed by Audouin and Latreille. According to Mr. Macleay, the first piece of its dorsal surface or meta-notum, the *præ-scutum*, is very distinct in *Polistes*, while the scutum is concealed within the thorax, being developed inwards to form a phragma, only a part of it being visible laterally, but which, as usual, is connected with the posterior pair of wings, a circumstance that invariably characterises the scutum in all insects. In *Ichneumon Atropos*, the *præ-scutum* exists immediately behind the scutellum of the meta-thorax, and covers part of the *scutum*, (4 *b*,) which, although much encroached upon in the median line by the developement backwards of this part and the scutellum of the preceding segments, is a distinct region on each side of the meta-notum, and gives origin to the posterior pair of wings. This sufficiently identifies the part as the proper scutum, otherwise it might be mistaken for the præ-scutum of *Polistes*, which is considerably more developed than in *Ichneumon Atropos*. But the greater part of the scutum is developed inwards, and forms a deep cleft or incision, that divides the segment into two parts transversely, the poste-

* Op. cit. p. 169.

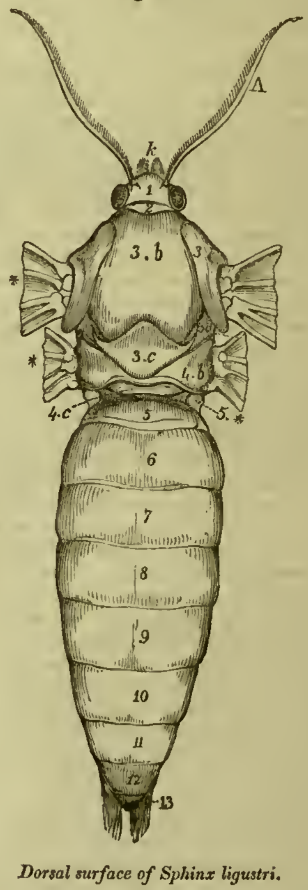
† Annales de Sciences Naturales. 1831.

rior portion of which, according to Mr. Macleay, is the proper scutellum (5) enormously enlarged, while Audouin regards it as being the dorsal surface of the fifth segment of the larva, so that, if the latter opinion be correct, the thorax of Hymenoptera must be composed of four instead of three segments. We must confess that at first we were inclined to Audouin's opinion, more especially on account of what we shall presently find in Lepidoptera, in which the fifth segment, in its atrophied condition, is as much connected with the thorax as with the abdomen. On further examination, however, we are satisfied that that portion of the meta-thorax which is posterior to the incisure belongs to the third segment of the thorax; but we differ from Macleay in regarding it rather as the scutellum and post-scutellum united, than as the scutellum alone. Its proper boundary is marked on each side of the segment by an elevated ridge or frænum, (4 *d*,) which is extended across the incisure from a little behind the insertion of the wings,—where it is continuous with a ridge of the meta-notum,—as far as the posterior margin of the acetabulum for the insertion of the coxa of the leg. The post-scutellum, therefore, may be regarded as having coalesced with the scutellum, and assisted in the enlargement of that part. It is distinct, but of small size in *Polistes*, and is connected at its upper part with a short ligament, or *funiculus*, that is attached to the anterior margin of the sixth segment (6), the first segment of the abdomen, which it assists to support. But we have yet to trace the fifth segment of the larva, which at first appears to be entirely lost. On carefully separating or removing the meta-thoracic coxæ of *Ichneumon Atropos*, we find a very short plate, reduced almost to a ligament, but still distinct as the remains of a separate segment. It is the connecting medium between the under surface of the thorax and abdomen. We regard it as the remains of the ventral plate of the fifth segment, of which the upper or dorsal plate has entirely disappeared, or exists perhaps in an altered form, as the funiculus just alluded to. We are strengthened in this opinion by an examination of several species of *Ichneumonidæ*, although in the generality of Hymenoptera the fifth segment appears to have coalesced with the sixth, to form the petiole or peduncle of the abdomen. The meta-sternum is formed of the same parts as in the preceding segments. The *paraptera* are situated immediately beneath the posterior wings, in the triangular space bounded in front by the epimeron of the preceding segment, and above and behind by the incisure and frænum, (4 *d*,) that connect the scutellum with the scutum. The episternum is concealed by the preceding segments, and the sternum is reduced to a small triangular piece, situated between the coxæ. The *epimeron* (4 *h*) is large, to give attachment to the large coxæ, but the *trochantin* does not exist as a piece distinct from the coxa (*l*), with which it appears to have become united. The meta-thoracic or second pair of *spiracles* (* *) are situated in the anterior lateral parts of the scutellum. The situation of the spiracles has sometimes been considered as indicatory of the different segments, but, as remarked by Mr. Macleay, these parts are unsafe guides, since they exist in certain segments in some species, but not in others, and their situation is often changed during the metamorphoses from the larva to the perfect state. We have seen that the meta-thoracic spiracles of the larva are placed at the most posterior part of the fourth segment, (*fig.* 356,) but in the perfect insect, as we now find, this is not the case. If the situation of these parts were alike in the two states of the insect, there would be no difficulty in identifying the segments of the imago with those of the larva. We believe, however, that the true thorax is formed of the second, third, and fourth segments in all insects, and that the fifth segment, always greatly reduced in size, and sometimes, as in this order, almost entirely atrophied, is not in reality a part of the true thorax, but is sometimes connected more or less with that region, or with the abdomen, being intermediate between the two. Hence we have ventured to designate it the *thoracico-abdominal* segment.

The number of segments in the *abdomen* of perfect Hymenoptera appears on a cursory examination to vary considerably; those in which the abdomen is supported on a pedicle or foot-stalk having fewer than others in which the abdomen is of the same width as the thorax, and the sting or borer of the female is not concealed, as in *Sirex juvencus*. This insect on a cursory inspection seems to have nine segments in the abdomen, besides a very large terminal joint, more than twice as large as any of the others, which is pointed at its extremity, and on the under surface of which is situated the anal aperture. In reality, however, there are but nine segments in this most developed form of abdomen, the tenth being only a large meta-thoracic post-scutellum, which is extended over the base of the abdomen, while the thirteenth and fourteenth segments of the larva, instead of becoming atrophied, as is usually the case in other insects, during the metamorphoses, have coalesced and become enormously enlarged in order to afford sufficient space for the muscles required for the employment of the strong *terebra* or borer with which the insect penetrates the solid timber of living trees to deposit her eggs. In the *Tenthredinidæ*, as in *Allantus scrophulariæ*, there are nine distinct segments besides the post-scutellum, and this is probably the case in *Atholia centifoliæ*, although we can discover but eight distinct ones in that species. We suspect that the last three segments in this insect become united to form the parts connected with the female organs. In the males there is the same number of segments as in the females. This is also the case in *Ichneumon Atropos* (*fig.* 390), in which there are nine distinct segments to the abdomen besides the minute plate at the base of the sixth, the remains of the thoracico-abdominal segment before noticed. In the wasp, hornet, and bee, only six segments are at first evident in the abdomen, which arises from the circumstance that the anal segments, which form part of the organs of generation, are retractile within the abdomen. The sixth segment is concealed, and the seventh and eighth segments, particularly the latter, which is greatly enlarged, form the chief portion of the abdomen. In the common honey-bee there appear at first to be but five segments; but one segment, the sixth, which forms the base of the abdomen, is almost concealed, and the others constitute the sting and retractile organs of generation. In the male or drone two segments are lost in the termination of the male organs of generation. Thus, then, the actual number of the segments is the same in all Hymenoptera, the apparent difference being occasioned by the retraction of one or more segments within those which precede them. To so great an extent is this carried in some species, as in the *Chrysididæ*, that the abdomen at first sight appears to be formed of only four segments, the margin of the posterior being armed with several spines. But even in this family the number of segments is exactly the same as in the Ichneumon above noticed, in which all the segments are apparent. The five last segments are retractile within the abdomen, and when extended form a long jointed tube, which is employed by the insect for the purposes of oviposition. Thus then the ovipositor of the Tubulifera, the sheath of the sting in the Aculeata, and that of the terebra or borer in the Terebrantia, are all derived from the terminal segments of the body. But we have already seen that in the hymenopterous larva there is an additional segment to the body, which from the existence of an *apparently* additional organ in the perfect insect, may reasonably be supposed to be especially connected with the developement of that part. On examination, however, it is discovered that it is not from the fourteenth or terminal segment that the ovipositor, or sting, is entirely derived, but from at least the *two* last segments, the sheath being developed from elongated portions of the thirteenth or penultimate segment, while the fourteenth forms only a short valve at its base, like the extremity of the abdomen in *Sirex*. From these circumstances it is evident that the defensive organs of the aculeate Hymenoptera are simply developments of certain parts only of the sides of the abdominal segments, while the tubulated joints of the ovipositor of the *Chrysididæ*, with which there are many analogies among the Lepidoptera, are the entire segments. It is evident also that although the fourteenth segment is certainly connected with the sting or borer, it does not become its chief part, the sheath of the organ being always formed by parts of the thirteenth and sometimes also of the twelfth segment, so that these organs are simply developements of parts which already exist in all insects. The analogues of the ovipositor are found in the *Panorpidæ* among the Neuroptera, and in the *Bombycidæ* among the Lepidoptera; while those of the other forms of the same part, the terebra and sting, exist in the exserted ovipositors of the female *Gryllidæ* in the Orthoptera, and in the prehensile ones of some of the *Arctiidæ* and other species, in almost every instance the parts being derived from similar segments.

In Lepidoptera the size of the three segments of the thorax is more unequal than in Hymenoptera. The prothorax is reduced to a very thin plate or ring, more especially on its upper surface or pronotum. On the prosternal surface the primary parts, although greatly reduced in size, are still distinguishable. The *prosternum* is a small square piece, which is articulated in front by suture with a part of the anterior of the basal joint of the first pair of legs, and which we are inclined to regard as the *trochantinus* (*fig.* 392, 2 *k*). Immediately above this is a short semicircular piece, which is perhaps the analogue of the epimeron, and which is united by suture to a large broad lunated piece, that forms the greater part of the lateral surface of the prothorax, and is continuous with the narrow ring on the upper surface (*figs.* 391, 392, 2). The meso-notum is enormously developed. The *præscutum* (*fig.* 391)

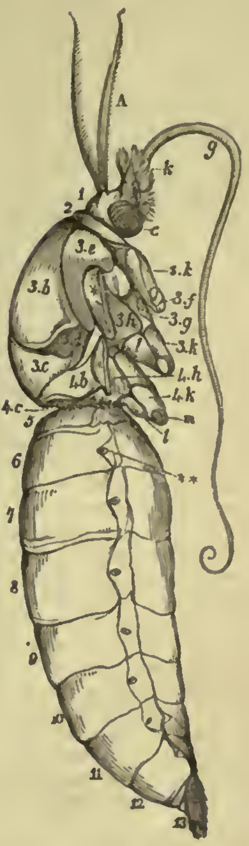
Fig. 391.



Dorsal surface of Sphinx ligustri.

is hidden within the segment and forms the *prophragma*, the anterior boundary of the segment. Laterally it is extended on each side beneath the scutum as far as the anterior boundary of the wings, where it is developed on each side into a little inflated eminence, which we regard as simply an extended portion of the præscutum unto which the *parapteron* is attached (3 *c*). The *scutum* (3 *b*) forms a broad convex plate, marked in the middle line by a raphé. It extends from immediately behind the narrow ring of the pronotum on each side to the insertion of the anterior pair of wings, and from thence backwards to a point opposite to the margin of the posterior pair, thus forming the greater portion of the proper thorax of the insect. It gives attachment on its internal surface to some of the most powerful muscles of the wings, and consequently requires to be more developed than any other part of the thorax. It is separated by a deep triangular suture from the *scutellum* of the mesothorax (3 *c*), which as in Hymenoptera is a large and important part. It forms the lozenge-shaped posterior part of the mesothorax, and if carefully examined its angles are seen to pass under the sides of the scutum, by the enlargement of which it has been carried backwards. The *post-scutellum* (3 *d*) has almost disappeared; a portion only of it is seen on each side at the base of the anterior pair of wings, bounded by an elevated margin, which extends outwards to join a frœnum that is connected with the posterior margin of the anterior pair of wings. Besides these parts, which form the mesonotum, there are also two broad moveable plates, the *paraptera* (3 *e*), that cover the base of the anterior pair of wings. They are called by Kirby and Spence *putagia*, or tippets, and are loosely attached by a part of their concave surface to the little eminences which we have before noticed at the sides of the præscutum. They are broad arched plates, which in form resemble scapulæ, and extend from the anterior part of the scutum, the sides of which they entirely cover as well as the insertion of the first pair of wings. They are always covered with long hairs, and are more developed in Lepidoptera than in any other order. In Coleoptera we saw them placed beneath the wings on the anterior part of the sides of the mesothorax. They were then unimportant organs; in Hymenoptera they were removed to a position above the wing, but in this order they have arrived at their maximum of development, and appear to be of great importance to the insect. The *meso-sternum* in Lepidoptera is a part of very difficult examination, and we are not confident that we have rightly made out the analogies of its different parts with those in other insects. The meso-sternum is greatly reduced in size, while the base of each leg is considerably enlarged. It appears to be formed by an union of the *trochantinus* (*fig.* 392, 3 *k*), and of the *coxa* (*l*), these parts in each limb appearing to be united, and distinguished laterally by a very marked suture. The base of the limbs thus occupies the greater part of the meso-sternal region. The part which we thus regard as the trochantinus is articulated in front with the sternum (3 *g*), and the coxa with the *epimeron* (3 *h*). The *sternum* extends upwards on each side of the segment

Fig. 392.



Lateral surface of Sphinx ligustri.

as far as the upper portion of the epimeron, a little below the insertion of the wings. It is marked transversely by a depression which has the appearance of a suture. At its anterior margin, on the front of the meso-sternum there is a very distinct plate which is united to it by suture, and which appears to be the proper episternal piece (3 *f*). The *spiracle* or *meso-thoracic* stigma is situated in a little fossa immediately beneath the *patagia* on each side before the anterior pair of wings, and communicates with the tracheæ between the pro- and meso-thoracic segments. The *metathorax*, which bears the posterior pair of wings, is considerably reduced in size by the developement backwards of the scutellum of the meso-thorax, which encroaches upon this segment posteriorly, as the scutum anteriorly does upon the prothorax, but not to so great an extent. The præscutum, as in the preceding segment, is concealed within the thorax, being developed inwards to assist with the post-scutellum of the preceding segment in forming the meso-phragma, while only a portion of the *scutum* is visible on each side of the scutellum of the meso-thorax (4 *b*), where it forms a triangular space, from the sides of which originate the second pair of wings (*). It is bounded posteriorly by a short thick ridge, the remains of the scutellum (4 *c*), the extremities of which pass outwards and are connected with the base of the wings. The *post-scutellum* (4 *d*) is also a very short fold, that forms the most posterior part of the true thorax. It is developed inwards and becomes continuous with the remains of the upper portion of the fifth or thoracico-abdominal segment (5). At each side it is connected with the lateral portions of the scutellum, and with it is connected to the base of the posterior wings, and also with a membrane or frænum (5*) that passes from the base of the posterior wings to the posterior margin of the thoracico-abdominal segment, thus clearly indicating the relation which this segment bears to the last segment of the thorax. The *metaphragma* or septum that exists between the thorax and abdomen is formed during the metamorphoses by a constriction in the middle of the fifth segment, and as the changes proceed, a portion of the fourth segment, the post-scutellum, is included in the fold or constriction, and assists to form the *metaphragma*, so that the fifth segment, at least in Lepidoptera, is common both to the thorax and abdomen, and cannot properly be said to belong more especially to one than to the other. Only a short portion of the fifth segment exists on the dorsal surface of the abdomen, posterior to the thorax, while the inferior portion, which was more reduced in extent during the changes than the upper, is reduced to a very short piece, which has entirely coalesced with the under surface of the sixth segment, the first true segment of the abdomen. In the meta-sternal surface there are the same parts developed as in the meso-sternal, the arrangement of all the parts being precisely similar to those of the meso-thorax. The *trochantinus* (4 *k*) is united with the *coxa* (*l*), from which it is distinguished, as in the limbs of the preceding segments, by a lateral suture. The first is articulated anteriorly with the *sternum* (4 *g*), and the second posteriorly with the *epimeron* (4 *h*). The second or meta-thoracic *spiracle* is situated in a deep cavity behind the wings.

The abdomen in Lepidoptera consists of nine distinct segments, or the remnants of that number of the larva if we include the segment which we have thus seen is connected with the thorax. We prefer, however, to consider the fifth as a distinct segment, although a portion of it covers the base of the abdomen. Each segment is formed, as in other insects, of two arches, a superior and an inferior one. The superior one is a strong corneous plate, and is equal to nearly a complete semicircle. The inferior plate is similar in its form, but does not include so large a portion of an arch, and is not so completely solidified. The lateral margins of the inferior arches are nearly straight, but those of the superior ones are emarginated or notched, each notch or incisure being near the middle of the edge. It is occupied by an oval corneous ring, the *stigma* or spiracle which exists in the soft membrane or *conjunctiva* that connects the margins of the superior and inferior arches of the segments. A similar membrane connects the different segments together longitudinally in such a manner that the anterior margin of one segment is drawn beneath the posterior of the one that immediately precedes it. By this arrangement of the parts of the segments the abdomen can be elongated or shortened at the will of the insect, and expanded or contracted during respiration, which takes place in the abdominal as well as in the thoracic region. There are nine *stigmata* or spiracles on each side of the body. Two of these we have seen are situated in the thorax, and the remaining ones in the abdomen, from the sixth to the twelfth segment; but the twelfth is apparently closed, and probably does not take part in the function of respiration, which is carried on chiefly through the thoracic spiracles. It is worthy of note also that there appears to be a change in the situation of one of the spiracles during the transformation of the larva and pupa state. In the larva a spiracle exists in the fifth segment, but this does not seem to be the case in the perfect insect, in which the spiracle is removed forward to the base of the wing in the fourth, a circumstance which is highly interesting from the fact that the wings are directly connected with the organs and function of respiration.

We will not enter further upon an examination of the thorax and abdomen in the different orders, sufficient illustrations having been given of the parts of which they are composed, and of the manner in which they are developed from the almost uniform body of the larva.

3. *Organs of locomotion.—The wings*, the organs of flight in Insects, differ from those of Birds in being supernumerary parts adapted especially for aerial motion, as the legs, the proper organs of progression, are for terrestrial. The wings of Birds are simply modifications of the anterior pair of extremities, which are employed in most other Vertebrata either as organs of prehension or of terrestrial or aquatic locomotion, and form parts of the normal type of the skeleton.* But the wings of Insects have no more analogy with the legs, the proper organs of locomotion, in the invertebrated than in the vertebrated classes. They are derived entirely from the respiratory structures, and have sometimes been aptly designated *aerial gills*. They are expanded portions of the common tegument of the sides of the meso- and meta-thorax, occasioned by the enlargement and extension of numerous tracheæ and the accompanying passages for the circulatory fluids, and their motions are intimately connected with the function of respiration. These tracheæ ramify throughout every part of the wing, and immediately after the assumption by the insect of the imago state become solidified like the rest of the skeleton. They are hollow for the reception of air like the proper respiratory organs within the body,

* See the Article AVES.

They afford strength and lightness to the wings, with which they are in direct communication like the bones in the wings of birds, although the organs themselves in these different classes are not analogous. Dr. Leach formerly designated these solidified tracheæ in the wings of insects *Pterigostia*, or wing bones, a name that seems appropriate, both on account of its convenience and as being indicatory of their principal function, although it has sometimes been objected to as incorrect on account of their forming part of the respiratory system. But it may be remarked that the true bones in the wings of birds also communicate with the respiratory organs, and perform functions similar to these in insects, while the interesting fact noticed by Odier, that in their solidified condition they are composed of the same kind of earthy matter as that which enters into the composition of other parts of the skeleton, is sufficient to warrant us in retaining the designation. There appears to be no part of the body in vertebrata analogous to the wings of insects, except, perhaps, in the single instance of one of the Saurian reptiles, *Draco volans*, in which a pair of supernumerary organs to assist in locomotion are developed from the sides of the body, and which are formed by the ribs, directed horizontally outwards and covered only by the skin. We have thus in appearance the remains in one class of the vertebrata of a condition which is permanent in another class in the invertebrata, which resemble them in their general form and metamorphoses. In every instance, then, the wings of an insect, like these appendages of the thorax in the reptile, are perfectly distinct in their origin from the proper organs of locomotion; they have their normal condition in the lower invertebrata in the superior branchial tufts of the Annelides, and, consequently, are not more analogous to the wing of the Bat, as they have recently been supposed,* than to that of the Bird. We have already seen that the full developement of the wings takes place at the last change of the insect, but it is commenced in the earlier periods of the larva state, in which, with Oken and Carus, we have detected these organs in their most rudimentary condition. They are distinctly seen on the second or third day after the insect has assumed its last larva covering, before changing to the pupa. They are then scarcely so large as the head of a moderate sized pin, and appear like newly-formed folded portions of delicate tegument, extensively supplied with ramifications of minute air-vessels, derived directly from the principal tracheæ. They are at that time situated immediately beneath the external covering, at the inferior part of the sides of the meso- and meta-thoracic segments, and continue to increase in size during the growth of the larva. When the insect has discontinued to feed, about a day before changing into the pupa state, and the new skin of the future pupa is nearly completed beneath that of the larva, these rudiments of the wings have become so much enlarged that their existence is distinctly indicated by the swollen appearance of the segments. It is at this period of the larva state that they were formerly discovered by Swammerdam.* At the moment of fissuring the skin of the larva, they are suddenly somewhat enlarged, and when the skin has been cast off, and the delicate parts of the newly exposed naked pupa are beginning to be agglutinated together and folded upon each other previously to becoming solidified to form the strong pupa case, they again acquire a considerable increase of size, owing to the extension and enlargement of the tracheal vessels within them, together with a corresponding increase in the quantity of the fluids in the circulatory canals, by which they are every where accompanied. The wings are then expanded so as to cover the whole under-surface of the thorax and limbs, and when the insect subsequently bursts from the pupa case and is assuming the perfect state, they are again suddenly enlarged, and acquire their full expansion through the recurrence of similar phenomena.

It is thus evident that the wings are formed from extensive ramifications of vessels inclosed between two membranes, which are continuous with, and are expanded portions of, the common tegument. In many instances, as in Neuroptera, they are perfectly naked, or are covered only with a few scattered hairs, as in Hymenoptera. But in others they are densely covered with peculiar cuticular developments in the form of flattened scales, closely imbricated upon each other, and inserted each by a little footstalk or quill into little spaces in the external membrane.† In other instances, as in the Coleoptera, the anterior pair become solidified and adapted to a new function, but are then entirely useless as organs of flight. They serve as covers to protect the posterior pair, which, in a state of rest, are carefully folded beneath them; and when these are entirely absent, as in some of the *Tenebrionidæ*, the anterior pair become united together and form a strong covering for the abdomen. Now we have seen that the solidification of the tracheæ alone affords sufficient strength to the membranous wings, which are always employed as organs of flight, and that the earthy matter by which they are consolidated is similar to that which is the means of consolidating other parts of the dermo-skeleton. It is by the deposition of a greater quantity of the same kind of earthy matter, not alone in the tracheæ, but throughout the whole substance of the wings, that the anterior pair in Coleoptera are rendered entirely useless, by their rigidity, as organs of flight, and at the same time are made to assume a new form and office, and become the means of protecting the posterior pair, in those insects whose habits might otherwise expose these necessarily light and delicate organs to occasional injury. This modification of structure, then, in the form of *elytra*, consists simply in the solidification, or, if we may venture so to

* Mod. Clas. Ins. vol. i. p. 11.

* Biblia Natura, Tab. xxxv. fig. II. e.

† Dr. Roget's Bridgewater Treatise, vol. i. p. 354.

call it, ossification of the entire organs, and not in any difference in their normal condition. In every instance the anterior pair of wings, or elytra, like the posterior pair, are formed of numerous tracheæ, accompanied by circulatory canals extensively ramifying throughout their whole structure, as may be well seen in the imperfectly solidified wings of Orthoptera and Hemiptera, and in the perfectly formed ones of many of the Coleoptera, although it has sometimes been supposed that the elytra are entirely destitute of these structures.* Excepting in a few instances, as in the Strepsiptera,† the elytra are almost entirely motionless during flight, and are either simply elevated or directed horizontally in order that they may not impede the motions of the true wings. Thus the number and condition of the parts employed in flight are seen to vary in different insects. In Coleoptera the posterior wings alone are actively employed, in Neuroptera and Hymenoptera both the anterior and posterior, but in Hymenoptera the latter are smaller and less important than the former, while in Diptera the posterior are reduced to mere appendages of the atrophied meta-thorax, and the office of flight devolves entirely upon the anterior pair, which are the only ones developed for such purpose. On the other hand, in some species, instead of a reduction in the number of these parts, there is an evident tendency to repetition, as is beautifully shown in the existence of two circular membranous appendages or winglets *(alulæ)* developed at the inner angles of the elytra, and continuous with the delicate membrane that lines the under surface in the great *Hydröus* and the *Dyticidæ*. Similar appendages are observed in the posterior wings of some Lepidoptera and Hymenoptera, and in the proper wings of some Diptera. The non-developement of the posterior wings in Diptera evidently seems to be the natural result of the excessive developement of the meso-thoracic segment, which bears the proper wings, the analogues of the anterior pair in Hymenoptera, and the consequent atrophied condition of the adjoining meta-thoracic segment, from which a posterior pair ought to have been developed. But that all insects, even the Diptera, have primarily the same number of these organs, is exemplified in this order in the existence of a pair of appendages to the meta-thorax, in the form of little club-shaped bodies denominated *haltères* or poisers, and which exist modified in form in every Dipterous insect. In the common gnat they are simple footstalks surmounted by a round knob, attached one on each side of the atrophied meta-thorax. This is their form in the house-fly and many other genera. That these are the proper representatives of the posterior pair of wings is now the opinion of the most recent observers, and is most decidedly confirmed by the results of our own examinations. They are generally more or less concealed beneath the winglets, from which they are perfectly distinct, being always connected with the meta-thorax, while the winglets are attached to the scutellum of the meso-thorax, and in some instances, as in *Tabanus bovinus*, are continuous with the margin of the meso-thoracic wings.

* Westwood, Text Book, p. 283.
† Dale in Curtis's British Entomology, fol. 226.

The articulations of the wings are formed upon the same principles as those of the legs, but are more simple in their construction. Those at the proximal extremity of the cubital nervures, or *pterigostia*, are of a somewhat cotyloid form to allow of free motion in several directions, and often, as in those at the base of the elytra, are furnished with a long spine or process, to which some of the powerful muscles are attached. Those by which the wings are folded beneath the elytra are imperfectly formed ginglymoid joints in the nervures, and seldom allow of motion in more than one direction. In most Coleoptera, as in *Scarabæidæ, Hydrophilidæ*, &c. there is only one of these joints in each wing, but in the *Brachelytra*, in which the wings are closely packed beneath very short covers, there are often so many as four in each wing,* while in other species, as in the *Buprestidæ*, in which the wings are not folded but are only of the length of the abdomen, these joints are entirely absent. In every instance the membranous portions of the wings are either plaited longitudinally or folded transversely when the wings are concealed beneath the elytra.

In the *neuration*, or distribution of the tracheæ in the wings, *pterigostia*, which by the French entomologists are called *nervures*, on a casual inspection there appear to be many remarkable variations. But when the wings are attentively examined, it is found that there is always a great uniformity in the distribution of the principal nervures, and this is so precise and regular in many orders that it has been employed by some naturalists as strongly characterizing different groups. The irregularity which at first is supposed to exist in the distribution of these nervures in some families arises entirely from the greater or less relative enlargement of the principal trunks or their branches. The characters derived from these parts were formerly employed by Frisch in Germany and Harris† in this country, but have of late years been more particularly applied to the classification of Hymenoptera by Jurine,‡ St. Fargeau, and Mr. Shuckard, the first two of whom have founded their arrangements of Hymenoptera upon characters derived almost entirely from these structures, each of which they have designated by a distinct name. Mr. Shuckard, who has studied this subject with much care, gives the following description of the anterior wing in Hymenoptera.§ " The contour of the wing is formed by its anterior, apical, and posterior margins.

* Straus, Considerat., &c. p. 127.
† Exposition of English Insects, 4to. London, 1782.
‡ Nouvelle Méthode de Classes les Hymenoptères et les Dipteres, par L. Jurine, tom. i. 4to. Geneve, 1807.
§ Transactions of the Entomological Society of London, vol. i. p. 209.

The *anterior margin* is that portion which is situated anteriorly upon its expansion in flight, extending from its base to its distinctly visible extremity of the costal nervure, a little beyond the marginal cell; at its termination the *apical margin* commences, and extends to the *sinus* of the wing, which is the incision at the apex of the *posterior margin*, which latter extends from this sinus back to the base, and it is by this margin that the upper and under wings are connected in flight. The *costal* nervure is the first longitudinal nervure of the wing (*fig.* 393, *a*), and, as we have seen, extends

Fig. 393.

Wing of Hymenopterous insect (Shuckard).

a, costal nervure; *d*, post-costal; S, stigma; *e*, externo medial; *f*, anal; *g*, transverso-medial; 1, costal cell; 2, medial; 3, interno-medial; 4, anal; *h*, radial nervure; 5, marginal cell; 6, cubital nervure.

upon the anterior margin to just beyond the extremity of the marginal cell. The second longitudinal nervure is the *post-costal* (*d*); this extends to the *stigma* (*s*), which is that thickened point or spot upon the wing placed upon its anterior margin at about two-thirds the distance of its base and extreme apex, and appears to me to be a dilatation of the costal nervure. The third longitudinal nervure is the *externo-medial* (*e*), which proceeds in a direct line nearly parallel with the preceding for a little more than half the length of the post-costal, or about one-third of the entire length of the wing, and then leads off at an obtuse angle to join the post-costal just before its junction with the stigma. The *anal (f)* is the fourth longitudinal nervure, which also extends from the base to the sinus at the apical extremity of its posterior margin: a transverse nervure unites the externo-medial and anal, and which I purpose calling the *transverso-medial* (*g*). These nervures, which I consider the primary nervures of the wing, severally inclose what have hitherto been called collectively the basal or humeral cells, but to which I purpose applying different names (derived from the nervures which inclose them), that they may be more readily distinguished from each other. The first, or that very narrow one between the costal and post-costal nervures, is the *costal* cell (1); the second is that placed between the post-costal and externo-medial nervures, and which I call the *externo-medial* cell (2): that inclosed between the externo-medial and anal nervures parallelly, and terminated at its apex by the transverso-medial, is the *interno-medial* cell (3); and the cell seated between the anal nervure and the posterior margin of the wing is the anal cell (4).

"From the interior margin of the stigma arises the *radial nervure* (*h*), which makes a curve and then joins the costal upon the margin of the wing: the lanceolate space thus inclosed forms what is called the radial or *marginal* cell (5). The *cubital nervure* (6) is nearly parallel with the radial and originates from the externo-medial near its junction with the post-costal; this extends to the apical margin of the wing just below its extreme apex (6 *i*). The space thus inclosed is divided by three transverse nervures, which I propose calling the *transverso-cubitals* (*m*, *m*, *m*, *m*), inclosing as many spaces forming so many cubital or sub-marginal cells, a fourth being formed in consequence of the nervure extending to and joining the apical margin (*g*). The third nervure, originating from the primary nervures of the wing, is what I call the *discoidal* nervure (*k*), (it is from this that I anticipate the chief results), and which, commencing at the transverso-medial, extends in a direct line to the disc of the wing directly between the stigma and the sinus, when it makes a sudden curve at a right angle backwards and joins the anal nervure close to the sinus (*k*). From this discoidal nervure at the centre of its apical return another springs, forming what I call the *sub-discoidal nervure* (*l*), and which here extends to the posterior margin of the wing. From the cubital nervure two others originate; these are called the *recurrent* nervures, the first of which always inosculates at the angle of the discoidal nervure, and the second just beyond the centre of the sub-discoidal. By the reticulation of these four nervures several cells are formed upon the disc of the wing; the first of these, which is inclosed between the discoidal and anal nervures, I call the *first discoidal* cell (10). The *second* is that placed between the externo-medial cubital, first recurrent, and discoidal nervures (11). The *third discoidal* cell is that inclosed by the second recurrent, sub-discoidal, discoidal, and first recurrent nervures (12). The space inclosed between the second recurrent, sub-discoidal, and cubital nervures, and the pical margin of the wing, forms the *first opical* cell (13), and there is a second only when the sub-discoidal nervure extends to the apical margin, by which and a portion of the discoidal cell it is inclosed."

The distribution of the nervures in the wings of the males of some of the Orthoptera affords some curious peculiarities, by which the pterigostia become instrumental in the production of sounds. At the base of the superior pair of wings in *Acrida*, at the inner angle of each wing, is an oval or nearly circular space (*fig.* 394, *a*), in which the membrane is more transparent and free from ramifications of nervures than in any other part of the wing. These spaces have long been known to be connected with the production of sound. The membrane itself appears to be thinner than in other places, and more tense, and the nervures by which it is inclosed are thick and strong.

Fig 394.

B, upper surface of the right, and, C, under surface of left wing of *Acrida brachelytra*, shewing the tympanum *a*, and bow *c*, across which the file *b* acts.

b, the file magnified.

Until recently it has been supposed that these were the only parts in the male Acrida concerned in the production of sound, the mechanism of which has been explained by Burmeister* as consisting in a quick attrition of the wings against each other during a forcible expiration of air from the thoracic tracheæ and spiracles, which are situated beneath, and are covered by the edges of the wings; that the air in rushing out of these spiracles is driven against the tympani, which are thus occasioned to vibrate and produce the sound. But this ingenious explanation is not entirely correct; the means employed do not appear sufficient to explain the phenomenon, besides which a part of the structure that is chiefly instrumental in producing the sound has been overlooked. In addition to the tympanum, and parts by which it is inclosed, there is also another part which has not until recently been described. It is a strong, transversely elongated horny ridge, situated immediately behind the tympanum, near the base of the wing, and is most distinct on the upper surface of the wing of the left side. This part was first shown to us by the late Mr. William Lord, in the wing of *Acrida viridissima*, in February 1838, but it had previously been described by M. Goureau, in an elaborate paper on the Stridulation of Insects.* When examined minutely, this ridge, which is of the colour and appearance of tortoise-shell, is found to be striated transversely, so as to resemble a rasp or file. Goureau has called it the *bow;* a similar ridge or file exists on the under surface of the right wing, but less strongly notched, and is called by Goureau the *false bow*. When the wings are rubbed briskly together, these rasps or bows produce a loud grating against some projecting or elevated nervures on the borders of the wings, by means of which the drum is made to vibrate like any other tensely stretched membrane when agitated, the intensity of the sounds produced depending entirely upon the rapidity and force employed by the insect during the attrition of the parts concerned, and being entirely independent of any forcible expiration of air from the thoracic spiracles, which is thus seen to be unnecessary for the production of the sound. That this is really the case is proved by the fact that in *Acrida brachelytra* (B, C), the wings are so exceedingly short and narrow that they do not cover, nor are they even near any part of the spiracles, so that the air in passing out of these orifices cannot possibly be driven against the tympanum. On the other hand the tympanum in this species (*fig*. 394, B, C) is considerably larger than in others of the same genus, and not only has its margins more elevated, but has also a strong bar extended across near its base (*c*), is itself more tense and vibratory, and has a short, strong bar (*d*), connected with the ring by which it is inclosed, and also, at a right angle, with the origin of the great marginal nervure of the wing. It is remarkable that both in *Acrida viridissima* and *Acrida brachelytra*, the tympanum in one wing differs from that of the other in being less regular in its form, much more opaque, and traversed by several tracheæ, a circumstance which leads us still further to infer that the sounds produced result from the vibrations of one only of these organs, besides which the proper tympani are not in corresponding wings in these two insects. In the former, in which the base of the left wing is covered by that of the right, the proper tympanum is in the left wing, while in the latter insect, in which the right wing is covered by the left, the tympanum is in the left wing, which is remarkable in being entirely deficient of the file or bow, but which is largely developed on the under surface of the left wing. The analogue of the file in the right wing is evidently a strong portion of the rim of the tympanum nearest to the base of the wing. It is remarkable also that in this species the whole surface of the right wing, in which the tympanum is situated, is more transparent and free from nervures than the corresponding part of the left wing, so that the whole surface of the wing may perhaps be rendered sonorous. It is remarkable also that

* Manual (translat.), p. 470.

* Annales de la Société Entomologique de France, 1837, p. 31. Entomological Magazine, January, 1838, p. 89 et seq.

in newly developed specimens, particularly in *Acrida viridissima*, the teeth or markings on the file are more distinct than in those which have been a longer time in the perfect state, in which the teeth appear as if partially obliterated by use. The sounds, as remarked by M. Goureau, may be readily produced in the dead insect by gently rubbing the bases of the wings together, a further proof that the rushing of air from the spiracles is totally unconnected with their production. A similar structure exists in the wings of *Acrida grisea* and others of the same genus. In the *Achetidæ* the parts for stridulation are somewhat differently constructed. The wing of the common house-cricket, *Acheta domestica*, differs materially in the two sexes. In the male (*fig.* 395) the two

Fig. 395.

Wing of the male House-Cricket, Acheta domestica, shewing the file, b, and tympanum, a.

wings exactly resemble each other, and the nervures are more irregularly disposed than in the female, in which they are arranged either longitudinally or diagonally with but very few that run in a transverse direction. When the wing of the male is attentively examined, nearly one-half of its surface is found to be adapted to perform the office of a tympanum. This part is more transparent and elastic than the other, and is crossed by many nervures in a manner somewhat similar to the tympanum in *Acrida brachelytra*. Besides these there is on the under surface of each wing a large nervure, which is curved and placed somewhat transversely near the base of the wing, as in *Acrida*. It is the file or bow, and is covered by a vast number of minute, but freely elevated, semicircular teeth, which gradually decrease in size as they approach the external angle of the wing (*fig.* 396). The smallness of the teeth, and the extent of surface over which they are passed when the two wings are rubbed briskly across each other, is probably the cause of the very acute sounds produced by this insect. In *Gryllotalpa*, which is said to produce a hoarse croaking sound, the two wings exactly resem-

Fig. 396.

The round file of Acheta domestica.

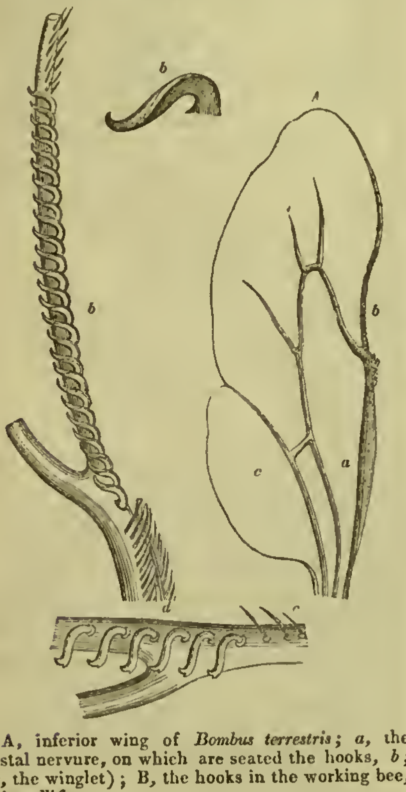
ble each other, as in *Acheta*. The nervures are thick and strong, and there is no distinct vibratory membrane, but on the under surface of each wing are a vast number of minute sharp-pointed teeth arranged closely together along the middle of the nervures, not only upon that one which is analogous to the file in *Acrida* and *Acheta*, but also upon three others which run in a parallel direction with it, as well as on their transverse or connecting branches, so that the whole of the nervures at the base of each wing are covered with files, which, when the two wings are rubbed across each other, produce, owing to the shortness of the nervures, a low grating sound. We do not at first perceive the necessity for a stridulatory apparatus on the under-surfaces of both wings, if the sounds produced result simply from the attrition of the wings against each other, and the wings have always the same relative position. But on close examination it is found that, although in the *Gryllidæ* the right wing either constantly overlaps the left or the left the right, in the *Achetidæ* this is not the case, but that sometimes one wing and sometimes the other in the same insect is the superior. With regard to the acuteness of the sounds produced by the house-cricket, it probably depends much upon the length of the vibrating nervures on the large tympanum, as well as the smallness of the teeth in the file, as the hoarse sounds do, perhaps, upon the shortness of the nervures in *Gryllotalpa*. In *Locustidæ* the stridulation is not connected with the structure of the wings.

Besides these various parts for the production of sounds, the wings of some insects are furnished with others equally remarkable, but designed for a different purpose. These consist of certain little hooks and foldings on the margins of the wings, by means of which in some families the two pairs are united during flight, in order that the motions of these organs may be in perfect unison with each other. In some genera, as in the Lepidoptera, the males alone are provided with these hooklets, as was formerly noticed by Mr. Haworth* in *Apatura Iris*, in which the wings of the male are connected at their base by means of a strong elastic spring, which arises from the base of the costal

* Lepidoptera Britannica, 8vo. Londini, 1803.

nervure of the inferior wing, and is received into a socket near the base of the main nervure on the under side of the upper wing. This apparatus for connecting the wings appears to give additional strength to the insect, since it exists only in those species which fly most rapidly, and continue for a great length of time on the wing. But in those insects in which the body is very large in proportion to the size of these organs, and which are necessitated by their habits to be constantly abroad, and to fly to a great distance, as is the case with the Hymenoptera, the means of uniting the wings is more perfect. It consists not of a single hooklet, as in Lepidoptera, but of a series of very minute hooks of a somewhat spiral form (*fig.* 397), and arranged along a curved portion

Fig. 397.



A, inferior wing of *Bombus terrestris*; *a*, the costal nervure, on which are seated the hooks, *b*; (*c*, the winglet); B, the hooks in the working bee, *apis mellifica*.

of the costal nervure, at the anterior superior margin of the second pair of wings. These hooks are described by Mr. Kirby,* and are found in nearly all the Hymenoptera. They are arranged in a slightly twisted or spiral direction along the margin of the wing, so as to resemble a screw, and when the wings are expanded attach themselves to a little fold on the posterior margin of the anterior wing, along which they play very freely when the wings are in motion, slipping to and fro like the rings on the rod of a window curtain. The form of the hooks is very similar throughout the whole order, each hook being twisted at its extremity a little to one side and recurved. They are always situated at the same part of the wing, but vary in number in different genera, and even in the sexes. In *Uroceridæ*, *Sirex juvencus*, they are few and scattered along the margin of the wing, and this is also the case in *Trichiosoma*, but we have found them far more numerous in *Ichneumon Atropos*. In the sterile female or worker of the common wasp, *Vespa vulgaris*, we have found them very strong, and about twenty in number, besides five stiff spines which are not bent in the form of hooks. In most instances, particularly in the *Bombi*, the hooks are less numerous in the males than in the females. Thus, in the male of *Bombus terrestris* there are but eighteen in each wing in the male, but twenty-five in the fertile female. In the male of *Bombus lapidarius* there are only eighteen in each wing, and there is the same number in the worker or sterile female, but there are twenty-three in each wing of the fertile female. In *Anthophora retusa* there are only twenty in the male, but twenty-two in the female. In *Osmia* there are twelve in the male and fifteen in the female. But the reverse is the case in *Anthidium manicatum*, in which there are thirty in the male, but only twenty-five in the female. In *Megachile* there are sixteen in the female, but in the cuckoo-bee, *Melecta punctata*, there are thirteen hooks and four imperfectly developed spines. In the male of *Eucera longicornis* there are only thirteen hooks, but in the female twenty-three, while in the female *Cœlioxys conica* there are only twelve. In the queen or fertile female of the common hive-bee there are only seventeen slender hooks, arranged at some distance apart, and different in their appearance from those of the common humble-bee. In the sterile female or worker there are nineteen, but in the heavy male, or drone, there are twenty-one. In the male, as in the fertile female, of the hive-bee, the hooks are placed further apart, and are more slender than in the workers, besides which they are differently shaped in the neuter, in which each hook has also a little tooth near its apex. On reviewing this difference in the number of hooks in the two sexes, we are certainly confirmed in the opinion that it has some relation to the comparative powers of flight of the respective insects, and is not a sexual distinction. The great object of the hooks evidently is to keep the wings steady during flight, in order that they may act in unison, and thereby enable the insect to continue much longer on the wing with less muscular exertion, because, when the two wings are made to act but as one, the effort of flying becomes more concentrated, and the wings strike the air with greater effect than if they were separated or but imperfectly connected. It is well known that the males of the humble-bees, *Bombi*, are much feebler on the wing than the fertile females, and it is the same with the individuals of the genus *Osmia*,

* Monographia Apum Angliæ, vol. i. tab. 13, fig. 19. Ipswich, 1802.

and perhaps also with those of *Anthophora*, in which, although the flight of the males is as rapid as that of the females, we suspect that it is not so long continued. But in *Anthidium manicatum* the number of hooks is in correspondence with the apparently greater power of wing in the male, which pursues his partner unceasingly, and darts down upon her with great rapidity at the season of connubiality. A similar remark is applicable to the male of the hive-bee, which at the period of swarming is exceedingly active, and constantly on the wing in the open air, in search of the queen or solitary female, who leaves the hive but for a few hours on the first or second day after swarming. Now we have seen that the number of hooks in these males is greater than in the females, and that their powers of flight are also greater, and that in the *Bombi* the reverse is the case with regard to both these circumstances. Consequently it is but fair to infer that the number and strength of the hooks are in direct relation to the powers of the insect.

We have before remarked that the different forms and appendages of the body are invariably the result, not of the introduction of new elements into the composition of parts, but of the greater or less extent to which those primary parts are developed. There is a beautiful illustration of this principle in the development of the *hamuli*, which are only spinous processes often observed on the wings of other insects. In proof of this we need but examine the wing of the common working-bee, in which there are several of these spines arranged in a line with the hamuli, and inserted in a similar manner into the nervure of the wing upon which the hooks are situated. In some instances the transition of form from that of spines to hooks is distinctly marked. Those which are most distant from the proper hooks retain the perfect form of spines, while those which are nearest are bent in the same direction, but to a less extent than the proper hook, but sufficiently so to mark very distinctly their proper analogy.

In Hemiptera, instead of being connected by hooks as in Hymenoptera, the whole margin of a portion of the anterior wing is hooked over a corresponding recurved part of the posterior, as formerly noticed by Chabrier* in the *Pentatomidæ*. In the Homoptera the wings are connected in the same manner as in Hemiptera, as noticed by Mr. Ashton† in *Membracis cornuta*. This is also the case in other Homoptera. Thus in *Tettigonia bifasciata* there is a triangular membranous process extending from the anterior margin of the inferior wing, and which on its distal border is furnished with four very distinct but exceedingly minute hooks, resembling those of Hymenoptera. This process of the posterior wing is curved a little upwards and received into a fold of the posterior margin of the anterior wing. There is a similar structure in the wing of *Cercopis sanguinolenta*, with this difference, that the hooks are very indistinct, while the triangular process of the wing is more pointed and hooked upwards. In *Tettigonia spumaria* the structure is exactly the same. In *Iassus viridis* the triangular process is shorter, but more extended along the costal margin of the wing, and is furnished with a great many very minute imperfectly developed hooks, which attach themselves to the folded linear margin of the anterior wing.

The legs, the proper organs of locomotion, are constantly six in number in every order of insects, but are subject to much variety of form. Each leg is composed of five distinct parts. First, (*fig.* 332 and 398,) the *coxa* (*a*) or basial

Fig. 398.

Legs of insects, from Burmeister, Curtis, and Hope.

joint, which is inserted into the acetabulum, and connects the limb with the thorax. Of this part the *trochantin* is believed to be an appendage. Secondly, the *trochanter*, a minute joint attached to the extremity of the coxa. It is not lettered in our figure of the leg (*fig.* 332, 3, 4), but is placed between the coxa and the third portion of the limb, the *femur* (*b*), with which it is freely articulated. The femur is the proper thigh of the insect, and in general is of considerable size. It is connected by ginglymoid articulation to the fourth portion of the limb, the *tibia* (*c*), which is usually a long slender joint, at the extremity of which is articulated the fifth and last portion, the *tarsus* (*d*). This part is always composed of several distinct joints, varying in number in different insects from two to six. The more common number is five. These are the pri-

* Sur le Vol des Insectes.

† Proceedings of the Entomological Society of London in Transactions, vol. ii. p. 20.

mary divisions of the leg, connected together by distinct articulations, and in the most developed condition of the limb are almost invariably found in every insect. The articulation of the coxa with the acetabulum is either *ginglymoid*, as in the Lamellicornes and many others, or *cotyloid*, as in most of the Rhinchophora; that between the coxa and trochanter, and between the trochanter and femur, is chiefly of the former kind, which also invariably exists between the femur and tibia, while the articulations of the different joints of the tarsus with one another, and also with the tibia, are almost invariably cotyloid, as in *Lucanus*, except in the four posterior legs of the Hydradephaga and other water insects, in which they are usually ginglymoid, because the tarsi of these insects being used chiefly for one purpose, that of swimming, this form of joint appears to be necessary to give greater strength to the tarsus, which is employed to strike the water almost wholly in one direction.

Although the number of joints in the tarsus varies in different insects, it is very constant in some families, which are also connected by other circumstances. Thus in a large group of the Coleoptera the tarsi are invariably composed of five joints, besides a terminal claw, and upon this character they have been formed into one group, the *Pentamera;* while in another, the *Heteromera*, there are constantly five joints in each tarsus of the pro and mesothoracic legs, but only four in each of the two metathoracic. This tendency to the production of the full number of joints is remarkably shewn in many instances. Thus in a large number of families, *Pseudo-tetramera*, in which on a cursory examination there appear to be only four joints in each tarsus, it is found on a closer inspection that a fifth joint actually does exist, in the form of a very minute articulation (*fig.* 398, A, 4), at the base of the terminal joint in each tarsus. So again in another group, *Pseudo-trimera*, in which there appear at first to be only three joints in each, it is found that there are actually four (B, 3), the additional joint being, as in the preceding instances, developed at the base of the terminal one, but more distinctly than in the *Pseudo-tetramera*. This tendency to a reproduction of parts is also shewn in the *claws* at the extremity of the tarsi. In many Coleoptera, as in the *Melolonthidæ* (C), each claw is double; while in others, as in *Lucanus*, in which the proper claw is simple, and articulated to the terminal joint of the tarsus, there is also an *unguicula* or little claw, supported upon a distinct joint, which is articulated separately from the proper claw, with the last joint of the tarsus, in the middle line below the larger one.

The variations that occur in the form of the parts of the leg, as in other parts of the body, are directly referable to the habits or necessities of the insect. Thus where the legs are employed chiefly in *running*, as in the *Cicindelidæ*, *Carabidæ*, *Scaritidæ*, and *Harpalidæ*, they are usually long and slender, particularly the tarsi and tibiæ; the coxæ are very freely articulated with the body, and the trochanters, particularly those of the hinder pair of legs, are remarkably large. But when, as in the *Gyrinidæ*, *Dyticidæ*, and *Hydrophilidæ*, they are employed entirely in *swimming*, they are long, as in running insects, and the tarsi of the second and third pairs are flattened and broad like oars, and their margins, apparently to increase the breadth of their oar-like form in the water, without the inconvenience of an actual enlargement of the limbs, are densely clothed with long stiff hairs (K). Besides this, the posterior pair, on which the chief action of swimming depends, are much longer than the others, and the tarsi are ciliated to the very articulation of the unguis. The extremity of each tibia is also armed with one or more long spines, which may assist the insect perhaps in burrowing into the mud. When the legs are employed simply in *walking*, and the motions of the insect are slow, the legs are all of the same length, and, as in the *Chrysomelidæ*, are often covered on the under surface of the tarsi with little hairy cushions, *pulvilli*. These are generally present also in *climbing* insects. In the common house-fly, and others of the same genus, instead of hairy cushions the terminal joint of each tarsus is furnished near its extremity with two funnel-shaped membranous suckers (E), by means of which the insect is enabled to adhere to smooth surfaces, and suspend itself in an inverted position. Each of these is concave, and covered by a membrane, and the manner in which the insect attaches itself is by exhausting the air beneath each sucker. The cushions are particularly large in those anomalous insects the Strepsiptera, in which they form a broad heart-shaped surface to each joint of the tarsi (M). They are also present, but in a less perfect form, in some of the running insects, the *Cicindelidæ* and *Carabidæ*, as in *Dioryche torta** (Mac'L.), in which the joints of the anterior tarsi are furnished with a little hairy cushion. But in these families the tarsi of the anterior legs of the males are always enlarged for the same purpose as in the *Dyticidæ*, that of more securely attaching themselves to the female. This is also the case in *Hydrous*, in which the terminal joints of the anterior tarsi (*fig.* 330, A) are very much dilated. In the *Dyticidæ* the first three joints of the anterior tarsi are consolidated together, and form a broad circular disc, covered with many minute funnel-shaped suckers, two or three of which are much larger than the others; in some, as in *Hyderodes Shuckardi*, Hope,† a New-Holland species (H), all the suckers are of nearly the same size. They exist also in the first three joints of the second pair of tarsi (I). A somewhat similar structure exists in the males of some of the sand-wasps, *Crabronidæ* (F). It is supposed to be designed for the same purpose as in the *Dyticidæ*. But in those insects it consists of a broad and slightly convex dilatation of the anterior tibiæ, and not of the

* Coleopterist's Manual, Part ii. tab. 2. fig. 4, *d*.

† Op. cit. pl. 3, fig. 5. *a. b.*

tarsi, as in the latter instances.* Those insects which support themselves upon the surface of water, as the common gnat, have the under surface of each tarsus covered with rows of fine hairs, which repel the water, and support the insect upon the surface. If the under surface of the tarsi be wetted with spirits of wine, the insect can no longer support itself upon the surface, but immediately sinks down.† When the legs are employed in *jumping*, as in *Haltica*, the destructive flea-beetle of the turnip, and the *Gryllidæ* and *Locustidæ*, the posterior pair, upon which devolves the greatest effort, as in the swimming insects, are considerably larger than the others; the thighs in particular are enlarged and lengthened, to allow room for the insertion of the muscles. But when the legs are employed in *digging* or *burrowing*, it is the anterior pair that become the most important, as in the mole-cricket, *Gryllotalpa* (G). In that insect the coxa (*a*) is of an enormous size, and the trochanter attached to its inferior margin consists of two distinct articulations, one of which projects in a lobulated form, and probably is useful in assisting to remove the earth during the operations of the insect. The femur (*b*) is short and broad, and is articulated both to the coxa and trochanter, and thus derives additional strength from its more secure connexion with the base of the limb; while the tibia (c), which is the part immediately employed in burrowing, is also short, and divided at its extremity into four strong curved spines, directed outwards, and forming as it were a broad hand, like the claw of the mole, for digging into and rapidly removing the earth in its burrow. The tarsus (*d*), which appears to be almost useless in these subterranean labours, consists of three short articulations, which are attached to the external surface of the tibia. A similar conformation of the tibia exists in other burrowing insects, since it is always this part of the limb that is employed in digging, and not the tarsus, which is used only in scraping or scratching away loose soil, as by the oil-beetles, *Meloë*, and the sand-wasps. Thus in the *Scarabæidæ* and *Geotrupidæ* the anterior tarsi are broad and dentated laterally, and the posterior ones are armed with strong spines. In some genera, as in the *Coprides* and *Onthophagi*, the extremities are not only strongly spined, but are also broad and club-shaped, to assist them in penetrating into the loose excrement beneath which they are accustomed to burrow.

There are circumstances connected with the organs of locomotion in insects of considerable interest, and which cannot be passed over. These are the aberrations of form which they undergo as a consequence of incomplete development, and the occasional existence of supernumerary limbs, the result of an opposite tendency in the development of the germ. We have already alluded to the changes of form occasioned by the former of these circumstances, and we have now to notice the not less remarkable occurrence of the latter. Although every part of the body is subject more or less to these occurrences, the supernumerary parts are almost always antennæ or legs. We do not remember a single instance of a supernumerary wing, or elytron, or organ of manducation, although the whole of these parts are occasionally subjected to an aberration of form in consequence of imperfect development. Many instances of this kind are given by Dr. Herrmann Asmuss,* who has collected a multitude of facts connected with this interesting subject, from which it appears that abnormal forms are more frequent in the antennæ and legs than in other parts of the body. Only one instance is given of abnormal form of the mandible from arrested development, but several of the antennæ and legs. But the most frequent abnormal condition is found in the existence of supernumerary parts. Of these he has given two instances in which the antenna on one side of the head was double. These occurred in one of the *Elateridæ*, *Athous hirtus*,† and *Carabus auratus*,‡ and one instance also in which it was trifurcated, in *Helops cæruleus*.§ But it is remarkable that the most frequent occurrence of supernumerary parts is of the legs. Of these Asmuss has collected eight examples, and it is remarkable that in six of them the parts on one side are treble. Of the two instances in which the parts were double the first occurred in *Agriotes obscurus*,‖ in which there were two perfect prothoracic legs on the right side of the body, connected with the sternum by two distinct coxæ. In the other instance, which occurred in *Telephorus fuscus*,¶ there were two meso-thoracic legs on the left side, connected together, and attached by a single coxa to the sternum. To these we may add a third instance, which occurred in *Chrysomela hæmoptera*, captured by Mr. Curtis, and described in his British Entomology.** In this specimen the supernumerary part is a tibia, apparently moveable, and developed from the extremity of the femur of one of the hinder pair of legs. A similar remarkable condition is described by Tiedemann†† as having occurred in *Melolontha vulgaris*, in which three tibiæ and tarsi originated from a single coxa of the right metathoracic leg. Asmuss alludes also to the specimen of *Oryctes nasicornis* described by Audouin,‡‡ in which a similar number originated from the right prothoracic leg; and to a second example of *Melolontha vulgaris*,§§ in which three tibiæ and tarsi originated from a triangular, spatula-formed femur of the right prothoracic leg. another of the *Melolonthidæ*, *Rhizotrogus castaneus*,* three distinct legs originated by separate trochanters from a single prothoracic coxa of the right side (*fig.* 399, A). But per-

haps the most remarkable example is that given by Lefebvre† of *Scarites Pyrachmon* (B), in which from a single coxa on the left side of the prosternum two trochanters originated (*fig.* 399, B, C). The anterior one, the proper trochanter, supported the true prothoracic leg; while the posterior one, in the form of an oblong lanceolate body, attached to the base of the first, supported two additional legs equally well formed as the true one. Dr. Asmuss has also given an example in *Carabus perforatus* of a treble fifth joint in the tarsus of the left meta-thoracic leg (E, F, G), in which all the claws of three distinct tarsi exist.

The principles upon which the modifications of form, and the existence of supernumerary parts depend, as attributable to retarded or excessive development, have been particularly insisted upon by Saint Hilaire, Professor Grant, and other comparative anatomists, in reference to the development of the body in vertebrata, and are equally applicable to that of the invertebrata. That these aberrations of form really depend upon an arrest of development is well shown in the instance we formerly gave of *Geotrupes stercorarius* (*fig.* 332), in confirmation of the views of Savigny, respecting the different kinds of appendages in each segment being simply modifications of the same normal structure. That retarded development is capable of producing these aberrant forms we once satisfied ourself by experiment made on a specimen of *Sphinx ligustri*. We carefully watched a larva that was about to undergo its change into the pupa state, and when it was beginning to assume that condition, retarded its development by repeatedly touching and otherwise disturbing it, the result of which was that the projecting case that usually exists on the point of the perfect pupa of this insect was not developed in the pupa in question, which we still possess, and which exhibits an uniform appearance of its exterior almost precisely similar to that of *Sphinx populi*. With regard to the existence of supernumerary limbs, it is presumed, in the absence of any evidence that these additional parts exist also in the larva, as we suspect they do, as well as in the perfect insect, that they do not originate simply by a greater development of one part than of another during the changes of the insect, but upon an original tendency to the production of them which existed in the germ itself. This opinion seems to be supported by the circumstance, that although there is a tendency to the reproduction of the same parts as a normal condition of the wings in some insects, such reproduction is not known to occur as an abnormal condition, which appears to be accounted for by the circumstance that the wings themselves are simply developments of parts of other structures, the respiratory organs.

The muscular system of Insects, like that of other Articulata, is contained within the dermo-skeleton. It is composed of an immense number of distinct, isolated, straight fibres, which are not constantly aggregated together in bundles, united by common tendons, or covered by aponeuroses to form distinct muscles, as in Vertebrata, but remain separate from each other, and only in some instances are united at one extremity by tendons. The greater number of these fibres are flat, thin, and of the same size throughout their whole length, a few only being slightly conical. They are arranged parallel to each other, and form layers, or series of fibres. These series of fibres, or layers, we prefer to regard as separate muscles, rather than as aggregations of muscles, as they were formerly regarded by Lyonet,* because we are thereby enabled to simplify our description of the muscular system of these animals. But besides these layers of fibres, which form the greater part of the muscular system, there are also certain sets of fibres which are united by tendons to constitute distinct muscles, but they are not inclosed by aponeuroses. The muscles of insects differ, then, as remarked by Straus,† from

* Traité Anatomique de la Chenille qui ronge le bois de Saule, 1760.

† Considerations, &c. p. 145.

those of the larger animals in not being inclosed by aponeuroses, and in being formed of fibres which are always free, straight, and frequently are not connected with or arise from tendons. There is no instance, as Straus has correctly remarked, of a digastric muscle in insects. *Each fibre* is composed of a great number of very minute fibrillæ, or fasciculi of fibrillæ, into which the fibre may be easily torn, after it has been hardened for some time in spirits of wine. Professor Wagner has seen transverse striæ on the fibres of insects as on those of vertebrated animals, and we have also observed them very distinctly on the dorsal longitudinal fibres of *Lucanus cervus*, and more particularly on the fibres of the longitudinal muscles of the back, in the abdominal segments of the larva of *Odonestis potatoria;* Professor Muller states that the voluntary muscles of insects are wholly constituted by these transversely striated fibres, each of which has a very delicate sheath, which can often be perceived forming a transparent border to the fibre.* Those fibres which are entirely without tendons are attached by their whole breadth either directly to the flat internal surface of the dermo-skeleton or to elevated ridges, which are intussuscepted portions of the tegument within the body, the apodemata of Audouin, of which the phragmata before described are examples. *The tendons*, or hard uncontractile ends of the muscles, like the phragmata, are formed by an elongation inwards of parts of the internal lamina of the dermo-skeleton.† They exist more generally in the perfect insect than in the larva, and in the muscles of the head of the larva than in other parts of the body. The cause of this appears explicable by the fact that there is a higher developed condition of body in the perfect insect than in the larva, and in the head of the latter than in other parts of its body. Distinct tendons exist most frequently in the muscles of the extremities and organs of manducation, as in the *Lucanus cervus* (*fig.* 388, 2), in which a large flat tendon, of great strength, is attached to the external condyle of the mandible, and on each side of which the fibres that compose the great extensor penniform muscle are inserted. Tendons exist also of great length in the legs of Orthoptera (*fig.* 409, *a*, *b*, *c*), and between the forked processes of the thoracic segments, and the margins of the coxæ. *The muscles with tendons* are arranged by Straus under two divisions:‡ first, the *conical*, in which the tendon is short and occupies the axis of the muscle, where it is expanded into a broad plate, unto which the fibres of the muscle, originating from a broad base, and converging to one point, are attached, and the tendon then proceeds alone to the point of insertion; second, the *pyramidal*, in which the tendon, as in the conical, is surrounded by short fibres, and is broad and divided into several laminæ; third, the *pseudo-penniform*, in which the fibres originate in a row, and, converging, are attached sometimes on one side, and sometimes on both sides of a long narrow tendon; fourth, the *penniform*, which differ from the last in the margin of the tendon being fibrous. Like the latter the fibres orignate sometimes on one side only, and sometimes on both. Fifth, the *compound*, or those which consist of several muscles, each formed of two or more fibres, united by a tendon, and these tendons of two or more muscles united into one bundle; or in which the tendons of several bundles of muscles are united. Unto these five forms Burmeister has added a sixth, the *cylindrical*,* the tendon of which is a flat round plate, to which the fibres are attached on one side, and from which a process extends on the opposite to the point of insertion, as in the muscles of the wings. Audouin calls these tendons *epidèmes*, and regards them as processes of the thorax.

* Elements of Physiology, (translation,) part iv. p. 882.

† Straus.

‡ Op. cit. p. 146.

The *muscles of the larva* present great uniformity of size and distribution in every segment, the motions of each of these divisions of the body being almost precisely similar. The differences which exist in the number, distribution, and functions of the muscles, are to be sought for in the first four segments, which compose the head and thorax of the perfect insect. Thus, in the head of the larva there is a greater aggregation of muscles than in any other segment of its body, because a greater number of organs exist, and consequently require these additional muscles. The presence of a greater number of organs in this than in the succeeding segments is readily accounted for, when we remember that the head is composed of several sub-segments, and that the appendages belonging to it are those of these originally distinct parts. But the situations and the form of the muscles have become changed from those of the simple muscles of a segment, and some have become united to others. This may explain the cause of the greater complexity of the muscles of the head of the larva than of those of the other segments, and why so few are simple like those of the abdominal regions, but, on the other hand, are frequently complicated, and end in tendons, and more or less resemble in form the muscles of Vertebrata. Hence the muscles of the mandibles are large and occupy the greater part of the lateral and posterior region of the cranium, the extensor muscles being attached to the lateral and posterior surface of the cavity, like the extensor muscles of the legs in the thoracic segments, and the flexor more internally to parts that correspond to the *laminæ squamosæ* in the head of the perfect insect, the analogies of which in the thoracic segments are the forked processes to which the flexor muscles of the legs are attached, like the corresponding muscles of the mandibles on the head. The muscles of the three

* Manual of Entomology, (trans.) p. 249.

segments that follow the head, and form the thorax of the future imago, are more numerous and complex than those of the abdomen, because unto those segments belong the muscles of the proper organs of locomotion; besides which they contain also the rudiments of the muscles for the future wings. The muscles in the abdominal segments are fewer and far more simple than in the anterior part of the body, but their number, even in these, very far exceeds what at first might be expected. So numerous are they in every segment that Lyonet, in his immortal work on the anatomy of the larva of *Cossus ligniperda*, found two hundred and twenty-eight distinct muscles in the head alone, and, by enumerating the fibres in the layers of the different segments, reckoned one thousand six hundred and forty-seven for the body, and two thousand one hundred and eighteen for the internal organs, thus making together four thousand and sixty-one muscles in a single larva. In the larva of *Sphinx ligustri* we have found the muscles equally numerous with those discovered by Lyonet in the *Cossus*, but in attempting to describe them it has appeared preferable, as we have stated, to consider each layer of fibres collectively as a separate muscle. In describing the muscles of the ventral portion of a segment, we formerly* ventured to designate them by names which were indicatory either of their position or use, and we shall continue to do so on the present occasion. A description of the muscles of a portion of a segment will suffice to convey some idea of their multiplicity and use. We may first state generally that those muscles which form distinct layers or act in concert with each other, are inserted into slightly elevated ridges of the tegument, while a single muscle, or the tendon of many muscles united together, is attached to an elevated process of the tegument, which at that point is thicker than in other places, and thus affords a means of attachment. There are always three ridges for the attachment of muscles between two abdominal segments. The middle one is the largest, and affords both origin and insertion to the straight or longitudinal muscles, while the others in like manner afford origin and insertion to the oblique ones.

On removing the fat and viscera from the abdomen of the larva, the first layer that presents itself, and forms the interior parietes of the body, consists of many longitudinal fibres, which extend from the margin of one segment to that of another as flat, straight muscles, resembling the *recti abdominales* of vertebrated animals. These muscles extend from the anterior margin of the sternal surface of the second segment to the posterior part of the twelfth; but it is only at the anterior margin of the sixth segment, which is in reality the commencement of the true abdomen, that they can properly be considered as recti muscles, since it is at this part of the body that they begin to be fully developed. While passing through the thoracic segment they are narrower, thinner, and somewhat differently arranged. They are connected anteriorly with the head, and posteriorly with the sphincters. They are the most powerful of all the muscles of the abdomen, and are those which are most concerned in shortening the body, and effecting the duplicature of the external teguments, during the changes of the insect. They are also those which mainly assist in locomotion during the larva state. There are four sets of these longitudinal muscles, two on the dorsal and two on the ventral surface of the body (*fig.* 400, A A). Those on the dorsal surface are placed one on each side of the dorsal vessel or heart, and those on the ventral one on each side of the nervous column. The dorsal sets extend from their attachment to the upper part of the head through the thorax and abdomen to the anus, in the thirteenth segment. In the thoracic region they are narrow like the corresponding muscles of the ventral surface, but when the insect is undergoing its changes they become enormously enlarged in this region, and form the great depressor muscles of the wings (*fig.* 402, *x*), which are some of the most powerful muscles of the thorax, and extend between the meso- and meta-phragma. The ventral recti consist of four sets of fibres, two on each side of the nervous cord (*fig.* 400, 1, 2), and between which there is a slight interspace. That set which is placed nearest to the nervous cord and median line of the body, is composed of only three narrow fasciculi of fibres, and may be called the *recti minores* (2), while the other set, situated more externally and covering the greater portion of the ventral surface of the segment, is broad and powerful, and consists of from twenty to twenty-five distinct fasciculi or fibres, and may be called the *recti majores* (1). The origins and insertions of these are different from those of the smaller recti. The recti majores of one segment arise from the middle ridge between two segments (3), and are inserted close to the origin of the corresponding muscles of the next segment, while the recti minores arise from the most posterior of the three ridges, about one-fifth of a segment posterior to the middle ridge, over which they pass, and proceed in a direction parallel to the larger ones to be attached to part of the corresponding ridge in the next segment. There is a small muscle that originates from the same ridge as the greater rectus, between it and the smaller, which, from its passing directly to the alimentary canal, and connecting that viscus to the exterior tegument of the body, may be called the *retractor ventriculi* (5). There is one of these muscles, as shown also by Lyonet in the Cossus, on each side of the nervous cord, from the fourth to the eleventh segment. On removing the recti, we expose two layers of very fine thin muscles. The upper layer (B) consists of nine distinct fasciculi of fibres, which pass backwards and outwards, in a slightly diagonal direction (6), but less diagonally than the second layer (7), that lies immediately

* Phil. Trans. part ii. 1836.

Fig. 400.

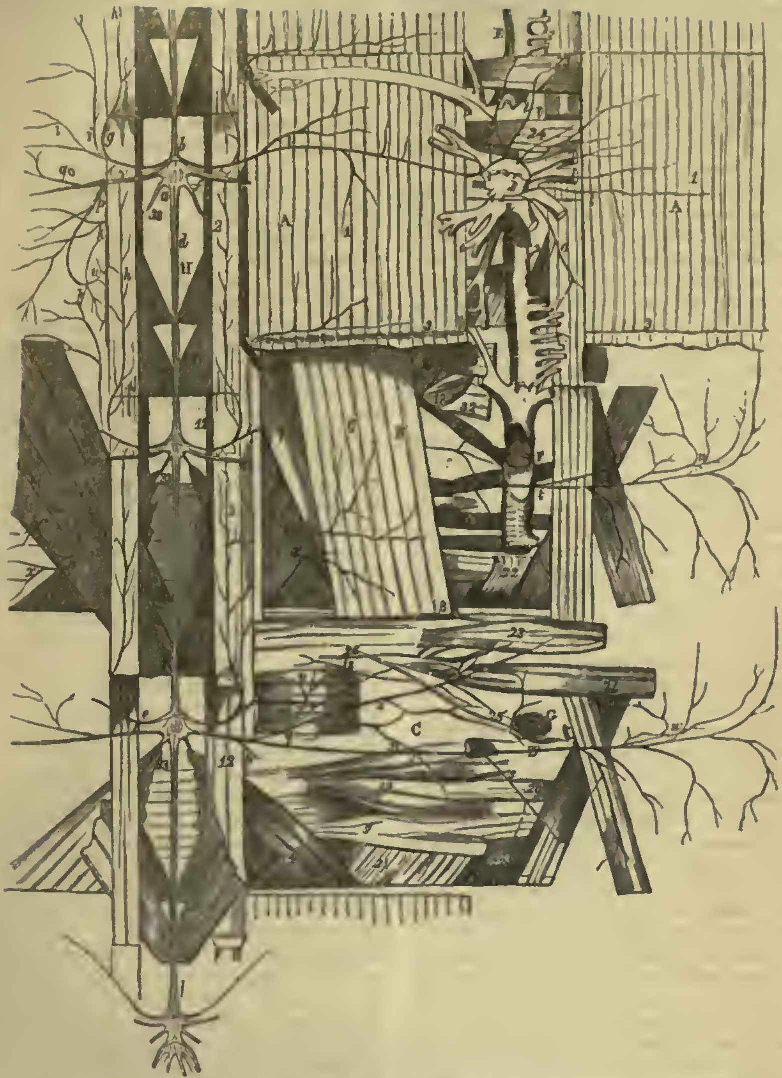

Diagram of the muscles and nerves of the ventral surface of the segments in the larva of Sphinx ligustri. (Newport, Phil. Trans.)

beneath the upper one. The second layer consists of seven distinct fasciculi, which extend from the anterior margin of the segment, close to the smaller rectus, and beneath the larger, about half their breadth across the segment. They run backwards and outwards in a diagonal direction, and are attached to the middle ridge below the rectus as far across the segment as the outer margin of that muscle (8). These layers of muscles when in action draw the outer part of the anterior margin of the following segment diagonally forwards in the direction of the median line of the body, and, consequently, when these muscles in several segments on one side of the body act ogether, they bring forward the posterior porion of the body of the same side, and bend it in a semicircular direction. When these layers on both sides of a segment act together, they draw forwards the posterior part of the body in a straight line. The most internal of these layers (6) which lies close to the rectus may be called the *first oblique*, and the other the *second oblique* (7). Beneath this there is another diagonal layer of fibres which originates close to the median line of the body (9), beneath the nervous cord, almost in a line with the insertion of the smaller rectus. The origin of this set is exceedingly narrow and distinctly tendinous, and the fibres diverging pass diagonally upwards and outwards, forming a flat triangular muscle, the *third oblique* (9, 10), which is attached to the posterior ridge, and extends outwards to the margin of the greater rectus. These oblique muscles are the antagonists of the recti, and when acting alone draw the posterior part of each segment backwards and to the median line; consequently, when the layers of only one side are in action, the anterior part of the body is flexed laterally in the form of a curve, but when those on both sides are in action the anterior part of the body is carried directly backwards. Beneath these oblique muscles there is another, which is formed of only two broad fibres. It arises from the anterior of the three ridges of attachment in the median line, and passing diagonally forwards and outwards parallel to the third oblique, beneath its inner margin, is attached to the third ridge of insertion. This may be called the *fourth oblique* (11). Beneath the posterior extremity of this muscle lies the *third rectus* (12), which is formed of three fibres, somewhat broader than those of the second or smaller rectus, but running longitudinally in exactly the same direction, and having the same origin and insertion. On removing the third rectus we expose the eighth layer of muscular fibres. This arises from the anterior ridge, and is formed of three broad fibres which are partially crossed at their origin by the third rectus. It passes diagonally outwards, and is attached to the third ridge, extending as far as the margin of the rectus and third oblique, by which it is concealed. This is the *fifth oblique* (13). When this layer is removed, the triangular and transverse muscles are exposed. The *triangularis* (14) is composed of nine distinct fibres, which originate in a longitudinal series that extends about half-way across the segment. The fibres pass from their origin diagonally backwards and outwards, with varying degrees of obliquity, and are inserted by strong tendons into the anterior of the three transverse ridges (16). They arise also by distinct tendons, which indigitate with a set of short transverse fibres, ten in number, and which occupy the median line beneath the nervous cord, and form the *transversus medius* (15). This muscle contracts the diameter of the middle of the under surface of a segment. The triangularis, when acting with its fellow of the opposite side, shortens the posterior half of the ventral surface of the segment; but when acting singly, or in conjunction with the third oblique, shortens that side of the segment, and assists to bend the body laterally. It is a very powerful muscle in locomotion, and probably is of great use in shortening and contracting the segments during the transformations. The *transversi abdominales* (17) are six short broad and thick fibres, that form two sets, and originate at some distance from the median line, posteriorly to and on the outer side of the tendons of the third oblique, and passing transversely outwards are inserted directly into the tegument, about half-way across the segment. Like the transversus medius they contract the diameter of the ventral surface of the segment, and bring the sides towards the median line. Anteriorly to these muscles, but further from the median line, is another set of six short fibres, the *abdominales anteriores* (18), which arise at some distance from the median line, and passing transversely outwards are inserted into the lateral part of the segment. The *abdominales laterales* (19) are situated in the posterior half of the segment. They are inserted by three great fasciculi of narrow tendons into the inner and inferior part of the segment, and consist of eight muscular fibres connected in the first tendon, four in the second, and seven in the third. They form very powerful muscles, which interlace with each other, and originate directly from the tegument of the sides of the segment, at different distances posteriorly to the spiracle. Some of them (20) are much longer than others, and the whole of them are connected with the false feet of the abdomen. On removing these muscles we expose the attachment of the *obliquus posterior* (21), which is composed of nine small fibres that pass diagonally outwards from their origin, the anterior ridge, to their insertion in the tegument at different distances beneath the lateral abdominal muscles. Another set of nine distinct fibres, the *postero-laterales obliqui* (22), which originate from the same ridge at the lateral part of the segment, cross over the last lateral abdominal muscle, and are inserted between it and the one immediately before it. Besides these layers of fibres there are four other sets which seem to be particularly concerned in the function of respiration. Of these the *transversus lateralis* (23) arises tendinous from beneath the lateral part of the great rectus, and passing upwards, internal to the great longitudinal trachea (E), which it crosses, is inserted beneath the external margin of the dorsal rectus (A). The second *transversus lateralis* (24) arises posteriorly to the first, crosses the trachea, and continuing its course upwards is inserted into the tegument of the back, about half-way across the dorsal rectus. These muscles appear to be directly concerned in contracting the segments during expiration. Besides these muscles there are also the *retractor spiraculi* and the *retractor valvulæ*, which belong also to the ventral and lateral surface of each segment. The *retractor spiraculi* (25) is attached by a long tendon (26) to the third ridge of insertion. It is a long, fleshy, and somewhat conical muscle, which passes upwards and obliquely backwards to the spiracle, unto the lower margin of which it is attached, and is blended with the circular fibres that constitute an orbicular muscle to that orifice. It appears to be directly concerned in forcible expiration, and draws the spiracle inwards and downwards, and when the orbicular muscle acts in conjunction with it assists in closing the spiracle. The remaining muscle, the *retractor valvulæ* (27), is the direct antagonist of the last. It is composed of five distinct fibres (*fig.* 401, *c*), which arise from the posterior margin of the spiracle, and partly also from the attachment of the *retractor spiraculi* (*e*), and then, converging, end in a tendon that passes diagonally upwards and backwards, and is inserted into a little elevation in the tegument. It is the proper retractor or levator muscle of the spira-

Fig. 401.

a, anterior margin of spiracle with portion of the trachea; b, the valve; c, retractor valvulæ; e, retractor spiraculi; d, nerve supplying these muscles.

cular orifice, and acts upon the internal valve (*b*), which is situated a little within the spiracle. This valve is a thick, moveable, dark-coloured duplicature of the lining membrane of the posterior border of the spiracle, and closes on that of the opposite side (*a*), which is a concave crescent-shaped margin, not acted upon by muscles—like a cushion or pad.

These muscles of the larva of the Sphinx differ but little from those described by Lyonet in the Cossus. In all insects they give passage between them to the ramifications of tracheal vessels, which are most extensively distributed throughout the whole body, to every muscle, nerve, or other organ. They are also covered in many places by numerous connected vesicles filled with adipose matter, which exist in the greatest abundance in the larva state in all insects, occupying the interstices between the muscles and tracheæ. The same general structure of the muscular system as that which we have just described in the Sphinx exists in all larvæ that undergo a complete metamorphosis, whether they belong to the Coleopterous, Hymenopterous, or Lepidopterous classes, although in the particular distribution and form of the muscles in each there are necessarily some differences dependent upon difference of species and habit. Thus Burmeister found a similar general conformation of parts in the larva of *Calosoma sycophanta** (*fig.* 354), one of the more perfect Coleoptera, both in the existence of the rudiments of muscles for the wings and in the longitudinal muscles of the dorsal and ventral surfaces of the body. The muscles of the larvæ of Coleoptera, as Burmeister has remarked, bear a greater resemblance to the muscles of the perfect insects than those of the larvæ of other classes. It is not difficult to recognise in them the same general arrangement of particular muscles which are afterwards found in a more or less developed state in the perfect insects. An admirable exemplification of the muscular system of Coleoptera is given by Straus Durckheim in his splendid work on the anatomy of *Melolontha vulgaris*, in which many of the muscles that exist in the larva state may be distinctly identified, although greatly modified in form and size to fit them for new modes of action, which have been rendered necessary by the changes that have taken place in the habits and modes of life of the insect. Thus, as also remarked by Straus,† the great ventral series of recti muscles which we have just seen in the larva, form successively the retractor muscles of the labium, the depressors of the head, the retractors or depressors of the pro-sternum, or those which draw that part to the meso-sternum, and the pretractors of the post-furca or triangular process of the metasternum; and, lastly, the inferior recti muscles of the abdomen. But in each of these instances the size and form of the muscles are greatly altered, more especially in the thoracic region, while in the abdominal region those of the posterior segments exist with less change of form than in the thoracic, but are greatly reduced in size, and those of the anterior abdominal segments, in which the ventral plates of two or more segments have become consolidated together, are atrophied and have almost disappeared. In like manner the dorsal recti of the larva exist in the imago in the new form of elevators of the head, superior retractors or elevators of the prothorax and scutellum, and levators, depressors, and adductors of the wings and dorsal longitudinal recti of the abdomen. In the latter region neither their form nor direction have been changed, but like the ventral recti they have been much reduced in size, because there is less necessity for their active employment in the perfect than in the larva state, in which nearly the whole of the locomotive powers of the individual are entirely dependent upon those muscles. Their form and direction have not been changed because the direction in which they are employed in the perfect state is precisely similar to that in which they are employed in the larva. But this is not the case in the thoracic region, in which not only have they been enormously increased in size and changed in form, but their relative position has also been altered, owing to the changes that have taken place during the metamor-

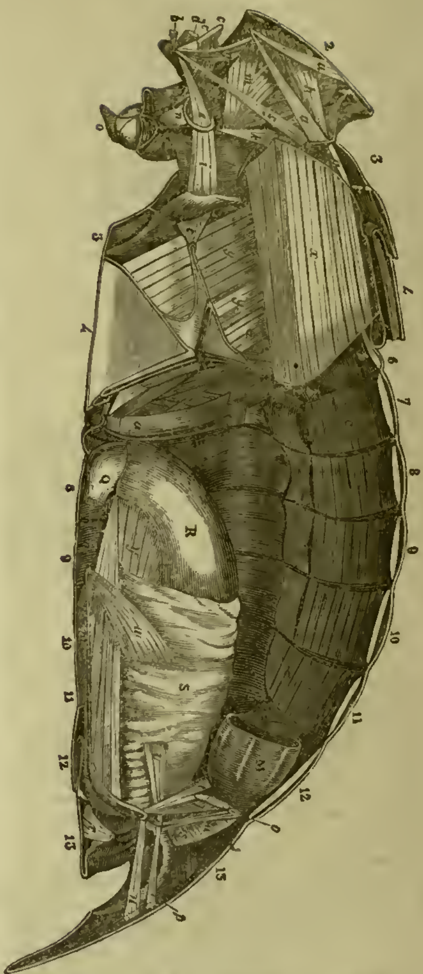
* Trans. Entom. Society, Lond. vol. i. p. 335.
† Considerat. Generales, p. 149.

phoses in the position of parts of the tegumentary skeleton, to which the muscles are attached. Hence the direction in which these muscles are now required to act is also changed, and from constituting, as in the larva, only one continuous series of uniform muscles, acting in one direction, in the perfect insect they become muscles that act in several directions, at different angles of the body, and in some parts exceed in importance and size every other division of the muscular system. Thus, in the thoracic region, the dorsal muscles, which were parts least employed in the larva, are those which are of the greatest importance in the perfect insect, both as regards size and function. In the larva, as we have seen, locomotion depends chiefly upon the abdominal recti; but in the perfect insect, on the contrary, nearly the whole of this power is transferred to the dorsal muscles of the thorax. Hence the arrangement of these muscles is more or less intricate, and differs in different classes, according to the habits of the insects. Thus, in those classes in which the prothorax is short, and almost or entirely anchylosed to the meso-thorax, as in the Hymenoptera, Lepidoptera, and Diptera, and in which, consequently, scarcely any motion of the prothoracic segment is required, the muscles become almost entirely atrophied and cease to exist, or, as is sometimes the case, their attachments are transferred to a different part of the tegumentary skeleton.

The most generally developed form of the muscular system of the thorax is found in the Coleoptera, of which Straus has given so admirable an illustration in his anatomy of *Melolontha*. It is from his description of the muscles of that insect that we shall chiefly derive our general description of these parts in perfect insects. We shall, however, for the sake of uniformity, adopt the nomenclature applied to these parts by Burmeister, identifying it with the names originally employed by Straus.

The muscles that connect the head with the thorax are contained within the prothorax (*fig.* 402,2), and are of three kinds, *extensors*, *flexors*, and *retractors*. The extensors, *levatores capitis* (*a*, *a*), consist of two pairs, one of which arises from the middle line of the pronotum, and diverging laterally from its fellow of the opposite side, passes directly forwards and is inserted by a narrow tendon into the anterior superior margin of the occipital foramen. The other arises further back from the prophragma. It is a long narrow muscle that passes directly forwards through the prothorax, and is inserted by a tendon near the superior median line of the foramen; so that while this muscle and its fellow of the opposite side elevate the head almost in a straight line, the one first described, when acting alone or singly, draws the head a little on one side; but when the whole of these muscles act in unison, they simply elevate the head upon the prothorax. The depressors or flexors, *depressores capitis* (*b*), are exceedingly short muscles, which arise from the jugular plate, or, when that part does not exist, from the border of the pro-sternum, and are attached

Fig. 402.



Section of the body of Melolontha. (Straus.)

to the inferior margin of the occipital foramen. They simply flex the head on the prothorax. The lateral flexors, *depressores externi* (*d*), are two little muscles that arise from the same point as the preceding, and are attached to the lateral inferior margin of the occipital foramen. The rotatory muscles, *rotatores capitis* (*c*), are two flat muscles like the elevators, which arise, one at the side of the ante-furca and the other from the posterior jugular plate, and passing upwards and outwards are attached to the lateral margin of the occipital foramen. The *retractor* or flexor of the jugular plate is a small muscle (*e*) that arises from the margin of the ante-furca, and passing directly forwards is inserted by a small tendon into the middle of the jugular piece. The *oblique extensor* of the jugular plate is a long slender muscle (*f*) that arises from the external margin of the pronotum, and passing obliquely downwards and forwards traverses the prothorax and is inserted by a narrow tendon to the jugular plate immediately before the retractor. The other retractor (*g*) arises from the anterior superior boundary of the pronotum, and passing downwards is inserted into the jugular plate between the larger levator and the flexor capitis.

The muscles proper to the prothorax consist of four pairs, by which it is united to the succeeding segments. The first of these, the superior retractor, *retractor prothoracis superior* (*h*), arises by a broad fleshy head from the anterior external margin of the pronotum, and passing directly backwards is inserted by a tendon into the prophragma a little on one side of the median line. The next muscle of importance, the *inferior retractor* (*i*), arises from the anterior border of the medi-furca, and is united to the posterior of the ante-furca, thus forming with that muscle part of the great recti of the larva. This muscle must be considered as the proper depressor of the prothorax. The *elevator prothoracis* (*k*) is narrow, pyramidal, and arises fleshy from the lateral surface of the prophragma. It passes downwards and is attached by a narrow tendon to the superior portion of the ante-furca. The *rotatores prothoracis* are the largest of all the muscles of this segment. They arise, one on each side (*l*), by a narrow head from the posterior part of the pronotum, and passing beneath the prophragma are considerably enlarged and attached to the tegument between the two segments, and also to the anterior portion of the mesothorax. The remaining muscle proper to the prothorax is the closer of the spiracle, an exceedingly small muscle not shewn in the drawing. The other muscles of this segment are those of the legs, which are of considerable size. There are three distinct flexors of the coxa (*m*, *n*, *o*). The first of these arises from the superior lateral border of the pronotum, the second from the superior posterior border, the third from the sides of the prothorax, and the fourth a little nearer posteriorly, and the whole of them are attached by narrow tendons to the sides of the coxa. But there is only one extensor muscle to this part. In like manner the extensor of the trochanter is formed of three portions, (*fig.* 403, *a*, *b*, *c*,) but there is only one flexor (*d*) and one abductor (*e*). In the femur there is one extensor (*f*), a long penniform muscle that occupies the superior part of the thigh, and is attached by a tendon to the anterior posterior margin of the joint, formed by the end of the tibia. There is also but one flexor (*g*) in the femur, which, like the preceding muscle, is penniform, and occupies the inferior portion of the femur, and its tendon is attached to the inferior border of the tibia. In the tibia itself there is also one flexor and one extensor. The flexor (*i*) occupies the superior portion of the limb, and ends in a long tendon (*l*) that passes directly through the joints of the tarsus on their inferior surface, and is attached to the inferior margin of the claw (*g*). The *extensor* (*h*) occupies the inferior portion of the tibia and is shorter than the preceding muscle, like which it ends in a long tendon that is attached to the upper margin of the claw. Besides these muscles, which are

Fig. 403.

Muscles of the anterior leg of Melolontha vulgaris. (Straus.)

common to the joints of the tarsus, there are two others belonging to the claw, situated in the last joint. The first of these, the *extensor* (*m*), is short and occupies the superior portion of the last phalanx of the tarsus, and the other, the *flexor* (*n*), is a much longer penniform muscle, which occupies nearly the whole of the upper and under surface of the posterior part of the phalanx, and is attached, like the long flexor of the tarsus, to the inferior part of the claw. These are the muscles of the prothorax and its organs of locomotion, as shewn by Straus, and exemplify the extent unto which the muscular system is developed in perfect insects. The muscles of the other segments of the thorax differ considerably from these in their form and arrangement, but the length unto which this article has already been carried prevents us from entering particularly into their consideration. The great depressor muscle of the wings, *musculus metanoti* (*fig.* 402, *x*), occupies with its fellow the chief portion of the dorsal surface of the meso- and meta-thorax, and the elevators and pretractors, *musculi laterales metanoti* (*y*, *y*), the lateral superior parts of the same segment, and descending obliquely backwards are attached to the metaphragma and base of the post-furca. The other muscles which belong to the legs and those that connect the thorax to the abdomen are of considerable size. One of those of the posterior legs, the second *flexor* (*z*), is seen immediately behind the muscles of the wings, and the *extensors* (*a*, *a*) at the posterior part of the segment. In the abdomen the chief muscles are the dorsal *recti* (*c*, *c*) on the upper surface, and the corresponding ones on the ventral, which are now chiefly subservient to the motions of the organs of generation.

From the number and complexity of the muscles in these "miniatures of creation"—insects—we feel less surprised at the agility of their movements and the variety of motions which many of them perform, and less astonishment at the wonderful strength which many species possess. But still there are instances of some of them possessing a degree of power that is almost incredible. The great stag-beetle, *Lucanus cervus*, which tears off the bark from the roots and branches of trees, has even been known to gnaw a hole an inch in diameter through the side of an iron canister in which it was confined, and on which the traces of its mandible were distinctly visible, as proved by Mr. Stephens, who exhibited the canister at one of the meetings of the Entomological Society,* an indication of an amount of strength possessed by these insects of which before we could have had no conception. But hardly less surprising is the strength possessed by *Geotrupes stercorarius*, which can support uninjured, and even elevate an immense weight, and make its way beneath almost any amount of pressure. In order to ascertain the amount of strength possessed by this insect, we have made a few experiments from which it appears that it is able to sustain and escape from beneath a pressure of from twenty to thirty ounces, a prodigious weight when it is remembered that the insect itself does not weigh even so many grains. But this amount of strength is not confined to the short thick-limbed beetles. We once fastened a small *Carabus* (——— ?), weighing only three grains and a half, by means of a silken thread to a small piece of paper, upon which the weight to be moved was placed. At a distance of ten inches from its load the insect was able to drag after it, up an inclined plane of twenty-five degrees, very nearly eighty-five grains. But when placed on a plane of five degrees it drew after it one hundred and twenty-five grains exclusive of the friction to be overcome in moving its load.

The *motions* of the insect in *walking* as in *flying* are dependent in the perfect individual entirely upon the thoracic segments, but in the larva chiefly upon the abdominal. Although the number of legs in the former is always six, and in the latter sometimes so many as twenty-two, progression is simple and easy. Müller states † that on watching insects that move slowly he has distinctly perceived that three legs are always moved at one time, being advanced and put to the ground while the other three propel the body forwards. In perfect insects those moved simultaneously are the fore and hind feet on one side and the intermediate foot on the opposite, and afterwards the fore and hind feet on that side and the middle one on the other, so that, he remarks, in two steps the whole of the legs are in motion. A similar uniformity of motion takes place in the larva, although the whole anterior part of the body is elevated and carried forwards at regular distances, the steps of the insect being almost entirely performed by the false or abdominal legs.

In *flight* the motions depend upon the meso- and meta-thoracic segments conjointly, or entirely upon the former. The sternal, episternal, and epimeral pieces, freely articulated together, correspond in function with the sternum, the ribs, and the clavicles of birds.* The thorax is expanded and contracted at each motion of the wings, as in birds and other animals, and becomes fixed at each increased effort as a fulcrum or point of resistance upon which the great muscles of the wings are to act, thus identifying this part of the body in function as in structure with that of other animals.

The Nervous System.—Comparative examinations of the nervous system in Articulata, and the changes which it undergoes, more especially in Insects, as well as the existence in it of parts which we regard as analogous to the motor and sensitive portions of the spinal cord in vertebrata, have invested this division of our subject with more than a common amount of interest.

It has been shewn in a former part of this work,† that in Articulata the most rudimentary condition of the nervous system exists in the form of two longitudinal cords, extended along the median line of the under surface of the body, parallel with each other, and nearly close together, excepting at their anterior part, where they diverge, and pass upwards, to embrace between them the commencement of the alimentary canal. In a more advanced stage of organization each of these cords has a series of enlargements or ganglia in its course, situated at certain distances apart, and varying in number according to the number of segments into which the body of the animal is divided. These enlargements correspond precisely in situation in both cords, so that the nervous system in this condition may be described simply as composed of two knotted, parallel cords. The enlargements in one cord are either placed close to the corresponding ones in the other, or are separated only by a very slight interspace. This is the form in which the nervous system exists, as we have seen, in the Talitrus,‡ in which the ganglia are approximated together, but are still distinct from each other, and form a double series of enlargements, united by intervening cords. This is also the condition in which the nervous system exists in its most rudimentary state in the larva of hexapodous insects. But these parallel cords, which together form the analogue of the cerebro-spinal system of vertebrata, and correspond one to each side of the body, are not in themselves simple structures, each one being composed of

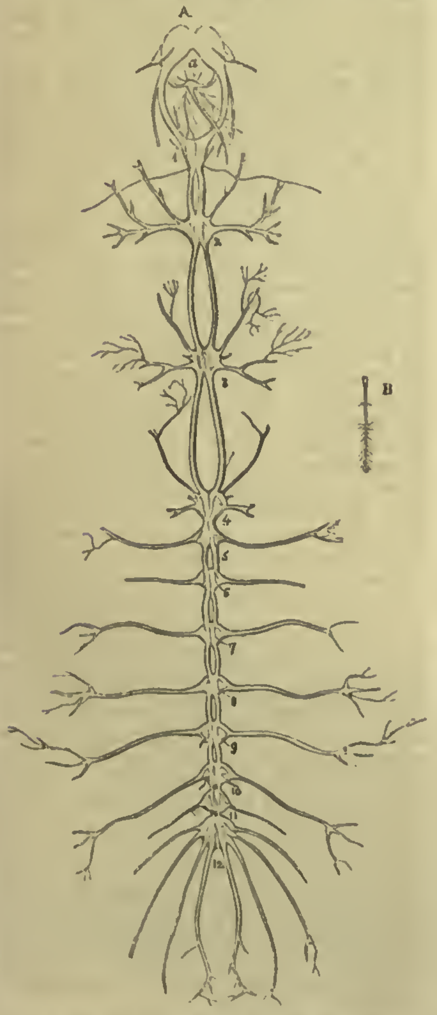
‡ CRUSTACEA, vol i. p. 763, fig. 391.

two distinct columns of fibres, placed one upon the other, and closely united together in every instance. The under or *external* column, which is nearest to the exterior of the body, is that in which the ganglia or enlargements are situated. The upper one, or that which is *internal* and nearest to the viscera, is entirely without ganglia, and passes directly over the ganglia of the under column without forming part of them, but in very close approximation to them. In some species, as in the larvæ of *Timarcha tenebricosa*, (*fig.* 404, 2, 3, 4,) and *Proscalabæus vulgaris*, among the Coleoptera, and of the Bee and other *Aculeate* Hymenoptera, this column is more apparent than in the larvæ of Lepidoptera, in which it is indistinctly seen, excepting when it is beginning to pass over or is just leaving the surface of a ganglion.

Fig. 404.



Nervous system of the larva of Timarcha tenebricosa. B, natural size.

The ganglionless upper or internal column of fibres is the part which we believe to be analogous to the motor column of vertebrata, and the external or under one, in which the ganglia are situated, we regard as the analogue of the sensitive. Thus the two cords are each composed of a motor and a sensitive column, and represent, we believe, the cerebro-spinal system of vertebrata. In the Aculeate Hymenoptera, the ganglia of the cords are in a state of development similar to those of the Talitrus; they are approximated together laterally, but still remain distinct from each other, and thus present a transitory condition in the larva state of an insect similar to their permanent one in the lower Crustacea. In the *Timarcha*, the anterior pair, or supra-œsophageal ganglia, still continue distinct from each other, (*fig.* 405, A A,) and retain their rudimentary form, as in the Talitrus, and the cords are also separated; but the several pairs of subœsophageal ganglia have each coalesced into a single mass.

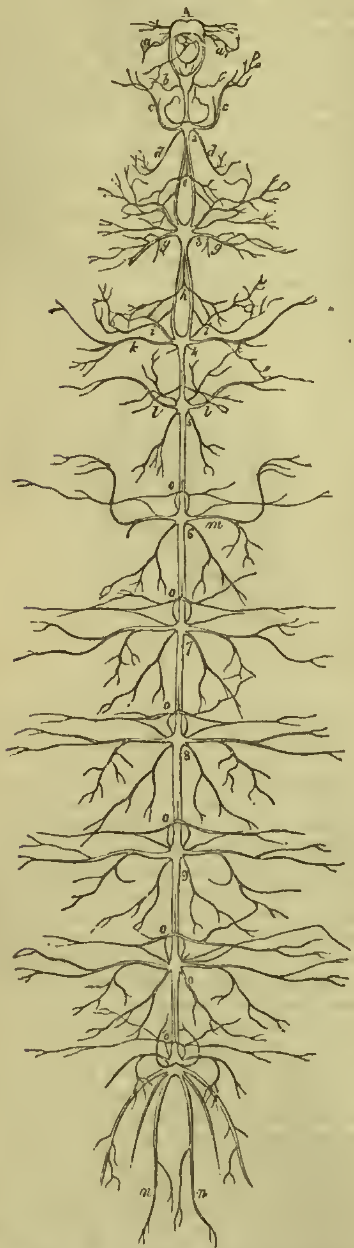
Fig. 405.

The supra-œsophageal ganglia, or brain of larva of Timarcha tenebricosa. (Newport, Phil. Trans.)

A similar coalescence of the ganglia, but carried to a less extent, exists in the larvæ of Lepidoptera, in which the form of the nervous system of insects has been most frequently examined. Malpighi and Swammerdam examined this structure in the Silkworm, and Lyonet in the larva of the Goat-moth, *Cossus ligniperda*. We have also examined it in the larva of the Privet Hawk-moth, *Sphinx ligustri*, in which we shall now describe its general form and distribution.

Cord and nerves of the larva.—In the larva of the Sphinx, (*fig.* 406,) as in most others of the vermiform type, the normal number of double ganglia is thirteen. The anterior pair (A) situated above the œsophagus, represent the *brain*, and the first of those which are situated below it, (*b*,) the *medulla oblongata*. These are the proper ganglia of the head or first segment, and the cords by which they are connected together, and which descend one on each side of the œsophagus, in like manner represent the *crura*. Posteriorly to the medulla oblongata, which we shall distinguish as the first subœsophageal ganglion, the cords pass directly backwards into the second segment, where they form the second subœsophageal ganglion (2). They then diverge a little from each other, and include between them the insertions of the first set of diagonal muscles, and at the posterior part of the third segment again approach each other, and form the third ganglion (3).

Fig. 406.



Nervous system of the larva of Sphinx ligustri.
(Newport, Phil. Trans.)

They then again diverge, and continuing their course into the next segment, pass on each side of the insertion of a second set of muscles, and approaching at the hinder part of the fourth segment form the fourth ganglion, (4,) from which they continue their course side by side, and in the next segment form the fifth and last ganglion, (5,) that enters into the composition of the thoracic portion of the nervous cord in the perfect insect. From the fifth ganglion the cords are continued in a direct line, into the sixth, seventh, and succeeding segments, forming in each a double ganglion, to the eleventh, where they form the terminal ganglion (11, 12). This is considerably larger than any of the preceding, being in reality composed of two distinct pairs, which originally were separated from each other by intervening cords, and belonged to the eleventh and twelfth segments, but which seem to approach and become closely approximated to each other during the earlier period of the larva state, as suggested by Dr. Grant, and supported by the fact that these ganglia are found more or less approximated together in different individuals, the terminal ganglion in some being distinctly formed of two pairs, scarcely united, and in others so completely coalesced as hardly to be distinguished. In other Lepidoptera, as in *Odonestis potatoria* and *Lasiocampa neustria*, and as represented also by Lyonet, in *Cossus ligniperda*,* the ganglia continue distinct, and are separated by a very short portion of the cords. But in the *Timarcha*, the eleventh and twelfth ganglia have completely coalesced, and it is remarkable that they are also united even in the rudimentary form of the nervous system in the aculeate Hymenoptera, as in the larva of the bee, and even in its still more rudimentary state in the larva of *Ichneumon Atropos*, in both which there are originally thirteen distinct pairs of ganglia, including the supra-œsophageal ones, although Burmeister has imagined that the apodal larvæ of Hymenoptera have a nervous system without ganglia,† similar to what he has observed and figured in the larvæ of some Diptera. It was shown by Swammerdam,‡ that in the Lamellicornes, as in *Oryctes nasicornis*, the cords are united laterally, and do not extend beyond the fourth segment, from whence the nerves radiate into the abdomen. In *Dyticus*, according to Burmeister,§ the two approximated cords are very short, and the pairs of ganglia are contiguous to each other, and he has found a similar form of the nervous system in the Hog-beetles, *Calandra sommeri*, in which there are twelve pairs of closely approximated subœsophageal ganglia. The supra-œsophageal pair in this species are distinct, as in Timarcha, but each pair of the subœsophageal has coalesced into a single mass, as in that insect, and the whole do not extend beyond the fifth segment, from whence the nerves radiate into the abdomen, as in the Lamellicornes. These are the conditions which the double cord presents in the different classes. In describing the nerves that proceed from it, we shall divide them into those of the head, the thorax, the abdomen, and the organic functions.

* Plate ix.
† Manual, (translat.) p. 279.
‡ Biblia Natura, Tab. xxviii. fig. 1.
§ Op. cit.

Nerves of the head.—When the first pair of ganglia, which always constitute the brain, are viewed from above, they each present a convex uniform appearance, and are distinguished from each other by a depression between them, which is more apparent on their anterior than their posterior surface, and is occasioned by the lateral part of each lobe or ganglion being carried a little forwards, so that the two lie across the œsophagus in a curved or lunated direction. On their under surface they are concave, to adapt them to the form of the œsophagus, above which they are situated. From the anterior and lower part of each lobe originate four remarkable nerves, which belong to the organs of sense and the viscera. The first and largest of these, the *optic*, passes a little forwards and outwards to the stemmata, a little behind the mandibles; the second, the *antennal*, passes a little more anteriorly, to the palpiform antenna; the third, and most inferior, descends at the side of the pharynx, and uniting with its fellow of the opposite side forms a loop or collar around the œsophagus, to the under-surface of which it distributes a few filaments. We consider it as analogous to the *glosso-pharyngeal* nerve of vertebrata. The fourth is situated between the second and third. It passes a little forwards from its origin, and then ascending above the pharynx, meets its fellow of the opposite side, with which it forms a minute ganglion, from the hinder part of which a single nerve passes backwards (*b*) beneath the brain, in the median line above the œsophagus, to the stomach and viscera. This nerve was discovered by Swammerdam,* who called it the *recurrent*, from the manner in which it originates and is distributed, and it was afterwards minutely figured and described by Lyonet. Müller has since described it minutely, and figured it in many species, in his paper on the sympathetic nerves of insects, as the proper visceral nerve, analogous to the *sympathetic*. In a paper in the Philosophical Transactions in 1832, we described it as the *vagus*,† of which we believe it is the proper analogue. At that time we were led to suppose that it had previously been so described by Straus Durckheim, but such, as we have since found, was not the case. We shall presently return to our description of this nerve, in the perfect insect, as belonging to those of the organic functions. Besides these four pairs of nerves from the anterior part of the brain, there is also one minute pair from the posterior, which is directed backwards, and developed on each side of the head into two pairs of little ganglia, (*a*,) which constitute part of the *sympathetic* system. The first of these ganglia was discovered and rudely figured by Swammerdam,‡ and afterwards more correctly by Lyonet, and the second by Straus Durckheim. We have designated them from their situation the *anterior lateral ganglia.*§

* Op. cit. tab. xxviii. fig 2.
† Part 2, p. 386.
‡ Op. cit. tab. xxviii. fig. 3 i.
§ Philosophical Trans. p. 2, 1832, page 387.

These are the proper cerebral nerves of the larva, and belong to the senses and organic functions. The *medulla oblongata*, or first subœsophageal ganglion, also gives origin to four pairs of nerves. The most anterior pair of these is given to the labium; the next to the palpiform maxillæ; the third, the analogue of the fifth of vertebrata, conjointly to the muscles of the mandibles and maxillæ; and the fourth, the most posterior pair, to the silk vessels, the proper salivary organs of the larva.

The nerves of the thorax belong to the second, third, fourth, and fifth subœsophageal ganglia, and their intervening cords. The first pair of nerves from the second ganglion (2) are exceedingly small, and are given to the retractor muscles of the head. The second pair (*c*) are large, and are divided into many branches that are given to the whole of the muscles of the lateral and superior part of that segment, and the third (*d*) are directed backwards, and supply the anterior or prothoracic legs. The third ganglion (3) produces also three pairs of nerves. About midway between the second and third ganglion the cord produces on each side a single nervous trunk (*f*), which is directed a little backwards, and unites at an angle with the first nerve from the third ganglion. These together from a single trunk, which in the early stage of the larva is exceedingly small, but increases much in size as the period of changing into the pupa state approaches. It is the first *alary* nerve, and is given to the future anterior pair of wings, and is now distributed among the muscles of the anterior part of the segment. It is also connected with one set of the transverse nerves (*e*), which exist in each segment loosely attached to the cords, and which we shall describe more particularly hereafter. The second pair of nerves from this ganglion produce each at their base a small branch, which has the appearance of a distinct nerve, and which is distributed laterally to the deep-seated muscles, while its main trunk (*g*) is given to the second, or mesothoraçic pair of legs. Half-way between the third and fourth ganglion the cord again produces on each side a single nervous trunk (*i*), which, like the corresponding one in the preceding segment, is directed backwards, and unites with the first nerve from the third ganglion. It is the second *alary* nerve given to the muscles of the future second pair of wings. Like the corresponding nerve in the preceding segment, it is very small during the early period of the larva state, but is greatly enlarged as the period of transformation approaches. It also unites, like the former, with a set of the transverse nerves (*h*), and then passes outwards about midway across the recti muscles, between which it penetrates, and pursues its course upwards to the lateral and dorsal muscles of the segments, and which are to act upon the future wings. The second nerve from the ganglion divides, like the corresponding one from the ganglion of the preceding segment, into two branches, one of which (*k*) crosses the smaller rectus muscle, and passes beneath the larger to the dorsal muscles of this segment, and the second is given directly to the third pair of legs. The fifth ganglion (5), which is situated at the anterior part of the fifth, or thoracico-abdominal segment, belongs, as we shall hereafter see, to the thorax. Like the abdominal ganglia it gives off two distinct pairs of nerves, the anterior of which crosses the smaller, and descends beneath the larger rectus, and is distributed to the muscles which afterwards connect the thorax and abdomen of the perfect insect; and the second, a smaller pair, passes diagonally backwards below the third rectus, to the triangular and transverse abdominal muscles. These are the nerves of the thorax in the larva of the Sphinx. In other species there are some marked differences in their mode of distribution. Thus, in the *Cossus ligniperda*, as shown by Lyonet, the first and second subœsophageal ganglia are closely approximated together, and have no intervening cords, and their nerves, consequently, pass diagonally backwards, and not transversely, as in the Sphinx. The nerves for the future wings are not derived, as in the Sphinx, from the ganglionless parts of the cord, but from the ganglionated portion alone, and the distance between the fourth and fifth ganglia is considerably shortened. In the larva of the nettle butterfly, *Vanessa urticæ*, as formerly shown by us,* the *alary* nerves are derived directly from the cord itself, between the second and third and third and fourth ganglia, but they do not unite, as in the Sphinx, with a nerve from the next ganglion, but only with the transverse nerves. But in some of the *Bombycidæ*, as in *Odoncstis potatoria*, we have found the same connexion to exist between the alary nerves and those of the ganglia, as in the Sphinx, and a similar union also between them and the transverse nerves. This is particularly interesting from its proving that three distinct branches enter into the formation of the nerves for the future wings. We have found a similar double origination of the alary nerves in the vermiform larvæ of Hymenoptera, as in *Athalia centifoliæ;* and Burmeister has detected a similar condition of the same nerves in the larva of one of the Coleoptera, *Calosoma sycophanta*, and, as we shall presently see, a similar condition exists even in some perfect insects. Burmeister, who observed these connexions of the nerves in *Calosoma*, and called them *auxillary connecting nerves*, has somewhat curiously remarked that he believes they have not before been observed in any insect, particularly in the Lepidoptera, in proof of which he adduces Lyonet's description and delineation of the nerves in *Cossus*, in which, as we ourselves have found, they certainly do not exist. The reason for this difference of manner in which nerves that are given to similar parts in insects of the same order and family originate, is a matter worthy of much consideration.

Nerves of the abdomen.—All the nerves from the sixth to the terminal ganglion belong to the abdomen, and are nearly uniform both in number and distribution in the segments. Each ganglion produces one pair of large, and one of small nerves, entirely distinct from the series of transverse nerves (*o*) that lie loosely upon the cord.

It will be remembered that, according to our view of the structure of the cord and nerves, each nerve from a gangliated portion of this cord is formed of one set of fibres from the external or gangliated part, and one from the aganglionic or motor column (*fig.* 400), which passes over the ganglion (*a*), but so closely attached to it as to appear as if it formed a part of that structure. These, therefore, are quite distinct from the transverse nerves (*c*). The anterior pair of these nerves from the gangliated cord pass laterally across the smaller rectus, having first received a minute branch from the transverse nerves, and, while passing beneath the larger rectus, each one gives off its first branch (*p*), and when passing between the second and third oblique muscles its second branch (*q*), which is directed forwards, and a little farther onwards its third (*r*), and its fourth (*s*), which are directed backwards. The main trunk (*t*) then crosses the great lateral trachea, and having received another filament from the transverse nerve (*n*), divides into two branches (*t*), which pass upwards between the dorsal oblique and recti muscles, and are divided into numerous ramifications. About midway across the dorsal recti some of the branches form a small plexus (*v*), before they are ultimately distributed to the muscles and tegument. The two first divisions of this nerve merit particular attention. The first (*p*) passes backwards beneath the greater rectus, and divides into two branches. The anterior one (*v*) is distributed to the four oblique muscles, and to the external or under surface of the rectus, which, as we shall presently show, is supplied on its internal surface from the transverse nerves (*l*). The second division passes backwards and is given, one portion to the under surface of the smaller rectus, and the other to the great oblique, while the termination of this portion (*w*) is continuous with a filament of the second branch of the transverse nerves (*l*). Some branches from this nerve pass between the triangular and second oblique muscles (*x*), and others are given to the latero-abdominal. The second branch (*q*) of the great moto-sensitive nerve passes beneath the great oblique, and gives off branches to the transverse abdominal muscles (*y*), and the latero-abdominal (*z*), while another supplies the latero-abdominal (31) and the oblique constrictor of the spiracle (25), and then divides into two portions, one of which is given to the *retractor valvulæ* (27), and the other to the transverse lateral muscles (24). The divisions of this branch of the moto-sensitive nerve are particularly interesting. Before dissecting these nerves we had supposed that the constrictor of the spiracle (25) and the retractor of the valve (21) were supplied by the transverse nerves, and hence were surprised on finding that their nerves were derived from the great moto-sensitive of the gangliated cord,

* Phil. Trans. 1834.

by which it is presumed they are thus endowed with voluntary power and sensation. But on reflection it will appear that this ought really to be the case. To enable the insect to make a forcible expiration and close its spiracle, which is evidently an act of volition, the great constrictor of the spiracle ought to be endowed with voluntary nerves. On the other hand, since, as we know from experiment that the insect has a voluntary power of closing, it must also have a similar power of opening the orifice, and, consequently, the retractor valvulæ ought to be supplied from the same source as the constrictor. The remaining portion of the trunk of these nerves passes forwards and outwards, crosses the retractor of the spiracle and gives off its third branch, which is again divided, and sends one portion backwards to the anterior (18) and the transverse abdominal muscles (17), and the other forwards to the transverse lateral (23). The remaining portion of the nerve is distributed to the dorsal muscles and teguments. The second nerve from the gangliated part of the cord is much smaller than the first. It passes diagonally backwards and outwards, and divides into two branches, the first of which is given to the latero-abdominal muscles, and the second to the triangular and transverse median, while the other (*k*) passes downwards and outwards, and is continuous with part of the third branch of the transverse nerves (*i*).

Besides the nerves thus described as belonging to the moto-sensitive cord in the thorax and abdomen, there are others that merit particular consideration, both from the circumstance of their lying loosely above the cord, and from their special distribution. These nerves, which were formerly distinguished by us* as *transverse nerves* from the direction of their principal branches, and as *respiratory* from their special distribution to the respiratory organs, were discovered by Lyonet, and are delineated and particularly described in his anatomy of *Cossus ligniperda*. There is a plexus of them in every segment of the thorax and abdomen. Like the alary nerves of the cord in the thorax, there is a little difference in the distribution of some of them in the Sphinx from that of the corresponding plexus in the Cossus. In our earlier examinations of these nerves† we believed them to originate from the posterior part of each ganglion of the cord, and this also was the opinion of Lyonet with reference to those in the Cossus which constitute the second and third plexus of the thorax, and the last of the abdomen, and which, he expressly states, do not come from the cords, but from the ganglia.‡ We have since been satisfied that the plexus in one segment is connected with that in each succeeding one by means of a minute filament, derived from the transverse portion of these nerves, and which, passing laterally over and very close to the ganglion of the cord, joins its fellow of the opposite side, in the middle line behind it, to form the longitudinal portion of the next plexus, such filament gathering a few additional ones from the upper or motor surface of the cords. Hence, as we have stated,* these nerves are of mixed character, and contain some voluntary motor fibrils. Each plexus is formed of these two filaments, which, closely approximated together, pass backwards along the median line above the cord, until they arrive just before the next ganglion, where they diverge nearly at right angles, and are closely approximated to another series of fibres that runs in a commissural manner transversely across the body, from one side to the other. On each side a filament (*e*) is given off from the transverse nerves to unite with the moto-sensitive (*f*) close to the inner side of the smaller rectus. Near the external margin of that muscle it gives off another branch (*g*), which passes forwards upon the muscle, unto which it gives filaments, and then turns suddenly outwards (*h*), to join a branch from the great moto-sensitive nerve, while a smaller branch is continued onwards to supply the remainder of the muscle. This union is exceedingly interesting, and illustrates the fact that, even in the Invertebrata, some of the nerves in one part are connected by loops with those in others, as noticed by physiologists in the Vertebrated classes. The next branch (*i*) of the transverse nerves is equally interesting from the same circumstance. It is continuous in the same manner with another branch of the moto-sensitive (*k*). This branch is composed of fibres that are approximated to the transverse trunk, and pass some from without inwards, and others from within outwards, to form the nerve (*i*), leaving between them at its base a little triangular interspace, covered by a membrane and resembling the plexus (*b*). This nerve passes directly forwards until it arrives at the insertion of the greater recti (*j*), where it gives off a large branch to those muscles, and then passing beneath the oblique muscles, unto which it is distributed, and to the triangularis, becomes connected by loops with the second pair of moto-sensitive nerves (*k*) in the preceding segments. Neither of these two branches have been delineated by Lyonet in the Cossus. The next branch (*l*) of the transverse nerves is given to the tracheæ and visceral surface of the great rectus, after which the trunk of the nerve passes outwards until it arrives at the tuft of tracheal vessels which are situated just behind the spiracle (F). It there divides (*m*) into two branches, one of which passes on each side of these tracheæ. Some filaments from the anterior branch pass inwards along the trachea towards the alimentary canal, while others are distributed to the transverse lateral muscles, dorsal recti, and lateral muscles of the dorsal vessel. The other division of the nerve also gives branches to the tracheæ

* Phil. Trans. 1832, part ii. p. 389, and 1834, part ii. p. 401, also 1836, part ii. p. 544.
† Op. cit. 1832.
‡ Traité Anat. de la Chenille, 1760, also 1762, p. 98 and 204.

* Phil. Trans. part ii. 1836.

and to the moto-sensitive nerve (n), and, like the other, the obliqui and recti muscles and dorsal vessel. This division of the transverse nerve into two branches before it arrives at the trachea is not figured by Lyonet in the Cossus. In his delineation the transverse nerve crosses the trachea singly, posteriorly to the spiracle, where it communicates, as in the Sphinx, with the first moto-sensitive nerve from the gangliated cord, but does not give off a large branch anteriorly to the spiracle. We are thus particular in our description of these nerves, because it has sometimes been supposed that their distribution is precisely the same in all Lepidoptera, but which it is thus seen is not the case.

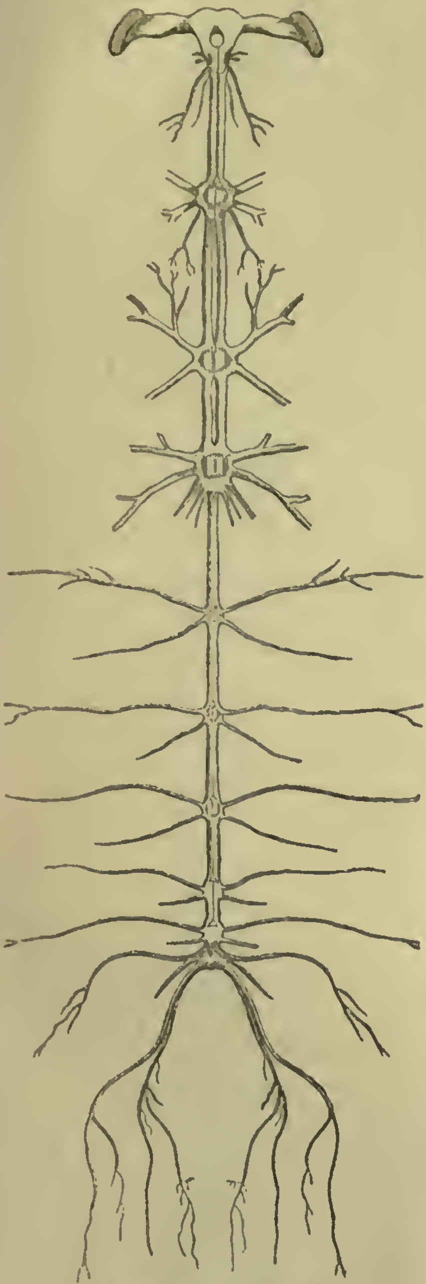
Such, then, are the origins and the distribution of the nerves in the larvæ of Lepidoptera, into the description of which we have entered thus minutely in order to show that some nerves are distributed, more especially than others, to parts concerned both in the organic functions and the voluntary motions of the animal, and that others are given almost exclusively to parts that minister entirely to sensation and volition. Of the first kind are those which we have designated respiratory nerves; of the second are those we have described as the moto-sensitive, the proper nerves of the cord. The distribution of the first so especially to the respiratory organs is a circumstance which justifies us, we think, in still regarding them by that designation, whether they be considered as constituting a distinct system, as formerly supposed, or as being of a mixed character, connecting the organic with the voluntary functions of the body, as suggested by Professor Müller, and as we now regard them. In our earliest inquiries into the structure and uses of parts of the nervous system in insects, we first described these nerves with reference to function, as *respiratory* nerves, but it was afterwards suggested by Professor Grant that these '*might* be motor nerves,' an opinion founded analogically upon the existence of a loose and easily detachable structure situated upon the nervous cord in the Scorpion and the Centipede, and which was imagined to be the motor tract, but which has since been shown to belong to the *vascular* instead of the *nervous* system. The structure which we regard as the true motor column, we have always found in close apposition with the sensitive, and in no instance lying freely upon or loosely attached to it. That the transverse nerves are indeed of a mixed character may readily be inferred from the description we have above given of their peculiar structure, which was in part noticed by Lyonet,* who called these nerves *brides epinières*. It is distinctly seen that three sets of fibres enter into the composition of them. The commissural set, which runs transversely across the cord to each side of the body, is perfectly distinct from the longitudinal that form the single loosely attached longitudinal portion of each plexus above the cord. The peculiarity of their distribution is also as remarkable as their structure. We have seen that they are given to the muscles of the wings, not separately, but approximated to other nervous trunks, which are derived both from the compound cord and from the ganglia; that they are given to the muscle that connects the alimentary canal to the general muscular structures of the body; that they are connected with the nerve from ganglia of the cord in each segment, are also given separately to the organic structures, the tracheæ and dorsal vessel; and that these nerves alone follow the course of the tracheæ inwards to their distribution on the alimentary canal; from all which it may be inferred that their function is certainly in part organic; while the fact of their being also in part continuous with some of the nerves from the cord which are distributed to voluntary muscles renders it equally apparent that they are in part also connected with the function of volition.

The nervous system of the perfect insect differs considerably in the size and relative position of its parts from that of the larva. Instead of its being almost equally distributed to every segment of the body, the greater proportion of it is removed forwards and concentrated in the head and thorax. This concentration takes place in every insect that undergoes a complete metamorphosis. The great principle upon which the development of the nervous system depends, is the approximation and concentration of the ganglion of the different segments, the shortening of the cords, and the formation of new trunks, by the enlargement, the changing of place, and the aggregation of several nerves into one bundle, occasioned and rendered necessary by other changes that take place in the body at a certain period. A concentration, therefore, of the nervous matter is regarded, both in the perfect and larva condition, as a proof of a higher stage of development in an insect than when the nervous matter is more equally distributed. On this account partly it is that the Coleoptera are considered the higher forms of insects, because, in addition to a more perfectly developed form of the tegumentary skeleton, there is also in them a concentration of the nervous masses, which, in the more perfect species of the order, are confined entirely to the region of the head and thorax. This is the case even in the larva condition of some of the Lamellicornes, *Scarabæidæ*, *Geotrupidæ*, and *Melolonthidæ*, in which the nervous masses are confined to the first five segments, and the nerves radiate from them into the abdomen, as formerly shown by Swammerdam in *Oryctes nasicornis*. But although an aggregation of the nervous masses into one region of the body is usually, it is not invariably, a proof or an accompaniment of high development; since a condition similar to that of the larvæ of the *Melolonthidæ* exists even in some of the lowest forms of larvæ of other orders, as in the larvæ or common maggots of Diptera, and in some of the perfect insects, as in the Gad-fly, *Œstrus equi;* while, on the contrary, a lengthened

* Op. cit. p. 201.

form of cord and distribution of ganglia exists even in many of the more perfect Coleoptera, as in the *Carabidæ* (*fig.* 407) and *Hydrophi-*

Fig. 407.



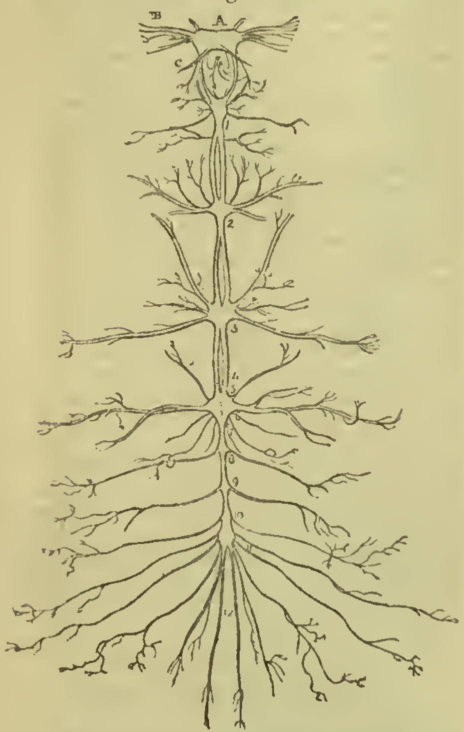
Nervous system of Carabus monilis.

lidæ. Swammerdam long ago showed this aggregation of nervous matter in the maggot of the cheese-hopper, and Burmeister has since observed even a more concentrated form in the larva of *Eristalis tenax*, the rat-tailed maggot of cesspools and privies. In the latter instance, as seen also by ourselves, the nervous system consists of a short nodulated cord, which does not extend beyond the three very short thoracic segments, and the greater portion of the body, the nine posterior segments, receives its nerves directly from the cord in the thorax, and not from a ganglion in each segment. This is a circumstance the more remarkable, if, as believed by Straus and others, the existence of the ganglia is regulated entirely by the mobility of the segments or the existence of appendages, because, in these instances, the extremities of those segments in which the cord is placed are undeveloped, or only, as in Eristalis, in the most rudimentary form and almost useless, the sole organs of locomotion being the abdominal or false legs, while in the common maggots (*fig.* 358) both the abdominal and thoracic legs are absent, and locomotion is performed equally by every segment of the body. In addition to this it may be stated that in some of the active larvæ of the most perfect Coleoptera, as in the *Carabidæ*, there is a lengthened form of cord and a ganglion in almost every segment of the body. Burmeister found the brain and twelve sub-œsophageal ganglia in the larva of *Calosoma*, and yet the insect possesses only six thoracic legs, the abdominal ones being entirely absent, excepting only the caudal leg or extremity of the abdomen, in which segment there is no ganglion. These facts will prove that although a concentrated form of the nervous system usually exists with a more perfect development of other parts of the body, it exists also when the development of other parts is imperfect. It is not, then, the immobility of the segments that regulates the disappearance of the ganglia, since, as Burmeister has justly remarked, there is as little motion of the segments of the abdomen in the perfect *Carabidæ* and *Lucanidæ*, in which cords and ganglia exist, as in the *Melolonthidæ*, in which they are absent. Neither is it necessary that ganglia should be present as a means of supplying energy in segments upon which, as in *Eristalis*, the entire locomotive power of the insect depends, or that when ganglia are present they are necessarily connected with the function of motion.

The most concentrated form of the nervous system in all its states exists in the *Lamellicornes*, the *Scarabæidæ*, and *Melolonthidæ*; but it is remarkable that even in these the development of the brain or supra-œsophageal ganglia is less perfect in the larva state than any of the other ganglia, and is not more advanced than in the Lepidoptera, in which, in the caterpillars of the nettle butterfly, *Vanessa urticæ*, so late as the middle of the last period of the larva state we have found these ganglia very distinct from each other, being only approximated in the middle line by their convex surfaces. Towards the latter period of the larva state they become rapidly more and more united, and at the time of change have formed one continued mass, placed transversely across the œsophagus. A similar condition of the brain exists in the soft-bodied larvæ of the

Lamellicornes, as shown in Swammerdam's drawing of *Oryctes*,* and Burmeister has delineated a like condition in the larva of *Calandra Sommeri*.† We have before seen (*fig.* 405) that such is also the case in the brain of *Timarcha*. From this it would appear that the cerebral ganglia are the parts of the nervous system last perfected in the larva, while it is interesting to observe that the reverse is the case as respects the terminal ganglion; that part, as correctly remarked by Professor Grant,‡ being the first to advance forwards and become united to the penultimate ganglion, to form the great caudal mass, at an early period of the larva. This is evident in the *Timarcha*, in which the eleventh and twelfth ganglia have coalesced into a single mass, while the cerebral ganglia only just meet above the œsophagus. But this is not the case in the perfect insect, (*fig.* 408,) in which the cerebral ganglia (A)

Fig. 408.



Nervous system of perfect state of Timarcha tenebricosa.

A, cerebral mass or brain; B, optic nerves; C, origin of sympathetic.

have become greatly enlarged, united together, and represent a distinct brain, from which proceed the nerves of sense, and united by long crura to the medulla oblongata (1), from which are given off as before the nerves of the organs of manducation. The cords are enlarged, as also are the three ganglia of the thorax and their nerves, and a coalescence has taken place between the fourth, fifth, and sixth ganglia, their intervening cords being entirely obliterated, and the nerves aggregated together are now derived from one mass, the great meta-thoracic ganglion, the last part of the nervous system in the thorax. A similar change has also taken place in the remaining part of the cord and ganglia, which now forms the abdominal portion. The cord between each of the ganglia has been shortened, and the tenth, eleventh, and twelfth are united and form the caudal mass, which is situated about half way across the abdomen. Such are the changes that take place in the nervous system of an inferior type of Coleoptera; in the higher forms, as in the *Melolonthidæ*, the series of approximated ganglia does not extend beyond the middle of the meta-thorax, the cords being terminated by a kind of *cauda equina*, all the nerves that go to the abdomen are aggregated together and extended into that region over the post-furca. A similar structure, but in a less complete form, exists in the *Dytiscidæ*, in which, as in the *Hydaticus cinereus*, a short cord is found with seven constrictions upon it, corresponding to that number of ganglia which probably existed in the larva state, but have nearly disappeared during the metamorphoses. But that this concentrated form of the nervous system is not necessarily connected with high development of other parts of the body is further shown in the common Earwig, *Forficula auricularia*, in which there are ten distinct sub-

Fig. 409.

œsophageal ganglia. The first, or medulla, is large and closely connected by very short crura with the brain, there being only a narrow

* Biblia Nat. tab. xviii. fig. 1.

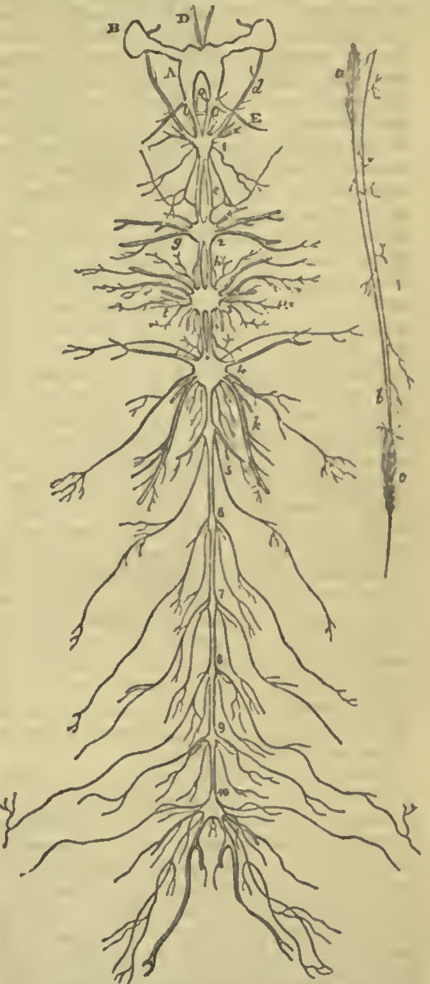
passage between the two for the œsophagus. Each segment of the thorax contains a ganglion, the meta-thoracic one, which gives nerves to the wings, being the largest. In the abdominal portion of the cord, which extends as far as the penultimate segment, there are six double ganglia very distinct from each other. This is exactly the number found by us in the same portion of cord in the *Carabidæ*, although, according to Burmeister, there are only five. Thus, then, in the *Forficulidæ*, in which there is the most extensive motion of the segments of the abdomen, there is the same number of ganglia as in the *Carabidæ*, in which most of the abdominal segments are anchylosed together and immovable, as in the Lamellicornes, in which the whole of the cord is situated within the region of the thorax. In the oil-beetles, as in *Proscarabæus vulgaris*, there are as usual three thoracic ganglia, the largest being the meta-thoracic, although the proper wings, and scarcely even the elytra, do not exist. In the abdominal region there are five ganglia, but smaller than those of the thorax, although it is stated by Burmeister* that these ganglia of the thorax are larger than those of the abdomen when perfect organs of flight are developed, but smaller when they are absent. So far as our own observations have extended, we have invariably found the thoracic ganglia larger than the abdominal, whether organs of flight exist or not, a condition that might naturally be expected whether the ganglia be connected with the production of nervous energy in the parts, or be only the centres of sensation. In the full-grown larva of this insect, of which we have examined a considerable number, but which at present appears to be scarcely if at all known to naturalists, we have found twelve perfectly distinct sub-œsophageal ganglia. Of these the fifth was the largest and separated from the fourth only by a very short cord, as were also the eleventh and twelfth, besides which the twelfth was larger than the eleventh, and appeared as if formed at an early period of two approximated ganglia. That in the earliest state of this insect there are thirteen sub-œsophageal ganglia seems highly probable. On watching the changes that take place it is found that this double terminal ganglion becomes united to the eleventh, and that a similar union takes place between the fourth, fifth, and sixth, so that only five separate abdominal ganglia exist in the perfect insect. In the *Forficula*, which does not undergo a perfect metamorphosis, a similar change appears to take place at a much earlier period, the terminal ganglion being distinctly formed of two masses, and the ganglion of the meta-thorax or wing-bearing segment of three. A similar change appears also to occur in the *Staphylinidæ*. In *Creophilus maxillosus* (*fig.* 341), in which the abdominal segments are as freely moveable as in the Earwig, but which undergoes a more complete metamorphosis, there are nine sub-œsophageal ganglia, only the last three of which are abdominal, the last five segments being entirely without ganglia.

* Op. cit. p. 281.

There is exactly the same form and position of the nervous system in the common species, *Goërius olens*. On comparing these circumstances it is found that a much smaller number of ganglia in general exists in those perfect insects which have undergone a complete metamorphosis than in the larva state, and than in those that scarcely change their form. In the *Gryllidæ*, *Acrida viridissima* (*fig.* 410), there is

Fig. 410.



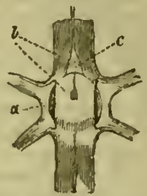
Nervous system of Acrida viridissima.

A, brain; D, antennæ; B, optic nerves; *d*, mandibular nerve; *e*, auxillary connecting nerve; *g*, nervo of prothoracic legs; *i*, of second pair of legs; *k*, third pair; *a*, tendon of flexor muscle with its nerve accompanying it to its insertion at extremity of the femur; *c*, second head of the same flexor muscle at the end of the tibia.

the same number of ganglia as in the Forficula, and a similar difference in the size of the thoracic ganglia. But in this insect there is also a closer lateral approximation of the abdominal cords, and a comparatively smaller size and more elongated form of their ganglia, evidently shewing a tendency to a more concentrated structure, although the cords still remain more distinct from each other than in the higher forms of Coleoptera. In the *Achetidæ*, of which the Mole-cricket affords us an example, as combining amazing strength and activity with apparently highly developed instinct, there is a more complete general form of the nervous system than in the *Acrida*. The ganglia of the thorax are particularly large, but the ganglia of the pro-thoracic segment, in which, and in the enormous limbs, nearly the whole strength of the insect, as we have before seen, is concentrated, does not equal in size the meta-thoracic ganglion, which is nearly one-third larger than either of the others, although the wings unto which it is given, as well as to the legs, are only of secondary importance as organs of locomotion, and although a fifth and much smaller ganglion is also attached to the meta-thoracic. The cord of the thorax is also large in proportion to the size of the ganglia. In the abdomen the relative size of the cord is less than in the *Acrida*, and there are only three small oval ganglia in it besides the large terminal one, so that the cord is extended scarcely half way through the abdomen, and yet the whole of the segments, and more especially the posterior ones, are capable of the most free and extensive motion. Thus, then, although in these and other forms of insects, particularly in the Hymenoptera, Lepidoptera, and Diptera, the ganglia are usually aggregated together in certain segments, apparently as a means of concentrating the energies of the animal when one particular region of its body is more actively employed than another, the presence of ganglia in the different segments is not more indispensable to the mobility than to the sensibility of these parts to external impressions, since the nerves that convey both motion and sensation to them may be derived from ganglia in distant segments, and yet the freedom of motion be not less than when each segment contains its own ganglion, and derives its nerves immediately from it.

The *structure of the cords* in the perfect insect is almost as distinct as in the larva, although the whole of the parts have become more opaque and closely connected together. In some instances it is more strongly marked than in others after the cord has remained for some time in spirits of wine, which is necessary before an examination of its structure is attempted. In many of the Coleoptera the motor column is seen passing in almost a direct line over the ganglia of the sensitive, but the transverse nerves are less easily detected, and in many instances appear to have become united with the other structures. We have, however, seen what we regard as such in the *Gryllidæ*, and more distinctly in *Gryllotalpa*, lying upon and above the motor column. In some specimens we have not found them from their being easily detached in those insects, and, probably, removed during dissection. But in these families we have always found the motor column strongly marked, particularly while passing over the ganglia of the thorax. In the *Carabidæ* (*fig.* 411) the course of the motor column (*b*) is distinctly indicated as it passes over the surface of a ganglion (*a*) by a

Fig. 411.



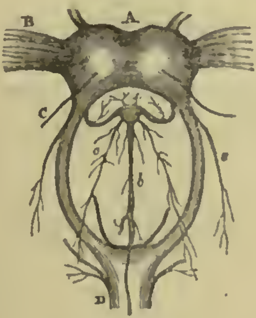
A portion of the gangliated abdominal cord of Carabus monilis.

a, a ganglion of the external or sensitive column; *b*, the upper or motor column; *c*, a ganglion of the transverse nerves.

longitudinal sulcus. Just as it is entering upon and also as it is leaving the surface of the ganglion, the motor column gives off a minute branch to join with the large branch from the ganglion of the sensitive column, and with it form a compound nerve. At a part of the cord corresponding to the anterior margin of each ganglion, lying upon and attached to the motor column on each side, is a minute gangliform mass (*c*), which we regard as the analogue of the plexus of the transverse nerves. It is of an obtusely angulated shape, and is attached to the motor column by a minute filament from its base on either side, and which passes outwards in the direction of the anterior pair of nerves. From its upper part in the median line extends another filament, the course of which we have not been able to follow. In *Lucanus cervus* the motor column is slightly elevated while passing over the ganglia, and at the anterior margin of each gives off a filament to join with the nerve from that part of the cord. We have sometimes observed attached to the motor column, just as it had passed over the meta-thoracic ganglion, on each side a little gangliform mass, which may possibly be part of a series of nerves like those on the cord in the *Carabus*. In the aculeate Hymenoptera, in which the ganglia of the thorax are large, the motor column is readily observed, but in some of the Terebrantia, as in the Turnip-fly, *Athalia centifoliæ*, when the cord is examined by a strong light, the motor column is most distinctly seen both on the ganglia of the thorax and abdomen, and in this insect exhibits an appearance which we have not observed in any other. This is a slight increase in the diameter of the column when it has passed about half-way over a ganglion, and a decrease to its original size when leaving it. Two filaments appear to be given off from the column to join the nerve from the ganglion, one as usual at the anterior margin of the ganglion, and the other, which appears to be the analogue of the transverse nerves, united to the motor column when about half-way over the ganglion. This enlargement of the motor column is greatest where it is passing over the thoracic ganglion, but is best seen on the abdominal ones. This fact has appeared particularly interesting to us, as we have elsewhere remarked,* from its seeming to be analogous to similar enlargements on those parts of the spinal cord in man and other vertebrata, from which proceed the nerves to the arms and lower extremities of the body, and corresponds to the apparent greater necessity for accumulations of nervous matter at those parts of the cord. In Lepidoptera the cord is less easily examined in the perfect than in the larva state owing to its increased opacity, but the transverse nerves are not only distinct but have been removed forwards and now pass off on either side midway between the ganglia.

The brain and its nerves do not acquire their full development until near the termination of the pupa state. The supra-œsophageal ganglia (A) of the larva, which, for convenience of description, we have called after Burmeister the *cerebrum*, are in reality the analogues of the *corpora quadrigemina*, and the first sub-œsophageal of the *medulla oblongata*. Burmeister has designated this the *cerebellum*, but of that part of the brain in vertebrata we believe there is no analogue in any of the invertebrata. Instead of the cerebral mass being divided into two ganglia, as in the larva, it has now (*fig.* 412, A) acquired a compact form; it is

Fig. 412.



A, *brain of Timarcha tenebricosa*; B, optic nerves; C, origin of the sympathetic and the crura; D, the medulla oblongata; *b*, the vagus or visceral nerve passing back from its ganglion; *e*, lateral nerves from the ganglion.

convex on its upper surface with a slight depression in the middle line, and concave on its under, to adapt it to the form of the œsophagus, across which it is placed. At its sides it gives off the large optic nerves (B), which are almost equal to it in diameter. They pass directly outwards and are usually swollen into the form of an oblong ganglion, but are again constricted before they arrive at the optic foramen, through which they pass and are immediately expanded into an immense number of fine filaments for the complicated organ of vision. There are enlargments upon these nerves at their base even in the larva state (*fig.* 405). From the most superior portion of the cerebrum originate the nerves of the *ocelli*. They vary in number from one to three, and are little pyramidal elevations situated on each lobe, as seen in *Acrida* (*fig.* 410), posteriorly to the antennal nerves (D). They are each covered by a dark choroid, and in other respects are distinct nerves of vision. When three exist, as in Hymenoptera, the third is situated in the middle line between the others, and appears to be derived in part from each lobe, so that in this ocellus the vision of both sides of the brain is combined. In the *Vespadæ*, however, according to Burmeister, the three ocelli originate from a single foot-stalk, and not separately, as in the *Apidæ*. On its anterior surface the cerebrum gives off the antennal nerves. These also, in many instances, have a ganglionic enlargement at their base, as is well seen in some of the *Ichneumonidæ* and other Hymenoptera, and as shown by Straus Durckheim in *Melolontha*. The antennal nerves vary in position, being sometimes near the middle line and at others close to the base of the optic, but in every instance anterior to them. At its anterior and inferior surface the cerebrum produces the two remaining pairs of nerves. The most external, the glosso-pharyngeal, unites with its fellow of the opposite side to surround the œsophagus, as in the larva. It is seen very distinctly in the pupa state (*fig.* 415, *f*) of the sphinx, and also in many perfect insects, as in *Acrida* (*fig.* 410). It supplies the under-surface of the throat and part of the œsophagus, and a small branch is also given from its base to the sides of the mouth. At its inner side originates the recurrent or *vagus* nerve, which, after passing a little forwards, ascends and forms its ganglion on the upper surface of the pharynx, and then passes backwards along the œsophagus, as in the larva. In some insects, as in Orthoptera, it originates from a portion of the crura, as in Crustacea, but its course and direction are always the same although appearing to vary, as we shall presently show when describing it as an organic nerve. The sympathetic originates, as in the larva, from the posterior part of the brain. One circumstance that particularly distinguishes the brain from the other ganglia is its more uniform opacity and greater softness, and disposition to deliquesce when exposed for a short time to the air. It is usually larger than most of the other ganglia, excepting perhaps the mesothoracic. In Hymenoptera it is larger than in other insects, a curious circumstance this if it may be supposed to have any reference to the comparative instinct of different species. In Diptera and Orthoptera it is also of great size. We were once desirous of knowing whether it contains any cavities or ventricles, but after the most careful search we have been unable to detect any. It is an almost homogeneous mass, penetrated throughout its whole substance by minute air-vessels, which ramify within it and also in the substance of the optic nerve. This is one of the circumstances that lead us to suspect, as formerly suggested by Dr. Kidd in his anatomy of the Mole-cricket,* that the course of the blood in the different structures

* Prize Essay, p. 11.

* Phil. Trans. 1826.

always accompanies that of the trachea. The *crura* vary much in length in different species. In Neuroptera, Hymenoptera, Lepidoptera, Diptera, and Homoptera they are short and thick, and form with the medulla a thick collar, through which the œsophagus passes as a narrow tube; but in the *Gryllidæ (fig.* 410), and more particularly in the *Lucanidæ (fig.* 413), they are excessively elongated, and they are also of great length in the *Timarcha*. The *medulla oblongata* varies much in size; in some, as in the Lepidoptera, it is as large as one of the lobes of the cerebrum, while in others it is scarcely thicker than the crura. It is always largest where large nerves are required for the parts of the mouth, which in all cases are derived from it. In this respect there is a striking analogy between it and the medulla oblongata of vertebrata. The anterior pair of nerves from this part are given to the labium and lingua, while the two next pairs are given to the mandibles and maxilla. In the distribution of these nerves there is great similitude to that of the fifth pair in the higher animals. In the larva state these nerves are always distinct from each other, but in the perfect they are often united at their base into one trunk. This is the case in the *Timarcha* and *Gryllidæ*. The anterior pair is the largest in mandibulated insects, and supplies the powerful mandibles, while the posterior pair is given to the maxillæ. The union of these nerves at their base is interesting from the circumstance that during manducation a consentaneous movement of these parts is required, since, while the mandibles are employed in chewing, the maxillæ are also employed in turning and assisting to pass the food into the pharynx. In the *Sphinx ligustri*, and other Lepidoptera, the chief portion of the mandibular nerve has disappeared in the perfect state, in consequence of the atrophy which has taken place in the mandibles during the transformations; but one branch of the nerve which exists in the larva state appears to have become approximated to the maxillary nerve, which is now greatly elongated and given to the proboscis, the representative of the maxillæ of the larva. The branch that appears to have belonged to the mandibular nerve is extended along the concave or inner side of each half of the proboscis, where the sense of taste may justly be suspected to reside, and is traceable very nearly to the extremity of the organ, where the papillæ we formerly noticed are situated, and in the direction of which this nerve is extended. From this we believe it to be analogous in function to the gustatory portion of the fifth nerve in vertebrata. In *Lucanus cervus* the mandibular nerve is of great length, and is so extensively developed as to afford almost a proof of the elongation of nerves during the metamorphoses of the insect. We have traced this nerve from its origin *(fig.* 413, *c)* into the base of the mandible, which it enters a little external to the insertion of the flexor muscles, where it is divided into three trunks, the inner one of which we have traced very nearly as far as the apex of the mandible. The other two are situated more externally.

Fig. 413.

Nervous system of Lucanus cervus.

A, the brain; B, optic nerves; C, sympathetic; D, antennal nerves; *a*, ganglion of the vagus nerve; *b*, the nerve; *i*, its division on the œsophagus; *d*, nerve to the first pair of legs; *f*, nerve to the wings, giving off at its base a small nerve to the elytra; *g*, nerve to second pair of legs; *k*, to third pair; *l*, abdominal cord and ganglia.

The most posterior one is given to the muscles within the head, and the other passes along the outward part of the interior of the mandible to its apex. The *medulla oblongata* with the continuation of the nervous cord in all Coleoptera passes under the bony arch or *tentorium* at the base of the skull, protected on both sides, as in *Melolontha*,* *Dyticus*, and *Hydröus*, by the *laminæ posteriores*, which inclose it, as in a canal, distinct from the œsophagus, that passes along above it, and from which it is separated by a fine fibrous membrane. The crura and the base of the cerebrum rest upon and are partly protected on each side by the *laminæ squamosæ*, which thus, as it were, form a kind of internal skeleton for the protection of the soft part. The optic nerves at their base rest upon the laminæ in their course to the eye, and extend as far outwards as the *laminæ orbitales* through the foramen in which they pass, and are immediately expanded into an immense number of filaments which form part of the organ of vision, as we shall presently describe. The whole of the cerebrum is loosely covered by a fine transparent membrane that is continuous with the fibrous membrane that covers the cord. In some instances, as in the *Bombus terrestris*, it is very distinct, and in others, as shown by Burmeister, is studded with minute opaque rounded elevations, arranged in the form of squares. It appears to be reflected along the course of the optic nerves, and to be continuous in part with the margins of the *laminæ squamosæ*, and separates the brain from the muscles, by which it is on almost every side inclosed. In *Lucanus cervus*, instead of the medulla passing under a simple arch or tentorium, the laminæ laterales are approximated and form a double ring (*fig.* 388, *f*), through the inferior of which, as through the ring of a vertebra, the nervous cord passes in its course to the prothorax. In the Orthoptera, as in *Blatta Americana* and *Gryllotalpa*, we have seen the same structure, but in these the ring is lengthened and forms a more distinct canal. In the Hymenoptera, as in the hornet and humble-bee, the form of the part is exactly the same, and the cord passes through a short bony ring in its passage to the thorax. There is a somewhat similar structure in Lepidoptera as in *Sphinx ligustri*, only that it is much less complete, the arch being simply a bar extended across the occipital foramen and dividing it into two, through the lower one of which the cord passes, and also on each side of it the flexor muscles of the head. A like form exists in the Homoptera, but much less perfect.

The *cord and nerves of the thorax*, which are usually much larger than those of the abdomen, we regard as the proper cerebro-spinal system, and the abdominal portion as the caudal. This is the view taken of these parts by Burmeister, with whose opinion we perfectly coincide. The prothoracic ganglion is situated immediately before the *ante-furca*, between which the cord passes to the metathorax, when it forms a great ganglion anterior to and beneath the medifurca, and then passes onwards over the post-furca to the abdomen. In the Lamellicornes and others in which the cord terminates in the thorax, and the nerves radiate from thence into the abdomen as a *cauda equina*, they pass over the post-furca in a bundle, and do not separate until they enter the latter region. In the Gryllidæ, in which most of the segments are equally developed, and there are three large thoracic ganglia, the metathoracic one is situated in the middle of the segment, and the succeeding or fourth subœsophageal ganglion on the rudimentary post-furca. In the Hymenoptera, in which there are but two ganglia in the thorax, the anterior and smaller one is situated at the margin of the metathorax, and the great ganglion at the posterior, and the cord continued from it passes through a strong bony canal or ring in the medifurca, somewhat resembling that which exists in the head, and then forms a smaller ganglion before it enters the abdomen. In the Hemiptera, in which it has been supposed that there is only one ganglion in the thoracic region, the cord between the medulla and prothoracic ganglion is exceedingly short, but is protected in its passage through the elongated neck, and then is developed into a large prothoracic ganglion, the second ganglion being situated in the middle of the meso-thorax before the medifurca. These parts are very distinct in *Nepa grandis*. In the Lepidoptera, in which the form of the thorax is more compact even than in the Hymenoptera, the cord passes on each side of the medifurca or part to which the triangular muscles are attached, and is so much enlarged as to appear almost like a portion or continuation of each of the two great ganglia situated before and behind it. The cords and ganglia of the thorax are covered in by a strong white membrane like those of the head. In the Lepidoptera this is particularly firm, so that the nervous system is not included within the cavity of the thorax.

In the *distribution* of the nerves there are some peculiarities. We have seen the *auxillary connecting nerves* of Burmeister, as shown by us formerly in the larva of the Sphinx* (*fig.* 406), in many species. They exist between the cord and all the ganglia of the thorax in the *Gryllidæ* (*fig.* 410, *c*, *h*,) and between the cord and the nerves to the wings in *Athalia centifoliæ* and *Panorpa communis*. We have seen them also in *Oiceoptoma*, *Proscarabæus*, *Creophilus*, *Lampyris*, *Forficula*, *Blatta*, and even in an imperfect form in *Œstrus*, as well as in some of the Lepidoptera. They are invariably connected with the nerves to the wings, of which they form one portion, and are far more frequently met with than Burmeister appears to have supposed. We formerly† remarked on a peculiarity in the distribution of the thoracic nerves in the Sphinx, and the opinion then ventured with regard to its nature we have since had reason to believe was well founded. We have seen the auxillary

* Straus, Considerat. &c.

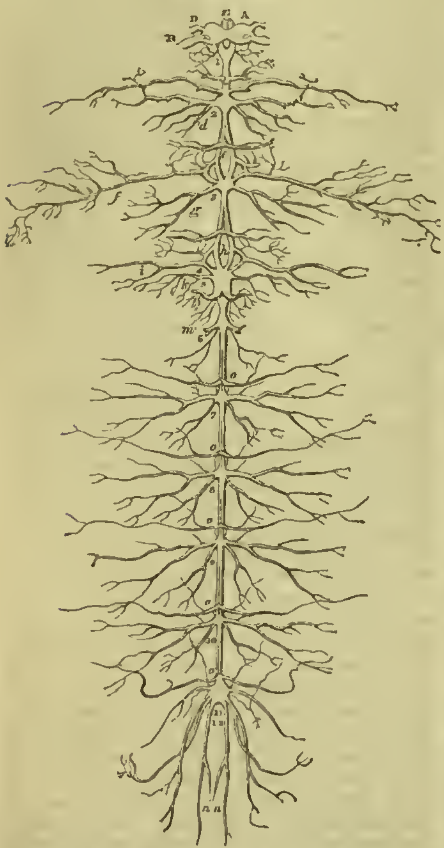
† Phil. Trans. 1834, part ii. p. 394.

connecting nerves in the larva forming one portion of the nerves for the future wing of the perfect insect. The nerves for both pairs of wings are then derived separately from two portions of cord and two distinct ganglia, and this is the state in which they are also found soon after the insect has changed to a pupa (*fig.* 414).

Fig. 414.



Pupa of Sphinx ligustri. (Newport, Phil Trans.)

The connecting nerves are then derived from the cord (*e*, *h*), and being joined each to the first nerve from the next ganglion assist to form the future alary nerves (*f*, *i*). Now as the change to the perfect insect proceeds, the second ganglion (2) becomes approximated to the third (5), which gradually disappears, and the cord between it and the fourth becomes enlarged and shortened, and passes on each side of the insertion of the muscles in the centre of the meso-thorax, the cord between the second and third ganglion having also become obliterated, so that there is then no ganglion intervening between the origins of the two pairs of wings, but only a portion of cord. The nerves for the two pairs of wings then approach each other diagonally, the anterior pair being directed backwards, and the posterior forwards, until they meet and form a plexus, their roots still continuing distinct from each other; the root of the anterior being derived from the cord posterior to the united second and third ganglia, and that of the posterior from the cord connected with the united fourth and fifth ganglia. After forming the plexus, the nerves are again separated and given to the anterior and posterior wings. The reason for this curious union and complexity in the distribution of the nerves to the wings is not at first very evident, but on a little reflexion it is found to be regulated by one of those beautiful provisions in the animal economy by which the most perfect harmony in the exercise of all the functions of the body is preserved. The wings, the most powerful and most constantly employed organs, are not merely required to act with energy, but in the most perfect unison with each other, more especially in insects of long-continued or rapid flight, and hence must be supplied with power from the same centre, not merely that of voluntary motion but also of sensation. That this is the reason for this curious union of the nerves for the wings seems apparent from the circumstance that it exists in very many tetrapterous insects of rapid or powerful flight, as in the *Apidæ* and *Ichneumonidæ*, while in others, even of the same order, as in *Athalia centifoliæ*, which is well known to fly heavily and but a short distance, there is no such combination. In the Scorpion-fly also, *Panorpa communis*, it is absent, and the alary nerves originate by double roots without forming a plexus as in the larva of the Sphinx, while the flight of the insect is sluggish and but of short duration. Besides this it may be remarked that in many Coleoptera in which the anterior wings or elytra are merely elevated and nearly motionless during flight, the nerves are derived separately from the cord, and proceed to their destination without being first combined in a plexus.

The cord and nerves of the *abdomen*, as before stated, we regard merely as a *cauda equina*. We have before explained the varieties in the formation of the cord in different insects, and need but further remark that in each instance the cord in the abdomen, as in other parts, is covered in by a strong fibrous membrane, which separates it from the cavity of the abdomen. In the *Gryllidæ* we have distinctly recognised muscular fibres running transversely above the cord from one side of the body to the other. They have also been observed by Burmeister, who supposes them to assist in the function of respiration by contracting the segments, and thus aiding in the act of expiration. We have seen similar trans-muscles lying above the membrane that binds down the nervous cord in the abdomen of *Bombus terrestris*. The membrane is continuous with that which covers the cord in the thorax. A similar membrane was formerly noticed by Lyonet in the Cossus,* and subsequently by ourselves in the Sphinx.† Between this membrane and the cord there is a

* Recherches sur l'Anatomie et les Metamorphoses des differentes Espèces d'Insectes, ouvrage posthume de Pierre Lyonet. Paris, 1832, fig. 18, p. 52.

† Phil. Trans. 1834, part ii. p. 395, pl. xiv. fig. 9.

vessel which we regard as connected with the circulatory system, as we shall hereafter show.

As *nerves of organic function*, we have now to consider those which are especially given to the different internal organs, and not to the voluntary muscles. Having already considered the transverse nerves, which are distributed so especially to the respiratory organs, as nerves of mixed character, those which we regard more especially under the above designation are the *sympathetic* and the *vagus* or visceral nerves. The *sympathetic*, or *anterior lateral ganglia* (*fig.* 415, C), are situated two on each side of the œsophagus behind the brain, and anterior

Fig. 415.

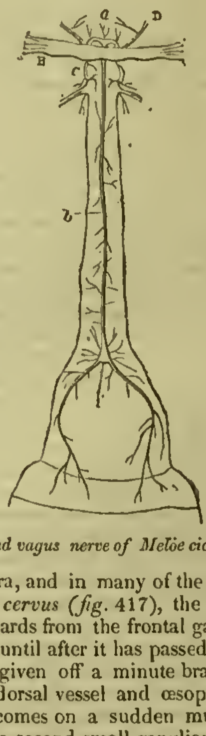
to the great muscles of the œsophagus and pharynx. They are of considerable size, being each about one-third as large as one-half of the cerebrum, and they are connected with most of the other nerves in the head. Thus, besides their connexions (*a*) with the brain, one nerve passes forwards beneath the optic nerves, and joins with a minute filament from the nerve to the antennæ, (*g*,) and also with one to the mandibles, while another passing across the œsophagus is united with the main trunk of the visceral or vagus nerve (*e*), as it passes along to the stomach, and another branch joins with the first set of transverse nerves (*h*), while other filaments passing outwards are distributed to the muscles of the œsophagus and pharynx. This latter fact, which we have most distinctly ascertained in *Meloë cicatricosus*, a large species well adapted both for an examination of this and of the visceral nerve, is particularly interesting from the circumstance that, after the most careful examination, we could not find any other nerve given to those muscles (*fig.* 416, C). We have observed a similar distribution to the muscles of the œsophagus in *Lucanus*, and also in the Sphinx, so that from their connexions we may justly conclude these ganglia to constitute at least a portion of the true sympathetic system. From their relative situation they appear to be analogous to the superior cervical ganglia of the sympathetic in Vertebrata. It is, however, an interesting fact, as noticed by Burmeister,* that these ganglia appear to be largest in some of those insects in which the recurrent nerve which we have described as the *vagus* is least developed. Thus, as shown by Muller, Brandt, and Burmeister, these ganglia of the sympathetic system have a large size in the Orthoptera, and, instead of being traceable scarcely beyond the region of the head, send off one or two branches which run along the sides of the œsophagus to a great distance, while the recurrent or vagus nerve, after uniting with these ganglia behind the brain, appears to terminate or be lost in the nerves that originate from them. In *Gryllus migratorius*, Burmeister has shown† that after the recurrent nerve has formed a minute ganglion just behind the brain, and united with the first of these sympathetic ganglia, it appears to terminate, while the same ganglion sends off posteriorly two branches, which run along the upper surface of the œsophagus, where the external one forms a small ganglion, and that the second, or most external of these anterior lateral ganglia, also sends a large nerve backwards, at the side of the œsophagus, as far as the crop, where it forms a ganglion and sends off nerves, and at the hinder part of the crop a second ganglion, from which nerves are given to the cœcal appendages of the alimen-

* Op. cit. p. 288.
† Id. pl. xxxi. fig. 6.

tary canal. Muller* had previously shewn a similar arrangement of these ganglia in *Gryllotalpa vulgaris*, and Brandt † has since further elucidated the distribution of these structures in the same insects. We have ourselves recently found a somewhat similar distribution of these nerves in one of the Coleoptera, *Buprestis chrysis*, in which the first of the anterior lateral ganglia, on each side, besides its connexion with the brain, gives off three distinct nerves, one of which passes outwards to the muscles of the œsophagus and pharynx, and another inwards to unite with the great trunk of the recurrent nerve, while the third passes backwards for a short distance, and then forms the second of the lateral ganglia, from which, in like manner also, proceed three other nerves. The first of these passes outwards to the sides of the œsophagus, and the second inwards to join a large ganglion formed at the extremity of the recurrent nerve, while the third branch is of considerable length and traceable for a great distance along the sides of the œsophagus. From the ganglion at the termination of the recurrent nerve, and which most certainly belongs to this trunk, are also given off two nerves, which are soon again divided, and distributed along the posterior part of the œsophagus. From these connexions, and the relative size of the parts, it still appears to us that although the sympathetic and recurrent nerves are most intimately connected, and appear in certain instances almost to supply the place of each other, there is reason for still considering them as distinct, and for describing the latter, as we formerly designated it,‡ as the *vagus*.

The *vagus*, or visceral nerve of Professor Müller, after arising, as in the larva, from the anterior part of the base of the cerebrum, and forming a ganglion on the upper surface of the pharynx, always passes backwards beneath the brain, along the middle line of the œsophagus. We shall first describe its course in Lepidopterous insects, and point out what we conceive to be its analogies to the vagus of vertebrata. In the *Sphinx* it originates in the perfect insect, as in the larva, from the lowest part of the anterior surface of the brain by two roots, one on each side, which we regard as analogous to the two vagi in the higher animals. Each root gives off from its base a small branch to the sides of the mouth, after which the two roots ascend, and meeting above the pharynx, form the frontal ganglion, from the anterior surface of which a few nerves are given to the mouth and palate, and also to the bifurcation of the dorsal vessel, which, after having passed along the œsophagus and beneath the brain, is divided in front of the brain into several branches. The frontal ganglion at the junction of these roots of the vagus we regard as analogous to the enlargement on the vagus nerve in vertebrata after it has passed out of the skull by the foramen lacerum posterius. From the ganglion thus formed by the approximation of the two roots, a single trunk passes backwards along the median line, lying upon the œsophagus and beneath the dorsal vessel, and giving to both several branches in its course. When arrived at the dilatation of the œsophagus, the *air-bag* or *crop*, it first distributes a few filaments to that part, and then divides into two primary branches, which run along the sides of the stomach, and are again subdivided and distributed to it. Behind the brain, the vagus in the Sphinx receives but one branch of communication on each side from the sympathetic ganglia, which connexions appear to be analogous to those between the vagus and sympathetic in vertebrata. In passing along the median line of the œsophagus, the single vagus in insects is in close relation with the anterior or aortal portion of the dorsal vessel, which may represent the two carotids of the higher animals united, and thus its relation to these parts is also precisely similar to that of the vagus, carotids, and œsophagus in these animals. There is a like analogy in its distribution to the anterior part of the stomach, beyond the middle portion of which it has never yet been traced. At its point of division the single vagus nerve often forms a very distinct ganglion, as in the Meloë (*fig*. 416, *i*). This is the usual distribution in a large majority of insects, more particularly in the Lepidoptera, Coleoptera, Neuroptera,

Fig. 416.



Brain and vagus nerve of Meloë cicatricosus.

Hymenoptera, and in many of the Orthoptera. In *Lucanus cervus* (*fig*. 417), the nerve, continued backwards from the frontal ganglia (*a*), is of large size until after it has passed beneath the brain, and given off a minute branch on each side to the dorsal vessel and œsophagus, after which it becomes on a sudden much smaller, and forms a second small ganglion, (*e*,) which is connected on each side by a single branch with the sympathetic ganglia (C,) which have assumed an elongated form, and are greatly enlarged. After this the vagus nerve is continued as a single trunk, (*b*,) until it

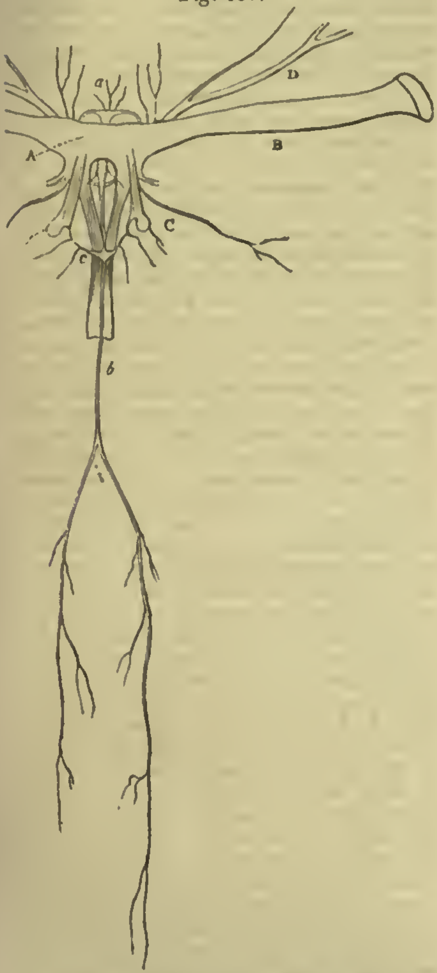
* Nova Acta Curios. Nat. vol. xiv.

† Annal. des Sciences Natur. tom. v.

‡ Phil. Trans. 1832.

has passed half-way along the œsophagus, (*fig.* 428, H,) when it divides into two branches, which pass on each side of the œsophagus as far as the gizzard, (I,) where each forms a very minute ganglion, from which are given a few filaments to the substance of the gizzard.

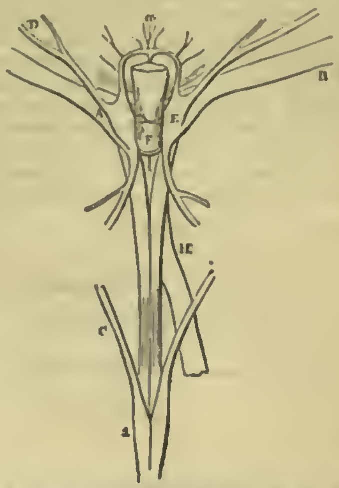
Fig. 417.



Brain, sympathetic ganglia, and vagus nerve of Lucanus cervus.

Each nerve thus passes on to the stomach, (K,) and we have succeeded in tracing it about half-way along that organ, when it can be followed no farther, being lost by minute subdivisions. As connected also with the vagus nerve both in function and by analogy of distribution, is the nerve which we noticed so particularly in the larva, the glosso-pharyngeal, (*fig.* 418, F,) which is remarkably distinct in *Lucanus,* and as in the larva gives branches to the under-surface of the œsophagus. It is remarkable, also, that in this insect each root of the vagus arises from a ganglion on each side, situated below the cerebral lobes, but closely connected to them, and from which ganglion the antennal nerves (D) originate, and a third nerve, which is directed backwards among the muscles, but the course of which we have not yet traced, but which probably is a compound nerve ; it appears to be formed in part by the ganglion, (E,) and partly by a portion of the cerebrum, which is united to it.

Fig. 418.



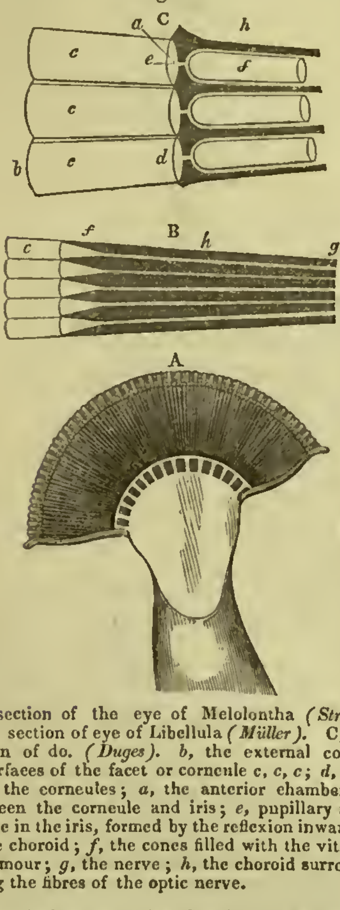
Under-surface of brain, &c. of Lucanus cervus.

The form which the frontal ganglion usually assumes is nearly triangular, but in some instances, as in *Carabus monilis,* it is elongated, oval, lying transversely across the pharynx, but in almost all the insects we have examined, excepting the *Buprestidæ* and some of the Orthoptera both in the larva and pupa state, as in *Timarcha, Meloë, Anthophora,* and *Bombus,* whatever be its form, the single nerve continued from it has more resembled in its distributions and relations the vagus than the sympathetic. These are the reasons for our continuing to describe it as the former rather than as the latter of these nerves. The fact, however, of its disposition to form ganglia in its course appears, indeed, as observed by Professor Müller,* to assimilate it most in character with the sympathetic ; but we conceive this fact to be satisfactorily explained by the anatomy of these nerves in *Buprestis,* in which the middle or recurrent nerve, although exceedingly short, is very large, and is terminated by a ganglion, as in the *Gryllidæ*, and from which, in Buprestis, two small nerves are continued along the œsophagus, while the corresponding nerves in *Gryllus* have become approximated to those from the lateral ganglia, and assist to form the long gangliated nerve at the side of the œsophagus. The functions of the vagus and sympathetic in insects would thus appear to be nearly similar, and that, as is sometimes the case with these nerves in vertebrata, as we have seen, for example, in the neck of the calf, the two become often closely approximated together, as noticed also by Professor Müller, in the Myxinoid Fishes, in which the vagus and sympathetic form only one nerve, the chief portion of which is the vagus, and which is extended to the anus.

* Müller's Archiv, No. v. 1837, Jahresbresht, p. lxxxv. to viii.

Organs of vision.—The eyes of Insects are of two kinds, simple and compound, and have been attentively examined by Professor Müller, Straus Durckheim, Duges, and others, from whose admirable investigations we shall chiefly derive the following description. The large convex corneæ which cover the external surface of the head are divided, as we have seen, into an immense number of facets, generally of an hexagonal shape, or in very rare instances somewhat quadrangular. Each facet, (*fig.* 419, B,) or as it has sometimes been called, *corneule*, is the proper cornea of a distinct eye, and is perfectly transparent. It is somewhat broader at its base or external surface (B, C)

Fig. 419.



A, section of the eye of Melolontha (*Straus*). B, section of eye of Libellula (*Müller*). C, section of do. (*Duges*). *b*, the external convex surfaces of the facet or corneule c, *c*, *c*; *d*, base of the corneules; *a*, the anterior chamber between the corneule and iris; *e*, pupillary aperture in the iris, formed by the reflexion inwards of the choroid; *f*, the cones filled with the vitreous humour; *g*, the nerve; *h*, the choroid surrounding the fibres of the optic nerve.

than at its internal, (*d*,) and each one is separated from those by which it is surrounded by the interposition of a layer of dark-coloured pigment, so that the rays of light can pass through it only in a direction converging to its centre. In some instances, as in Lepidoptera, it is convex both on its external and internal surface, or lens-like, but in general is nearly plane. In the *Libellulina*, according to Duges, (C,) it is convex externally, and slightly concave internally, and it varies considerably in thickness in different insects, and in different facets in the same compound cornea. Immediately behind each corneule is a layer of dark-coloured pigment, (*h*,) which is believed to be continuous with the delicate pigment that is interposed between the corneæ. It covers the whole of the inner surface of the cornea, excepting only in the centre, where it is perforated by a minute hole or pupillary aperture, (*e*,) to admit the rays of light that have passed through the cornea. Between this pigment, which is the curtain or *iris* of the eye, and the end of the cornea, Duges found a space, (*a*,) filled with an aqueous humour. Behind the iris of each cornea is a little cone-shaped transparent body, (*f*,) with its apex directed backwards in the axis of the eye. It is filled with a perfectly transparent tenaceous fluid, the vitreous humour of the eye, into which the rays of light received through the cornea and iris are admitted, to fall upon the retina, or termination of the nerve, (*g*,) at the apex of the cone. The length of the cone differs greatly in different insects. It is shortest in the Diptera, and scarcely exceeds its breadth. In the Coleoptera and Lepidoptera it is five or six times longer than it is broad, and perhaps even exceeds this in some of the Libellulina. The apex of each cone is received upon the extremity of one of the many thousand of fibres (*g*) which we described as radiating from the bulb of the nerve, immediately after it has passed through the optic foramen. The choroid of dark pigment that forms the iris (*h*) is continued backwards over the surface of the cone and optic fibre to the bulb of the optic nerve, thus completely insulating every individual cone and fibre from those by which they are surrounded. It is in the spaces thus occupied by the choroid that the tracheal vessels and circulatory passages ramify, so that the choroid in the eyes of insects, as in those of the vertebrata, is the proper vascular structure of the organ. It is subject to much variety of colour in different insects, being in some nearly black, in others dark blue, violet, green, purple, brown, or yellow. In some there are two or three layers of pigment of different colours. The usual arrangement of these is first a dark coloured portion near the bulb of the optic nerve, then a lighter colour, and lastly, again, a darker near the corneæ. According to Duges, the base of the cone is rounded where it is covered by the iris, but Müller states that this is the case only when the cornea is devoid of facets or corneules, and is perfectly smooth. According to the same authority, the pupillary aperture is most distinct when the cones are short, as in Diptera. This aperture was discovered by Müller, and also the nature of the cones, which had been thought by Straus-Durckheim to be expanded terminations of the optic fibres. We have seen the iris and pupillary aperture very distinctly in the eye of *Pontia brassicæ*, the white cabbage butterfly, and also in *Sphinx ligustri* and *Nepa grandis*. In the two latter instances it is of a dark brown, or nearly black, and is particularly large in *Nepa*. In *Pontia* it is yellow, in the centre of which the pupil exhibits a glassy brightness. The manner in which the extremity of the nervous fibre is connected with the apex of the cone has recently been investigated by Professor

Wagner, who has found that the fibre is prolonged as a sheath over the sides of the cone, of which it is supposed to form a part. In this manner, each of the thousands of corneules or facets that form the compound eye, transmits impressions from without inwards to the optic nerve and brain, the perception of each being confined to that of the object immediately before it, or in a line with its axis of vision. On the exterior surface, between each cornea, there are often some very fine hairs, as on the cornea of the bee, which Burmeister likens to eyelashes, and thinks that they assist to confine the field of vision, as well as protect the cornea. This is the usual structure of the eye. In *Melolontha*, Straus-Durckheim describes the filament of the optic nerve as passing through a second or *common choroid*, and as afterwards uniting to form a general retina, which is connected with the optic nerve by means of short thick columns. The use he assigns to this structure is that of intercepting the impressions of light, which might otherwise be too powerful.

The *ocelli*, or simple eyes of insects, resemble those of Arachnidans,* in being formed of a very convex, smooth, single cornea, beneath which is a spherical crystalline lens, resting upon the plano-convex surface of the expanded vitreous humour, the analogue of the transparent cones of the compound eyes. The vitreous humour, as in Arachnidans, is more convex on its posterior or under surface, and is contained in the expanded retina at the termination of the optic tubercle, upon which each ocellus is situated, the exterior surface of the retina being covered by a dark pigmentous membrane, the proper choroid, which is reflected inwards upon the anterior portion of the vitreous humour, to form the iris and pupillary aperture. Müller, who discovered this structure in the stemmata of insects as well as Arachnidans, concludes that the function of the simple eyes is confined exclusively to the perception of near objects, and that of the compound eyes to more distant ones, and has given many facts in illustration of this opinion, and which shew that in many instances, particularly in the Orthoptera, the ocelli are so placed as to render it almost impossible that they can be used except in viewing near objects. In all insects that undergo a true metamorphosis ocelli constitute the only organs of vision in the larva state. They vary in number in different species; thus in the active larvæ of Hymenoptera, as in Athalia, there are only two, one on each side of the head; this is also the number in some of the carnivorous Coleoptera. But in others there are six on each side, as in Dyticus, and the same number is found in most of the Lepidoptera. We have recently detected what we believe to be organs of vision in a Dipterous larva, *Œstrus ovis*, (*fig.* 360,) which resides in the frontal sinuses of the sheep, into which, probably, a small amount of light may enter through the nostrils. These consist of two brown spots on each side of the head, (*h* 2,) placed at a little distance from each other, immediately beneath a convex and very transparent part of the tegument, which resembles a true cornea. This is the most simple form of eye we have yet met with in insects, and seems to be merely for the perception of light, like the eyes of the *Medusæ* discovered by Ehrenberg, but perhaps more organized, as the spots observed appear to be a choroid, which is seen to descend until it is lost in the substance of the part. No compound eyes exist in any larva that undergoes a complete metamorphosis. In those which undergo an incomplete one, as in the Orthoptera, the facets of the eye are larger and more convex than in the perfect state, and the true ocelli which exist in the perfect state are not developed. In the larva and pupa of *Reduvius personatus* there is an aggregation of simple eyes, like those of *Myriapoda*, very much larger and more convex than the facets of the compound eye of the perfect insect. Simple eyes exist in the perfect state in the Hymenoptera, Orthoptera, Hemiptera, Neuroptera, Trichoptera, Homoptera, and in some of the Lepidoptera and Homaloptera, and in a very few instances in the Coleoptera.

Organ of hearing.—Every naturalist who has at all attended to the consideration of the faculty of hearing in insects, is doubtless convinced that these little creatures are not merely affected by sounds, but that hearing constitutes one of their chief senses; yet it is hitherto undecided what organ or part of the animal is the seat of this function. We have above stated our opinion, (p. 892,) with many others, that it resides in the antennæ, which, if this be not confirmed, is at any rate supported by the experiments hitherto made upon these organs, and also by their structure and the manner in which they are employed by the insect. The nerves distributed to the antennæ have often a ganglion at their base, and are divided into many branches almost immediately after they have entered the organ, so that at present no difference has been detected between the distribution of the nerves to these parts and those to other structures. They certainly exhibit no bulbed extremity like the auditory nerves of the higher animals, while the manner in which the antennæ are employed by many insects has induced some observers to believe that they are simply organs of touch. This cannot be their primary function, since, as formerly remarked, they are too short to be employed as tactile organs by many insects, while their structure, we conceive, is in every instance adapted for hearing or perceiving the pulsations of the atmosphere.

Organs of touch.—The organs which appear specially adapted to the exercise of this function are the *palpi*, which derive their nerves, as above shown, from the medulla oblongata. These organs are employed in a similar manner by all insects to touch the food. It is with these that the insect, as it were, *feels* about when it is in search of nourishment, and hence these may be regarded as the proper tactile organs. It has sometimes been supposed that they are also concerned in the *function of taste*,

* See ARACHNIDA, vol. i. fig. 94.

but this opinion is not borne out by the physical condition of these parts, which, in almost every instance, is unadapted for such purpose, being covered by a hard bony exterior. In some instances the extremities of the palpi are covered with a soft bulb-like extremity, while in many others which are known to perceive the quality of food very quickly, they yet have the extremities of the part covered with a hard imperforate structure.

As to the seat of the *organ of smell* we are quite as ignorant of it as of that of taste. Cuvier and some others have imagined that the faculty of smelling resides in the mucous lining of the spiracles at the sides of the body, but experiment has still left the question undecided. From the few observations we have been able to make on this subject we certainly have been led to conclude that it is confined to some part of the head, and not seated at the different spiracles.

The development of the brain and nervous cord during the metamorphoses exhibits some of the most curious alterations of form that take place in any structure. These changes were first traced by Herold in the great cabbage-butterfly, *Pontia Brassicæ*, and subsequently by the writer of the present article in the privet hawk-moth, *Sphinx ligustri*,* and also in the nettle-butterfly, *Vanessa urticæ*. We have seen from the foregoing details, that during the last period of the larva state, at which time the insect has been most frequently examined, certain changes of form have already taken place in different parts of the cord, so that these changes of structure, which at first appear to be effected so rapidly at a certain period, have been for a long time in progress. We have seen that, besides the lateral approximation of the cords, the first change consists in an union of the eleventh and twelfth ganglia, the latter one being carried forwards; and that, although a complete coalescence of these has sometimes taken place so early as a day or two before the caterpillar casts its last skin, yet even at that period the cerebral ganglia have scarcely become united above the œsophagus. At a still earlier period, when the larva has not yet cast its third skin, we have found the eleventh ganglia perfectly distinct from the twelfth, with a small intervening portion of cord, and the cerebral ganglia scarcely touching each other above the œsophagus, and the distance, or extent of cord, between the fourth and fifth ganglia much greater than at the subsequent period when the insect is preparing to change into the pupa state.

We had commenced our observations on these changes in the nervous system on the larva and pupa of the *Sphinx*, when it appeared desirable also for various reasons to make similar observations on an insect in which these changes were commenced and completed within a short and known period, and for that purpose selected the commonest of our native insects, the nettle-butterfly, *Vanessa urticæ*, which undergoes its changes within fourteen days. The Sphinx remains in the pupa state during the whole winter, by which we are enabled to compare the same changes in an insect in which they have taken place slowly with those in another in which they have been completed more rapidly, and the extent of development at the completion of both is invariably found to be the same. In order to observe these changes correctly, a large number of the caterpillars was collected at the period when they have ceased to feed, and are about to suspend themselves to undergo their transformation, and the moment was carefully watched both when they suspended themselves preparatory to undergoing their metamorphoses, and also when they were in the act of assuming the pupa state. By these means a sufficient number of specimens was obtained, and their periods of transformation accurately known. Previously to commencing these observations on the nettle-butterfly, we had noticed in the pupa of the Sphinx a very singular appearance at the base of each optic nerve, which on close inspection was found to be a dark-coloured membrane of an ovate form, from which is developed the choroid of the future eye. The existence of this spot is exceedingly interesting as illustrating the manner in which the complicated organ of vision in the perfect insect is developed. This spot, which at first appears like a dark gelatiniform deposit, consists of five black tubercular elevations, having the appearance of so many parts of a corrugated membrane, and exists before the larva has changed into a pupa. We have never found it absent in any insect that is about to change, but have not observed it until the insect has ceased to feed.

Two hours after the larva of *Vanessa urticæ* has suspended itself to undergo its transformation, and in which state it remains from six to eight, ten, or even twenty-four hours, according to the strength of the individual and other circumstances, before it throws off its last larva skin a considerable alteration has already taken place in the body of the larva; the cerebral lobes are still distinct from each other, but are a little altered in form, although not yet enlarged. When viewed from above they exhibit a pear-shaped appearance, the anterior part of the lateral surface of each being elongated to give origin to the antennal and optic nerves. At the base of the latter, even at this early period, the dark rudimentary choroid is very distinct. The sub-œsophageal ganglion is enlarged to nearly twice its original size, and the crura are much enlarged and shortened, as well as the cords that connect the second, third, fourth, and fifth ganglia. The last two are separated only by a short interval. The fifth, sixth, and seventh ganglia are drawn closer together, the cords between them disposed in an irregular zig-zag manner, and the longitudinal direction of the ganglia is in consequence altered. The ganglia from the seventh to the terminal one remain as in the active larva.

By unremittingly watching a number of larvæ through all their preparatory stages, we are enabled to judge within a very short period when the transformation will take place. A little while before the old skin is thrown off

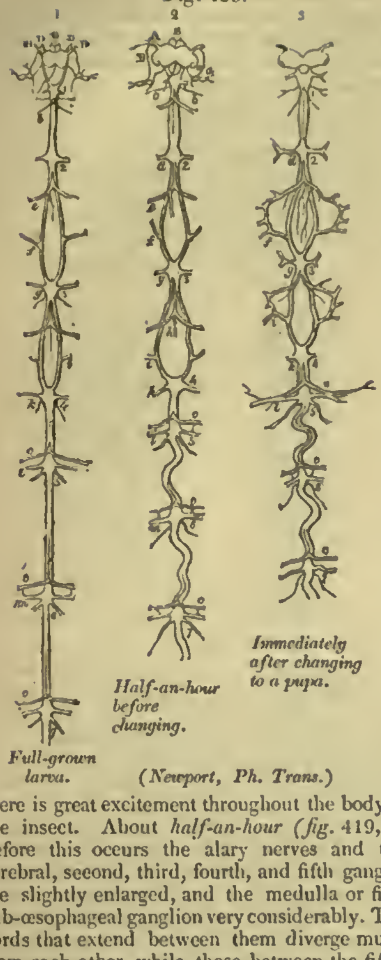
Fig. 420.



Full-grown larva. *Half-an-hour before changing.* *Immediately after changing to a pupa.*

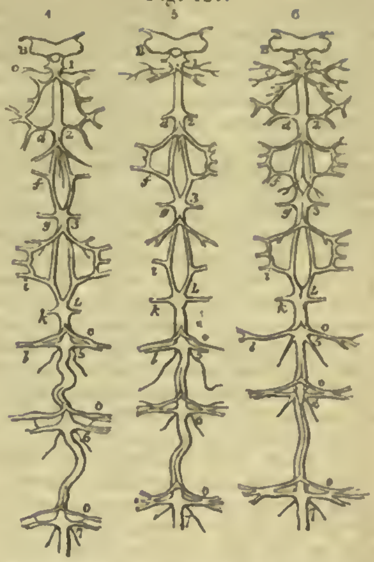
(Newport, Ph. Trans.)

there is great excitement throughout the body of the insect. About *half-an-hour (fig.* 419, 2) before this occurs the alary nerves and the cerebral, second, third, fourth, and fifth ganglia are slightly enlarged, and the medulla or first sub-œsophageal ganglion very considerably. The cords that extend between them diverge much from each other, while those between the fifth, sixth, and seventh ganglia, are disposed in a more zig-zag direction than in other parts of the body.

Immediately after the insect has entered the pupa state (3), all the ganglia are brought closer together in consequence of the cords being disposed more irregularly than at any other period, which has been occasioned by the shortening that has taken place in every segment, by which the cords are rendered too long to lie in a direct line. The cords which connect the first five ganglia are slightly increased in size, and the fourth and fifth and their intervening cords, in which the first great changes commence, are often nearer together, and have become more united at this period of the transformation, in some specimens, than in others at five or six hours later. This is in accordance with what we have observed in the *Sphinx ligustri*, in which the precise period when the union of ganglia takes place cannot positively be ascertained in consequence of its differing in different specimens according to the vigour of the insect, or to the temperature of the season at the time of changing.

One hour after *(fig.* 421, 4) the transform-

Fig. 421.



One hour after changing. *Twelve hours.* *Eighteen hours.*

ation the cerebral ganglia are found to be more closely united, the antennal nerves more distinct, and the optic nerves more enlarged at their base. The fourth and fifth ganglia are approaching each other, and the cords are enlarged at their connexion with the latter, the anterior part of which has become less distinct, and seems about to coalesce with them. The distance between the remaining ganglia is also reduced, and the investing membrane, or exterior surface of the cord exhibits a corrugated appearance as if in the act of becoming shortened. We have seen in the account previously given of the nervous system in the larva of the Sphinx, that besides the longitudinal cords and ganglia, and the nerves distributed from them, there are also the transverse nerves. There are like nerves in *Papilio urticæ*, and which are distributed to the same parts as in the Sphinx. They commence behind the first sub-œsophageal ganglion or medulla, where the first of them pass directly outwards in the course of the tracheæ that come from the first spiracle, and distribute and give some branches to the surface of the medulla and its nerves, and some also to the second ganglion (*d*), while the main branch passes along in the direction of the muscles of the back part of the head. Behind the second ganglion branches of tracheal vessels, and also a nerve from the transverse plexus, are given to the great alary nerve (*f*) that arises in this insect singly from the cord between the second and third ganglion, and not, as in the Sphinx, one portion from the cord and another from the ganglion posterior to it. From the cord between the third and fourth ganglion arises the second alary nerve (*i*), which like the preceding arises singly from the cord, but receives also a

* 1832.

branch from the transverse nerves posterior to the third ganglion. A plexus of these transverse nerves exists, as in the Sphinx, anterior to each ganglion (*o*, *o*), to the nerves of which they give a single filament near their base, and another when arrived near the spiracle, while their main branches, as in the latter insect, are distributed separately among the tracheæ and muscles. Those branches of transverse nerves which pass off laterally from between the fourth, fifth, sixth, and seventh ganglia, become approximated to the nerves from those ganglia, and in the development of the insect at this period afford an example of the commencement of the interesting fact of the formation of nervous trunks by the approximation of many fibres. The transverse nerves anterior to the fifth ganglion (5, *o*) are those that first become united to the moto-sensitive nerves from the gangliated cord, and at this period of the transformation the two are beginning to become united.

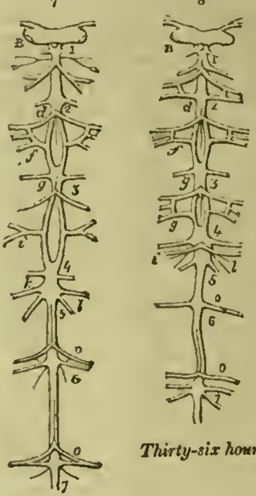
Seven hours after the insect has become a pupa there is a greater enlargement of the cerebral ganglia, optic nerves, and ganglia and cords of the future thoracic segments. The fourth and fifth have advanced closer together, and the cord between them has become so much shortened, enlarged in diameter, and approximated to its fellow, as to resemble in shape a separate elongated ganglion, and strongly to support the opinion formerly advanced by us* of the actual transmission forwards of the nervous matter within the investing membranes of the cord, rather han that of its deposition and accumulation at certain parts through the agency of the nutritive or vascular system. At this period also all the remaining ganglia have become slightly enlarged, and the distance between the fifth and sixth is much diminished, and the cords just anterior to each ganglion are also slightly enlarged and are disposed with less irregularity than at a previous period. At this stage of the transformation the transverse nerves (*o o*) also are beginning to assume their temporary ganglionic appearance, and the terminal nerves from the caudal ganglion are enlarged to supply the developing organs of generation.

At twelve hours (5) the fifth ganglion has almost completely coalesced with the cord and fourth, and has assumed an elongated triangular appearance, and the transverse nerves, which at seven hours were beginning to be united to the nerves from this ganglion, have now so completely joined them as almost entirely to have disappeared, there being in some instances only a triangular elevation upon the gangliated cord, with a portion of nerve passing outwards to indicate their previous separation, thus affording a further proof of the adhesion of contiguous parts, and of the manner in which nervous trunks are formed.

At *eighteen hours* (6) the whole of the ganglia, cords, and nerves have become more enlarged, particularly those of the wings, and the transverse nerves, although continuing separate, give filaments to the nerves from the ganglia, and themselves exhibit at their point of division more the appearance of ganglia; while the fourth and fifth ganglia of the cords have now so completely united as to appear like an irregular elongated mass. The abdominal portion of the cord is now extended in a more direct line in the body, and anterior to each ganglion is still enlarged.

Fig. 422.

7 8



Twenty-four hours. *Thirty-six hours.*

At *twenty-four hours* (*fig* 422, 7) the fourth and fifth ganglia are completely united, the fifth being larger than the fourth. The cords before the sixth are enlarged, as also are the transverse nerves of the thorax, which seem to keep pace with or rather to precede the development of the respiratory organs.

At *thirty-six hours* (8) the optic nerves have attained a size almost equal to that of the cerebral ganglia, and after this period become very little larger. During the preceding stages of the transformation the minute black patch observed at their base has been gradually more and more expanded, and carried forwards from the posterior superior part of each lobe to its lateral part, which at this period it is beginning to cover, while the optic nerves appear as if developing from within outwards, and have a somewhat pear-shaped form. The first sub-œsophageal ganglion, or medulla, now forms with the cerebral ones a complete ring around the œsophagus, the crura having almost disappeared. The fifth ganglion has decreased in size and is now smaller than the fourth, while, in some specimens, the nerves that arise now come from the cords immediately behind it, thus giving a further proof that the nervous substance of the ganglion has been transmitted forwards. The sixth ganglion, which at twenty-four hours was much reduced in size, has entirely disappeared, but the nerves that belonged to it remain and are now derived from the cord, very near to those which belonged to the fifth ganglion, thus further proving, as formerly remarked by us,* that the nervous substance has been transmitted forwards along the cord. This view of the manner in which these changes in the form and

* Phil. Trans. 1834.

size of different parts of the nervous system is effected is in full accordance with the recently developed facts of Ehrenberg and others respecting the tubular nature of the primary nervous fibres.

At *forty-eight hours*, (*fig.* 423, 9) the whole of the cords have regained the longitudinal direction, and the seventh ganglion, which had begun to be decreased in size at the last period, has now also entirely disappeared, and its nerves, like those of the fifth and sixth, come from the cord, while the ganglia of the thorax are acquiring a great size.

Fig. 423.

Forty-eight hours. *Fifty-eight hours.*

At *fifty-eight hours* (10) a further change has been effected. The second and third thoracic ganglia have united, and the double ganglion thus formed is only separated from the larger thoracic mass composed of the fourth, fifth, and part of the sixth ganglia, by the short but greatly enlarged cords which pass, as before noticed, on each side of the central attachment of the muscles. The transverse plexus are united with the nerves to the wings, and the whole of these gangliated portions of cord have been carried forwards, and now occupy the middle portion of the immensely enlarged meso-thorax. The optic and antennal nerves have nearly attained their full development, and those numerous and most intricate plexus of nerves in the three thoracic segments of the larva form only a few trunks, which can hardly be recognized as the same structures. The arrangement of the whole nervous system is now nearly as it exists in the perfect insect. The whole of these important changes are thus seen to take place within the first three days after the insect has undergone its metamorphosis; and they precede those of the alimentary canal, generative system, and other organs, which are still very far from being completed, and indeed, as compared with the nervous system, have made but little progress.

Such is the rapidity of these changes, as observed by us in June, 1832, in a species that usually undergoes its metamorphosis from the larva to the perfect state in about fourteen days. On repeating our observation on the same insect in the following August, when, from the increased temperature of the season, the whole of the changes in the body were completed in about eight days, we did not observe that these had become much accelerated, although the changes in the other structures were hastened. The whole of these phenomena are induced by an alteration which takes place in the external tegument, and the permanent contraction of the longitudinal and diagonal muscles of the body, by means of which the anterior margin of one segment is drawn beneath the posterior of that which immediately precedes it. This is carried to a greater or less extent in the different segments, and the nervous cord being in consequence rendered too long to lie in a direct line, a disposition is thus induced in its various parts to coalesce.

Organs of Nutrition.—The chief organs of nutrition in insects, the *alimentary canal and its appendages*, assume a variety of forms in the different classes, and undergo changes almost as remarkable as those of the nervous system. From being scarcely more than a simple elongated tube, with a few slight enlargements in its course, as in some of the apodal Hymenoptera, the alimentary canal becomes in the perfect individual a long convoluted organ, thick, muscular, and divided into several compartments, each of which is adapted to a peculiar function, but subservient to the more general one of assimilating the food received, into one homogeneous material, fitted for the nourishment of the whole body. But whatever be its particular form, the alimentary canal may be regarded as composed of three distinct coats or tissues, which we shall distinguish as the external or *peritonæal*, the middle or *muscular*, and the internal or *mucous*.

The *peritonæal* coat, or layer, is an exceedingly transparent, white, shining, and delicate membrane, and is observed only with great difficulty. It covers the outer surface of the muscular coat throughout the whole course of the canal, and, as we are strongly induced to believe, although we have not positively ascertained it, is continuous with and reflected along the tracheal vessels that ramify on the stomach, and forms their external covering. We have never been able to detach it from the muscular coat, which it completely invests, and to which it closely adheres, but we have seen it most distinctly in recently killed insects more particularly in the *Apidæ*, as in *Anthophora retusa*, when the canal has been removed from the body and viewed by transmitted light. It is then seen most distinctly extending along the sides of the canal, directly across the angles formed by the contraction of some part of the muscular coat, where this is thrown into folds or depressions.

The *muscular*, or middle coat, is very strongly marked. It is composed of transverse and longitudinal fibres, interlaced with each other, and also of a series of oblique fibres, which, as shewn by Lyonet in the *Cossus*, sometimes in part form the *retractores ventriculi* muscles, that assist to retain the canal in its proper position in the body, and connect it with the whole muscular system. Burmeister states,* that distinct transverse and

* Op. cit. (trans.) p. 121.

longitudinal *vessels* can be discovered in the muscular coat, but we have never been able to observe them. The muscular coat is most distinct in the *proventriculus* or gizzard, the *ventriculus* or digestive stomach, and the *colon*, but may be traced throughout the whole of the canal. The longitudinal and transverse fibres are each developed to a greater or less extent in different insects; in some, more especially in the larva state, as in the Lepidoptera, the longitudinal fibres form six strong bands, arranged at equal distances around the canal, and extended from one extremity of it to the other, more or less developed in different parts of their course; while in other instances, more particularly in the perfect state, the circular fibres are most developed, as in the Hymenoptera, in which the longitudinal fibres on the stomach are scarcely observable.

The *mucous*, or internal coat, analogous to the mucous coat in the higher animals, is divided into two layers, each of which has been considered as a distinct structure by different anatomists. The most internal of these layers forms the proper lining of the alimentary canal, and is a smooth soft membrane, particularly distinct in the upper part of the canal, but less so in the lower. It is continuous with the lining of the mouth and pharynx, and is often plaited or folded longitudinally, but seldom transversely, excepting where it covers a fold of the other structures to form a valve at any part of the canal. It is this membrane which is often solidified at the upper part of the canal, and developed into rows of strong horny teeth, as in the Orthoptera and some carnivorous Coleoptera, or is covered entirely with exceedingly minute ones over its whole surface, as is particularly the case in *Gryllus migratorius*. In some instances it is very loosely attached, and forms, as it were, a soft and easily separated lining to the canal, more particularly in the ventriculus, as in the *Meloe* and some other genera. The other layer of this coat, which has been regarded as a distinct structure, is situated between the proper mucous or lining membrane and the muscular coat. It is this layer which is considered by Straus as the proper skin or lining. It is usually thin, flocculent, and frequently without indications of distinct texture, although it is occasionally found to possess it, as shewn by Burmeister in *Hydrophilus*. Straus has sometimes observed horny prominences in it, which he considers of a glandular nature. The markings in Hydrophilus appear to be of the same description. Ramdohr mistook this layer for a layer of transuded chyle; Straus and Burmeister regard it as perfectly distinct from the mucous coat, and Professor Grant in alluding to it seems to regard it as a loose intermediate *cellular* tissue.* This is our own opinion also of its nature, because we have been unable to trace it as a distinct layer throughout the whole of the canal. It exists most distinct in the ventriculus, but we have not been able to trace it in the colon, excepting, perhaps, in the Lepidoptera, in which it appears to be what we have regarded as an *adipose coat*. The inner or true mucous layer is very distinct, and in some, as in *Cerura vinula*, is covered with minute rounded glands.

The alimentary canal is retained in its position in the body partly by means of the retractores ventriculi, which we have observed most distinctly in the larvæ of Diptera, as in *Eristalis tenax*, as well as in Lepidoptera and others; but more especially by means of ramifications of the tracheal vessels, which pass from the great longitudinal tracheæ, near the spiracles, and are distributed in profusion over the alimentary canal throughout its whole course. Burmeister says that a peritonœum, such as retains the intestines in their place in the higher animals, does not exist in insects. This, however, as we have above shewn, is not strictly the case, since a peritonœum certainly exists as a coat of the alimentary canal, although we have never been able to observe it forming, as stated by Professor Grant,* "a distinct thin mesentery," connecting the convolutions of the intestines with the interior of the abdominal segments.

The parts of the alimentary canal are the *mouth* and *pharynx*, the *œsophagus*, (*fig.* 424, *h*,) and, in the Lepidoptera, (*fig.* 430, *t*,) Hymenoptera, and Diptera, the *crop*, which is a dilatation of the œsophagus carried to so great an extent as to form a distinct appendicular cavity; the *proventriculus* or gizzard (i), the *ventriculus* or proper digestive stomach (*k*), the *ilium* or short intestine (*l*), and the *colon* (*m*, *n*) and *rectum* (*o*). These exist in the most developed form of the canal, but not invariably or to the same extent in every insect. The crop is frequently absent, as are also the proventriculus and the rectum, but the remaining parts are almost constantly present. Besides these as forming parts of the digestive apparatus, there are the appendicular structures, consisting of the salivary glands (*a*), the gastric (*a*, *b*, *c*), and the so-called biliary (*p*) and the anal vessels (*s*). Of these the supposed biliary vessels are almost constantly present, and less frequently the salivary and gastric, and least frequently the anal vessels, which have not been observed in many species.

Alimentary canal of the larva.—The most simple form of alimentary canal we have yet met with in insects exists in apodal larvæ of parasitic Hymenoptera, as in *Ichneumon Atropos*, which undergoes all its changes within the cavity of the abdomen, between the alimentary canal and muscular structures of the larva and pupa of *Sphinx ligustri* or *Acherontia Atropos*. It consists simply of an elongated sac, very much dilated, and greatly resembling a Florence flask, and occupies nearly the whole of the interior of the body of the parasite. The œsophagus is short and very distinct, and terminates in the second segment in a well-developed valve formed by a duplicate of the mucous and muscular coats. Behind this the whole forms one dilated continuous cavity, extended as far as the anal segment, but completely imperforate and slightly intussuscepted at its extremity, where, when the part is carefully

* Outlines of Comparative Anatomy, p. 349.

Fig. 424.

Alimentary canal of Carabus monilis.

h, œsophagus; *i*, gizzard, or proventriculus; *k*, ventriculus or digestive stomach; *l*, ilium; *m n*, colon, with cæcal glands; *o*, rectum; *p*, hepatic vessels; *q*, their point of insertion; *s*, anal vessels; *a*, *b*, *c*, a gastric vessel; *a*, *b*, a portion of the lining of the gizzard.

examined by transmitted light, there is a slight appearance of circular fibres. Its texture throughout is distinctly muscular, both longitudinal and transverse muscular fibres being distinctly visible in every part of it, and of nearly uniform size. This is a remarkably low form of development in an insect which afterwards becomes one of the most perfectly organized of its class. The next simple form of alimentary canal occurs in the same order of insects, as in the larva of the common Hornet, *Vespa crabro*, in which it consists of a straight and gradually enlarging tube, extended as far backwards as the eleventh segment, where it becomes constricted, and forms a short small intestine, receiving at the same time the insertions of very minute hepatic vessels, after which the intestine becomes again slightly enlarged to form a rudimentary colon. The next somewhat more developed form is found in the *Apidæ*, as in *Anthophora retusa*, in which the canal forms a distinct œsophagus, which terminates in a very slight dilatation, and then gradually enlarging, passes onwards, as in the Hornet, until it acquires its largest diameter in the eleventh segment, and becomes constricted to form the small intestine, receiving laterally at the same time the insertions of the hepatic vessels. The small intestine then passes forwards, and after making one short sigmoid turn backwards, ends in a straight colon and anal aperture, which is distinctly developed in this insect towards the latter part of the larva period, at which time, after the insect has become full grown and ceased to feed, we have observed fæces passed from it, but we have reason to believe that the anal aperture is not developed until that period, since no fæces are found in the cell in which the larva is inclosed until after the larva is full-grown, and has eaten the whole of the food that was stored up with it when the cell was closed by the parent. In the larvæ of some Coleoptera, as in the *Lamellicornes*, there is almost as simple a form of the alimentary canal as in the *Apidæ*. In these, as in *Melolontha vulgaris*, (*fig.* 425,) it commences in a short and narrow œsophagus, which opens by a valve into a very capacious stomach that extends backwards to the twelfth segment of the body, where it is gradually decreased in size, and ends in a narrowed pylorus, which is divided internally by a valve from a short and narrow intestine, that passes forwards beneath the stomach, and ends in a very large colon, which at its commencement is dilated into an immense cœcum, and is in general distended with fæces. It terminates beneath the middle of the posterior half of the stomach in a rectum, which passes directly to an anal aperture. In our dissection of this larva we did not observe the exact point at which the biliary vessels enter, but nevertheless they exist, although less distinct than in the perfect insect. They were observed by Swammerdam in the larva of *Oryctes nasicornis*,* entering, four in number, at the pylorus. In this and other lamellicorn larvæ the surface of the digestive cavity is increased by the addition of three series of cœcal appendages. The first surround the cardiac extremity, and consist of twelve cœcal tubes, with their apices directed forwards, and dilated on each side into four smaller cœca, so that each one has somewhat the appearance of a fern-leaf. From the situation which they occupy, these may perhaps be regarded as salivary organs. A little beyond the insertion of these

* Biblia Nat. tab. xxvii. fig. V. c.

Fig. 425.

Lateral view of the alimentary canal of the larva of Melolontha vulgaris, with the three series of gastric vessels.

vessels the stomach is slightly constricted, and receives the insertions of another set of cœca, which differ from the last in being single, conical, and directed backwards. At some distance beyond these, the stomach is encircled by a third set of cœca, which differ from both the preceding in being united in pairs at their base, and inserted, with their apices directed forwards, near the posterior part of the stomach. Those cœca, both of the second and third series, which are nearest to the upper part of the stomach, are the shortest. These cœca are not analogous to the hepatic vessels, or rather those usually so designated, but to the gastric glands which cover the stomach in the *Carabidæ (fig.* 424) and *Lucanidæ (fig.* 428), and appear in this voracious larva designed to secrete a fluid that may be necessary to enable the stomach to digest the immense quantity of vegetable matter taken into it. In the Lepidopterous larvæ the canal is scarcely more developed than in the Coleopterous, since, although the œsophagus is elongated, and the larger intestines are somewhat more complicated, no series of gastric glands are developed. We believe we have seen those which surround the cardiac extremity in some *Bombycidæ*, as in *Odonestis potatoria*, immediately after the insect was killed, but merely as little rounded protuberances, the character of which was completely lost after the insect had been preserved for a short time in spirits of wine. They exist also very distinctly in the Sphinx. In this order it commences by a distinct œsophagus *(fig.* 364, *c*), which terminates by a valvular orifice in the third segment in a long and very muscular stomach (C), around which the six longitudinal bands are very distinct, as also are the transverse muscular ones. At the commencement of the eleventh segment it becomes constricted, and terminates in a distinct pylorus, which ends in a short ilium (*e*), into the middle of which, on each side, are received the united termination of the hepatic vessels *(f)*, which, having extended along the sides of the stomach as far forwards as the seventh segment, are convoluted around this and the remaining portion of the canal. Immediately behind the ilium the canal is developed in a six double-lobed cœcum (*g*), and immediately afterwards into an immense sacculated colon (*h*), terminated by a very short rectum. The longitudinal bands are particularly distinct on the colon, and extend from its posterior part to the external muscular tegument forming the retractors of the colon and rectum. In the active larvæ of Coleoptera the alimentary canal becomes still more developed. It commences in the larvæ of the *Carabidæ*, *Calosoma sycophanta (fig.* 426), according to Burmeister,* in a very short œsophagus (H), that opens at the posterior part of the pro-thoracic segment into a large cylindrical stomach (K), which is extended throughout the greater part of the body, very similar in appearance to that of the Lepidoptera. This is called by Burmeister the *craw*. It opens directly into another cylindrical stomach, much narrower and nearly of the same length, but more muscular than the preceding, and receiving its posterior extremity (Q), where it forms internally a distinct pyloric valve, the hepatic vessels. Burmeister remarks that there is no valve of separation between the first and second of these stomachs, nor any rudiment of the gizzard, which exists in the perfect insects of this order *(fig.* 424, *i*). These are succeeded by a small intestine or ilium (L), which is of some length, and together with the second stomach forms several convolutions in the body between the first stomach, or craw, and the great intestine or colon (M), which follows it, and terminates the canal in a protruded anal aperture (O). The colon, as in most larvæ, is very muscular and folded transversely, and altogether the canal is more developed than in the preceding instances, as also are its appendages the hepatic vessels, which are exceedingly long, although no cœca are developed upon them. In the Rhinchophora and Longicornes there is a still higher form of alimentary canal, as observed by Burmeister† in *Calandra*

† Zur Naturgeschichte der Gattung Calandra. Berlin, 1837.

Sommeri, and as seen by ourselves in *Callidium luridum*. In *Calandra*, which in external appearance is scarcely more perfect than the apodal larva of Hymenoptera, the alimentary canal (*fig.* 427) approaches much in form,

Fig. 427.

Alimentary canal of the larva of Calandra Sommeri. (*Burmeister.*)

size, and complication of its parts to that of the perfect insect. It commences behind the pharynx in a very short pear-shaped œsophagus (H), which opens by a valve into a dilated bag-shaped crop (I), analogous probably to the first stomach of the larva of *Calosoma*. This is continuous by a narrowed passage with the proper digestive cavity, around the middle part of which (K) are developed many conical glandular papillæ or gastric vessels, that do not appear to have been noticed in the larva of *Calosoma*, which instead of subsisting upon hard vegetable substances like these *Curculionidæ*, preys upon the soft bodies of living caterpillars, and consequently does not require for the digestion of its soft animal food and juices so complicated a structure as those which devour large quantities of crude vegetable matter, as is the habit of the *Lamellicarnes*, or the hard and less easily solvent woody fibre or coverings of insects devoured by the *Calandra* or the perfect *Carabidæ*. At the posterior extremity of the digestive stomach in this larva are inserted, as before seen, the biliary vessels, not singly around the sides of the canal, but by the union of four of these tubes in a common duct. This peculiarity is remarkable, as it occurs in some species in the perfect insect. Besides these vessels there are two others somewhat smaller, which are inserted separately, a little anterior to the common duct. These have been supposed to be analogous to pancreatic vessels, but they are similar in almost every respect to those which are inserted by a common duct, and hence may be supposed to have nearly the same functions. We have noticed similar vessels inserted separately from the supposed hepatic vessels in the *Dyticidæ* and in *Timarcha*, which certainly leads to the conclusion that they have some difference of function. The ilium (L) is of great length, and more convoluted than we have yet seen it in any larva, and ends in a very muscular cylindrical colon (M N), terminated by a short rectum. A similar and perhaps even more highly developed form of alimentary canal exists in *Callidum luridum*, in which the anterior portion of the œsophagus commences with a small neck, and is then enormously dilated, after which it becomes gradually narrowed and constricted, and is joined to a second stomach, which in like manner is also dilated at its anterior extremity. In the middle part of its course it is twice folded, and is covered with minute cœca, as in *Calandra*, like which it terminates in a valvular pylorus, and receives at the same time the insertions of the hepatic vessels. The ilium is also of considerable length, is exceedingly muscular, and is dilated in two parts of its course before it terminates in a straight and very muscular colon and short rectum, as in *Calandra*. The length and complication of the intestines, therefore, appear to have some reference to the quality of the food to be digested, since it is well known that the food of these latter insects is of difficult assimilation, being as it is chiefly the hard ligneous fibres of vegetable matter; but they cannot be received as always indicatory of a carnivorous vegetable feeder, since, as above remarked, the length of the canal is considerable in one entirely carnivorous larva, while it is much shorter in some herbivorous, and particularly in pollenivorous larvæ, as in the *Melolontha* and the apodal Hymenoptera.

In the perfect insect, the length of the alimentary canal is not more indicatory of the habits of the species than in the larva. It is nearly as long, and is more complicated, in the rapacious *Carabidæ* (*fig.* 423) than in the honey-sipping Lepidoptera, whose food is entirely liquid, while, as we have seen, it is only a very short tube in the pollenivorous larva, which subsists upon a mixture of pollen and honey; but in the perfect insect, which subsists upon honey alone, and which it might be supposed requires little power of digestion, the canal is long and tortuous. In the rapacious *Carabidæ*, it is from two to three times the length of the whole body. At its commencement at the pharynx it is funnel-shaped, and opens directly into the œsophagus (*fig.* 424, *h*), which is gradually enlarged as it passes through the thorax, until it arrives at the meta-thoracic segment, where it becomes greatly dilated, and forms a large bag or crop, which we shall presently see more perfectly developed in the Haustellata. While passing into the abdomen, this part becomes suddenly constricted, and terminates in a short neck, immediately behind which is an oval and very muscular gizzard (*i*), which is developed internally into four broad longitudinal horny ridges (*a*, *b*), armed with strong sharp bristles, as formerly shewn by Leon Dufour* in insects of this family. Between these ridges are two channels armed in like manner with a double row of minute hairs, which assist in more minutely comminuting the hard parts that are passed into the gizzard and escape trituration by the ridges. The substance of the gizzard is particularly muscular, and resembles in colour the gizzard of a bird. On its external surface the thin shining peritonœal coat is very distinctly seen. At its base the gizzard is much constricted, and the ridges within it meet together so as to form a distinct valve, by which this is divided from the next portion of the alimentary canal, the chylific ventricule (*k*). This part is capacious and muscular, and the double mucous lining within it is very distinct. It is of considerable length, and is gradually decreased in size from its commencement to its termination at the pyloric valve, where, as in the larva, it receives the hepatic vessels. It is covered throughout its whole course by an immense number of apparently cœcal vessels (*a*, *b*, *c*), which in the upper half of its course are of considerable length, but in the lower become gradually more and more shortened. Burmeister† thinks these cœcal vessels are derived entirely from the inner or mucous coat of the ventricule by intussuscepted portions, which pass through the muscular coat between the fibres which are pushed aside by them, and consequently that they do not derive any covering from the muscular coat, but of this we have considerable doubt. Internally they certainly open each by a distinct valvular orifice, derived from the mucous lining, as we have seen in *Carabus monilis* (*b*), and externally are covered by the peritonœal coat, and on each side are furnished with a minute ramifying tracheal vessel, derived from the tracheæ which are distributed over the alimentary canal, as shewn by Dufour. We cannot, however, imagine that they derive no covering from the muscular coat of the ventricule, more especially while it is admitted that the cœcal appendages attached to the anterior and posterior portion of the ventricule in the *Gryllidæ* derive a portion of their structure from the muscular coat as well as the mucous. These are most decidedly secretory organs, and elaborate a fluid, probably distinct in its chemical composition from that of the biliary vessels at the pyloric extremity of the stomach. The ilium (*l*) is of considerable length. On its exterior surface the longitudinal muscular bands are distinctly marked. It is much longer in proportion to the other parts of the intestine in the perfect insect than in the larva. It terminates in a very large pear-shaped colon (*m*, *n*), the upper part of which corresponds to the cœcum, which we shall see highly developed in some other species. It is there marked by six elongated elevated glandular protuberances, situated between the longitudinal muscular bands. These elevations seen on the exterior of the part correspond to others which we have found equally strongly marked in the colon of Hymenoptera, and we suspect are the mucous glands of the great intestine. The colon is usually distended with fæces, and terminates in a very short narrow rectum (*o*). At each side of the colon are situated the *anal or urinary* vessels (*s*), which we shall presently describe. This may serve to illustrate the general form of the alimentary canal in carnivorous Coleoptera. In certain parts of its course it is, however, more developed in other species. Thus in the *Dyticidæ*, we have found the œsophagus in *Hydaticus cinereus*, as described by authors in *Dyticus*, expanded into a large crop-shaped bag, and the stomach shorter than that of the *Carabidæ*, and covered by long cœca throughout its whole extent. It receives at its base the insertion of four large hepatic vessels, and also two very much smaller ones, similar to those just seen in the larva of the *Calandra*. The anal vessels are also present, but their excretory bladder is larger, and its neck much shorter than in the *Carabidæ*. The most remarkable structure is in the proventriculus or gizzard. The external appearances of this part resembles that of an acorn in its cup. It is exceedingly muscular, and is armed internally with four remarkable teeth arranged around its inferior portion, between four horny ridges developed from the mucous lining of the part, and covered with very strong stiff hairs, as in the *Carabidæ*. Each of these teeth is broad and somewhat oval at its base, and in shape resembles a helmet, the crest of which is acute, and armed with two sharp-pointed prominences adapted for cutting the food, which it is known is swallowed more rapaciously and less comminuted by these insects than by *Carabidæ*. This form of alimentary canal with a gizzard and gastric cœca exists in the *Silphidæ*,* and most of the carnivorous feeders. Thus it exists also in *Staphylinidæ*,† in which we have found the gizzard in *Creophilus maxillosus* armed with double longitudinal horny ridges, covered with stiff hairs as in *Carabus*, like which also the stomach is covered with gastric cœca, which are larger at the anterior than at the posterior part of the organ. The anal vessels are also largely developed. Dufour has observed the same in *Staphylinus erythropterus*. The gizzard is also found in some of the Neuroptera. It is very largely developed in the carnivorous *Panorpa communis*, in which, however, we have not found it thrown into regular longitudinal folds, but into transverse and oblique rugæ covered with stiff hairs. The alimentary canal in this species is of considerable length, perhaps nearly three times that of the body. The œsophagus is short, but is developed at its under surface into a minute oval crop, perfectly distinct from

* Annales des Sciences Naturelles, tom. ii. pl. 20.
† Op. cit. p. 132.

* Dufour, op. cit. tom. iii. pl. 13, fig. 5.
† Id.

the common cavity of the œsophagus, although not separated from it by a valve, neither is the œsophagus separated by a valvular structure from the gizzard. The chylific stomach is exceedingly long and cylindrical, but is without gastric cœca, like the larva of *Carabidæ*, since like that, the *Panorpa* appears to subsist rather by sucking the juices than by swallowing the hard parts of the body of its victims. Thus, then, although in the *Cicindelidæ* (*fig.* 37, vol. 1), the canal is scarcely longer than the body, as formerly shewn by Dufour, and since frequently instanced as proving that the length or shortness of the canal is characteristic of a carnivorous or phytophagous feeder, we cannot admit that the length of the digestive organs, and the existence of a gizzard and gastric vessels, are indicatory of predacity of habits in the insect, because a similar conformation of parts exists often in strictly vegetable feeders. The existence and length of these parts seem rather to refer to the comparative digestibility of the food than to its animal or vegetable nature.

Among the more omnivorous feeders, as in the *Forficulidæ*, the gizzard is still present. In *Forficula auricularia* the œsophagus is long and dilated, and a short, broad, and very muscular gizzard is present. Internally it is thrown into six longitudinal folds, which project for some distance at their extremity into the cavity of the digestive stomach, to the entrance of which, when closed, they serve as a valve. The canal of this insect, which, although in part carnivorous in its habits, certainly is not of the most rapacious nature, but lives equally upon the juices of fruits and flowers, is scarcely longer than that of the most predaceous *Cicindela* or *Dyticus*, since it passes almost in a direct line through the body, making but one slight convolution, a further proof that the *length* of the canal must not be taken as a criterion whereby to judge of the habits of a species. This will apply equally to the omnivorous *Gryllidæ*, in which there exists a short alimentary canal, but a gizzard of more complicated structure than that of *Dyticidæ*. In these insects the two layers of the mucous coat are visible even in the œsophagus. The second layer is distinctly glandular and secretory, and in it there are many thousands of very minute granulary glandular bodies, which probably secrete the fluid that is often ejected from the mouth of the insect when captured. The inner layer, or proper mucous lining, is often folded longitudinally, and in *Acrida viridissima* these folds, which are six in number, assist to form a valve between the œsophagus and gizzard. They are each armed with five very minute hooked teeth, and continued into the gizzard develope many more in their course through that organ. These first teeth are arranged around the entrance to the gizzard, and seem designed to retain the insufficiently comminuted food and pass it on to that organ. Next to these in succession on each of the longitudinal ridges are four flat, broad, and somewhat quadrate teeth, each of which is very finely denticulated along its free margin. These extend about half-way through the gizzard. They appear to be alternately elevated and depressed during the action of the gizzard, and to serve to carry on the food to the twelve cutting teeth with which each ridge is also armed, and which occupy the posterior part of the organ. These teeth are triangular, sharp-pointed, and directed posteriorly, and gradually decrease in size in succession from before backwards. Each tooth is very strong, sharp-pointed, and of the colour and consistence of tortoise-shell, and is armed on each side by a smaller pointed tooth. These form the six longitudinal ridges of the gizzard, between each two of which there are two other rows of very minute teeth of a triangular form, somewhat resembling the larger ones in structure occupying the channels between the ridges. The muscular portion of the gizzard is equally interesting. It is not merely formed of transverse and longitudinal fibres, but sends from its inner surface into the cavity of each of the large teeth other minute but powerful muscles, a pair of which are inserted into each tooth. The number of teeth in the gizzard amounts to two hundred and seventy, which is the same number in these *Gryllidæ* as found formerly by Dr. Kidd* in the mole-cricket. Of the different kinds of teeth there are as follows: seventy-two large treble teeth, twenty-four flat quadrate teeth; thirty small single-hooked teeth, and twelve rows of small triangular teeth, each row being formed of twelve teeth. This is the complicated gizzard of the higher Orthoptera. In the same insect immediately posterior to the gizzard the chylific stomach is expanded on each side into two large rounded cœca, into the upper part of which some minute vessels are traced which in appearance resemble the hepatic vessels. Posteriorly to these cœca the stomach becomes narrowed and makes one convolution, and receives around its termination the hepatic vessels, which are small but very numerous. It then is continued backwards as a long ilium, and terminates in a muscular banded colon without a distinct rectum. The whole length of this alimentary canal does not exceed more than about one length and a half of that of the body. A similar structure exists in the *Blattidæ*. In these insects eight large vessels are inserted around the commencement of the stomach behind the gizzard. Four of these are long and four short, and as observed by Burmeister, these have been thought to be analogous to pancreatic or gastral salivary organs. In the proper *Locustidæ* there is only a rudimentary gizzard, as Burmeister has shown in *Locusta migratoria*, in which the interior lining of the whole œsophagus and crop is covered by an immense number of very minute horny teeth, for the purpose of comminuting the hard ligneous matter which we have sometimes found in foreign specimens. The rudiments of the gizzard exist in six flat pieces, studded with minute teeth like the lining of the œsophagus. The commencement of the stomach is surrounded by two sets of cœcal appendages, six in each set, and similar in form to those of the second set in the larva of *Melolontha*, like which those on the under surface are the

G, anterior muscles of the pharynx; H, œsophagus; I, gizzard; K, chylific stomach; L, ilium; M, colon (cœcal portion of); N, colon; O, rectum; *a*, frontal ganglion on the vagus; *b*, vagus; c, anterior lateral ganglion connected to the vagus.

longest. These are evidently analogous to the vessels in *Blatta*.

But one of the most remarkable forms of alimentary canal with reference to the habits of the insect exists in the male *Lucanus cervus* (*fig.* 428), which subsists entirely upon fluid aliment, as proved by the observations of naturalists, and confirmed by the fact that its mouth is unfitted for mastication. In this insect the œsophagus (H) is usually long and narrow, and terminates in the meso-thorax in a well developed gizzard (I), as in the *Carabus*, and this is succeeded by a long chylific stomach (K), covered throughout its whole extent by very minute rudimentary cœca, as first noticed by Dufour. It makes three distinct convolutions, and is then divided by a pylorus, which receives four hepatic vessels (P) from an exceedingly short ilium (L), which passes directly in an enormous colon. The upper portion of this (M) is divided from the lower (N), which is thus divided into colon and cœcum. It terminates in a long folded rectum (N, O), and the whole are usually filled with fæces. Now this insect, in which both gizzard and gastric vessels are present, can scarcely require these parts for the purpose of triturating its food, which is entirely fluid, besides which, being one of those species that undergo a complete metamorphosis, it can scarcely be supposed to be simply a remains of what existed in the larva state. The presence of the gizzard may be looked upon as somewhat anomalous. Again it may be remarked, that in Hymenoptera the stomach, which in many species digests only liquid concentrated food in the form of honey, is much longer than in those instances, as in Orthoptera, in which the food is less easily digestible. In the *Apidæ* there is a large alimentary canal with an immense number of biliary vessels attached to it, while in the *Tenthredinidæ*, which, besides honey, subsist partly upon the pollen of flowers, as we have observed in *Athalia centifoliæ*, there is a very short alimentary canal and even a distinct gizzard (*fig.* 429, I), situated between the

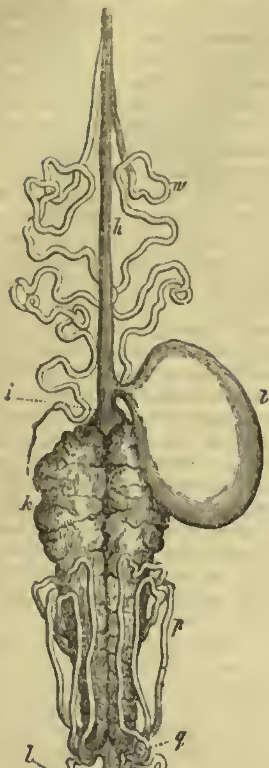
Fig. 429.

Section of the crop (H), *gizzard* (I), *and stomach* (K) *of Athalia centifoliæ.* (*Newport, Prize Essay*).

stomach (K) and the dilated œsophagus (H) or crop of this order. We have detected pollen in the proventriculus of this insect, so that in these we have still further proof that the length of the canal is not always indicatory of the habits of the species.

In the Lepidoptera, which, we have seen, in the larva state have a short intestine, have a comparatively long one in the perfect. In the *Sphinx ligustri* (*fig.* 430), the œsophagus (*h*) is long and narrow, and in the metathoracic segment is dilated into a large crop (*t*) connected by a distinct neck, but not divided from it by a valve. This is usually filled with air, and has thence been called the *sucking stomach*, but in the Diptera, in which it also exists, and commencing much nearer the pharynx is extended backwards as a long and gradually enlarging tube until it reaches the anterior part of the abdomen, where it is expanded transversely into a large bag, we have certainly found it partially filled with food. This has often been found to be the case in the common flesh-fly. In *Eristalis floreus* (?) we have found it partially filled with yellow pollen from the flowers of the ragwort, upon which the insect was captured. We have at the same time observed

Fig. 430.



Alimentary canal of Sphinx ligustri.

the pollen in the canal leading to the bag, in the œsophagus, and in the stomach itself. A gizzard does not exist either in the Diptera or Lepidoptera, but there is a slight rudiment of it in the Sphinx (*i*). The stomach of Lepidoptera is in general short, oval, or a little elongated (*k*), and always very muscular, and as in other insects, the hepatic vessels (*p*) enter at its pyloric extremity (*q*). The ilium (*l*) is of considerable length. In the Sphinx it makes seven folds, and then passes straight to the

Fig. 431.

Alimentary canal of Pontia brassicæ.

colon, which is developed anteriorly into a very large cœcum (*m*), and terminates in a narrow short rectum (*n*). Throughout its whole course it is covered by the hepatic vessels. In the *Pontia brassicæ (fig.* 431), the digestive stomach is preceded by a very muscular and transversely banded portion of canal resembling the stomach of Hymenoptera. It is in the precise situation of the gizzard in other orders, and appears to be the representative of that part in this insect. The true stomach is long and oval, and the ilium is longer than in the Sphinx, and the cœcum, colon, and rectum are all distinct. In the Diptera the alimentary canal is usually very long, and is scarcely at all shorter in the carnivorous than in the omnivorous feeders.

Appendages of the canal.—The first of these, the *salivary glands*, are very frequent in most of the orders, but vary greatly in form and number. In Lepidoptera they are simple elongated tubes (*h*), which extend into the thorax and are convoluted beneath the œsophagus and anterior portion of the alimentary canal. In the larva they constitute the *silk vessels,* and empty themselves by a single duct through the spinneret on the floor of the mouth. They are formed of three portions; first, the excretory, which is thin and transparent, and is gradually enlarged as it passes backwards along the body; second, the apparently secretory portion of the organ, which is of an elongated cylindrical form, externally transversely marked as if formed of muscular fibres, and internally covered with a vast number of rounded glandular bodies, as we have seen in the recently detached vessel of *Vanessa urticæ*; and lastly of a third portion, which consists of a minute vessel, extended from the apparently cœcal extremity of the middle portion of the organ, as formerly shewn also by Lyonet in the Cossus. In the perfect insect these parts still exist, but very much reduced in size. In the Cossus Lyonet has shewn four of these vessels, two of which, the proper silk vessels, open by a single excretory duct, and the others separately into the cavity of the mouth. In some Coleoptera, as in the *Blapsidæ*, these organs are formed of many ramifying tubes united on each side of the œsophagus into a single duct. In others, as in the Orthoptera and Hymenoptera, they consist of an immense number of rounded, opaque, glandular bodies, aggregated together in small clusters, which communicate by many small ducts, inserted at irregular distances, with a large and partially convoluted common or excretory duct, that opens on each side of the mouth, so that each of these collections of glands resembles a bunch of grapes or currants. Each of these rounded granules, or acini if we may so call them, receive a minute vessel, but whether this is distributed over its surface or is received directly into its substance we have been unable to ascertain. These aggregations of salivary glands are usually situated on each side beneath the œsophagus in the prothorax, and are very distinct in the Orthoptera and Hymenoptera, in which they have been often noticed. Müller has seen them in *Phasma*, Treviranus in *Apis*, Burmeister in *Locustidæ*, *Gryllidæ*, and *Termes*, and we have also seen them in *Locustidæ* and *Gryllidæ* among the Orthoptera, and in *Bombus*, *Apis*, *Anthophora*, and *Athalia* among the Hymenoptera. Their existence in the latter genus is somewhat interesting from the circumstance that the large quantity of salivary fluid which these organs seem calculated to produce appears to be entirely employed in moistening the dry pollen of flowers upon which the perfect insect chiefly subsists, before it is passed into the œsophagus, and not in the habits or in constructing of a nest, as is the case with the bee, which always employs it as a solvent for the wax in the construction of its combs. In the latter insect, according to Burmeister, the evacuating duct of these organs is a minute spiral vessel resembling a trachea, and empties itself into the tube of the proboscis or ligula. The form and number of these salivary organs varies in the different classes; the usual number is two, but in *Apis Cimex* and *Pulex* there are four, each pair of which unite into one duct, while in *Nepa* there are as many as six.* In the *Tabanidæ* there are only two short cœcal tubes, into which many minute vessels empty themselves.† Those *gastric vessels*, which are inserted at the commencement of the digestive stomach we have above stated have been regarded as salivary organs, but there is considerable doubt respecting their real function. Burmeister considers them to be analogous to the pancreas, but if this be admitted to be the case in the Orthoptera, those vessels also which cover the exterior of the digestive stomach in the carnivorous Coleoptera must be of the same description, since both empty themselves into the digestive stomach. But we cannot coincide with him in this opinion, since from an experiment which we shall presently notice there is reason to believe that the fluid poured into that cavity during digestion is of an acid nature, analogous to that which is found under similar circumstances in the stomach of vertebrata; while that of the proper salivary organs is believed to be alkaline, as was formerly supposed by Rengger. Treviranus also believed the same of the saliva of the honey-bee, having witnessed its employment by this insect in the formation of its combs. We have also seen this insect reduce the perfectly transparent thin white scale of newly secreted wax to a pasty or soapy consistence, by kneading it between its mandibles, and mixing it with a fluid from its mouth, before applying it to assist in the formation of part of a new cell, so that we have good reason to believe that the salivary fluid thus employed as a solvent for the otherwise brittle wax is of an alkaline quality.

The *Malpighian* or supposed *biliary vessels* (*fig.* 432, *p*) usually enter the canal, as we have seen, at the pylorus. They vary greatly in number from two to twenty or even a hundred, as in some of the Orthoptera and Hymenoptera, but in all insects their function appears to be similar. They are usually from four to six in number, and are very long tubes that pass from their insertion or opening into the canal behind the pylorus directly forwards about half way along the sides of the stomach, and are then reflected backwards as far as the ilium, around which and the colon they make many convolutions, and in the Lepidoptera terminate, or perhaps we ought rather to say originate, each in a minute vessel, which becomes smaller and smaller in proportion to its length, and in which we can perceive no disposition to form a cœcal termination, although we have been unable to trace it to its origin, which is certainly in the vicinity of the posterior part of the colon. Of this we have satisfied ourselves by following these vessels in the larva of *Odonestis potatoria*, which the colour of their contents, an opaque bright yellow, has rendered practicable. We have traced them until the yellow colour has disappeared in an opaque white, and this has been also lost in a perfectly transparent fluid, after which we have been unable to follow the vessels further. In other insects they appear to end in cœcal extremities, but we certainly could not observe this in the larvæ of Lepidoptera. It has also been supposed by some anatomists that these vessels form a double communication with the alimentary canal, but this has entirely escaped our observation. In the larva of *Sphinx ligustri* and most other Lepidoptera these vessels are covered by an immense number of minute oval cœciform dilatations (*fig.* 432, *a*), as is also the case in some of the perfect Coleoptera, *Melolontha*,* as shown by Dufour, Straus

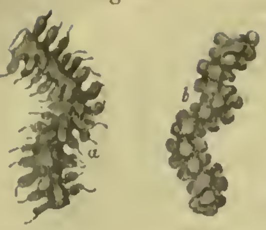
Fig. 432.



a, part of the hepatic vessel of the larva of Sphinx ligustri when nearly full grown, showing the cœca; *b*, part of the same in the pupa, the cœca disappearing.

Durckheim, and others. From each of these supposed cœca in the larva of sphinx we have traced an exceedingly minute and transparent vessel which has appeared to be connected with other delicate ramifications, and sometimes with the immense quantity of adipose sacculi with which the whole viscera are surrounded. These Malpighian vessels undergo considerable changes while the insect is passing from the larva to the perfect state. The cœca begin to disappear soon after the insect has entered the pupa state (*b*), and not a trace of them is discoverable in the perfect insect, so that the function of the organ is gradually diminished in activity. During the larva state they exhibit a remarkable peculiarity at their connexion with the alimentary canal which seems to have some reference to their function. It is a dilatation at the point of union of these vessels in the sphinx to form a single duct that opens into the ilium, and if these be hepatic vessels may represent a gall-bladder, as once observed to us by Dr. Grant, but the exact function of the vessels is very difficult to determine. The following observation which we made in the summer of 1832 and have since repeated seems a little to show the nature of the contents of these vessels, and also of other parts of the alimentary canal. We gave sugared water, coloured with indigo, to some specimens of *Vanessa urticæ* which had been confined for several hours without food after they had left the pupa state. On examining the insects about two hours afterwards the stomach was found filled with fluid containing a great quantity of pink-coloured granules, which appeared to be the vegetable indigo acted upon by the acid contents of the stomach by which it had become saturated, thus distinctly indicating the presence of an acid in the stomach during digestion. But it was remarkable that some of the indigo that had passed the pyloric extremity of the stomach, where these supposed biliary vessels enter, and had also passed throughout the whole length of the ilium and even in part into the colon, had been restored again to its original dark blue colour, thus indicating the presence of an alkalescent fluid secreted either by the hepatic vessels or the ilium along which the indigo had passed. But another curious circumstance was that the hepatic vessels also partook of the same pinkish hue as the contents of the stomach, which seemed to indicate that the contents of these also are acid. The conclusions we drew from these observations, which we repeated very carefully in 1834, were, that there is an acid gastric juice secreted in the stomach during digestion, that the contents of the so-called hepatic vessels are probably also acid, and that an alkaline fluid is secreted by the ilium, otherwise the indigo reddened in the stomach could not have been restored to its original colour. These circumstances seem to lead to the conclusion that the Malpighian vessels are rather uriniferous than biliary, more especially as they have been found by Chevreul* and Audouin† to contain uric acid; but if this be really their function, a question then arises why they are inserted so near to the pyloric extremity of the stomach in almost all insects, and the excreted fluid be thus required to traverse nearly one-half of the whole alimentary canal before it is ejected from the body? This consideration still inclines us to suspend our opinion as to their true function, and leads us still to believe that they may be in some way connected with the function of digestion and assimilation.

The anal or proper uriniferous organs.—We agree with Burmeister that the anal are the true urinary organs. They do not in general evacuate their contents directly into the canal, but on each side of the anus. They exist, as we have seen, in the *Carabidæ* (*fig.* 424, *s*), and their general form, as long ago shown by Dufour in these insects, is that of a long vessel convoluted upon the colon and emptying itself into an oval or kidney-shaped vesicle on each side of the colon, and terminating in a single duct close to the anus. Dufour found the minute vessel on the colon connected with an aggregation of rounded glandular bodies, each connected with the vessels by a very minute filament, but we have overlooked this structure in our own examinations. Neither have we seen it in the *Dyticidæ*, in which each uriniferous organ commences in two apparently cœcal tubes, which, after being a little convoluted, unite into one which empties itself into a vesicle on each side of the colon and rectum. Similar vesicles have been shown by Dufour in the *Staphylinidæ*, as in *Staphylinus erythropterus* and in the *Silphidæ*, in both which we have ourselves distinctly seen them arising by a single vessel which empties itself into an urinary bladder on each side of the anus. In the *Silphidæ* this bladder opens directly into the termination of the rectum.

The adipose tissue.—This tissue, which it is necessary to allude to in connexion with the organs of nutrition, consists of an immense number of little transparent membranous vesicles filled with opaque adipose matter, which, in the generality of insects, is perfectly white, but in others, as in the butterflies, is of a bright yellow colour. The vesicles are usually very irregular in form, being sometimes nearly oval and at others elongated or triangular. They communicate freely with each other and form a most intricate web or reticulated structure. They cover the whole of the abdominal viscera

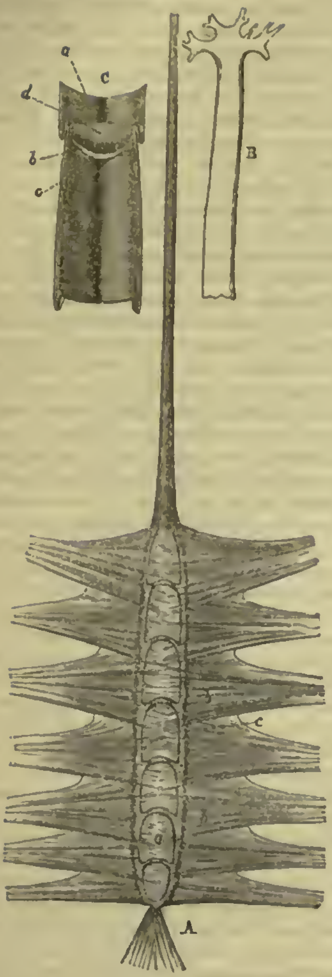
* Straus Durckheim, Considerat. &c. 1828, iv. 251.
† L'Institut. 135.

like the omentum of the higher animals, and they are extended also among the muscles, between which they occupy the interstices, both between the different layers and the tegumentary skeleton. They do not form in the abdomen one continuous surface like the mesentery, but are simply attached to each other, and to the surrounding structures by constricted portions, which allow of the freest communication. They are most abundant in the abdomen, but are extended into the thorax and cover more particularly the nervous cord. There are but very few in the region of the head or in the extremities. We have never yet seen them in actual communication with bloodvessels, although we have observed them attached by minute points along the whole course of the dorsal vessel, in the abdomen, as if they were in some way connected with the return of the blood to the auricular space that appears to surround that organ. It is amongst these vesicles in particular that the Malpighian or so-called biliary vessels extend around the alimentary canal, and the tracheæ ramify among them in the greatest abundance, but we have not observed them distributed over the sides of individual vesicles as over some other structures. These circumstances lead us to suspect that the vesicular structures are in some way connected with the circulatory system, although they cannot be regarded either as arteries or veins. May they not serve the purpose of lymphatics, while they become at the same time depositaries of the nutrient matter? Oken and Treviranus appear to have considered them as analogous to the liver, and the latter author has supported his opinion by the existence of a somewhat analogous structure in the scorpion, which is believed to be the liver of that animal. That they are most intimately connected with the function of nutrition is proved by the circumstance that they exist in the greatest abundance at the period when the larva ceases to feed, just before it enters the pupa state; that their contents are gradually diminished during that condition; and that they disappear most rapidly towards the latter end of the pupa state, when the organs of generation are in the most rapid progress of development. After the insect has entered the perfect state their contents have nearly disappeared. Added to these circumstances we have observed that, during the earliest periods of the larva state, the quantity of adipose substance contained in the vesicles is very small, and also that in all perfect insects that pass the winter in a state of hybernation the quantity of adipose matter is much greater than in those which do not live through the summer, while it has nearly all disappeared in these insects after they have left their hybernacula in the spring. We have remarked these circumstances particularly in the later broods of butterflies, which being hatched at the end of autumn pass the winter as hybernants and appear again in the spring, and we have constantly noticed the same thing in the large females of *Bombus terrestris*, which live through the winter. From these circumstances there can be no doubt but that the adipose matter is intimately connected with the function of nutrition and the circulatory system, while the free communication which we have constantly observed to exist between the vesicles seems to favour our opinion that they may serve the office of lymphatic vessels. That they cannot be supposed to answer the purpose of a liver seems evident from the increase and diminution of their contents at certain periods, while their apparent connexion with the Malpighian vessels seems to support the opinion we have advanced, more especially if these be regarded as uriniferous rather than as biliary organs.

Circulatory system.—It was formerly supposed that there was a total absence of a circulatory motion of the fluids in insects, and that the whole body was nourished by a simple imbibition of fluids that occupied the cavities of its different regions. This opinion was strengthened by the circumstance of the air-vessels being distributed to every separate structure and ramifying extensively even upon the most delicate organs, a fact so remarkable that it appeared entirely to obviate the necessity for a motion of the fluids, and led to the promulgation of Cuvier's beautifully ingenious theory, that as the blood could not be carried to be aerated in a separate organ or lung, the air was in consequence brought into contact with it throughout the whole body. But the discovery of Carus in 1827 of an actual motion of the fluids, and subsequently the discovery by Straus Durckheim of a structure in the dorsal vessel, which clearly indicates the true use of this organ as a centre of circulation, have sufficiently shown that insects do not differ from other animals in the absence of a circulation of their fluids, whatever modifications may exist in the form and situation of the organs by which it is accomplished.

The heart or *great dorsal vessel* (*fig.* 433, A) is an elongated tapering organ, which, in every insect, occupies the middle line of the dorsal surface of the body, and extends from the posterior part of the penultimate segment of the abdomen, through the thorax, into the first segment or head of the animal. That portion of it which is situated in the abdominal region is the proper analogue of the heart of other other animals, and is composed of a certain number of separate compartments or chambers (*a*). It is distinctly muscular, and is of considerable diameter, and is that part which is actively employed in circulating the blood. The other part which extends through the thorax is much narrower than the preceding, and is not divided into chambers, but is one continuous vessel that becomes gradually narrower as it passes through the thorax to the head, where it is divided into separate branches (B). This part is less actively employed than the abdominal, being only the great vessel through which the blood is sent from the muscular heart to the system, and, consequently, represents the *aorta*. In the *structure* of the abdominal portion or true heart we recognize three separate coats, two of which are most distinctly marked, and form the substance of the organ; but the third or external one is very delicate and not easily observed. Straus Durckheim recognises but two distinct structures, the

Fig. 433.



A, *dorsal vessel or heart of Lucanus cervus.*
a, the valves or chambers; *b, b*, the lateral muscles; *c*, the supposed auricular space around the vessel.
B, *the division into vessels of the anterior or aortal portion of the dorsal vessel in the larva of Vanessa urticæ.*
C, *interior of the dorsal vessel (Straus).*

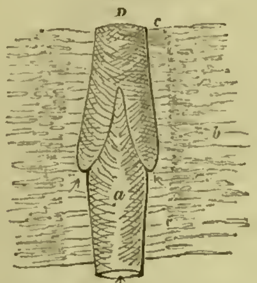
internal one (C, *a*) formed of a transversely folded and striated membrane which is thickest towards the middle of each chamber, and an external one formed of strong, smooth, muscular, longitudinal fibres. Burmeister* has suggested that these may be only two layers of one muscular structure, and that the presence of a structureless lining or inner membrane must then be presumed, although it be too delicate to be actually detected by observation. The third or external coat is a transparent structureless membrane which covers the outer surface of the heart, and is extended directly over it without following the reflexions inwards of the muscular coat, where it forms the valves or separations between the different chambers. The division of the organ into separate chambers is effected by means of an intussusception or reflexion inwards and forwards of the whole muscular structures. A portion of each side of the heart is first extended inwards so as very nearly to meet a corresponding portion from the opposite side, and then reflected backwards forms, according to Straus,* the interventricular valve (*d*), which separates each chamber from that which follows it. Posteriorly to this valve, at the anterior part of each chamber, is a transverse opening or slit (*b*), the *auriculo-ventricular orifice*, through which the blood passes into each chamber, and immediately behind it is a second but much smaller *semilunar valve* (*c*), which, like the first, is directed forwards into the chamber. It is between these two valves on each side that the blood passes into the heart and is prevented from returning by the closing of the semilunar valve. When the blood is passing into the chamber the inter-ventricular valve is thrown back against the side of the cavity, but is closed, when, by the contraction of the transverse fibres, the diameter of each chamber is narrowed and the blood is forced along into the next chamber. The number of these openings and chambers in different species of insects does not yet appear to have been satisfactorily ascertained. Straus has figured nine chambers in *Melolontha*, and consequently eight pairs of openings, but we have not been able to observe more than seven pairs of openings in *Lucanus cervus*, in which the anterior pair is almost hidden at the commencement of the aorta. Burmeister† states that he could not find more than four pairs of openings in the larva of *Calosoma*, while he remarks that according to Müller's description of the heart in *Phasma* there appears to be but one pair in that species. In *Bombus terrestris* we have as yet detected but five pairs, but we nevertheless suspect that these discrepancies, or apparent differences in the number of these openings, arise less from so great a diversity in the actual number than from some of them being overlooked during dissection, since we have invariably found eight pairs in *Sphinx ligustri*, both in the larva and perfect state, as well as in other Lepidoptera; while in the Bombus examined by us the dissection was not so carefully made as to enable us to state positively that there are not more than we have mentioned. The external form of the chambers in the very thick and muscular heart of *Lucanus* is shown in the drawing we have given of this structure. When the heart is examined by transmitted light, there is seen around it a bright space (A, *c*) in which we have observed the blood flowing very freely in living specimens of *Agrion*, and which we regard with Straus as an auricular cavity, apparently bounded by a loose membrane, and

* Op. cit. p. 156.

* Considerat. &c. p. 356.
† Op. cit. p. 154.

into which the blood is received both in returning backwards from the head and thorax and laterally from the sides of the abdomen. We have observed a similar space in many insects, particularly in *Asilus crabroniformis* (*fig.* 434, D), and also in *Bombus terrestris*.

Fig. 434.



One valve of the heart of Asilus crabroniformis.

a, the chamber; *b*, the lateral muscles; *c*, the auricular space; the arrows denote the course of the blood.

In this insect we have observed the fibres of the heart crossing each other in an oblique direction, forming as it were a series of festoons around the posterior part of each chamber. These, like the transverse fibres observed in *Melolontha* by Straus, contract the diameter of each chamber, and extend the vessel. Besides the proper muscular structure of the heart itself, there are attached on each side of the organ several sets of muscular fibres, arranged in pairs along the upper and under surface of each chamber. Each set of these fibres, converging to a tendon, and passing outwards, forms a triangular muscle (A, *b*, *b*), which is attached to the lateral surface of each segment. These, which have been called *the wings* of the heart, assist by their contraction to shorten and expand the chambers at the *auricular*, or receiving period of the heart's motions, while, as just explained, the transverse and diagonal muscles occasion the *ventricular*, by their contracting and narrowing the diameter of each chamber. It is between the upper and under set of the lateral muscles that we believe the auricular space to exist, bounded by a delicate membrane. The thoracic or *aortal* portion of the heart commences at the anterior part of the first abdominal segment, where the organ bends downwards to pass under the metaphragma, and enter the thorax. When it has entered that region it immediately ascends again between the great longitudinal dorsal muscles of the wings, and passes onwards until it arrives at the posterior margin of the pronotum; it then again descends and continues its course along the upper surface of the œsophagus, with which it passes beneath the cerebrum, anterior to which, and immediately above the pharynx, it is bifurcated and divided into several branches, as formerly noticed by us in the sphinx.* Previously to our notice, however, Carus had seen the course of the blood in the head of insects following directions corresponding to the situations in which we have been able to trace a distinct division of the aorta into vessels. We have found a similar division of the aorta into branches in several species of Coleopterous insects, as in *Meloe*, *Blaps*, and *Timarcha*, although we have omitted to trace it in *Lucanus*. In the *Sphinx* and *Vanessa urticæ*, immediately after the aorta has passed beneath the cerebrum it gives off laterally two large trunks, which are each equal in capacity to about one-third of the main vessel. These pass one on each side of the head, and are divided into three branches, which are directed backwards, but have not been traced farther in consequence of their extreme delicacy. Anterior to these trunks are two smaller ones, which appear to be given to the parts of the mouth and antennæ, and nearer the median line are two others, which are the continuations of the aorta. These pass upwards and are lost in the integuments. The whole of these parts are so exceedingly delicate that we have not as yet been able to follow them beyond their origin at the termination of the aorta, but believe them to be continuous with very delicate circulatory passages along the course of the tracheal vessels. It is in the head alone that the aorta is divided into branches, since throughout its whole course from the abdomen it is one continuous vessel, neither giving off branches nor possessing lateral muscles, auricular orifices, or separate chambers. In the larva state it is far more difficult to recognise the true structure of the vessel by actual dissection than in the perfect, because the valves are only in a rudimentary condition. But it is easy to observe it in the bodies of living transparent specimens, as done by Carus, Wagner, Bowerbank, and others in the *Ephemeridæ* and *Agrionidæ*, in which not only the form of the valves and motions of the vessel are distinct, but also the abundance of globules that circulate in every direction. Even in some of the opaque-bodied maggots of Diptera we have seen the form of the valves very distinctly through the tegument in the eight posterior segments. When viewed in that state each chamber appears to be much narrower at its anterior and posterior extremity than in its middle (*fig.* 358, D), and the valves formed by the reflexion of its parietes inwards, although distinct, are very small. Near the middle of each chamber there is attached on each side a narrow muscle, which passing backwards is attached to the anterior margin of each segment. Between the muscle and the heart in each segment, a large tracheal vessel crosses to anastomose with its fellow on the opposite side, and on each side of the dorsal vessel, nearly in the course of the lateral muscles, there is a faint indication of a line which seems to form the boundary of what we regard as the auricular space in which the blood is collected before passing into the chambers, of which there are eight very distinct ones in these larvæ.

The motion and course of the blood, as will be seen from the above account of the structure of the chief organ of the circulation, is first

* Phil. Trans. 1832, p. ii. p. 385.

directly forwards in the middle line of the body, and then backwards by the sides of the thorax and abdomen, to the lateral and posterior parts of the heart, into which it is received, by means of transverse currents in each segment, through the auricular space and orifices. This course, as discovered by Carus, is indicated in the description and diagram given in a former part of this work.* The blood, which is usually of a very transparent greenish or yellowish colour, is filled with a great number of little particles, which were described by Carus as oblong or oval, but more correctly by Mr. Bowerbank † as flattened oat-shaped masses, which retain their form while circulating through the body, but like the particles of blood in Vertebrata become globular immediately they are brought into contact with water. It is stated by Burmeister ‡ that they vary in diameter from $\frac{1}{663}$th to $\frac{1}{300}$th of a line, but they differ also in size in the same individual, and are often rough or tuberculated as noticed by Edwards,§ and as distinctly seen in the blood of *Sphinx ligustri*. The motions of the blood, rendered perceptible by the presence of these particles, was first observed by Carus in the aquatic larva of *Ephemera*, in which, as in other aquatic transparent bodied larvæ, the particles are very distinct. Baker‖ and some of the older observers in this country had long before seen motions of the fluids in the limbs of some insects, but Carus first discovered the existence of a complete circulation. Carus saw the blood distributed in several streams from the aortal extremity of the dorsal vessel in the head returning in currents, that entered the base of the antennæ and limbs, in which it formed loops, and then flowing into the abdomen entered the heart at its posterior extremity. Wagner¶ confirmed Carus' discovery, and added some new observations. He saw the blood flowing backwards in two venous currents, one at the sides of the body and intestine, and the other alongside of the dorsal vessel, and he discovered that the blood not only entered at the extremity of the dorsal vessel, but also at the sides in each segment, at the valves discovered by Straus. Both Carus and Wagner, however, believed that the currents of blood observed by them were not inclosed in distinct parietes or vessels. Mr. Bowerbank,** in repeating these observations, saw also the blood distributed by the dorsal vessel forming loops in the antennæ and limbs, and then passing backwards in lateral and transverse currents, enter at the valves into the dorsal vessel. And he also observed and clearly defined the structure and action of the valves. He discovered, however, that the currents of blood along the sides of the body are really inclosed in distinct parietes, and do not flow in the common abdominal cavity, as previously supposed, the boundaries of the vessels inclosing these currents being clearly definable. He has also expressed his belief that a "much greater portion of the circulation than we can clearly define is carried on within given vessels, as the blood may frequently be seen flowing in curved and other lines, and confined within very narrow limits, but so deeply seated amidst the muscles and intestines as totally to prevent the boundaries of the current from being clearly observed." We are ourselves most distinctly of the same opinion, having formerly, through the kindness of Mr. Bowerbank, been allowed to examine the circulation in *Ephemera* by means of his powerful microscope. We believe also that we have seen distinct vessels passing transversely across the dorsal surface of each segment, in the direction of the anterior part of each chamber of the dorsal vessel, in the large pupæ of *Acherontia Atropos* and *Sphinx ligustri*,* but whether these are vessels returning to or distributed from each chamber, as we are most inclined to believe, is not certain. If they be not vessels distributed *from* the heart, it is a somewhat curious circumstance that the whole of the blood should be first sent to the head of the insect, and the viscera of the abdominal region be nourished only by the returning blood, which has in part passed the round of the circulation. The only instance in which vessels had previously been supposed to be distributed directly from the heart in the abdomen was pointed out so long ago as 1824 by Professor Müller,† who discovered a connexion of the oviducts with the inferior surface of the organ in many insects; but these were afterwards believed by Carus, Treviranus, Wagner, and Burmeister to be only ligamentous connexions. We have observed these connexions in many insects, and certainly believed, when we first noticed them, without being aware that they had previously been seen by Müller, that they were vascular structures. We have traced them, especially in the *Carabidæ*, into direct connexion with the organ, but have been unable to observe at what point the cavity of the ovarial tubes commences, or where the supposed ligamentous portion begins. We have seen these connexions not only in the perfect insects but also in the larvæ, more especially in the males of *Sphinx ligustri* and *Odonestis potatoria*. In these larvæ the two oblong testicles, not united into one mass as in the perfect state, are each attached, side by side, by two short filaments to that chamber of the dorsal vessel which is situated in the ninth segment. One of these attachments proceeds from the anterior and the other from the posterior part of each testicle. Now, if these attachments be not distinct vessels, it is remarkable that these glandular and secretory organs should always be connected by mere ligaments with the great circulatory organ, since, if the object of their connexion were merely to retain them in their place in the abdomen, it would

probably be as well answered by an attachment to any other part. These considerations certainly lead us to hesitate to admit that they are mere ligaments. Whatever be their nature, as Müller has observed, their existence is indubitable.

Besides the parts now described, there is also another which is connected with and forms part of the vascular system, but the existence even of which has hitherto been almost overlooked. This is a distinct vascular canal, which is extended along the upper surface of the abdominal portion of the cerebro-spinal cord in perfect Lepidopterous insects, and which we have traced from the thorax to the termination of the cord. We have designated this structure the *supra-spinal vessel.* It is placed immediately above the cord, and is covered by transverse muscular fibres, which exclude it from the common abdominal cavity, and give to the whole cord, when removed from the body and examined by transmitted light, a flocculent appearance. This appearance was first noticed by Lyonet,* but the vessel between it and the cord was not detected by him. It was subsequently figured and described by us in the *Sphinx*,† and the whole of our recent observations‡ have confirmed the opinion we then entertained of it. It is a most distinct structure in the abdomen of the Sphinx, and may be readily seen after the abdominal cord has been carefully removed from the body with its surrounding structures and placed for some time in spirits of wine. We believe this vessel to be the chief means of returning the blood from the middle and inferior portion of the body to the posterior extremity of the dorsal vessel or heart, and that it is analogous to a structure which we have found to be a supra-spinal vessel § in the Scorpion and Centipede, that had previously been supposed to be a loose and easily detached portion of the nervous system, but which is now proved to belong not to the nervous but to the vascular structures. We are strongly inclined to suspect that this supra-spinal vessel in insects is connected with the anterior portion of the dorsal vessel or aorta, in a manner similar to the connexion which was shown by Mr. Lord ‖ to exist between the corresponding structure and the heart in Myriapoda. (See MYRIAPODA.) We believe also that we have seen a corresponding vessel in the larva of the Sphinx, but of so delicate a structure as almost always to elude detection. It will thus be seen that the blood certainly flows in distinct vessels, at least in some parts of the body in perfect insects, and that vessels exist even in the larva. But although a circulation of the blood has been seen by Carus, Wagner, and others in many perfect insects, it has been shown only in the appendages of the body, and in those chiefly in recently developed specimens, while it has been supposed to move only in intercellular spaces and not in distinct vessels. This opinion, however, is now invalidated by our discovery of a *supra-spinal* or great ventral vessel. A motion of the fluids has been seen by Carus in the wings of recently developed *Libellulidæ*, *Ephemera latea*, and *E. marginata*, and *Chrysopa perla;* among the Coleoptera in the elytra and wings of *Lampyris italica* and *L. splendidula*, *Melolontha solstitialis*, and *Dyticus*. But Carus was unable to detect it in the wings of Orthoptera, although, according to Humboldt,* Ehrenberg has seen it in a species of *Mantis*, and Wagner in the young of *Nepa cinerea* and *Cimex lectularius* among the Hemiptera; but it has not yet been observed in the Hymenoptera. Burmeister has seen it in *Eristalis tenax* and *E. nemorum* among the Diptera, and Mr. Tyrrel† in *Musca domestica* as well also as in *Geaphilus* and *Lithobius forficatus* in the Class Myriapoda. In addition to these Mr. Bowerbank has seen it in one of the *Noctaidæ*, *Phlagophora meticulosa*‡ in the Order Lepidoptera, in which it was seen also in the rudimental wings of some pupæ by Carus. Some of the most interesting observations that have yet been made upon the motions of the blood in these organs are those of Mr. Bowerbank § in *Chrysopa perla*. Mr. Bowerbank found that in the lower wing of this insect the blood passes from the base of the wing along the *costal*, *post-costal*, and *externo-medial nervures*, outwards to the apex of the organ, giving off smaller currents in its course, and that it returns along the *anal* or *inferior nervure* to the thorax. He states that the blood occupies the chief part of the cavities of these nervures, in each of the largest of which is a very small trachea. From this statement it has been rather hastily concluded that the nervures of the wings are only venous trunks, or passages for the circulatory fluids, and are not formed, as hitherto supposed, chiefly by ramifications of the tracheæ. He found tracheæ existing in the larger of these cavities, which measured only $\frac{1}{2222}$th of an inch in diameter, while the cavities themselves measured $\frac{1}{408}$ of an inch; but in others the tracheæ measured $\frac{1}{1340}$th, while the cavity measured only $\frac{1}{300}$th. He states also that the tracheæ very rarely give off branches while passing along the main nervures, and that they lie along the canals in a tortuous direction. In consequence of these most interesting observations we have examined the wings of some dried specimens of this insect, and have found that there exists, as Mr. Bowerbank remarks, a very large and perfectly transparent space around the tracheæ, which is more or less distinct in different specimens, but in a few instances is not observable. But we have invariably found that the tracheæ not only exist throughout the whole of the ramifications of the wings, but also give off branches at every nervure or space along which the fluid passes.

§ Op. cit. vol. iv. Oct. 1836, p. 179, pl. xv.

Now the opinion to which we have been led by our examinations of dried specimens, as we have not been so fortunate as to obtain living ones, since the commencement of these observations, is, that every nervure contains a distinct tracheal or air-bearing vessel, and that the free transparent space by which it is surrounded, and which is not discoverable by the naked eye, but only by the microscope, constitutes alone the proper circulatory passage; that the tracheæ, which are obvious to the naked eye, do not simply lie loosely in these spaces, but that the spaces lie chiefly at their sides and under-surface. These opinions have been derived from examinations of transverse sections of the wings of the *Chrysopa*, at parts in which, on a previous examination of the surface of the wing, we have seen both tracheæ and the spaces around them. On cutting the wing across at these parts, and then examining the edges, we have invariably found the tracheæ hollow, unyielding tubes, while the free spaces on each side, which appear as if bounded by the upper and under membrane of the wing, have appeared collapsed, and almost or completely closed, so as scarcely to exhibit any appearance of hollow spaces. On examining the wing of a dried specimen of one of the Lepidoptera, *Gonepteryx Rhamni*, by transverse sections, we have in every instance found the nervures formed of hollow unyielding tubes, with all the characters of true tracheal vessels, but have not been able to detect the proper circulatory spaces at the sides of these nervures, most probably owing to their dried and collapsed state. From these facts we are led to express an opinion which has been long entertained by us, that the course of the blood, whether simply along intercellular spaces, or bounded by distinct vessels, is almost invariably in immediate connexion with the course of the tracheæ. This opinion is founded upon the circumstance that nearly all the observations that have hitherto been made have shown that the currents of blood in the body of an insect are often in the vicinity of the great tracheal vessels, both in their longitudinal and transverse direction across the segments, and it is further strengthened by Mr. Bowerbank's observations on the course of the blood in the wings. During his observations Mr. Bowerbank observes that he "has used every endeavour to discover, if possible, whether the blood has proper vessels, or only occupied the internal cavities of the canals; and that he is convinced that the latter is the case, as he could frequently perceive the particles not only surrounding all parts of the tracheæ, and occupying the whole of the internal diameter of the canals, but it frequently happens that globules experienced a momentary stoppage in their progress, occasioned by their friction against the curved surface of the tracheæ, which sometimes gave them a rotatory motion." He remarks also that the usual course of the blood through the canals is in one continued stream, without pulsatory motion, excepting only when the insect under examination is struggling to escape, when the continuity of the stream is broken, and there are occasional oscillations, of which he observed, in one instance, in a vessel within a space of about one-fiftieth of an inch, twenty-one oscillations in a minute; and in another, in the same space, so many as eighty-four. He observed also in insects that had been captured and in confinement for several days, that the motions of the fluid became exceedingly languid and almost entirely ceased. These observations are exceedingly interesting in reference to the general velocity of the circulation, and the means by which it is carried on in the wings. The entire absence of pulsations is remarkable, as it completely identifies these vessels as veins, since it is well known that the circulation is carried on through the body by means of regular pulsations of the dorsal vessel. The number of these latter pulsations varies greatly in different insects. Thus Herold found from thirty to forty in a minute in a full-grown caterpillar, and from forty-six to forty-eight in a much younger one; Suckow observed but thirty, in the same space of time, in a full-grown caterpillar of *Gastropacha pini*, and eighteen only in its pupa state. But in one instance, when the insect was in a state of the most violent excitement, we have counted one hundred and forty-two in a female of *Anthophora retusa*. In a number of these insects captured just after they had left their hybernacula in the month of April, and confined for some time in a breeding-cage, we have found that the number of pulsations varies, as might, *a priori*, be supposed, according to their state of excitement. Thus on exposing the dorsal vessel in the morning, before the insects had been excited, we found the number of pulsations was about eighty per minute; at ten o'clock, when they had become active, the number of pulsations ranged from one hundred to one hundred and ten; but at three o'clock in the afternoon, when the insects were quite lively, and had been exposed to the sun for an hour or two, the number of pulsations amounted to one hundred and forty; while on another occasion, on a cold dull morning, when the bees were languid, the number of pulsations did not exceed seventy-five in any specimen that was examined. It has usually been supposed, since the discovery of a circulation in insects, that the pulsations are more frequent in the larva than the perfect state; but this certainly is not the case, if the mean number of observations in the two states be compared. Thus in a series of observations made by us on the *Sphinx ligustri*,* from the fourth day after the larva had left the egg until the perfect insect was developed, it was found that before the larva cast its *first* skin the mean number of pulsations, in a state of moderate activity and quietude, was about eighty-two or three per minute; before casting its *second* skin eighty-nine; while before casting its *third* it had sunk down to sixty-three; and before its *fourth* to forty-five, while previously to leaving its fourth, and before it had ceased to feed, preparatory to entering the pupa state, it was not more than thirty-nine. Thus the number gradually decreases during the growing larva state, but the force of the circulation is very much augmented. Now when the insect is in a state

* Phil. Trans. p. 2, 1837.

of perfect rest, previously to changing its skin, the number is pretty nearly equal at each period, being about thirty. When the insect has passed into the pupa state it sinks down to twenty-two, and subsequently to ten or twelve, and after that, during the period of hybernation, it almost entirely ceases. But when the same insect which we had watched from its earliest condition was developed into the perfect state in May of the following spring, the number of pulsations, after the insect had been for some time excited in flight around the room, amounted to from one hundred and ten to one hundred and thirty-nine; and when the same insect was in a state of repose, to from forty-one to fifty. When, however, the great business of life, the continuation of the species, has been accomplished, or when the insect is exhausted, and perishing through want of food or other causes, the number of pulsations gradually diminishes, until the motions of the heart are almost imperceptible. Insects, then, do not deviate from other animals, as has been supposed, in regard to their vital phenomena, although it has been somewhat curiously imagined that the nutrient and circulatory functions are less active in the perfect than in the larva condition. This supposed inferiority has been attempted to be accounted for on the hypothesis that as insects no longer increase in size after entering the perfect state, there is but little expenditure or waste of body, and that, consequently, they must require less nourishment. But we have elsewhere shown * that the expenditure of the body, whether in the larva or perfect state, is in the ratio of the amount of activity and length of life of the insect, while it will be remembered that those insects which exist but for a short time in the perfect state, and take little or no food, invariably have a supply of nourishment stored up within their own bodies, in immense accumulations of adipose matter; and that those which exist for a long period have within themselves only a small quantity of nourishment, but are by no means sparing in the quantity of food daily consumed by them, being, as they often are, some of the most voracious of the insect race.

Organs of respiration.—All perfect insects, whether inhabitants of air or water, breathe air alone; but some larvæ, that are constant inhabitants of water, respire the air which is mechanically mixed with the water, by means of branchiæ; but respiratory organs in the form of tracheæ *(fig.* 435) are almost as extensively distributed throughout every part of their bodies as in the perfect insects. We shall divide the respiratory organs into external and internal. The external are of three kinds, *spiracles*, *tracheæ*, and *branchiæ*. The internal are either simply *tracheal*, or *tracheal* and *vesicular*.

The *spiracles* are apertures situated along the sides of the body communicating directly with the internal respiratory organs. They are usually nine in number on each side. In Hymenopterous larvæ there are ten. Each spiracle consists of a horny ring, generally of an oval form, within which is a valve formed of a

* Phil. Trans. p. 2, 1837.

Fig. 435.

Portion of a tracheal vessel of the larva of Vanessa urticæ, shewing, a, the spiral fibre; and *b,* the loose investing covering. (*Newport, Phil. Trans.*)

series of converging fibres, and which opens perpendicularly in its long axis, guarding the external entrance. At a little distance within this valve the spiracle is somewhat enlarged, and there is a second valve of a more complicated form. This has already been noticed in our account of the muscular structure, but we must again describe it in connexion with the respiratory organs. The anterior half of this inner or second valve is strong, immovable, and of a horny texture, of the colour of tortoise-shell. It is thin and lunated at its margin. The posterior half is thick, rounded, and freely moveable, and closes on the anterior like a cushion or pad. This is the structure of the spiracle in the *Sphinx* and most other insects. But in some, in which the spiracle is concealed beneath a portion of the skeleton, the horny external ring is absent, and instead of it the entrance, or margin of the spiracle, is merely a little thickened and fringed with short hairs. This description of spiracle exists in the prothorax of some Coleoptera and Orthoptera as in *Gryllotalpa*, in which one portion or lip overlaps the other, thus forming as it were an outer valve or lid. In other instances, as in the Lamellicornes, the spiracles of the abdomen are very minute and circular, and their opening appears to be cribriform, or at most only very minute, and surrounded by short hairs. In others, again, as in some larvæ, the spiracles consist of a broad margin with a narrow middle space and central aperture that leads immediately into the tracheal vessel, the opening into which is exceedingly small. The *size* of the spiracles in different parts of the body varies very much in different insects. Those of the abdomen are always much smaller than those of the thorax, and the most posterior ones, which were of great importance in the larva state, are almost or entirely imperforate in the perfect. The reason for this appears to result from the changes that take place as regards the region of the body in which respiration is chiefly carried on in the two states of the insect. In the larva state respiration is carried on chiefly in the abdominal region, but in the perfect the chief part of the body concerned is the thorax. It is through the thoracic and first pair of abdominal spiracles that nearly the whole of the air enters and is expired at each act of respiration, and consequently it is found that the spiracles in these parts are very much larger than in the abdomen. The largest spiracle is usually the prothoracic, of which we have an example in *Geotrupes* and *Gryllotalpa*, and the next largest, as in *Geotrupes*, is the first abdominal. The *situations* in which the spiracles are placed also vary considerably in different insects. In Coleoptera and Orthoptera the first pair are situated in the membrane between the pro- and meso-thorax, and the remaining ones in the meso-* and meta-thorax and following segments of the abdomen. There is also a similar arrangement of the spiracles in Hemiptera. But in other insects, as in the larvæ of Lepidoptera, the first spiracle is situated in the prothorax, and the remaining eight pairs in the fifth and succeeding segments to the twelfth; while in the larvæ of Hymenoptera, in which there are ten spiracles on each side, they are placed in the second, third, fifth, sixth, and succeeding segments to the twelfth.

The *second* form of external respiratory organs, as Burmeister remarks, are simply elongated spiracles, and are found only in those insects which reside almost constantly in the water, but breathe pure atmospheric air, for which purpose they come to the surface of the water at intervals to respire. They are short horny tubes, which in some instances are surrounded by plumose setæ. They are always open at their extremity, and in general project beyond the body. They are chiefly met with in the aquatic Hemiptera, as in *Nepa* (*fig.* 352) and *Ranatra*, and are usually two in number, projecting from the extremity of the abdomen. In *Nepa* they are about half the length of the body, and in *Ranatra* as long as the whole body itself. It is through these tubes that the whole of the respiratory function is performed, and the air both inspired and expelled. They exist also in the larvæ of the *Dyticidæ* and *Hydrophilidæ*, in which they are the only respiratory passages, although it has been thought by some that lateral spiracles exist also in these larvæ, as subsequently found in their perfect insects. This form of respiratory organ exists also in the aquatic larvæ of some Diptera, as in the rat-tailed maggot, *Eristalis*, and the larva of *Stratiomys*. In the latter instance the insect supports itself at the surface of the water by a coronet of radiating setæ, in which it includes a bubble of air, and descends with it to the bottom of pools for the purposes of respiration, and comes again to the surface for a fresh supply when the store it has carried with it is exhausted. These organs are thus distinct from those by means of which the insects respire the air mechanically mixed with the water.

* Straus.

Branchiæ constitute the third form of external respiratory organ. This form is met with only in the larva and pupa state. These organs are always situated at a part of the body at which the spiracles are subsequently to exist. They are formed, as in the larvæ of Amphibia, of extensions outwards of the exterior or cuticular surface of the body, and are largely supplied with bloodvessels, and tracheæ ramify within them. They are never, as in the gills of fishes, developed internally, excepting when they exist at the anal extremity of the body, as in the *Libellulidæ*, but are extended from the sides as in the Tadpole, being simply expansions of the external surface. We are not aware that cilia have yet been observed on these surfaces, but judging from the analogies of structure and formation that exist between these parts in insects and the analogous ones in the larvæ of Amphibia, there seems reason to expect that they do probably exist. The necessity for such structures on the branchiæ may, however, be rendered less imperative from the voluntary power which the insect itself possesses of moving the branchiæ at pleasure, by which the function of cilia, that of effecting a constant renewal of the water in contact with the surface of the organ, is steadily accomplished. It is the belief of most entomologists,* that branchiæ absorb the air from the water, and convey it by the minute ramifications of the tracheal vessels, with which they are abundantly supplied, and which terminate in single trunks, into the main tracheæ, to be distributed over the whole body, as in insects which live in the open atmosphere. This is supported by the fact that the tracheal vessels, as seen in the transparent bodies of many aquatic larvæ, are filled with air; but the subject still admits of enquiry, why in these instances the usual function of branchiæ is so far departed from as to allow of the air being absorbed from the water into distinct vessels, to be distributed over the whole body, for the purpose of aerating the fluids, rather than that it should be brought into contact with the blood, and undergo the consequent changes at the surface of the branchiæ, as in the larvæ of Amphibia and Fishes.

The branchiæ of insects are of three kinds. The first exists in the form of elongated, slender, hair-like organs, collected together in tufts, that originate by single stems, as in the larvæ and pupæ of gnats.† This form is by far the most common. These filamentous parts are supplied each with a single trachea that is extended throughout their whole length, and which is connected with the great longitudinal tracheæ of the body. In a very few instances, branchiæ of this form originate separately, and not in tufts, as, according to De Geer,‡ in the

* Burmeister.

† Burmeister, op. cit. p. 167.

‡ Mémoires sur les Insectes, vol. iv. pl. 13, fig. 16.19.

larvæ of *Gyrinidæ*, in which they are arranged along the sides of each segment as short stiff bristles. This form of branchiæ is also said to exist in one solitary species of Lepidoptera, *Hydrocampa stratiotata*,* and perhaps, also, in the other species of the same genus, in which branchiæ of this form exist in the neighbourhood of false spiracles.

The second kind of branchiæ exists in the form of flat, oval, or lanceolate plates, extended from the sides of each segment of the abdomen, where spiracles afterwards exist in the perfect insect. In some instances, as in the *Agrionidæ*, these plates exist only at the extremity of the abdomen. In others, as in the *Ephemeridæ*, they exist both at the sides and at the extremity of the body. This form of branchiæ is found only in the Neuroptera and Trichoptera. In many of the latter instances these parts possess also the additional function of being the chief locomotive organs of the insect, and remind us strongly of the branchiform organs of locomotion in the post-abdomen of many Crustacea.

An anomalous insect, recently discovered by Mr. Hogg as a constant inhabitant of the river-sponge, and an account of which was read by Mr. Westwood at a meeting of the Entomological Society on the 3rd of December, 1838, possesses a third and most remarkable description of branchia. This insect, which was referred by Mr. Westwood to the order Neuroptera, genus *Acentropus*, Steph. very much resembles the larva of a neuropterous species, and has filiform branchiæ extended from the sides of the abdomen, which are distinctly *articulated*, and apparently five-jointed. Mr. Westwood informs us that he has distinctly traced tracheæ into the branchiæ, and that the open extremity of each vessel protrudes from the tip of the branchiæ, so that in this respect these organs resemble elongated spiracles.

Very few of those larvæ or pupæ that possess branchiæ have any lateral spiracles, excepting the *Culicidæ*. In some of these, as in the common Gnat, both larvæ and pupæ breathe by means of large tracheal vessels, extended outwards to some distance from the head and thorax, while the body is also furnished with filamentous branchiæ. The larva of *Chironomus*, remarkable for its blood-red colour, and which breathes through tubes, is furnished in its pupa state with branchiæ† at a part corresponding to that at which the first spiracles are to appear in the perfect insect. The true *Libellulidæ* have neither lateral nor anal branchiæ, but, according to Suckow and others, breathe by means of branchiæ in the colon. But in these insects, as in the *Ephemeridæ* with lateral branchiæ, the acts of respiration are also those of progression; since, although the imbibition and expulsion of water at the anal extremity are regular and constant, even when the insect is remaining perfectly quiet, they are increased both in number and force at every act of locomotion, and carry the body forward by darts or sudden impulses. The water is received at the anal orifice by an inspiratory or sucking action, as proved by the circumstance that small particles of substances floating in the water are drawn in with the stream at the anus at each inspiration, and again expelled from it when the water is ejected, and this occurs with the greatest regularity. The cavity into which the water is received is a *cloaca* distinct from the proper alimentary canal, analogous to the respiratory cloaca of the Holothuria and other lower invertebrata.

These external organs of respiration all communicate with elongated tracheæ, from which are distributed other branches over the internal structures. In the larvæ of all insects these internal respiratory organs are simply ramified tubes, but in perfect insects, and more particularly in volant species, these tubes are dilated into an immense number of minute vesicles, which not only allow of the most extensive respiration, but also render the body lighter, by enabling the insect to alter its specific gravity during flight. In all insects the vesicles are only dilated tracheæ, the structure of which is the same throughout the class. In the larva of the Sphinx and other insects the tracheal vessels consist of two elongated tubes, extended one on each side of the body, and which on their external side communicate by very short tubes with the spiracles, and on their opposite, towards the middle line of the body, give off near each spiracle a large tuft of vessels, about twelve in number, which extending inwards are distributed over the different organs within the body. The chief of these are distributed to the alimentary canal, while others pass upwards among the muscles, and ramify most extensively between them, and are given in great abundance to the dorsal vessel. In every segment other branches are extended to the median line above the vessel, and anastomose with corresponding branches from the opposite side of the segment. In the head one large branch passes forwards from the prothoracic spiracle, and anastomoses with its fellow from the opposite side above the œsophagus, behind the brain, and the two thus united then give off four branches, which passing forwards over the brain give off branches that ramify on the surface, and even in the substance of that organ and of the optic nerves. Other branches are given to the muscles of the head, the future antennæ, and the organs of manducation. On the under surface of the body the tracheal vessels distribute themselves among the muscles, as on the dorsal surface, some passing beneath the nervous cord to anastomose with those from the opposite side, while others are distributed to, and ramify extensively over the surface of each gangliated portion of the cord, giving off the most minute branches which penetrate the very substance of the ganglia (*fig.* 415, *i*, *i*), and also that of the nerves themselves, along which other minute branches are extended, so that even the most important and delicate organs of the body are plentifully supplied with tracheal vessels. Other branches of tracheæ also pass

* Id. vol. i, pl. xxxvii.

† Burmeister, p. 167.

between the fibres of the muscular coat of the alimentary canal, and ramify extensively between the mucous coat and a structure which we have described* as the *adipose coat*, which lies between the mucous and muscular, as is well seen in the colon and cœcum of the puss-moth, *Cerura vinula*, in the perfect state. It is in this layer that the ramifications of tracheæ anastomose very freely, but do not enter the mucous or internal coat. Besides these parts all the secretory and generative organs are supplied with anastomosing branches in abundance, and tracheæ are extended even to the very last joints of the tarsi in the limbs. The only parts into which we have not observed tracheæ penetrate are the adipose vesicles, upon which we have not often observed ramifications, although branches of tracheæ are distributed very extensively among them. In the larva state the tracheæ are always smaller than in the perfect, compared with the size of the individual, and they are smallest in those apodal larvæ of Hymenoptera which reside long in closed cells, as the *Anthophora retusa*, in which insect the communications of the tracheæ across the body are very distinct, as was shewn long ago by Swammerdam in the larva of the hive-bee.

The *structure* of the tracheæ has been described by Swammerdam, Sprengel, and others. Sprengel has described the structure as consisting of an external serous and an internal mucous membrane, inclosing between them a spirally convoluted fibre (*fig*. 435, *a*), which is elastic, and gives to the tracheæ the appearance exhibited by the tracheæ in other animals. The external or serous membrane (*b*) very loosely surrounds the spiral fibre (*a*). The mucous or internal lining, as we formerly remarked, and as noticed by Swammerdam, De Geer, Lyonet, and Bonnet, is continuous with, and is thrown off at the change with the external covering of the larva, and certainly is a distinct membrane, renewed at those periods, although Sprengel believes that it is only a means of connexion between the coils of the spiral fibre, and not a distinct structure.

The *vesicles*, or dilated tracheæ, exist in the greatest abundance in volant insects, although they also exist in a much less developed form in the saltatorial. These vesicles exhibit an appearance which was formerly noticed by Swammerdam in *Oryctes nasicornis*, and subsequently by Sprengel in other insects. It consists of an amazing number of punctured spots, discoverable only under a good microscope, but which, when attentively examined, exhibit somewhat the appearance of perforations. The precise nature of these spots is not well understood. Burmeister conceives that they are occasioned by the rupture of the spiral fibre during development, and that the spots are the spaces between the broken fibres. But Marcel de Serres and Straus Durckheim deny the existence of spiral fibre in the vesicles, while Suckow and Burmeister contend that it certainly does exist, and we also are of this opinion. Indeed, when it is remembered that the vesicles exist only in the perfect insect, and are only dilated tracheæ, and that the existence of spiral fibre in the tracheæ is undoubted, surely its existence can scarcely be questioned in the vesicles, although, probably, it is in an almost atrophied condition. Now the fact that the spots are not observed on the vesicles until the insect has entered the perfect state, was, perhaps, one of the circumstances that led Burmeister to his opinion respecting them; but that they are not caused by ruptured spiral fibre is proved by the existence of these spots in some of the tracheæ that communicate directly with the vesicles, and have not been dilated, and in which the spiral fibre is unbroken. It is also shewn by the circumstance of their not being in a regular series, over the course of the fibres, but distributed thickly and irregularly over the surface of the vesicles, and by their existing in the space between two parallel fibres in the tracheæ, and even in the substance of the fibre, as we have seen them in the vesicles of the male of *Bombus terrestris*. Besides this, they are sometimes seen to terminate in an abrupt and remarkable manner in the dilatations of the larger tracheæ in the same insect. The results of our own observations lead us to conclude that these spots are not ruptures of the spiral fibre, but are partial perforations of the vesicles,—that they do not pass through the internal or lining coat, and probably are little cells in the coats of the vesicles, through which the circulatory fluid can be freely submitted to the action of the air in the vesicles, as in the minute terminal cells in the lungs of vertebrata.

The use of the vesicles, as above remarked, and as formerly suggested by Hunter, appears to be to enable the insect to alter its specific gravity at pleasure, by enlarging its bulk, and thus rendering it better able to support itself on the wing with little muscular effort. That this is the use of the sacs may be inferred from their non-existence in the larva state, or in insects that constantly reside on the ground, more particularly in creeping insects; and it seems further confirmed by the fact that, among volant insects, those have the largest and greatest number of vesicles which sustain the longest and most powerful flight. Thus the vesicles are found most developed in the Hymenoptera, Lepidoptera, Diptera, and some Coleoptera and Hemiptera, in all which, in the larva state, there is not the slightest trace of them. A still further proof that they are for lightening the body is found in *Lucanus cervus*. In the male of this insect the large and heavy mandibles and head, but more especially the mandibles, are not filled with solid muscle, as in the *Hydröus* and others in which these parts are more in proportion to the size of other parts of the body, but with an immense number of vesicles, which in the mandibles are developed in the greatest abundance in rows from long tracheæ, that are extended from one end of the organ to the other, so that the interior is almost entirely filled with vesicles. By this beautiful provision these pro-

* Phil. Trans. 1836.

jecting and apparently unwieldy structures are rendered exceedingly light, while their solid exterior fits them for all the purposes of strength required by the insect. The large and apparently heavy body of the humble-bee is lightened in a similar manner. In this insect and others of the same order, the vesicles are fewer but very much larger than in Coleoptera. The lateral tracheæ in the abdomen form one continuous chain of dilatations, which are larger in the males of the species (*fig.* 436)

Fig. 436.

The lateral and inferior series of vesicular respiratory organs in the abdomen of a male individual of Bombus terrestris. (*Newport, Phil. Trans.*)

than in the females. The longitudinal tracheæ (*a*), that pass backwards from the thoracic region, are connected just as they pass through the petiole or thoracico-abdominal segment into the abdomen, by a very short transverse branch (*b*), which gives off two pairs of minute branches into the abdomen. The longitudinal tracheæ (*c*) pursuing their course onwards are dilated, soon after they enter the large first segment of the abdomen, into two enormously expanded vesicles (*f*), above which is placed transversely a third and much larger one, which is formed from the anastomosing branches of the opposite sides of the segment, and is also connected with the little branches given off from the transverse branch (*b*). Beneath this large vesicle passes the dorsal vessel, and between the two lateral ones (*f*) the alimentary canal. Besides the branches from the transverse tracheæ (*b*) there are two others from the large tracheæ (*c*), which pass longitudinally backwards, one on each side of the œsophagus. That on the left side (*c, e*) passes as far as the posterior part of the proventriculus, and then turning forwards distributes its branches to that organ. The other on the right (*d, d*) extends no farther than the anterior part of the proventriculus, immediately behind the crop or honey-bag, upon which it is chiefly distributed. The large vesicle (*f*) is connected with the dilated tracheæ in the succeeding segments, and the whole form one continuous irregularly-shaped vesicular cavity, which, along its under surface in each segment, is dilated into a funnel-shaped transverse trachea (*g*), that anastomoses with its fellow of the opposite side, passing beneath the muscles as in the larva. From the upper surface of the longitudinal canals similar funnel-shaped dilatations (*i, k*) pass over the dorsal surface of the abdomen and anastomose in like manner with those of the opposite side, besides which single undilated ramifications of tracheæ (*h*) pass inwards on each side and are distributed over the alimentary canal. At the posterior part of the body the vesicular canals communicate directly by a large branch (*l*), from which large trunks are given to the colon and organs of generation. Thus, then, the use of the vesicles is distinctly indicated, even in the peculiar distribution of undilated tracheæ to the whole of the organs of nutrition. The distribution of single ramified tracheæ from large vesicles appears to be constant in this order; it was formerly shown by Leon Dufour* in *Scolia hortorum*, and we have always found it in the *Ichneumonidæ* and other families. Burmeister states that he has been unable to ascertain whether this is also the case in Diptera, in which order the vesicles are both large and numerous. According to Marcel de Serres† the *Asilidæ* have an immense number of small elongated vesicles on each side. In one species they amount to so many as sixty. Burmeister remarks‡ that, in Lepidoptera, the vesicles in the *Sphingidæ* and moths are chiefly found in the males, which agrees with our own observations in Hymenoptera. In *Acherontia Atropos* he states also that the existence of spiral fibre in the vesicles is so distinct as not to be doubted.

This is the structure of the respiratory organs in volant insects, but throughout the class, whether in volant or creeping insects, there is always a complete anastomosis of the tracheæ on one side of the body with those on the opposite, as has been well exemplified by almost all insect anatomists, Swammerdam, Lyonet, Marcel de Serres, Dufour, Straus, and others.

The *development of the vesicles* begins to take place at about the period when the larva ceases to feed, preparatory to changing into the pupa state. At the time when the larva of the *Sphinx* enters the earth, and is forming the cell in which it is to undergo its transformation, the longitudinal tracheæ of the second, third, fourth, and fifth segments become a little enlarged. In the butterfly, *Vanessa urticæ*, which does not enter the earth, but suspends

* Journal de Physique, Sept. 1830.
† Mémoires des Muséum, tom. iv. p. 362.
‡ Op. cit. p. 181.

itself vertically to undergo its change, the dilatation commences while the insect is spinning the silken hangings from which it suspends itself; so that the changes commence at a corresponding period in both insects. It is in the butterfly that we have most closely watched the development of the vesicles. During the period that the insect remains suspended it makes several powerful respiratory efforts, accompanied by much muscular exertion, and these efforts are continued at intervals until the old skin is fissured and thrown off. It is at this period that the tracheæ become much enlarged, as we have found at about *two hours* after the insect has suspended itself. Meckel observed the sacs soon after the insect has entered the pupa state, but it will thus be seen that the expansion of the tracheæ in the formation of these sacs commences very much earlier. At about *half an hour* before the insect becomes a pupa we have found the whole of the tracheæ more distended, particularly those on the under surface of the thorax, from which branches are given to the legs, so that the elongation of these tracheæ is probably connected with the subsequent rapid development and extension of those organs. At this period the tracheæ of the abdomen have experienced but little alteration. It is at the actual period of transformation that all the changes take place most rapidly. At that time the laborious respiratory efforts made by the insect appear greatly to affect the condition of all the organs. When the skin is thrown off, these efforts cease for a few minutes, after which the abdominal segments become shortened, and the circulatory fluid is propelled forwards, and the wings, then scarcely so large as hemp-seeds, are gradually distended at their base, and at each respiration are perceptibly enlarged, and carried downwards over the under surface of the thorax and first abdominal segments. Carus* attributes the development of the sacs, and dilatation of the tracheæ, to the entire closing of the spiracles, and expansion of the air contained within them, which he thinks is *increased in quantity* during the development of the insect. But from the circumstance that all the tracheæ are enlarged immediately after the insect has entered the pupa state, it seems probable that this enlargement is occasioned simply by the closing of the spiracles, and the expansion of the air within the tracheæ, during the powerful respiratory efforts, aided by the receding of the circulatory fluid from the abdomen into the partially developed wings, suddenly removing pressure from the tracheal tubes, which then become distended by the natural elasticity of the air contained within them; and further, that the subsequent enlargement of these tracheæ into distinct bags is occasioned, not by an increased quantity of air in the vesicles, as Carus imagines, but simply by a continuance of the same cause that effects the first dilatation of the tracheæ, the elasticity of the contained air, since the dilatation appears to keep pace with the gradually decreasing size of the digestive organs, and the spiracles are not permanently closed during the pupa state, respiration being continued at intervals, excepting perhaps in the most complete state of hybernation. In accordance with this opinion we find that, at about *half an hour* after the change, the pro-thoracic tracheæ that ramified over the œsophagus are enlarged to double their original diameter, and have begun to be detached from that organ. At *seven* hours these changes have been carried much farther. At *twelve* hours they are still further enlarged, and the principal alteration observed is the diagonal direction of those from the seventh spiracles, which supply the posterior extremity of the digestive stomach, owing to that organ having now become shorter, previously to its subsequent change. At *eighteen* hours all the tracheæ of the head and thorax are still further enlarged, and those from the third spiracle are detached from the cardiac extremity of the stomach, and are more enlarged than the others, and those from the ninth spiracle, in the twelfth segment, which supply the colon, are beginning to be distinctly vesicular. At *thirty-six* hours not only have the longitudinal tracheæ and their many branches become dilated, but those distributed to the different viscera have also become vesicular. At *forty-eight* hours the development of these parts is so far advanced that the whole have assumed the vesicular form, and those at the anterior part of the abdomen occupy a great proportion of that region, and the dilatation of others proceeds until within a few days before the perfect insect is developed, before it is completed. The only difference we have observed between the development of these organs in the Sphinx and the butterfly is in the rapidity with which the changes are effected. The Sphinx remains many months in the pupa state, during a great part of which time the changes are almost or entirely suspended. The butterfly remains but a few days, and in consequence all the changes proceed with rapidity, which is either greater or less in proportion to the season of the year and temperature of the atmosphere.

Function of respiration.—Having dwelt so long upon the *structure* of the parts concerned in respiration we cannot venture at any length upon the phenomena connected with the *function*, which properly belong to a distinct subject. (See RESPIRATION.) We would remark, however, that the circumstances connected with it are in many respects particularly interesting, while the results are similar to those of the respiration in other air-breathing animals. Thus the *acts* of respiration consist of alternate dilatations and contractions of the abdominal segments, the air entering the body chiefly at the thoracic spiracles, and partly also at the abdominal, during which the dorsal and ventral arches of the abdomen are alternately elevated and depressed, like the ribs of Vertebrata. The number and frequency of these

* Introduction to Comparative Anatomy, translated by Gore, 1827, vol. ii. p. 167.

respirations vary, as in Vertebrata, according to the degree of activity and state of excitement of the insect. Thus when an insect has been subject to long-continued exertion, the acts of respiration are quick and laborious, as every one must have observed in the larger *Bombi*, when alighting after a long-continued flight. The contractions and extensions of the abdominal segments are then short and quick, and sometimes so labored that the whole abdomen is shortened and extended like the flanks and ribs of the race-horse, after a long and severely contested race. The number of respirations, when the insect is in a state of moderate excitement, varies also in different species as well as in the different states of the same insect, and at different periods. Thus in the green grasshopper we have noticed from thirty to forty regular contractions in a minute, alternating, at irregular periods, with others more long and deep than the rest. When this insect was much excited the intervals between the long inspirations were longer, and the inspirations when they occurred were more deep and laborious. When an insect is preparing itself for flight the act of respiration resembles that of birds under similar circumstances. At the moment of elevating its elytra and expanding its wings, which are, indeed, acts of respiration, the anterior pairs of spiracles are opened, and the air rushing into them is extended over the whole body, which, by the expansion of the air-bags, is enlarged in bulk, and rendered of less specific gravity, so that when the spiracles are closed at the instant the insect endeavours to make the first stroke with and raise itself upon its wings, it is enabled to rise in the air, and sustain a long and powerful flight with but little muscular exertion. In the pupa and larva state respiration is performed more equally by all the spiracles, and less especially by the thoracic ones.

The frequency of the acts of respiration seem to bear some relation to the expenditure of muscular energy by the insect in a state of activity. All volant insects respire a greater quantity of air in a given time than terrestrial, and both these in their perfect than in their larva state. Thus in the common hive-bee we have noticed from one hundred and ten to one hundred and sixty contractions of the abdominal segments in a minute, while in a less active state, when the insect was entirely undisturbed, the acts of respiration seldom amounted to one-half that number. In an exceedingly wild and irritable little bee, *Anthophora retusa*, which dies exhausted from the most violent excitement and exertion, in the course of an hour or two, after being captured and confined during summer, the acts of respiration are often performed so rapidly that, on one occasion on which we observed them, they amounted to two hundred and forty in a minute, and of course it was only by the closest attention that their number could be ascertained.

Next to the pupa state, a state of common repose is that in which insects respire with the least frequency. When a perfect insect or a pupa has remained for some time undisturbed, its respiration becomes gradually slower and slower, until at last it is scarcely perceptible. Thus, in the midst of winter, at a temperature of the atmosphere a little below freezing, we were unable to detect more than the very slightest trace of respiration during two or three days, and even at the expiration of fourteen days the quantity of carbonic acid gas formed was very small. But when the insect was removed into a much warmer atmosphere it began again to respire more freely, and the quantity of carbonic acid produced in a given time was considerably increased. In a specimen of *Bombus terrestris*, which had remained at rest for about half an hour, the respirations had become deep and laboured, and were continued regularly at about fifty-eight per minute. At the expiration of one hundred and forty minutes, during which time the insect remained in a state of repose, the respirations were only forty-six per minute, and at the expiration of one hundred and eighty minutes they were no longer perceptible. This same insect, when first captured, and in a state of moderate excitement, respired at the rate of one hundred and twenty-five inspirations per minute. We have noticed the like circumstances in a female *Sphinx ligustri*, which after it had been excited for a short time in flight breathed at the rate of forty-two respirations per minute, while after it had remained at rest about seventy-five minutes respired at the rate of only fifteen per minute. Hence the quantity of air deteriorated by an insect in a given time depends upon the state of activity and condition of life of the individual. In accordance with the frequency, and consequently the quantity of respiration, such are the results. In accelerated respiration the circulation of the fluids is increased, and in those conditions, noticed in another part of this paper, in which the circulation is accelerated, the acts of respiration are at the same time more frequent.

The *development of heat*, which is now found to take place in all insects as in the air-breathing vertebrata, depends mainly upon the quantity and activity of respiration, and the volume and velocity of the circulation. In Hymenoptera, in which, as we have seen, the capacity of the respiratory organs is greater than in other insects, and consequently the quantity of air deteriorated in a given time is also greater, the quantity of heat evolved during the process is proportionate to the quantity of respiration. In the larva, in which, in relation to its size, the quantity and energy of respiration are less than in the perfect insect, the quantity of heat developed is also less, so that in the larvæ of Hymenoptera it does not exceed from two to four degrees that of the medium in which the insect is placed; while in the perfect insect, in a state of little activity, the quantity of heat developed is apparently at its minimum amount at three or four degrees above the temperature of the surrounding medium. But when the same insect is in a state of moderate activity, and consequently is respiring more frequently, it amounts to even fifteen or twenty degrees. In all cases the amount of temperature depends chiefly upon the quantity of respiration.

We have seen that in a state of repose the acts of respiration become less and less frequent, and that at last they are scarcely perceptible. In like manner the amount of heat generated is proportionate to the diminished number of respirations, and continues to be lessened until the temperature of the insect has very nearly sunk down to a level with that of the atmosphere. There are also other circumstances which moderate the production of heat. When the insect is fasting less heat is generated, even during a state of activity, than when the insect is not deprived of its proper quantity of food. The cause of this deficiency seems readily to be accounted for on the consideration that no new material, the product of digestion, is taken into the general circulation, and requires to be assimilated with the circulatory fluids, and, consequently, there is less change in the chemical condition of the fluids at each respiration, than when the animal is taking its full amount of food. Other circumstances also tend to regulate the amount of heat. When the insect is respiring rapidly, the power and frequency of its circulation are augmented, and not only is there a greater quantity of gaseous expenditure from the respiratory organs, but there is also a greater amount of cutaneous expenditure, which tends to cool down the insect by evaporation from the surface of its body, and diminish the amount of heat developed. This expenditure is so enormous, as we have elsewhere shown,* that it is more than equal to the quantity of solid matter excreted from the alimentary canal in a given time, and, consequently, is a powerful means of reducing the temperature of the insect. One very marked difference which exists, in respect to the function of respiration and the evolution of heat, between these air-breathing invertebrata and the vertebrated animals is, not in their different powers of generating, but of maintaining their temperature. Insects in their low power of maintaining heat closely resemble the true hybernating animals. Any great or sudden change of temperature in the surrounding medium rapidly reduces the temperature of the insect. It is thus seen that a reduction of temperature takes place not only at the period of true hybernation, which insects undergo either in their pupa or perfect state, but also during vicissitudes of the season, as well as during natural repose. On the other hand, it is remarkable that the evolution of heat in insects takes place as rapidly as it becomes reduced. Its increase is perceptible by the thermometer within a very few moments after the insect has begun to respire more rapidly. The explanation of this circumstance must be sought for in the peculiar distribution of the respiratory organs, which are extended over the whole body, and aerate the blood in every part of it at the same instant, the result of which is the immediate evolution of a large amount of heat, from the changes that occur in the fluids in vessels that partake both of the venous and arterial character. Consequently a large amount of heat is liberated instantaneously, whether the oxygen of the atmosphere be absorbed into the circulatory system, or whether the whole of the changes take place, and carbonic acid be formed in the respiratory structures. The same rapidity with which the heat is evolved from the body accompanies its diminution when the quantity of air inspired is lessened. In confirmation of this view with regard to the production of heat being the result of the chemical changes in the air inspired, there is one remarkable circumstance that cannot be passed over. It is the *voluntary power* which we have found is possessed by some species of generating heat by means of accelerating their respiration. We observed this fact in the individuals of a nest of Humble-bees, *Bombus terrestris*, which were confined by us for the purpose of watching their habits. Huber formerly noticed that bees are in the habit of incubating on the cells of their pupæ, before the perfect insects are developed, and we have had ample opportunities of confirming his observations. It was during the time that we were engaged in watching these habits that we discovered that bees possess this voluntary power of increasing their temperature. The manner in which the bee performs her incubatory office is by placing herself upon the cell of a nymph that is soon to be developed, and then beginning to respire at first very gradually. In a short time the respirations become more and more frequent, until at length they are increased to one hundred and twenty or one hundred and thirty per minute. The body of the insect soon becomes of a high temperature, and on close inspection is often found to be bathed with perspiration. When this is the case the temperature of the insect soon becomes reduced, and the insect leaves the cell, and another bee almost immediately takes her place. When respiration is performed less violently, and consequently less heat is evolved, the same bee will often continue on a cell for many hours in succession. During these observations we have, in some instances, found the temperature of a single bee exceed that of the atmosphere more than twenty degrees. Thus when the temperature of the atmosphere was 73° 5 Fahr. that of four female bees, in the act of incubation, was 94° 1. On another occasion when the atmosphere was 72° 5, a single bee, nursing on a single cell, from which a perfect insect was developed about eight hours afterwards, afforded a temperature of 92° 3, the bulb of the thermometer being placed between the abdomen of the bee and the cell. The insect was then breathing at the rate of one hundred and twenty respirations per minute. In another instance, the temperature of the atmosphere being the same, that of another bee in the act of nursing was 94° 5. This extreme amount of heat was evolved entirely by an act of the will in accelerating the respiratory efforts, a strong indication of the relation which subsists between the function of respiration and the development of animal

* Phil. Trans. 1837, p. 2.

heat. These curious facts tend much to confirm the opinion as to the chief origin of animal heat, but for farther illustration of this interesting subject we must refer our readers to the article RESPIRATION.

Organs of generation.—These parts have already been treated of to some extent in a preceding article, (GENERATION, ORGANS OF,) and the forms which they assume in different orders, more particularly those of the male organs, having in part been described, we shall only briefly allude to them on the present occasion, in consequence partly of the great length to which this paper has already been extended, and partly that we shall necessarily return to this subject, more especially with reference to the functions of these parts, in describing that class of Articulata, which in every respect are so closely related to insects, the Myriapoda, to which we must refer.

In our observations on the skeleton we have shown that the terminal segments of the body invariably form part of the external organs of generation. The long ovipositor of the *Chrysididæ*, composed of four distinct annuli, retractile within one another, and even within the proper abdomen itself, are only the terminal segments of the body, which is thus made to consist of fewer, but proportionately larger annuli than the abdomen of those in which so many segments are not employed in the formation of the generative organs. A corresponding structure is also seen in the *Panorpidæ*, in which the separate annuli, not retractile to so great an extent as in the *Chrysididæ*, but capable of being extended to as great a length, are distinctly shown to form part of the abdomen, while the corresponding parts in the male, the terminal segments, are developed into a claw-shaped prehensile organ. A similar modification of structure exists in all other insects. In some species one or more of these parts becomes atrophied, or is developed to a greater extent than the others, and the result is that in some instances we find long, exsertile, and apparently new organs, while in others some parts, even of the annuli themselves, appear to be absent. But the normal number is almost every where present, either simply as terminal plates of the abdomen, between which the proper excretory portion of the organs of generation is concealed, or more highly developed, and forming a separate sheath for that structure.

In the *male* insect (*fig.* 437) the organs consist of an external portion, the *penis* (*h*), or "organ of intromission," in which is inclosed the termination of the *ductus ejaculatorius*, which extends backwards, and is connected with the *vesiculæ seminales* (*e*) and *vasa deferentia*, which are connected with the *epididymis* and the proper *testes* (*a*) These parts are found in a large number of insects, in some developed to a great extent, but in others almost entirely atrophied. This is the order in which the parts are met with when passing from without inwards.

The *penis* of the male, like the ovipositor of the female, assumes a variety of forms. It is usually inclosed between two lateral plates, the analogues of the sheath of the ovipositor, and which are derived from the terminal or penultimate segment of the body. Within this is a corrugated soft membrane, the *preputium*, which is continuous with, and is reflected inwards from the inferior margin of the anal aperture, and separates the organs of generation from the alimentary canal. When the penis is retracted it is covered by this membrane, which is corrugated upon it (*fig.* 402, s). In Coleoptera, as in the *Carabidæ* and *Melolonthidæ*, the penis is a long horny tube, retractile within the abdomen on the under surface as far as the anterior segments. The strong horny covering of this organ is simply a consolidated state of parts of the tissues which in other instances are soft and flexible. It contains within it the excretory portion of the ejaculatory duct. In most of the Coleoptera, and in many other species, it has this strong hardened exterior, necessary apparently for its employment by certain species, in which there is little flexibility of the abdominal segments, as an organ of intromission. In *Carabus monilis*, as noticed also in *C. clathratus* by Burmeister, the hardened case of the penis is gently curved downwards to facilitate its introduction into the vulva of the female. At its extremity on the under surface it is a little elongated, and it is terminated by a soft corrugated glandiform structure, which is perforated in its centre, and represents a *glans penis*, the perforation in its centre being the orifice of the excretory duct. In other Coleoptera the penis is also inclosed in a horny sheath, and presents a great variety of forms in different species. In many instances it is furnished at its extremity with short hooked spines, by means of which the male effectually retains his connexion with the female. The external sheath of the male organs, which incloses the penis, is analogous to that of the ovipositor of the female, and is employed when it is well developed to open the vulva of the female. In many species it is scarcely at all developed, being like the sheath of the ovipositor only a highly developed portion of the lateral plates of the terminal abdominal segments. The circumstances above referred to will not allow us to describe in detail the forms of these organs of generation in many species, we shall therefore content ourselves with a brief notice of some of those of the Hymenoptera (*fig.* 437). The general form of the penis in this Order is similar to that of Athalia, and consists of a

Fig. 437.

Male organs of generation of Athalia centifoliæ. (*Prize Essay.*)

short valvular projectile organ, covered externally by two pointed horny plates (*i*), clothed with soft hairs. Above these are two other irregular double-jointed plates (*l*), convex on their outer and concave on their inner surface, and surrounded at their base by a bony ring (*k*). They are half corneous half membranous, and folded together like a closed fan, and are furnished at their posterior margin with horny hooks (*i*), which are used as organs of prehension. Between these in the middle line are two elongated muscular parts (*m*), which when applied together form a pointed structure, and inclose between them in its retracted state the proper intromittent organ (*h*). These perhaps assist to dilate the vulva of the female, like the plates above noticed in the Coleoptera. In many instances, as in *Anthidium manicatum*, the posterior margin of the last true abdominal segment is armed with spines that are curved downwards, and serve to retain the female, and this is also the case in the *Chrysididæ*. In *Anthophora retusa* the horny penis formed of the last two segments of the larva has also two external plates developed into hooked prehensile organs, with which the insect grasps the abdomen of the female at the moment of actual connexion. In the Sphinx (*fig.* 391) and other Lepidoptera the appendages of the anal segment appear to be analogous to the sheath of the ovipositor in the preceding orders. On each side of these parts at their inner surface are two horny plates, which form the lateral boundary of the male organs. Within these is a cloaca, in which the anal aperture terminates, and immediately beneath it are situated the male organs. These consist of an extensile bifid, ejaculatory organ included between two soft valvular parts. They form the virile organ. In the Sphinx the posterior margin of the dorsal plate of the terminal segment is armed with a slender curved hook, bifid at its apex, and bent downwards, like the hooks in the body of Hymenoptera, for retaining connexion with the female. Among the Diptera the *Asilidæ* have the male organ formed in a somewhat similar manner. The terminal segment of the body forms a pair of broad horny plates, which inclose between them the double stiliform excretory canal.

The *ductus ejaculatorius* passes backwards from the penis as a single canal, which either is exceedingly short, as in *Athalia*, (*fig.* 437, *f*), or is a very long tube, forming many convolutions in its course, as in many of the Coleoptera. Into this canal open the *vesiculæ seminales* and the *vasa deferentia*. The *vesiculæ seminales* are usually long convoluted cœcal tubes, which assume a variety of forms, sometimes branched sometimes simple. They are two, and sometimes four in number. In some species, as in *Athalia* (*e*), they are exceedingly short, and very much dilated, serving evidently as receptacles for the semen as it is secreted by the testes, and conveyed towards the ejaculatory duct by the vasa deferentia (*d*). These, like the seminal vessels, vary in number according to the number of the testes. When the whole of the testes are aggregated together, the vasa deferentia that proceed from them are united from each set of testes into a single tube on each side (*b*), but when the testes remain distinct from each other, each deferential vessel passes at first separately from each testis for a short distance, and the whole are then collected together, and form on each side a single tube, which, after many convolutions, either is inserted into the extremity of the seminal vessel, or is inserted along with it into the commencement of the ejaculatory duct. The length of the common deferential vessels is sometimes so great, and they are so much convoluted, as to be readily mistaken for testes, much larger than the proper testicles. This is the case in Athalia (*d*). The proper testes are usually several rounded glandular bodies, in some instances, as in *Melolontha** and *Lucanus*, amounting to as many as six on each side, and in a few instances, as in *Athalia*, even to as many as thirteen. In form they are sometimes rounded, and sometimes are elongated cœciform tubes. They are usually regarded as cœcal organs, but in some instances we have distinctly traced minute vessels connected with them, but whether these vessels passed by open mouths directly into the cœca, or whether distributed over their surface, is perhaps still a question; our impression certainly is that they enter the testes. Besides these parts, there are in some instances structures that resemble an *epididymis*, as in *Hydrous*,† but these are generally absent.

These organs lie within the abdominal cavity, in general on each side of the alimentary canal, and sometimes above it, as in the instance of the Lepidoptera, in which the two separate testes of the larva (*fig.* 364, *i*) are united in the perfect insect into one mass, which is situated immediately beneath the dorsal vessel (*fig.* 366, *i*). In each of these cases the connexion with the vessel, as formerly noticed, is distinctly traced. Besides these parts we ought also to notice some which are appendages of the organs similar to appendages found in the female, but the function of which is not distinctly understood.

In the *female* the organs of generation are more simple than in the male. Of these we have first to notice those external parts which form, as we have stated, either the long extended *ovipositor* of the *Gryllidæ*, the sheath of the *sting* of the bee (*fig.* 438, A, *a*, *d*), or the sheath or valves of the ovipositor of the *Terebrantia* (C, *b*). The condensed description of these parts that has been given by Mr. Westwood‡ clearly explains their structure. He remarks that, " from the centre of the under side of the abdomen, near its extremity, arise two plates, each consisting of two joints, sometimes valvular and together forming a scabbard, sometimes more slender, and resembling palpi, and sometimes very long; between these plates, as they exist in the bee (A, *b*), under the form of two flattened plates, with a pair of terminal lobes, arise two other pieces which are very slender, serrated

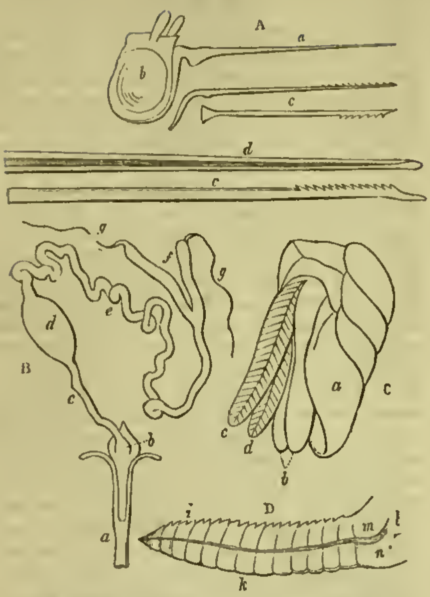
Fig. 438.



A, *lateral view of the sting of the Bee.* (*Westwood.*) *a*, the sheath; *b*, terminal segment of the abdomen; *c*, the barbs or proper sting; *d*, the channeled surface of the sheath of the sting in which the barbs are concealed.

B, the *poison-bag* and vessels of the sting of the *Anthophora retusa* (Newport); *a*, sheath of the sting; *b*, the dilated extremity of the poison duct; *c, d*, the bag; *e*, efferential vessel; *f*, the secretory organs; *g*, their vessels.

C, terminal segment of the abdomen of a saw-fly, *Trichosoma* (Lyonet); *a*, dorsal end of the terminal segment; *b*, sheath of ovipositor or terminal ventral arch; *c, d*, the inner plates or saws, analogous to the barbs, *c*, of the sting of the bee.

D, one of the double lancet-pointed saws of *Athalia centifoliæ.*

at the tip in the bees (*c*) but much broader in the saw-flies (C, *c, d*) and transversely striated, forming the saws with which these insects are provided: moreover these two pieces are received in the bees into a canal (A, *d*), but in the saw-flies this gutter is broad, flattened, and divided into two separated parts, forming the backs of the two saws. In the Ichneumons these various parts are so slender that at the first sight they appear to consist but of a single piece: on more minutely examining the instrument, however, it will be found that it consists of a scabbard, composed of two pieces, inclosing a fine hair-like bristle, which is, in fact, the exact analogue of the stinging part of the bee's sting, consisting of three pieces." This organ constitutes both a means of defence and also of depositing the eggs. There have been some doubts with regard to this fact in the bees, some having questioned whether the sting is at all employed in oviposition by these insects; but a most careful and accurate observer, Dr. Bevan, distinctly states that the ova pass along the sting of the bee to be deposited, and this statement is confirmed by the fact that this is certainly the case in the analogous instrument of the saw-flies, as we ourselves have distinctly witnessed in *Athalia centifoliæ*. The analogy, therefore, of the sting with the ovipositor of the *Gryllidæ*, of the saw-flies, and other insects, is distinctly proved. In *Athalia* the ovipositor is a very interesting organ. It occupies the under surface of the seventh and eighth segment of the body, and is approximated to the posterior margin of the sixth, a part of the seventh having been removed. Four tendons for the insertion of muscles originate from the extremity of the two halves of the ovipositor. In the membrane that unites on the under surface the two halves of the ovipositor, is situated the vaginal orifice between the two saw-shaped organs (C, *c, d*, D). Each of these parts is composed of two plates applied together back to back, and which together form a pointed instrument resembling a lancet (D). The upper one of these plates (*i*) is furnished with small sharp-pointed teeth directed backwards, and the under one (*k*) with fourteen long and slightly convex ones. With the point of this instrument the insect pierces the edges of the leaves of the turnip, separating the cuticle with its saw preparatory to depositing its egg, which is conveyed along its inner surface, which is slightly concave to allow of its safe transit along the plates. Posteriorly and external to these plates are the two sheaths of the ovipositor (C, *b*) analogous to one portion of the ovipositor of the *Gryllidæ*. In all those Hymenoptera furnished with an ovipositor there is also an apparatus for secreting a peculiar fluid, and this apparatus is believed to be analogous to the appendages of the male organs above alluded to, the use of which is not well understood. In the female these parts consist of an *excretory duct*, and *bag*, or receptacle for the fluid, a convoluted efferential vessel, and proper secretory organs. In the wild bee, *Anthophora retusa* (B), at the base of the sheath (*a*) in which the two barbs of the sting (A, *e*) are concealed, is a smooth dilated space, into which the poison is first received at the base of the sting. The poison is conveyed to this space by the efferential duct (*c*) from an oval sac (*d*), in which it is accumulated as secreted, and into which it is poured by a very large and much convoluted efferential vessel (*c*), which receives the fluid from two cœciform glandular organs (*f*), which unite as they enter the efferential vessel. These secretory organs receive at their apparently closed extremity each a minute vessel, which we have distinctly traced to some distance from them, but not to its termination. When the poison is ejected from the bag (*d*) into the base of the sting, it passes along between the two barbs, as in a little gutter, into the wound. Swammerdam delineated these parts in the honey-bee, but did not notice the vessels proceeding from the secretory organs. In another insect of the same class there are similar structures. Thus, in *Athalia* (*fig.* 439), the bag (*g*) is oval, but the efferential vessel is entirely absent, the fluid being poured directly from the secretory vessels (*h*) into the bag without passing along any other tube. The vessel is

Fig. 439.

Female organs of generation of Athalia centifoliæ. (*Prize Essay.*)

also absent between the bag and the base of the ovipositor, so that the fluid is forced directly from the bag at the moment it is employed. There is a somewhat similar structure in the Hornet, although the vessel between the bag and sting is present as in the bee. Burmeister has suggested that the poison-gland may perhaps be an *urinary* organ, but the circumstance of the fluid contained in it being employed by the insect to inject into the cavity in which it deposits its ova, seems opposed to this opinion, although that of its being employed by the bee as a means of defence may be favourable to it. The nature of this fluid is distinctly acid, as remarked by Dr. Bevan in the honey-bee, and as found by ourselves in several instances. The *vaginal aperture* at the base of the ovipositor forms the external orifice of the *common oviduct* or proper laying tube (*e*). This in some instances is simply a dilated orifice, the internal lining of which is continuous with that of the internal part of the ovipositor. This common oviduct is either a simple, straight, uniform tube, or in some instances is a little dilated laterally into pouches, in which are received the lateral appendages of the male organ, as in *Melolontha*. At its termination the common oviduct divides into or rather receives two separate tubes (*d*), one from each side, analogous to the efferential vessels of the male organs. On the upper surface of the common oviduct, there are appendages that vary in number from one to five. The chief of these, the *spermatheca* (*f*), alone exists in *Athalia*. It is into this sac that the fluid of the male is ejected during copulation. Audouin states that the male organ is projected into it. We have invariably found this vesicle, which is exceedingly large in *Meloe*, filled with white, opaque, seminal fluid after connexion with the male, previously to which time we have as invariably found this vesicle empty. This appendage is simple in many of the Orthoptera as well as in Hymenoptera, but in some other species there are also additional vesicular appendages which have been described as secreting a glutinous fluid. In all instances these are attached to and pour their contents into the common oviduct, through which the eggs pass to be deposited. In the middle line, at the union of the oviducts, are situated the terminal ganglia of the nervous cord (10, 11), when the cord is extended to the posterior part of the abdomen. But when this is not the case, and the nerves simply radiate from the thorax into the abdomen, the terminal pair of nerves still pass in a corresponding direction over the union of the oviducts, thus always occupying a position between the organs of generation and the termination of the alimentary canal. From the two oviducts originate the proper *ovarial tubes*. In *Athalia centifoliæ* there are eighteen (*a*, *b*, *c*) attached to each oviduct, but in some other instances, as in *Melöe*, in which the upper part of the oviduct on each side is dilated into an immense bag resembling an uterus, they amount to some hundreds of exceedingly short tubes containing each but one or two ova. In *Melolontha* and *Lucanus* there are six on each side, but in some instances, as in *Lixus*, as shewn by Dufour,* there are only two on each side. These ovarial tubes gradually decrease in size from their base to their apex, and those from each side are collected together at their apices, and are said to terminate each in a dilated cœcal extremity, but we must confess we have never yet traced this structure in any instance. Müller, as above stated, traced a connexion between the extremities and the ovarial tubes and the dorsal vessel in *Phasma*, and many other insects, as we have also done in several instances, but the nature of these connexions is disputed. They certainly appeared to us to be vascular, as supposed by Müller, and we have already stated the reasons that led us to the same opinion.

We shall enter on a consideration of the function of the organs of generation when considering this subject in Myriapoda.

In concluding this lengthened article we have only further to remark that the tegumentary appendages consist of *hair*, *scales*, and *spines*. The first of these serves as a covering for the bodies of many species, more particularly the Hymenoptera, and is also found under the limbs in many Coleoptera. The scales are peculiar appendages and may be considered, according to many, as simply flattened hairs. They entirely cover the bodies of many species, as for instance the Lepidoptera. The curious forms and marking of these parts are sometimes exceedingly beautiful; but the limits of our article will not allow of our entering at present on the consideration of them. The *spines* are found much on the wing of Hymenoptera and are often mistaken for true hairs, between which and spines, and also between these and scales, there is a difference of origin,

* Annales des Sciences Naturelles, tom. vi, pl. 20.

spines being usually developed directly from a trachea or part of a membrane in the immediate vicinity of a trachea.

(G. Newport.)

INSECTIVORA, *(Insecta, voro,)* a group of mammiferous animals, considered by some authors as a distinct order; by others, and particularly by Cuvier, as a family only of the great carnivorous order, named by that great naturalist CARNASSIERS. The peculiarities of structure by which the Insectivora are characterized appear to me to be equally important with those which have led me already to treat of the Cheiroptera as an ordinal group, and I shall therefore consider them in that point of view.

They consist of four very distinct groups, the relations of which are not very clearly fixed. I have ventured to consider them as four families, viz.:—

TALPIDÆ, typified by the mole, *Talpa*.
ERINACEADÆ, by the hedgehog, *Erinaceus*.
SORICIDÆ, by the Shrews, *Sorex*.
TUPAIADÆ, by the genus *Tupaia*.

Such at least appears to me, in the present state of our knowledge, to be a near approach to the natural groups of which the order is composed. In the *Talpidæ* I include the genera *Talpa*, *Condylura*, and *Chrysochloris*; in the *Soricidæ*, the genera *Sorex*, (with the subgenera, so called, into which it has lately been subdivided,) *Mygale* and *Scalops*, the latter genus being clearly osculant between the *Soricidæ* and the *Talpidæ*; in the *Erinaceadæ*, the genera *Erinaceus*, *Echinops*, and *Centenes*; and in the *Tupaiadæ*, the single genus *Tupaia*, or *Cladobates*, as it is named by Fred. Cuvier.

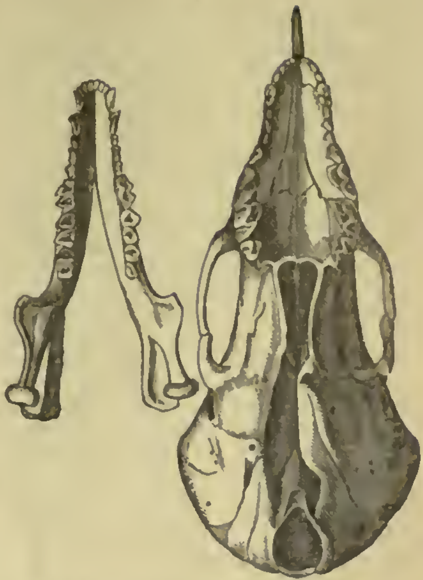
It will at once be seen, by reference to this enumeration of the types of form which occur in this order, that animals, differing greatly in their general structure and habits, are included in it. But it will also be found that they all agree in the general character of their teeth, which are in all instances furnished with elevated and pointed tubercles, for the purpose of breaking down the hard and polished elytra of coleopterous insects, upon which most of them in a greater or less degree subsist. This character has already been exhibited in the insectivorous group of the Cheiroptera, which we have considered as leading towards the present order; and even in the lower forms of the Quadrumana a similar tendency is evident, as in the Maki, the Loris, and others. They agree, also, in being for the most part nocturnal animals, and, with some exceptions, in living under ground, or at least in exhibiting a tendency to such a mode of life; and all those which inhabit the colder countries pass the winter in a state of torpidity. They all possess clavicles; their limbs are generally short, and they are plantigrade. They have ventral mammæ, the stomach is perfectly simple, and they are destitute of a cœcum.

The different families which I have named are as well characterized by their habits as by their external form, and their more intimate structure. The *Talpidæ*, the teeth of which are shewn in the genus Talpa *(fig.* 441,) and Chrysochloris *(fig.* 450), which are pre-eminently subterranean, are distinguished by their extraordinary habits of forming long and complicated burrows underground, passing their whole lives in a subterranean retreat, in which they are born, feed, breed, hibernate, and die; and which retreat, in the case of the common mole, is formed with the utmost art, and a beautifully complicated construction. The *Soricidæ (fig.* 449) are a sort of carnivorous mice; and although they do not actually burrow, retreat during the winter, and in their ordinary repose, into holes, feeding, however, on the surface or in the water, several of them being partially aquatic, diving with facility after aquatic insects, and remaining without difficulty a long time under water. In both these families there is a peculiar character in the structure of the hair, which favours the habits I have mentioned, and which will be presently described. In the *Erinaceadæ* (see *fig.* 451) we still have hibernating animals, but these, instead of burrowing or descending into deep excavations, conceal themselves only under leaves, or in any superficial hollow, and live upon food which they either find upon the surface or dig out of the ground with their hard moveable muzzle; the character of their integument is very peculiar, the hair being modified into spines of a greater or less degree of firmness, and the animals being mostly capable of rolling themselves into a ball, and thus presenting a panoply of sharp spines to their enemies. The last-named group, which I have named *Tupaiadæ*, (*fig.* 452) partake, as before observed, of the character of the Insectivorous Quadrumana; living in trees, which they climb with all the agility of a monkey or a squirrel. They consist but of a single genus, named by the late Sir Stamford Raffles, *Tupaia*, of which three species are well distinguished. They are natives of Java.

I. *Osteology.*—It can scarcely be said that there is any peculiarity of structure in the skeletons of the whole of the insectivora, in which they differ essentially from other groups; but on the other hand, there are many in which they differ from each other, according to the very striking and obvious diversity of their habits. In the family *Talpidæ*, the genus *Talpa* (*fig.* 440) presents itself as the type. In these animals the cranium is greatly elongated, and of a tapering or conical form, a character which it partakes with the *Soricidæ*, but to a still more remarkable degree. The cranium of the *Chrysochloris*, or Cape-mole, the South African representative of this family, presents this character in the most regular form. It is, in fact, a perfect cone, short, pointed at the muzzle, broad behind, where the base of the cone is distinctly circumscribed by a crest, which passes from the root of the zygomatic arch of one side, over the vertex, to the corresponding point on the other; on the sides of the head the zygomatic arches themselves complete the cone, passing obliquely and in a straight line from the maxillary to the temporal bone, and beneath it is completed by the inclination inwards of the symphysis, the rami, and the coracoid processes of the lower jaw. The portion posterior to the base of the cone is rounded.

In the genera *Talpa* (*fig.* 441) and *Condylura* the head is equally but less regularly conical, and the snout is more elongated; the zygomatic

Fig. 441.



arch is extremely slender, and rises obliquely, joining the cranium considerably above the auditory meatus. A similar conformation is seen in the genus *Scalops*, which I have already mentioned as leading from the *Talpidæ* to the *Soricidæ*. This form is admirably suited for their subterranean progression, as they push their way through the soil by their long moveable snout, which acts in some measure as a wedge. Amongst the *Soricidæ*, the *Scalops* approaches in its structure most nearly to the *Talpidæ*, having the almost perfectly conical form of the head which belongs to that family; and all the *Soricidæ* partake of it to a greater or less degree. But the cranium of the *Erinaceadæ* approaches more nearly to that of the Carnivora; and viewed from above, the sides are nearly parallel, the zygomatic arches projecting further than the posterior part of the cranium. The muzzle is shorter, more obtuse, and somewhat narrower than the cranium, which is compressed forwards. In *Centenes* the head is much more elongated and conical. The genus *Tupaia* has the head nearly oval, the muzzle straight, prominent, much smaller than the cranium, the zygomatic arches but slightly prominent, and the circle of the orbit closed posteriorly, a circumstance which is not found in any other of the order Insectivora. In this

Fig. 440.

genus the orbit is therefore circumscribed by being closed posteriorly by the union of the post-orbitar processes of the frontal and jugal bones ; in all the other genera the orbit and the temporal fossa are confounded in one cavity, without the trace of any attempt at forming a division between them. This peculiarity in the genus *Tupaia* shews a marked tendency towards the insectivorous Quadrumana.

The bones of the face are very early united in the *Talpidæ* and the *Soricidæ*. In the genus *Centenes* there is no jugal bone. There is therefore no zygomatic arch, notwithstanding the masseter muscle is of great size. This is attached by a single tendon to a sort of tubercle, which represents the zygomatic process of the maxiliary bone. In *Tupaia* the intermaxillary bones are very large, and their suture descends vertically, nearly half way between the nares and the orbits. The Shrews, like *Centenes*, have no malar bone, and the zygomatic process of the maxillary is even less conspicuous than in the former genus. Most of the subterranean forms have at the extremity of the muzzle, that is to say, around the opening of the nares, a small rim or border, which is especially conspicuous in the *Chrysochloris*, for the attachment of the large and moveable cartilages of the nose, so important to these animals in turning aside the earth as they make their way through the ground, as well as in seizing the worms and insects on which they feed.

The proportions of the spine vary greatly in the different families of Insectivora, as may be anticipated from the great difference in their habits. On this subject it may not be useless to subjoin the following table of the numbers of the separate classes of vertebræ, which is taken from the last edition of the Leçons d'Anatomie Comparée of Cuvier :—

	Dorsal.	Lumbar.	Sacral.	Coccygeal.	Total, including 7 cervical.
Erinaceus Europæus (Hedgehog)	15	6	3	12	43
Centenes ecaudatus (Tenrec).	15	5	3	10	40
C. setosus (Tendrac)	14	7	3?	9	40
Tupaia	13	7	2	25	54
Sorex araneus (Shrew)	14	6	5?	14	46
S. fodiens (Water-shrew) ..	13	6	5	17	48
Chrysochloris Capensis (Cape mole)	19	3	5	5	39
Talpa Europæa (common mole)	13	6	6	11	43
T. cæca (blind mole)	14	5	5	11	42
Condytura cristata (radiated mole	13	6	5	17	48
Scalops (mole-shrew)	12	7	6	10	42

It is worthy of remark, in taking a comparative glance at this list, that the length of the tail in the different species is in exact accordance with their habits, as far at least as we are acquainted with them. Thus, in Tupaia, we observe a tail as long as that of a squirrel, and obviously for the same object, that of balancing the animal when taking leaps from one branch to another ; and in the Water-shrew the tail is lengthened to assist in swimming, for which purpose it is also fringed on each side with stiff hairs. Of the habits of the *Condytura** we know little, and of that little nothing which accounts for the considerable proportion of the tail.

Of the form of the different vertebræ in the various groups of the Insectivora, little need be said, as there are few circumstances connected with these bones which bear materially upon any physiological point. It may be observed, however, that in the *Talpidæ* and the *Soricidæ* the cervical vertebræ form large rings, have strong transverse processes, and, excepting the second, do not possess any spinous processes. In the *Erinaceadæ*, and particularly in the Tenrec (*Centenes*) the transverse processes are particularly large, and the rings smaller than in the former families. The spinous processes are also wanting in the dorsal vertebræ of the mole.

The sternum offers some peculiarities worthy of notice. In the mole the first sternal bone is very large and compressed. To its anterior pointed extremity the thick short clavicles are attached, and further back to the same bone, the first rib is articulated ; to the second bone is fixed the second rib, and there succeed to these three elongated bones of the ordinary form, to each of which two pairs of ribs are articulated ; then a small bone. to which one pair of ribs is fixed, and then the xiphoid bone, which is long and narrow.

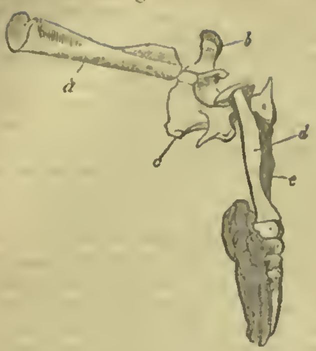
In the *Chrysochloris* the first bone of the sternum is equally compressed but less elevated ; and the anterior half is furnished on the upper part with two small aliform processes, which are concave, and support the first two ribs, which are extremely broad ; the long slender clavicles are attached at its anterior point; and then follow seven other oblong pieces, and an elongated xiphoid bone, which bears at its posterior extremity a semilunar cartilaginous dilatation.

The ribs in the mole and its congeners are nearly all of the same length, giving that peculiar cylindrical form to the body which characterises these animals, and which is so essential to their habits ; and in the *Chrysochloris* the first rib is very much broader than the others.

But it is in the bones constituting the anterior extremities, that the most remarkable and interesting peculiarities exist in some of the families of this group. In the mole especially, the anterior extremity (*fig.* 442) exhibits one of the most extraordinary modifications to be found in the whole of the Mammifera. The clavicle is fully developed in the whole of the Insectivora. In the mole (*b*) it offers the most

* From the name *condytura*, given to this genus by Illiger, it might be inferred that the tail is furnished with knotty tuberosities ; this, however, is only seen in dried specimens, which doubtless furnished to Illiger the characters of the genus, and suggested its name.

Fig. 442



abnormal deviation from the usual construction. It is extremely short and broad, forming in fact nearly a square; about the middle of its anterior margin a strong process rises, which gives origin to the subclavian muscle, which in this animal is greatly developed. It is articulated, as usual, with the sternum by its interior extremity, which may here be more properly called its interior margin; but by its external margin it is connected moveably with the head of the humerus, which connection is rendered more solid towards the anterior part by a strong ligament. Its connexion with the acromion of the scapula is by a ligament merely, which extends from the acromion to the posterior and outer angle of the clavicles. In *Condylura* and even in *Scalops* the construction of this bone is on a similar type; but in *Chrysochloris* it is long and slender as in the other Insectivora.

The scapula (*a*) in the mole is no less singularly formed than the bone just described. It is elongated to an extraordinary degree, being not less than six times as long as it is broad at the broadest part, which is at the superior extremity. Towards the middle it is contracted and almost cylindrical; and the spine, which runs nearly the whole length of the bone, is at this part almost effaced. The acromion, as before observed, has only a ligamentous connexion with the clavicle. In *Condylura* and *Scalops* the construction of this bone is somewhat similar, and in *Chrysochloris* it is also of considerable length.

The humerus in the mole (*figs.* 442, *c*, 443) is of so extraordinary a form, that were it examined alone, isolated from its natural connexions, it would be impossible to detect its true character. It is of a square form, extremely broad at the superior part, where it presents two articular surfaces; the anterior is very broad, slightly convex; the posterior and internal is narrow, but more convex than the former; by the first it is articulated to the clavicle, and by the latter to the scapula. Between the former, which may be considered as appertaining to the greater tuberosity of the bone, and the head, is a deep fossa. The body of the bone is short, thick, and very broad, and is curved upwards, so that its articulation with the forearm is placed actually higher than the shoulder, and the palm of the hand is consequently turned outwards. In *Chrysochloris* the form of this bone is not less remarkable. It is somewhat longer than that of the mole: its articulation with the forearm constitutes half a sphere; and the inner condyle is so elongated and inclined downwards, that the whole bone forms an arch of which the convexity is turned outwards. This condyle is articulated with a bone, which must be considered as a most extraordinary modification of the *os pisiforme*, which is as long as the radius, so that in fact the forearm may be said to be composed of three bones.

The bones of the forearm (*fig.* 442, *d*, *e*) in the extraordinary animal which offers so many deviations from typical structure, the mole, are no less remarkable than those of the shoulder. The *ulna* is very broad and much flattened; its superior extremity is enlarged transversely, the anterior surface concave, the posterior convex. The radius is separated by a considerable interval from the ulna throughout their length, and the two bones are only united at the upper extremity by a capsular ligament. But the articular surfaces of the two bones are flat, and the head of the radius is prolonged into a hook-like process, forming a sort of radial olecranon, so that rotation is impossible. The carpal bones (*fig.* 444) consist of two series of five in each, and an additional bone of a very peculiar construction. This is a large sickle-shaped or falciform bone, having the convex margin outwards; it extends from the carpal extremity of the radius to the first metacarpal bone. It is this bone which gives the great breadth to the hand, which is so important to this animal in its peculiar mode of life.

The phalanges of the fingers are very short, and covered by the integument in such a manner as to appear to belong to the meta-

Fig. 443.

Fig. 444.

carpal portion of the hand; and it is only the long sharp nails which extend beyond the skin, and are externally visible.

The position then of the anterior extremity of the animal is this: the humerus is so placed that the inferior or distal extremity is the most raised, so that the fore-arm is kept in a state between pronation and supination, the elbow raised, the radius and the thumb placed downwards, and the palm of the hand directed outwards. When to this we add the peculiar flexion of the last phalanx of the fingers with the enormous nails, we have a fossorial structure not equalled by any other in the whole of the vertebrated animals, and only imitated by the no less remarkable anomaly amongst insects, the *Gryllotalpa* or mole-cricket.

In *Chrysochloris* the third and fourth fingers are united by one large powerful nail, and are developed to an extraordinary size (*fig*. 445),

Fig. 445.

the fifth finger being reduced to a minute rudiment; and the carpal bones are placed in an abrupt curve, so that the outer side of the fifth finger approaches the first. The *os pisiforme* assumes also a peculiar development, being very much elongated, rises in the direction of the forearm, and is actually articulated with the internal condyle of the humerus.

The pelvis in the *Talpidæ* and *Soricidæ* is extremely long. The *ilia* are narrow and pointed at the anterior part. In the last-named family, the *pubis* and the *ischium* are especially long and narrow. In *Chrysochloris*, on the contrary, the ischium is very broad.

The femur offers but few and unimportant particularities amongst the *Insectivora*, unless it be that there is in the mole and *Chrysochloris* a sort of third trochanter; a process which is also found in some of the lower Quadrumana, and in some other of the Mammifera. The *fibula* is united to the tibia for nearly the inferior third of their length, in the *Talpidæ*, the *Soricidæ*, and the *Erinaceadæ*. In the mole this union is to a greater extent than perhaps in any other animal of the Mammiferous class.

The binder feet in the whole of this order are plantigrade. In the mole, as Daubenton and Meckel have observed, there is an additional tarsal bone, to those which are ordinarily found. It is of considerable size, and seems to answer to the falciform bone of the anterior extremities already described. It is of an uniform shape, of considerable size, and is articulated between the scaphoid and the first cuneiform bone, and extends forwards along the first metatarsal.

II. *Muscles.*—The extraordinary developement of the bones of the anterior extremity in the mole, will, of course, be associated with a no less remarkable structure in the muscles of the same part; and the known habits of the animal will account equally for the necessity of such a structure in both. I give a figure of the muscles of the anterior extremity and of the anterior part of the trunk from Carus. (*Fig*. 446.)

Fig. 446.

The cervical portion of the *serratus magnus* is simple, excessively thick and swelling, and is attached only to the posterior vertebræ. The *trapezius* consists only of two bundles of fleshy fibres, which arise from the lumbar vertebræ, and are inserted into the posterior extremities of the long and narrow scapulæ; and as these fasciculi are nearly parallel, their action would be rather to separate than to approximate the posterior parts of these bones, were it not for a strong transverse ligament which holds them together. Their application consists in moving the anterior part of the body upwards. The scapular attachments of the *rhomboideus* are principally to this transverse ligament of the two scapulæ, and as it is inserted into a sort of ossified modification of a cervical ligament, its office consists in raising the head with great force. The *levator scapulæ* is wanting; its existence would be obviously useless. The *pectoralis minor* is very slender; it is attached to the anterior parts of the first ribs, and to the ligament, already mentioned, which joins the clavicle to the scapula. There are also two muscles arising from the anterior part of the sternum, and inserted into the large head of the clavicles.

The most important muscles of the humerus are the *pectoralis major*, the *latissimus dorsi*, and the *teres major*, all of which are of great size; and it is by means of these muscles that the astonishing efforts of the animal are made in excavating his passages, and throwing the earth behind him. The *pectoralis major* is of extraordinary thickness. It is formed of six portions, which are all of them inserted into the broad quadrate portion of the humerus. Four of these portions arise from the sternum, the fifth from the clavicle; and the sixth passes across transversely from one arm to the other. The *latissimus dorsi* is also of considerable size, and is inserted into the posterior surface of the quadrate portion of the humerus. The *teres major*, which is of enormous thickness, is inserted near the former muscle.

The other muscles of the anterior extremity do not require particular description.

There is one peculiarity in the muscular system which deserves special notice; it is the enormous developement of the *panniculus carnosus* in the hedgehog, by which it is enabled to roll itself up in a ball with such astonishing force as to afford with its spiny covering a complete protection against its most powerful antagonists. I proceed to describe this apparatus and its uses.

As this muscular apparatus has no attachment but to the skin, it changes its position with every movement of the integument; and it is therefore necessary to consider it under the various relations which it assumes in the different positions of the animal. Considering it then, in the first place, as rolled up in a ball (*fig.* 447), either for defence or during repose,

Fig. 447.

the whole body is enveloped beneath the skin by a strong sac or covering, consisting of a mass of fleshy and concentric muscular fibres, of an oval form. All these fibres are attached intimately to the skin, and even to the base of the spines with which it is every where furnished, so that it is even difficult to detach the fibres in dissection. The thickest part of this fleshy sac is at the lower margin or mouth of the sac, at which part it forms a sort of sphincter, composed of orbicular muscular fibres. On the other hand, when the hedge-hog is unrolled, and at its full length (*fig.* 448), the muscle in question totally changes its figure and relations. The muscle now lies over the back, forming an oval covering, the middle of which is very thin,

Fig. 448.

and the circumference exceedingly thick and somewhat raised. To different portions of this circumference of the muscular covering are attached several accessory muscles. Anteriorly there are two pairs; one arising from the median line and inserted into the nasal bone; the other, more external, apparently confounded at its origin with the external orbicular fibres, is inserted into the side of the nose and incisive bones. Posteriorly a pair of broad muscles, of a pyramidal form, arise from the posterior part of the fleshy circumference, and are inserted into the side of the tail towards the extremity.

On the ventral aspect there are also several portions of muscle, belonging to the same apparatus. There is one beneath the throat, arising from the anterior part of the thorax, under the skin, and is inserted about the lateral parts of the head near the ears. Another arises from the median line of the sternum, and passes obliquely forwards over the shoulders, in front of them, to join the margin of the great orbicular muscle before described. There is another ventral portion which has a very extended connexion. It is attached around the anus, to the lateral parts of the tail and neighbouring parts, extends over the whole surface of the abdomen, and then divides into two portions; one internal, and larger than the other, passes under the axilla, and is inserted into the superior and interior part of the humerus; the other, external, passes laterally upwards, to be inserted into the margin of the great orbicular muscle near the neck. The muscles hitherto described lie superficially; but there are others which are seated underneath the great muscle of the back. One arises from the side of the head, being attached to the meatus auditorius on each side, and loses itself in the anterior point of the orbicular muscle. There is also a thin layer of fibres lying beneath the great muscle, of which the anterior are attached to the superior interior portion of the humerus, and the posterior to the third ventral muscle already mentioned.

We have here a very extensive and a very powerful apparatus, and it now becomes necessary to consider its application. When the hedgehog is rolled up in a ball, it is completely enveloped, as regards all the upper and lateral parts of the body, in the great orbicular muscle. When once brought into this position the simple contraction of the thick circumference of the muscle, which forms a true sphincter, is sufficient to retain it. If the animal unrolls itself, the disc of the great muscle contracts whilst the circumference is relaxed, allowing the exit of the feet and the uncovering of the belly and sides: then the whole muscle contracts together, and lies in a mass on the back. By this universal contraction, the necessary muscles become stretched, and in a condition to perform their several offices; by the contraction of the anterior ones the head, and by that of the posterior the tail, is raised, whilst those which lie beneath raise the head and neck together, and the animal is now ready for progression. On the other hand, on the apprehension of danger, or when reposing, it rolls itself into a ball by the following process. The orbicular muscle relaxes, and the muscles extending from it to the head and to the tail extend it in those directions, whilst the deap-seated transverse muscles which are attached to the external lateral portions, and lie on the belly, bring this part of the circumference downwards. At the same time the head is brought downwards towards the breast by the ordinary flexion of the head, and by the cutaneous muscles of the neck already described; the tail and the hinder legs are brought forwards under the belly, and the flexors of the limbs contract. The great orbicular muscle passes downwards over the sides, then contracts at the circumference, and forms a sort of sac or purse, enveloping the whole body and limbs.

III. *Digestive organs.*—It is, of course, in the structure of the digestive organs, and particularly in that of the teeth, that we find the distinguishing characters of the whole order; yet so nearly do these organs in the Insectivora approximate to those in the insectivorous division of the Cheiroptera, that it would not have been possible to separate the two groups, had there been no other important points of distinction. From the insectivorous Quadrumana they are distinguished by the plantigrade character of the posterior extremities; from the bats by the whole structure of the limbs, and from all the true Carnivora by the tuberculated teeth.

There is no inconsiderable difficulty in assigning the various anterior teeth in the Insectivora to their proper classes. In most of the genera, according to the statement of both the Cuviers and others, there are no canine teeth, and the false molares are very numerous; but it is in many cases doubtful whether the anterior false molares, as they are termed by these anatomists, be not theoretically canines modified in their form. On this point, however, there is no possibility of coming to a satisfactory conclusion, as every one will at last form his own opinion on each case; I shall therefore follow the arrangement of Frederic Cuvier as the most generally known, and, upon the whole, by far the best authority on the teeth of the Mammifera.

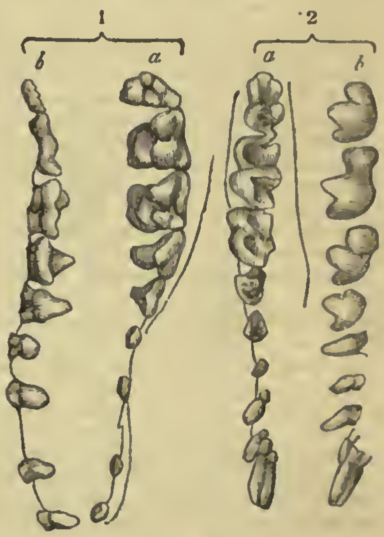
The incisive teeth vary greatly in the different genera. In *Mygale*, in *Scalops*, and in *Condytura*, there is in the upper jaw but a single incisor on each side, which is very strong and of a triangular form. In the first of these genera it is somewhat curved downwards and backwards, and slightly resembles that of some Rodentia. In *Sorex* (*fig.* 449) it is also single, very strong, curved, and similar to the canine tooth in the Carnivora, but furnished with a strong tooth-like process posteriorly, appearing almost like a distinct tooth.

In *Talpa* (*fig.* 441) there are three superior incisores on each side, which are small with cutting edges, like those of the Carnivora. In *Chrysochloris* (*fig.* 450), the single superior incisor is curved, convergent, obliquely truncate and pointed; and in *Erinaceus* (*fig.* 451) there are three pairs, of which the first is large, *Fig.* 449. *Sorex.*

Fig. 451. *Erinaceus.*

Fig. 450. *Chrysochloris.*

Fig. 452. *Tupaia.*



obtuse, and strong, separated by a considerable interval from its fellow, and convergent with it. The others are small and resemble false molares. In *Tupaia (fig.* 452) these teeth are two on each side, distant from each other, and from the first false molar. The inferior incisores also vary greatly in their form and number. In *Scalops* there are two, the first small, the second larger and resembling in form a canine tooth. In *Condytura* there are two, rounded in front, flattened behind. In *Talpa* there are four similar to those of the upper jaw, and in *Sorex* there is one only of a very peculiar form: it is very long from the anterior to the posterior part, somewhat hooked, pointed, and, in some species, the edge is notched or trifid. There are no true canines, according to the opinion of Frederick Cuvier, in any of these animals, excepting *Condytura, Talpa,* (in which they exist in the upper jaw only) *Centenes,* and *Tupaia.* The first tooth beyond the incisores, considered by Fred. Cuvier as the first false molar in the lower jaw in the mole, is by Baron Cuvier termed the canine. In *Centenes* these teeth are of the normal form; and in fact the general arrangement of the teeth in this genus indicates a marked approach towards the Carnivora. In *Condytura* the superior canine is strong and large; the inferior merely rudimentary.

The molares, as in the other Zoophaga, are divided into false and true. Those of the former class are very numerous and of very various form in the different genera, and the great diversity of number in the molar teeth depends in most cases upon these, the true molares being but three on each side both above and below in all the genera, excepting in *Chrysochloris*, in which they are $\frac{6}{5}:\frac{6}{5}$, in *Erinaceus*, in which they are $\frac{4}{3}:\frac{4}{3}$, and in *Centencs* $\frac{4}{4}:\frac{4}{4}$. In *Chrysochloris* the true molares are very curiously and beautifully formed: they are much compressed from before backwards, of a three-sided form, each of the angles terminating in a sharp elevated point; thus, in those of the upper jaw, there are two situated externally and one internally, and in the lower jaw one externally and two internally. The whole of the true molares, in all the Insectivora, are formed of three-sided prisms, either single or double, and surmounted by acute tubercles.

The salivary glands are generally much developed in the Insectivora. In the hedgehog the parotids are larger than the submaxillary; the sublingual are placed in two rows, of which the larger is situate nearest to the lower jaw. In the mole these glands are very large; the parotids are of an oblong shape, and the maxillary are formed of several rounded and detached lobes. In *Sorex* the maxillary glands are of larger size than the parotids, and the latter are situated very low to accommodate the oblique direction of the auditory canal.

The form of the stomach in this Order of animals is perfectly simple, and does not greatly vary in the different genera. It is situated transversely with regard to the axis of the body, is somewhat elongated, and the two orifices are distant from each other, as in many of the Carnivora, and in the insectivorous bats. The cardiac pouch is generally distinct and rounded; the pyloric extremity, on the contrary, is conical and perfectly even. In *Erinaceus* the cardiac point is considerable, the entrance to the œsophagus being at no great distance from the pylorus; and the internal coat forms numerous rugæ and folds. This form of the stomach and the existence of plicæ must be considered as indicating an aberration from the insectivorous type, and a certain degree of aptitude for the digestion of vegetable matters, and we find accordingly that this, with a slight exception or two, is the only family of the Insectivora which can exist upon any but the most exclusive animal aliment. The mole, the *Chrysochloris*, and all their congeners, are in this latter case; but the hedgehog, as is well known, will readily eat various vegetable substances, and often digs under the common plantain for the purpose of obtaining the roots, of which it appears to be very fond. The stomach varies a little in its form in the different genera of the *Soricidæ*. In the great shrew of India it is transverse, the pyloric portion conical, of moderate dimensions, the cardiac pouch small and the two orifices distant; a form which indicates an exclusive aptitude for insect food; but it would appear that the water-shrews (*Hydrosorex*) must occasionally have recourse to some kind of vegetable diet, as the pyloric portion is so much elongated as to resemble in some degree that of the *Pteropidæ* or fruit-eating Cheiroptera, exhibited in *fig.* 287, vol. i. p. 600. In the mole the œsophagus enters at about the middle of its anterior margin, and the lesser curvature is nearly straight to the pylorus. The membranes are extremely delicate and almost transparent. The form is essentially similar in *Chrysochloris* and in *Condyturu*. The stomach of *Tupaia*, according to the Baron Cuvier, is of a globular form.

The intestinal canal is upon the whole remarkably short in the Insectivora. There are some exceptions to this rule, but the only one bearing upon a difference of aliment is that of the hedgehog, which, as has been before observed, lives partially upon vegetable matters. In this animal it is, with regard to the length of the body, as 6.6 to 1. In *Talpa* and *Centenes* this proportion is even exceeded, but it is compensated for by the extreme narrowness of the canal; the diameter of which is to its length, in the mole, as 1 to 82; whilst in the hedgehog it is as 1 to 58. In *Sorex* its length is to its diameter only as about 3 to 1, or a little more. There is no cœcum known to exist in any of the Insectivora. Cuvier queries whether *Tupaia* be not an exception, but this we have at present no means of ascertaining. The liver is in general fully developed in all its parts; there are the principal lobe, to which the gall-bladder is attached, with a notch answering to the suspensory ligament, a right and a left lobe, and two smaller lobes or *lobuli*, a right and a left. The whole of these parts are generally found, but varying without any known law, or any ascertained relation to functional peculiarity. In the hedgehog and in the mole the left lobule is composed of two portions, a cardiac and a pyloric, as in the Rodentia. In Tupaia, according to the statement of Cuvier, the three portions into which the liver is divided belong to the principal lobe; there is no right or left lobe, and the right lobule is also wanting. The gall-bladder is for the most part of considerable size. In the hedgehog its fundus appears beyond the free margin of the liver, and is supported by a process of falciform ligament. In the Tenrec, on the contrary, it is as it were incrusted by the substance of the right portion of the principal lobe.

IV. *Nervous system.*—The form and proportions of the brain in some of the Insectivora exhibit a degree of developement not materially superior to that of the higher Carnivora; whilst others, and especially the mole, have the same higher proportion which are found in the Cheiroptera: thus in the hedgehog the volume of the brain is to that of the body as 1 to 168; whilst in the mole it is as 1 to 36. The proportion of the cerebellum to the cerebrum in the latter animal, however, indicates a considerable developement of the sexual functions, being as 1 to 4½. Supposing the theories of many modern physiologists to be correct, this fact is in perfect accordance with the necessities of the animal, whose means of obtaining access to the opposite sex are extremely difficult, and require intense ardour and perseverance to effect this object.

The most remarkable and interesting peculiarities which are to be met with in the structure of any of the Mammalia are to be found in the eye of the mole, and doubtless of the nearly allied forms of *Chrysochloris* and the other subterranean species. In these, in order to meet the requirements of their habits, the organ of sight is reduced to a mere rudiment, whilst those of hearing and of smell are developed to an extraordinary degree; and the theory of the *balance of organs* can scarcely boast of a stronger support in the whole range of animal organization than in this instance.

The question whether the mole possesses vision has been long and often debated. Without entering into an unnecessary examination of all that has been said on both sides of the question, it may be well to observe that the principal argument which has been urged on the negative is derived from the absence of an optic nerve. That this animal, at least our common species, does possess the faculty of vision to a certain degree cannot, however, be disproved, whatever may be the means by which the sense is communicated, that is to say, whatever the nerve may be which supplies the place of the true optic nerve; and the experiments of Henri le Court and Geoffroi St. Hilaire* would well nigh go to prove the affirmative of the proposition. It has been urged then that an optic nerve is absolutely necessary to the existence of vision; and that, therefore, either the mole has a true optic nerve, or that it does not possess vision. There have indeed been three classes of observers on this point; those who maintain that the mole sees, and that it possesses an optic nerve; those who contend that it is blind, and possesses no such nerve; and others have ventured to agree with the former as to its power of vision, and with the latter in denying the existence of the optic nerve.

The eye of the mole is extremely small, but differs not materially in its structure from that of other animals. The pupil is elliptic and vertical; the cornea even more convex than that of birds; there is a sclerotic and a true choroid. The crystalline lens is perfect, and much more convex than in most of the Mammalia; and the eye-ball, emptied of its contents, exhibits at the base a lining of a whitish colour. "In an injected subject," says Geoffroi, "the central artery of the retina was distinctly seen." Whether there be or not a true retina will be variously solved according to the views of different physiologists. If the nerve, whatever it may be, which takes here the place of the optic nerve, be really the seat of the sense of vision, there seems to be no objection to consider its expansion, upon which the pictures of objects are impressed, as a retina; giving the name rather to the physiological than to the anatomical character of the part; but be this as it may, from the posterior part of this minute eye there passes a distinct branch of a nerve. Perhaps, after all, the name and analogy of this nerve will be viewed differently according to the general views of organic developement entertained by different physiologists. Geoffroy considers it as the optic nerve, notwithstanding it has no connexion with that part of the brain which in all other cases is in immediate communication with it; and he founds this opinion upon the theory that all organs are developed from without. His words are as follow:—"Qu'est ce que ce nerf? La monstruosité et la nouvelle théorie sur le point de départ des développemens organiques assure ma marche: appuyé sur ces deux fanaux, aujourd'hui heureusement importés dans l'histoire encore si obscure des premières formations je ne doute pas que ce ne soit le nerf optique. C'est ce nerf, parceque cet appareil, qui est au complet comme globe oculaire, a du se former de toutes ses dependances jusqu'à l'empêchement qui en arrête le cours. Cette determination ne sauroit être douteuse pour qui reconnait que *les organes naissent à la circonférence de l'être*, d'ou ils envoient leurs rameaux s'embrancher au plus près dans le centre.*

Amongst those who assert that the mole possesses a true optic nerve is Müller. His statement is so brief, and, it may be said, so unsatisfactory, that it can scarcely be considered as sufficient to outweigh the carefully formed opinion of many who differ from him. His statement, as given in Dr. Baly's translation of his admirable book, is as follows:—"Some animals, though provided with eyes—for instance, the mole and the *proteus anguinus*—have been said to want the optic nerves; the sense of vision being then placed in the ophthalmic branch of the fifth nerve. This statement has arisen, in the case of the mole, from inaccuracy in the anatomical examination; and the same is the case probably in the Proteus. The mole has an uncommonly small optic nerve, as Dr. Henle has shewn me."† On the other hand, Serres, Gall, Desmoulins, and others have agreed in delaring that there is no nerve passing from the optic lobes to the eye; and Dr. Todd has recently verified this statement, and traced the nerve which *does* supply this organ, which he finds to be the ophthalmic branch of the fifth pair. I give an enlarged view of a dissection of this nerve, drawn by Mr. Bowman. (*Fig.* 453.)

a is the fifth nerve within the cranium, *b* the Gasserian ganglion, *c* the inferior maxillary nerve, *d* the ophthalmic nerve going to the eye (*e*,) *f* the superior maxillary nerve, *g* branch of the ophthalmic, supplying the side of the nose. Dr. Todd in a letter to me says, "I have been lately looking at the point about the optic nerve in the mole. I can see an optic commissure, but no optic nerve beyond it, and I can very distinctly trace a branch [the ophthalmic] of the fifth to the eye. I carefully searched to see if a second nerve were bound up in the cellular sheath with it, but could find none.

† Müller's Phys. by Baly, p. 767.

The chiasma is very distinct, without a trace of a nerve proceeding from it."

Fig. 453.

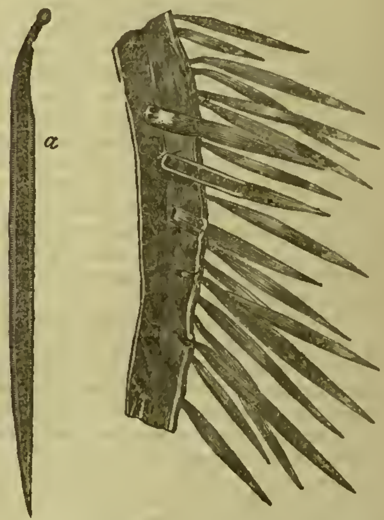
The organ of hearing in the mole is so constructed as to afford the greatest possible delicacy and acuteness of this important sense, and thus to counterbalance the deficiency in that of sight. It would indeed appear that the mass of compact bone constituting the petrous portion of the temporal, which surrounds the labyrinth in most of the Mammalia, must more or less diminish the powers of hearing, for we find it deficient in many animals, which from their habits require this sense to be in the greatest perfection. Thus, in the mole, the semicircular canals are free and visible within the cranium, without any preparation; and the parietes of the cochlea itself are almost as cellular and loose as we find in birds.

The ear of the mole possesses no concha; it is small in the shrews; and in the water-shrews *(Hydrosorex)* the external meatus is closed at the will of the animal by means of the antitragus; a provision obviously essential to its aquatic habits.

When it is considered that the sense of vision is only available on the rare occasions of the appearance of the mole on the surface, and then only for very limited objects, and that all its intimations of danger, and its only guide to the opposite sex, are by means of the sense of hearing, the necessity for this extraordinary developement of that sense at the expense of that of sight becomes obvious. And as, from the nature and situation of its food and its means of procuring it, the sense of smell is equally necessary for effecting this object, we find that the olfactory organ is also of considerable volume. The structure of the nose itself is highly curious and admirably suited to the habits of the animal. The cartilages of the nose are elongated into a tube or trunk, which extends far beyond the osseous basis, and is supported by a very delicate moveable bone, which is represented in the figure of the cranium of the mole at *fig.* 441. It is furnished with a muscular apparatus of considerable complexity (see *fig.* 446), consisting of no less than four pairs of muscles, which arise from above the ears, and passing forwards are inserted by separate tendons into the circumference of the extremity of the cartilaginous snout. This structure is of the utmost advantage to the animal in its subterranean search after worms and insects.

There is no order of Mammalia in which a greater contrast is exhibited in the external covering of the body than in the different groups of the Insectivora. The porcupine and the mouse, amongst the *Rodentia*, do not offer a more remarkable contrast in this respect than do the two families of the *Erinaceadæ* and the *Talpidæ*. The habits of the hedgehog depending for its defence upon the panoply of armour which it presents to its enemies, when rolled up in a compact ball by the muscular apparatus already described, it is furnished on all the upper and lateral parts of the body with hard sharp spines or quills. *Fig.* 454

Fig. 454.



is taken from a drawing by William Bell, engraved in the Hunterian Catalogue, vol. iii. from which also the following description is borrowed:—"On the cut edge of the skin may be seen the roots and sockets of the quills, extending to different depths from the surface, according to the period of their growth: the newly formed ones are lodged deep and terminate in a broad basis, the pulp being large and active, and the cavity containing it of corresponding size; but as the growth of the quill proceeds, the reflected integument forming the socket contracts, and gradually draws the quill nearer the surface; the pulp is at the same time progressively absorbed, and the base of the quill in consequence gradually increases in size, so that it is at last seen to be attached to the surface of the skin by a very narrow neck, below which the remains of the socket and theca are seen in the form of a small bulb." (*Fig.* 454, *a.*) "A completely formed prickle or quill cut longitudinally and magnified, shewing that it is hollow and filled with a pithy substance, which is transversely disposed, so as to divide the cavity into many sections." But the defence of the animal against attack is not the only object of this modification of the hair. I have more than once seen a hedgehog run to the edge of a precipitous descent, and without a moment's hesitation throw itself over, rolling itself up at the same instant, and on reaching the bottom run off perfectly uninjured. It is unnecessary to point out how perfectly this habit is provided for by the elasticity of the spines, dependent upon their structure, as exhibited in the figure. The under parts of the body and the limbs are covered with ordinary hair. The Tenrec and other *Erinaceadæ* resemble the hedgehog in these respects, and in some species the quills and hair are intermixed.

The mole, on the other hand, possesses hair of the softest and most flexible description. In its subterranean galleries, which are not large enough to allow it to turn round, it must often be obliged to retreat backwards; and the hair therefore is so constructed as to lie equally smooth in every direction. This has been supposed to be effected merely by its growing exactly perpendicular to the surface of the body; but it is in fact still more effectually provided for by a remarkable form of the hair itself. Each hair consists of three or four broader portions connected by intervening portions of extreme tenuity; so that there are several points in the length of each hair which present no appreciable resistance. The hair of the shrews is similarly constructed, and in each case it is to this structure that the peculiar and beautiful softness which characterizes it is owing. It is worthy of remark that the colouring matter of the hair exists only in the broader portions, the intermediate parts being wholly colourless.

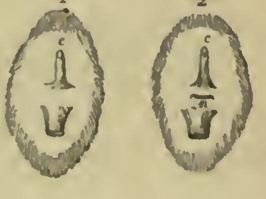
V. *Organs of reproduction.* — The reproductive organs of the Insectivora offer, in several instances, some remarkable peculiarities. The subterranean life of many of these animals renders the meeting of the sexes in their natural haunts a matter of almost fortuitous occurrence; and it is therefore necessary that the sexual desire should in the male be sufficiently powerful to force him as it were to seek and pursue the other sex through all the difficulties and disadvantages occasioned by their peculiar habits. Hence we find that in most of them the male organs are developed to an extraordinary degree; and in the mole the enlargement of the testes as the season of pairing advances is as remarkable as it is in the sparrow or in any other example of this seasonal increase of those organs. Two incompatible statements have been made respecting the testes in the mole. Cuvier asserts that they make their appearance externally during the season of propagation. Blumenbach declares that they belong to the true *testiconda*, with the hedgehog, &c. The truth is, as demonstrated with his usual ingenuity by Geoffroy St. Hilaire, that the testicles of the mole never make their appearance externally, although during the season of their greatest developement they would do so but for the peculiar construction of the parts in which the organs of generation in this animal are contained; for the abdominal cavity extends beyond the pelvis, as far as the first four coccygeal vertebræ, which in fact do not, properly speaking, in any degree constitute the tail, which is formed only of the posterior seven vertebræ, and the testes during the season are protruded so as to lie concealed under this portion of the caudal division of the spine, which forms as it were a continuation of the upper part of the pelvis. In the hedgehog the testes remain within the abdomen excepting during the spring, and even then they are but little protruded. The object of their being thus generally protected is obvious: in the hedgehog these organs, if external, would be exposed to danger from the act of rolling itself up, and in the mole and its congeners they would interfere with the act of excavating their subterranean passages. The penis in the mole possesses a remarkable peculiarity, which doubtless has reference to the condition of the female organ presently to be described. It consists in a small terminal bony appendage, covered but slightly by integument; it was considered by Daubenton as the *os penis*, but from its different situation it may be doubtful perhaps if it be in truth analogous to that part.

The male organs are in the hedgehog developed to an extraordinary degree, more especially the *vesiculæ seminales*. The testes are of an oval form, smooth, and although large in proportion to the size of the animal, are much smaller than the vesiculæ seminales; these are of enormous size, each consisting of four or five fascicles of extremely convoluted tubes, the membranous parietes of which are extremely thin and fragile. Cowper's glands and the prostatic gland are also of considerable size in this animal. The orifices of the *vasa deferentia*, *vesiculæ seminales*, prostatic gland, and Cowper's glands all open within the foramen cœcum of the urethra.

The female organs in the mole offer some peculiarities which deserve more attention than they have hitherto received.

In the first place, it appears that in this animal the urinary and genital orifices are

Fig. 455.



wholly distinct. The clitoris, (*fig.* 455, *c*,) which is of considerable length, and very much resembles the penis of the male, is pierced for the passage of the urine, and thus constitutes a true urinary penis. Beyond this is a transverse slit of a slightly crescentic form, (*fig.* 455, 2), which constitutes the opening of the vagina. There are none of those duplicatures of the integument which in other Mammalia constitute the *labia* and *nymphæ*, but the skin is smooth. But one of the most curious points in the structure of these parts is that in the virgin state this vaginal aperture does not exist, (*fig.* 455, 1,) the skin being perfectly and tightly drawn over the entrance; so that there are in this state but two openings, the urethral and the intestinal. So perfectly is this the case that it is very difficult to know a virgin female mole from the male by mere external examination. As this covering is so tense, the utility of the little bone at the extremity of the penis in the male is very obvious, and its pointed and tapering form is at once accounted for: it is clearly intended to perforate this tense covering to the vagina.

Another peculiarity in this animal is that the abdominal cavity being extended greatly beyond the pelvis, the vagina, the rectum, and the urinary passage terminate considerably further back than in other animals. The opening of the rectum is opposite to the articulation of the fourth with the fifth caudal vertebra.

The uterus is of considerable size in the mole, and its cornua much convoluted.
